The paramyxovirus F proteins belong to the class I viral fusion protein type, of which the longest-standing and structurally first characterized member is the influenza virus hemagglutinin (HA). In addition to the ortho- and paramyxoviruses, major human and animal viral pathogens feature class I fusion proteins including the retroviruses (i.e., HIV-1 Env/gp160), coronaviruses (i.e., SARS coronavirus S), filoviruses (i.e., Ebola virus G), and pneumoviruses (i.e., RSV F).[89,145,146,248,455] Models for class I viral fusion protein-mediated membrane merger have been developed, until recently, primarily based on the structural studies of HA.[548] The general mechanism for class I viral fusion proteins comprises initial folding of the uncleaved protein into a metastable prefusion state, which can be activated through distinct, virus family–characteristic stimuli to undergo large

structural reorganizations into a thermodynamically more stable postfusion conformation. The attainment of the prefusion state, its regulation, and its relative free energy as compared to the postfusion form are all key to the process by which class I viral fusion proteins function.

Class I viral fusion proteins and the helical hairpin (core trimer)

Biophysical data indicated that HRA and HRB form a complex, and crystallographic studies have shown that HRA and HRB associate into a helical hairpin or six-helix bundle (6HB) structure (core trimer) that is reminiscent of the low-pH–induced proteolytic fragment of influenza virus HA (TBHA2). The core trimers of PIV-5 and hRSV F,[18,254,661] HIV gp41,[62,76,583,629] Moloney murine leukemia virus envelope protein,[158] Ebola GP2,[332,630] and HTLV-1[276] fusion proteins all share this similarity in structure (Fig. 12.18A). Although the structural details vary, all reveal a trimeric coiled coil beginning near the C-terminal end of the hydrophobic fusion peptide. The C-terminal segment abutting the TM domain is also often helical and packs in an antiparallel direction along the outside of the N-terminal coiled coil, placing the fusion peptides and TM anchors at the same end of a rod-like structure (for PIV-5 6HB, see Fig. 12.18A). These 6HBs typically represent a relatively small fraction of the intact fusion protein, yet their structures are generally extremely thermostable, with melting temperatures near 100°C. Intermediates along the pathway of membrane fusion can be trapped by the addition of peptides derived from either the N-terminal (HRA) or the C-terminal (HRB) heptad repeat regions for many class I fusion proteins,[146,149,157,503,653] indicating that the intact protein undergoes multistep conformational changes that consecutively expose both HR regions, prior to assembly of the final 6HB. While structurally not yet characterized, these intermediates are believed to represent partially refolded forms of the fusion protein, with the hydrophobic fusion peptide anchored in the target cell membrane and the TM domains integrated in the viral envelope. The formation of the 6HB is linked to the merger of lipid bilayers and is believed to couple the free energy released on protein refolding to membrane fusion.[359,503] Resembling the requirements for HIV gp41–mediated fusion pore opening,[360] however, transition of paramyxovirus F into a 6HB causes fusion without full closure of the bundle configuration.[49]

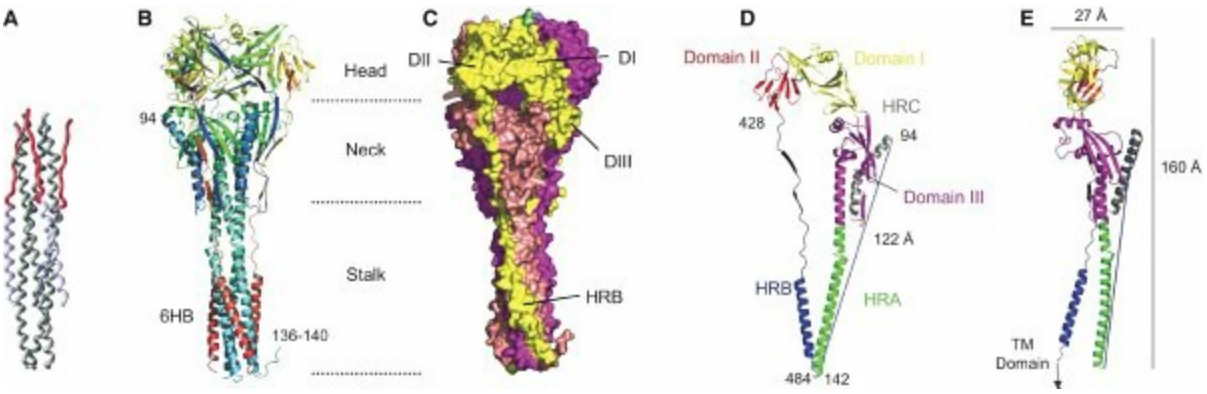

FIGURE 12.18 The F protein postfusion structure. **A:** The complete PIV-5 F1 core trimer is shown with the N1 helix colored *gray* and the C1 peptide colored *blue*, except for the extended chain N-terminal residues of C1 that are colored *red*. **B:** Ribbon diagram of the HPIV-3 solF0 trimer. The three chains are colored similarly from *blue* (N-terminus) to *red* (C-terminus). Residues 95 to 135 are disordered in all chains. Residue 94 is labeled in one chain, and residues 136 to 140 at the base of the stalk are ordered in one chain due to crystal packing interactions. **C:** Surface representation of the solF0 trimer. Each chain is a different color, and domains I to III and HRB for one chain (*yellow*) are indicated by the DI, DII, DIII, and HRB labels. One radial channel is readily apparent below domains I and II of the *yellow* chain and above domain III of the *red* chain. **D:** Ribbon diagram of the solF0 protein monomer colored by domain. The direct distance within one monomer between residue 94 at the end of HRC and residue 142 at the base of the stalk region is 122 Å. **E:** Ribbon diagram of the monomer rotated by 90 degrees, indicating the width and height of the solF0 monomer. An *arrow* at the C-terminus of the HRB segment points toward the likely position of the transmembrane anchor domain that would be present in the full-length protein. (Adapted from Yin HS, Paterson RG, Wen X, et al. Structure of the uncleaved ectodomain of the paramyxovirus (hPIV3) fusion protein. *Proc Natl Acad Sci USA* 2005;102: 9288–9293, with permission.)

Atomic structures of the paramyxovirus F protein

Structure of the prefusion F protein

The crystal structures of the PIV-5 F protein ectodomain, and subsequently of NiV, HeV, and MeV F, have been determined in their metastable prefusion forms.[201,637,638,648] To solve the atomic structures, the secreted PIV-5 and HeV F proteins were stabilized by the addition of a soluble trimeric TM domain (GCNt) that supplants the hydrophobic TM domain, or in the case of MeV F through engineered disulfide bonds added to the membrane-proximal F stalk domain. In all cases, the F trimer was found to have a large globular head attached to a three-helix coiled-coil stalk formed by HRB (Fig. 12.17B–E), orienting the head away from the viral membrane. The F head contains three domains (DI–DIII) per subunit that extend around the trimer axis, making extensive intersubunit contacts. A large cavity is present at the base of the head, with the bottom and sides formed by DI and DII. DIII (residues 42–278) covers the top of the cavity, HRA, and the fusion peptide (Fig. 12.17B–F). At the C-terminus of DII, an extended linker to HRB wraps around the outside of the trimer and into the center of the base of the head where the stalk begins. The structure has three lateral vertices projecting from the trimer axis, exposing the cleavage/activation sites adjacent to the fusion peptides (Fig. 12.17C, D). Helices line the central threefold axis at the top and bottom of the trimer. In DIII, two sets of six helices form rings sealing the top of the head, while the HRB three-helix bundle seals the bottom (Fig. 12.17D). The network of noncovalent interactions between the top of the stalk and base of the head domain is considered to contribute to conformational stability of the prefusion F trimer, and a cocrystal structure of MeV F with a small-molecule MeV entry inhibitor stabilizing an F prefusion conformation[138,456] demonstrated specific targeting of this intersection by the compound[201] (Fig. 12.17G–J).

Illustrated by example of prefusion PIV-5 F, the hydrophobic fusion peptide (residues 103–128) is wedged between two subunits of the trimer (Fig. 12.17E). The N-terminal end of the fusion peptide is exposed at the F surface and then proceeds inward, becoming increasingly buried from solvent. The fusion peptide adopts a partly extended, partly β sheet, and partly α-helical conformation and is sandwiched between DIII of its own subunit and DII of another. Residues 107 to 117 pack against the

hydrophobic edge of the neighboring DII domain. The fusion peptide folds back on itself, forming a small hydrophobic core between its N- and C-terminal ends, making less extensive contacts with DIII (Fig. 12.17E, F). Proteolytic maturation of F0 might allow the N-terminus of the fusion peptide to make additional contacts with DII and to affect intersubunit interactions, but the transition of prefusion paramyxovirus F from the uncleaved to cleaved form does not entail a major relocation of the fusion peptides, as has been described, for instance, for influenza virus HA fusion peptides.[561] The crystal structure of soluble NiV F, expressed at high concentration, revealed a unique high molecular weight supercomplex that was interpreted as a hexameric ring of F protein trimers.[638] The physiological significance of this higher-order F organization is not known, and analogous supercomplex structures have not been noted in crystals of PIV-5, MeV, or HeV F. It is furthermore challenging to reconcile a ring-like F arrangement with the regular F layer, arranged in sync with the M protein array, that was revealed by reconstruction of cryopreserved near-native MeV virions (Ref.[266] discussed below).

Structure of the postfusion form of the F protein

The atomic structure of intact uncleaved F protein in its postfusion form[647] has also been determined. The structure of the HPIV-3 F protein was solved by molecular replacement using as a model a fragment of the NDV F structure that had been obtained earlier.[80] The NDV F structure had revealed a trimer, with distinct head, neck, and stalk regions.

The HPIV-3 F also forms a trimer, with distinct head, neck, and stalk regions (Fig. 12.18A–D). The only part of the structure lacking electron density is the fusion peptide and cleavage site, but these residues would be draped flexibly on the exterior of the stalk region. Given that the uncleaved F ectodomain was secreted from cells by removal of the TM domain, it was initially unexpected that the structure contained a 6HB (Fig. 12.18A–D) that represents the postfusion conformation of the protein. It had been widely anticipated that cleavage of F at the cleavage site was a requirement for conversion to the postfusion form. Nonetheless, many lines of evidence suggested that the observed HPIV-3 conformation represented the postfusion form, although the polypeptide chains were intact in the crystal and the fusion peptide was not located at the appropriate end of the 6HB: (a) the 6HB was

well formed and undistorted, similar to the previously determined PIV-5 and hRSV F 6HB structures[18,662]; (b) the HPIV-3 structure appeared to be inconsistent with peptide inhibition data that show, at least for PIV-5 F, that the HRA and HRB peptides are exposed at distinct steps of the membrane fusion reaction[503]; (c) the HPIV-3 structure does not provide a simple mechanism for how membrane fusion could be achieved. Cleavage of the HPIV-3 solF0 protein would appear to simply allow repositioning of the fusion peptide to the N-terminus of the HRA coiled-coil and concomitant insertion into the anchoring membrane for the TM domain; and, (d) the HPIV-3 structure did not explain the behavior of F protein mutants that destabilize the prefusion conformation of F and significantly enhance its membrane fusion activity.[89,138,292,442,504,647]

The observation that the soluble, secreted HPIV-3 and NDV F proteins were in the postfusion conformation was unexpected, and there are at least two possible explanations for this finding. First, the TM anchor (and potentially the cytoplasmic tail[624]) could be an important determinant of the stability of the prefusion conformation, providing a significant fraction of the energy barrier that traps the protein in a metastable state. In this case, the secreted protein may fold into the prefusion form transiently but then refold to the postfusion conformation. A second possible explanation for the structural results is that the TM domain is important for the protein to attain the prefusion metastable state and that, in the absence of this region, the soluble F protein folds directly to the final, most stable postfusion conformation. In either case, it appears that the amino acids constituting the intact F protein ectodomain are not sufficient for the protein to fold to and maintain a metastable conformation. Hence, to preserve a soluble form of a paramyxovirus F protein in its metastable form, the prefusion stalk domain had to be stabilized either through in-frame addition of a trimeric GCNt or bacterial fold on domain as mimetics of the hydrophobic TM domain[48,637,648] or a scaffold of engineered disulfide bonds.[201]

Comparison of the pre- and postfusion F structures

The available prefusion F structures and the HPIV-3 postfusion F structure are in strikingly different conformations (Fig. 12.19), consistent with a transition from pre- to postfusion forms. None of the intersubunit contacts are conserved in the pre- and postfusion forms. The two F conformations are

related by flipping the stalk and TM domains relative to the F head. Substantial compacting of the head is observed in HPIV-3 postfusion F compared to the prefusion F structures. DI domains pivot slightly inward, shearing intersubunit contacts, and DII domains swing across, contacting neighboring subunits. Individual DI and DII domains in the two conformations remain similar. Closely related forms of the paramyxovirus F proteins have been observed in electron micrographs and crystal structures of RSV F of the pneumovirus family.[65,179,355,356,500,501]

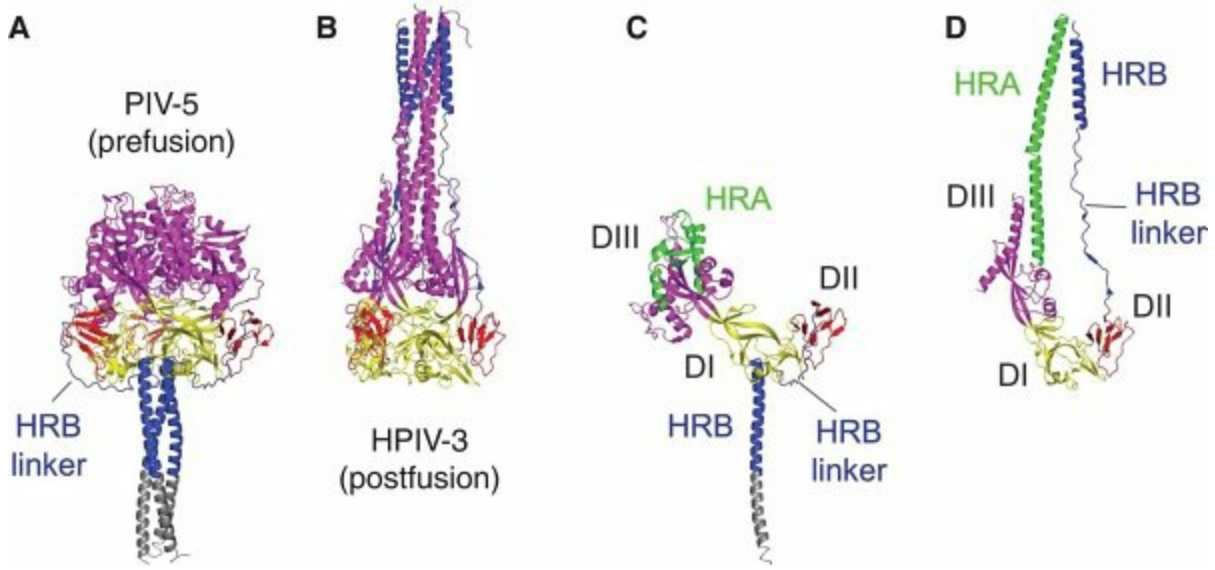

FIGURE 12.19 Structural changes between the pre- and postfusion F protein conformations. **A:** Ribbon diagram of the PIV-5 F-GCNt trimer. DI is colored *yellow*, DII is colored *red*, DIII is colored *magenta*, HRB is colored *blue*, and GCNt is colored *gray*. **B:** Ribbon diagram of the HPIV-3 (postfusion) trimer, colored as in **(A)**.

C: Ribbon diagram of a single subunit of the PIV-5 F-GCNt trimer, colored as in **(A)**, except for HRA residues, which are colored *green*. **D:** Ribbon diagram of a single subunit of the HPIV-3 F trimer, colored as in **(C)**. (Adapted from Yin HS, Wen X, Paterson RG, et al. Structure of the parainfluenza virus 5 F protein in its metastable, prefusion conformation. *Nature* 2006;439: 38–44, with permission.)

DIII undergoes major refolding between the two structures, projecting a newly assembled coiled coil (HRA) upward and away from DI, the prefusion stalk and the viral membrane. The fusion peptides, located at the top of this HRA triple helix coiled coil, move approximately 115 Å from their initial position between subunits in the prefusion conformation, allowing DII domains to reposition. None of the postfusion HRA intersubunit coiled-coil contacts are observed in the stabilized F structures. Instead, they are replaced by two sets of six-helix rings at the DIII interfaces (Fig. 12.17D). To assemble the HRA coiled coil to form, DIII must rotate and collapse inward, further compacting the head. In the prefusion conformation, HRA is broken up into four helices, two β strands, and five loop, kink, or turn segments. Thus, the conformational changes in HRA involve the refolding of 11 distinct segments into a single, extended α-helical conformation (Fig. 12.20).

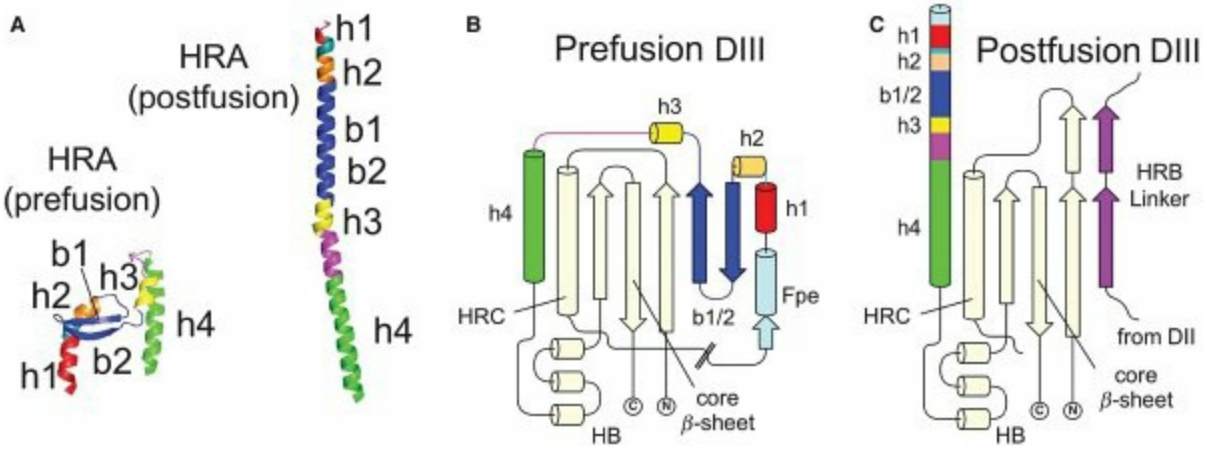

FIGURE 12.20 F protein refolding: the role of DIII in HRA folding and transformation. **A:** HRA refolds from 11 distinct segments (h1, h2, b1, b2, h3, h4, and the intervening residues) in the prefusion conformation into a single approximately 120-Å–long helix in the postfusion form. **B:** Secondary structure diagram for DIII in the prefusion (PIV-5) conformation. The "DIII core" includes three antiparallel strands, HRC, a helical bundle (HB), and h4 of HRA. HRA segments are colored as in **(A)**, and the cleavage site (//) and fusion peptide are indicated. The DIII core sheet is extended by the b1 and b2 strands from HRA. **C:** Secondary

structure diagram for DIII in the postfusion (HPIV-3) conformation colored as in **(B)**. The DIII core sheet is extended by one strand from HRB linker from a neighboring subunit (*dark violet*). (Adapted from Yin HS, Wen X, Paterson RG, et al. Structure of the parainfluenza virus 5 F protein in its metastable, prefusion conformation. *Nature* 2006;439: 38–44, with permission.)

The conformational change also requires the opening and translocation of the HRB stalk (Fig. 12.19). In the prefusion form, HRB is located at the base of the head region. During the conversion to the postfusion conformation, HRB segments must separate and swing around the base of the head to pack against the HRA coiled coil (hairpin formation). Since the C-terminal residues of HRB are neighboring the TM domains anchored in the viral envelope, hairpin formation most likely entails asymmetric refolding of individual monomers constituting the F trimer.

The mechanism of paramyxovirus-mediated membrane fusion

The pre- and postfusion F structures suggest how discrete refolding intermediates are coupled to the activation and progression of F-mediated membrane fusion. Although proteolytic cleavage of the paramyxovirus F protein is required for membrane fusion activity, it is not necessary for the formation of the postfusion conformation. In a current model of membrane fusion, the HRB helices melt in a first step (open-stalk form, Fig. 12.21), breaking interactions at the base of the head but leaving HRA in the prefusion conformation. This intermediate is consistent with effects of mutations of PIV-5 F residues 443, 447, and 449, peptide inhibition data, and inter–monomeric disulfide bonds engineered to link the top of prefusion MeV F stalk to the base of the head domain.[303,442,503,504] These disulfide bonds covalently stabilized prefusion F but allowed fusion to proceed when exposed to reducing conditions. HRA-derived peptides, which likely bind to the endogenous HRB segment, inhibited an early intermediate along the fusion pathway, while HRB-derived peptides inhibited a later intermediate by binding the endogenous HRA coiled coil. Opening of the HRB stalk could

initiate further changes in F by affecting the packing of DII and the fusion peptide (through the HRB linker) and by affecting the stability of the head intersubunit contacts, which shift during the conformational transition. It seems possible that transient dissociation of the F trimer could occur, analogous to dimer-to-trimer transition characterized in alpha- and flavivirus fusion proteins. The open-stalk intermediate is then likely followed by refolding of DIII, the assembly of the HRA coiled coil, and the translocation of the fusion peptide toward the target cell membrane (Fig. 12.21). This prehairpin intermediate has been trapped and coprecipitated with HRB peptides.[503] Removal of the fusion peptide from the intersubunit interfaces is believed to enable an inward swing of DII and the formation of new contacts with DI of a neighboring subunit, compacting the head. The refolding of DIII HRA would also expose its core β sheet and, together with the inward movement of DII, allow the HRB linker (at the C-terminus of DII) to form parallel β strands with the DIII core, likely preceding and initiating the final positioning of HRB (Fig. 12.21). The assembly of the final 6HB completes the conformational change and membrane merger.

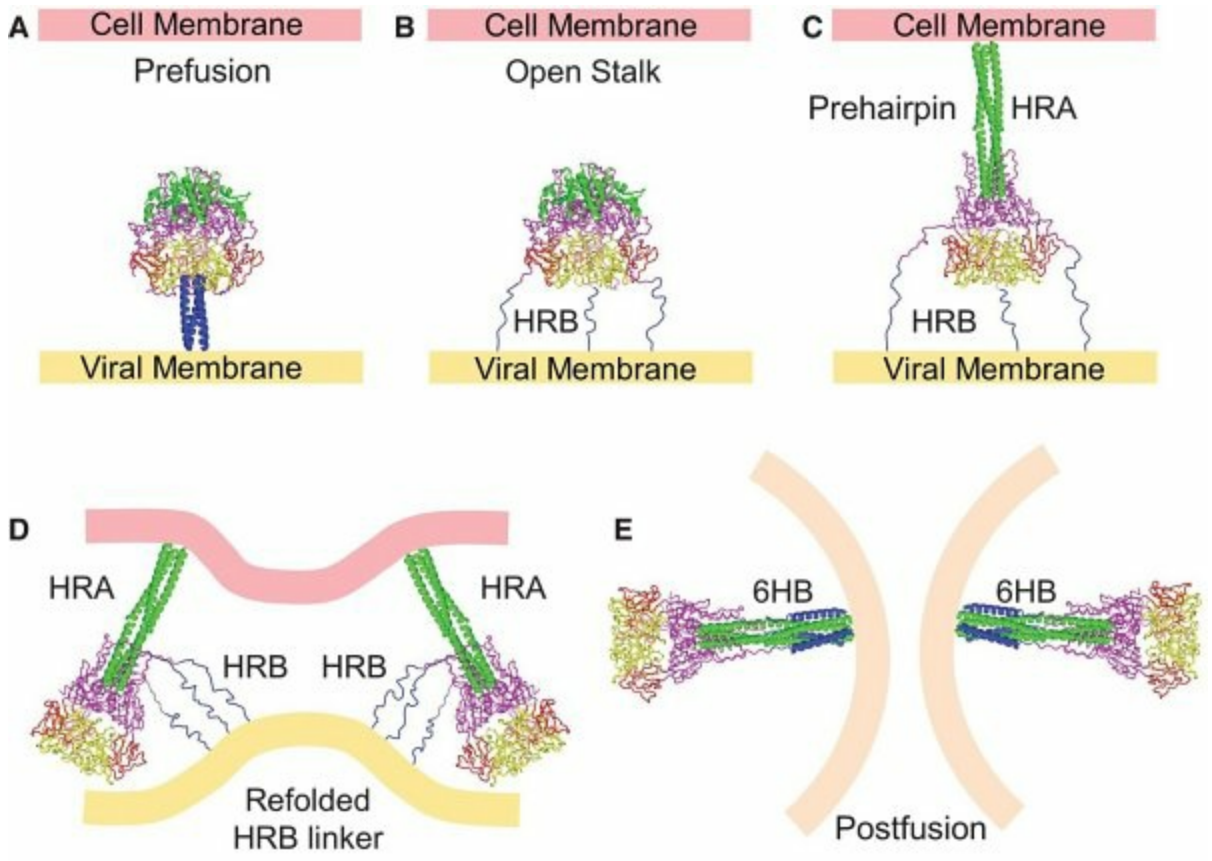

FIGURE 12.21 A model for F-mediated membrane fusion. **A:** Structure of the prefusion conformation. HRB is colored *blue*, HRA is colored *green*, and domains I, II, and III are colored *yellow*, *red*, and *magenta*, respectively. **B:** An "open-stalk" conformation, in which the HRB stalk melts and separates from the prefusion head region. HRB is shown as three extended chains because the individual segments are unlikely to be helical. This conformation is consistent with a low-temperature intermediate that is inhibited by HRA peptides, but not HRB peptides. Mutations of the switch peptide residues 443, 447, and 449 would influence the formation of this intermediate by affecting stabilizing interactions between the prefusion stalk and head domains. **C:** A prehairpin intermediate can form by refolding of DIII, allowing the formation of the HRA coiled coil and insertion of the fusion peptide into the target cell membrane. This intermediate can be inhibited by

peptides derived from both HRA and HRB regions. **D:** Prior to forming the final 6HB, the close approach of viral and cellular membranes may be trapped by folding of the HRB linker onto the newly exposed DIII core, with the formation of two β strands. **E:** The formation of the postfusion 6HB is tightly linked to membrane fusion and pore formation, juxtaposing the membrane-interacting fusion peptide and TM domains. (Adapted from Yin HS, Wen X, Paterson RG, et al. Structure of the parainfluenza virus 5 F protein in its metastable, prefusion conformation. *Nature* 2006;439: 38–44, with permission.)

The attachment protein activates the F protein for membrane fusion

The exact molecular triggering mechanism that regulates F protein refolding such that it occurs when a target cell is within reach is still unknown, although most paramyxovirus F proteins require the presence of the receptor-binding protein (HN, H, or G) for activation of cell-to-cell fusion (reviewed in Refs.[292,372,455]) and engineered paramyxoviruses lacking the attachment protein have not been recovered. The precise role of the HN, H, or G protein in stimulating the F conformational change remains to be understood, but the emerging picture indicates a highly controlled, complex biological machine.

For all paramyxoviruses, coexpression of F and HN, H, or G is required to mediate viral entry.[73,148,227,230,373,509,634,646] Furthermore, typically the homotypic attachment protein (i.e., of the same virus), and not a heterotypic protein derived from a different member of the family, has to be coexpressed in the same cell as the F protein to promote fusion,[227,230,533] although cases of heterotypic fusion activation between glycoproteins derived from different viruses within the same paramyxovirus genus (i.e., for the morbilliviruses) have been described.[302] However, expression of the F of PIV-5 alone causes some syncytium formation in transient cell-to-cell fusion assays,[8,227,255,419,440,443] and point mutations within NDV F render the protein somewhat HN-independent for fusion.[534] It therefore appears likely that the different paramyxovirus F proteins have different activation energy

thresholds for fusion activation and that HN, H, or G enable the F protein to cross this activation energy barrier in a receptor binding–dependent manner.

It was hypothesized that a type-specific interaction would occur between the attachment and F protein.[230,288,535] Immunoprecipitation assays show that F and attachment proteins coprecipitate specifically,[5,125,358,459,564,646] native MeV F and H proteins were found to first interact intracellularly in the ER of the infected cells,[458] and HPIV-3 F and HN have been shown to undergo antibody-induced cocapping,[646] indicating the formation of a protein complex. A lot of effort has been spent on mapping the regions of F and the attachment protein that interact. Mutations have been identified in the globular attachment protein head domain,[123,366] the helix repeat–like domains of the attachment protein stalk region,[52,124,302,358,421,466,535,565,584,657] and TM anchor[42,352] that decrease or abolish fusogenic activity with no or little effect on receptor recognition. Analysis of the fusion promoting activity of chimeric or engineered paramyxovirus attachment proteins largely suggests that the stalk domain and, in some cases, parts of the globular head impart productive interaction with F.[124,421,584,602] Crystal structures of the NDV HN ectodomain and the PIV-5 HN stalk[38,655] have revealed a parallel 4-helix bundle arrangement of the stalks, in which 11-mer and 7-mer helical repeat sections are separated by a central kink. In the NDV HN structure, the dimeric head domains flank the 4-helix bundles with one of the head monomers of each dimer directly associating with the stalk (Fig. 12.22). This conformation, termed a “heads-down” arrangement, is considered to represent the prereceptor-bound arrangement.[249] By contrast, the PIV-5 HN crystal structure posited the globular head domains oriented away from the stalk and receptor-binding sites facing toward the target membrane, which was hypothesized to resemble a postreceptor-bound “heads-up” organization[632] (Fig. 12.22C). Biochemical assessment of native MeV H tetramers revealed conformational changes upon receptor binding, suggesting that the HN-based observations likely extend to paramyxoviruses binding to proteinaceous receptors.[52] Extension of the helical MeV H stalk domain by 41 amino acids in α-helical arrangement, corresponding to approximately 7.5 nm in pitch or an elongation of the stalk by an additional half of its original length, was furthermore compatible with efficient fusion promotion in transient expression assays and engineered recombinant virions, provided the extension was placed downstream of stalk residue 118,[51,421] indicating that

MeV H stalk residues membrane-proximal of position 118 interact with prefusion F. The structural and biochemical data suggest a modular organization of the attachment protein, organized in a receptor-binding (head domains) regulatory module and an F-triggering (stalk domain) effector module. First demonstrated for PIV-5 HN and confirmed for MeV H, NiV G, and MuV and NDV HN, engineered "headless" attachment protein stalk domains are sufficient to specifically trigger homotypic F trimers in transient cell-to-cell fusion assays.[37,39,51,319] Presumably due to premature constitutive F activation, however, these isolated effector modules are unable to support efficient replication of engineered recombinant viruses.[51]

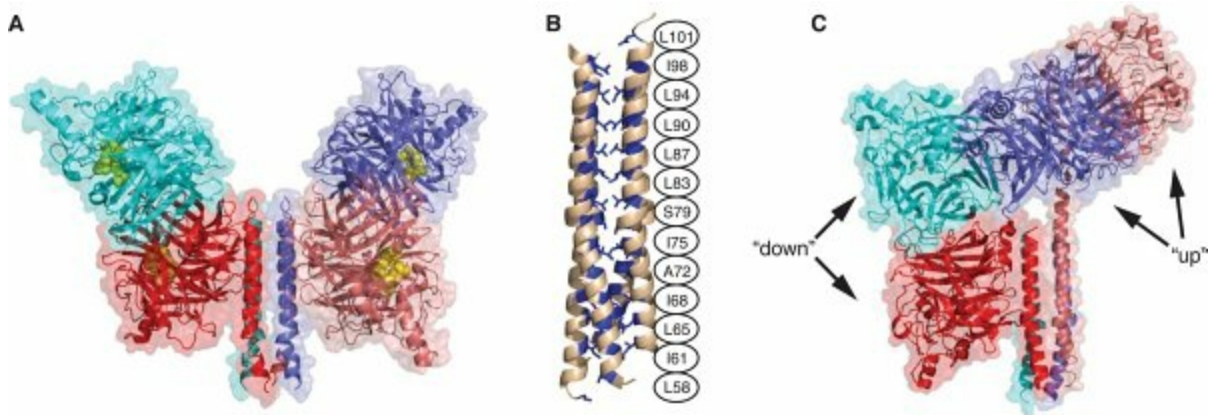

FIGURE 12.22 Crystal structures of the PIV-5 and NDV HN proteins.

A: The NDV HN structure (PDB ID: 3T1E) possesses four ectodomains in a "heads-down" orientation.[655] The receptor-binding sites (E400, R415, and Y525) are shown as *yellow spheres*.

B: Structure of the HPIV-5 HN stalk (amino acids of 56–108) (PDB ID: 3TSI) forms a four-helix bundle.[38] Residues that form the hydrophobic core of the four-helix bundle are labeled.

C: A crystal structure of the PIV-5 ectodomain (PDB ID: 4JF7) revealed an alternative conformation.[632] In this structure, one head domain dimer is in "heads-down" orientation and the other dimer in "heads-up" orientation (*black arrows*).

Initial mechanistic models of the fusion process considered that the paramyxovirus attachment proteins may stabilize associated F protein trimers in prefusion conformation, thus acting like a molecular clamp that prevents F refolding until receptor-binding–induced separation of the attachment and F protein oligomers. An implication of this model is that F protein trimers expressed in the absence of the attachment proteins should spontaneously assume a postfusion-like conformation, potentially immediately after insertion into the ER membrane but latest after proteolytic maturation. Through use of monoclonal antibodies that selectively recognize conformation-dependent epitopes present only in the prefusion forms of the PIV-5, MeV, CDV, or NiV F trimers, however, it was demonstrated that these F proteins remained in prefusion conformation when expressed on their own and did not convert to the postfusion form unless subjected to a trigger such as heat.[2,52,77,94] These observations and the constitutive fusion promotion activity of headless attachment protein effector domains called for an alternative triggering mechanism.

Rather than attachment proteins acting as a molecular clamp, the current model of paramyxovirus fusion promotion proposes that in the case of paramyxoviruses with HN-type attachment proteins featuring relatively short stalk domains, the prereceptor-bound heads-down conformation sterically prevents premature contact of prefusion F with the HN stalk (Fig. 12.23A). Receptor binding rotates HN head domains into the heads-up configuration, giving F access to the now exposed stalk effector module. Subsequent rearrangements in the HN stalk-F contact zone may alter the interface with F, activating the F trimer for membrane fusion.[249] Variations of this triggering mechanism appear to have evolved in the binding of paramyxoviruses, such as members of the *Morbillivirus* genus, to proteinaceous receptors (Fig. 12.23B). A seemingly counterintuitive inverse correlation between fusion promotion activity and strength of F-attachment protein interaction has been demonstrated for H-type and G-type attachment proteins of the *Morbillivirus* and *Henipavirus* genus, respectively,[96,367,459] and MeV F-H complexes are tightly associated in early secretory compartments of the host cell prior to proteolytic maturation of F and receptor binding of H.[458] Through use of headless MeV H stalks and F mutants stabilized in prefusion conformation, it has been shown that the MeV H head domains do not block F access to the stalk domain prior to receptor binding.[48] Rather, uncleaved MeV F0s tightly

preassemble with H stalks in the ER, and subsequent F maturation in the Golgi partially destabilizes this assembly, preparing for F activation. However, H head domains in prereceptor-bound configuration appear to suppress H stalk rearrangements required for F triggering until receptor binding. Receptor-induced rotation of the H head domains into a heads-up configuration may then be directly linked to stalk rearrangements at the H–F interface, triggering F.[3] The intracellular preassembly of the fusion complexes has been shown to affect MeV fusion profiles[48] and may account for the extremely high cell-to-cell fusion activity characteristic of the *Morbillivirus* genus.

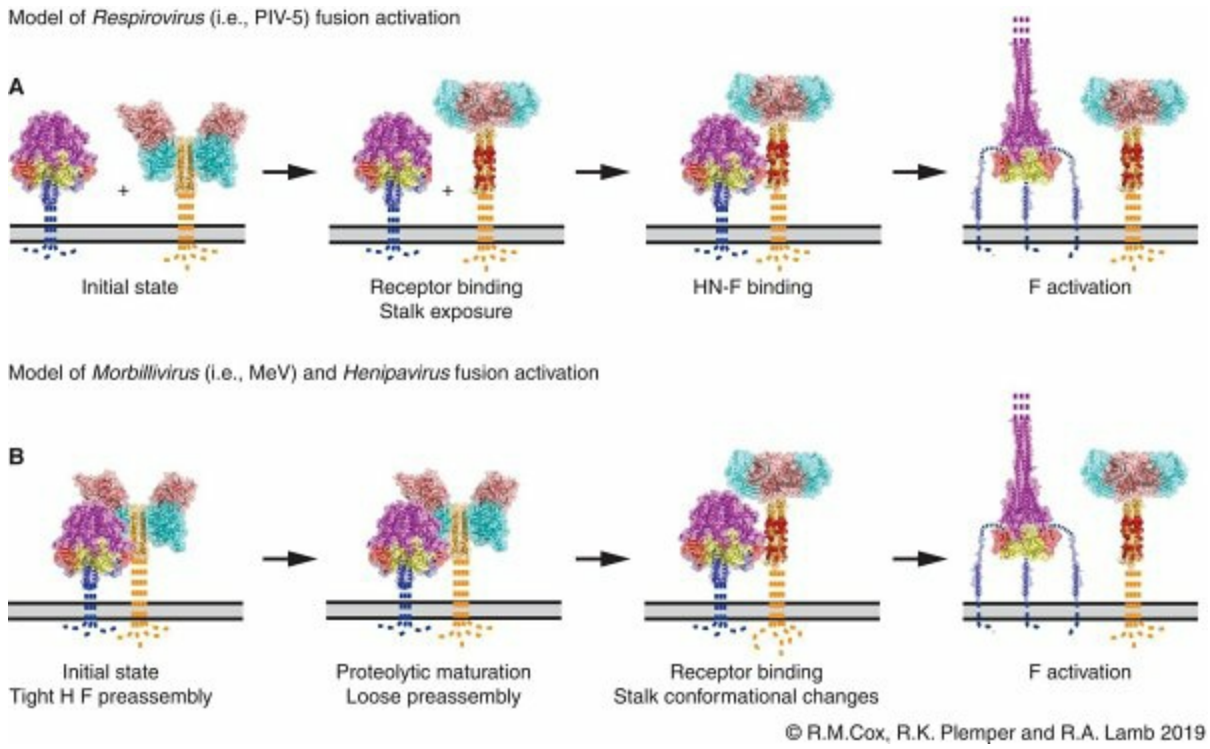

FIGURE 12.23 Models for paramyxovirus fusion activation. Presenting variations of common elements, two F activation models are favored for paramyxoviruses entering through carbohydrate (i.e., PIV-5) **(A)** or proteinaceous (i.e., MeV) **(B)** receptors. In **(A)**, the F binding site in the attachment protein stalk is masked by the head dimers in heads-down configuration until receptor binding. Then, the F binding domain in the stalk is

exposed and glycoprotein hetero-oligomers associated, triggering F refolding. In **(B)**, a longer stalk domain allows tight intracellular preassociation of envelope glycoprotein hetero-oligomers. Proteolytic maturation of F late in the secretory system relaxes the interaction, and receptor binding by the attachment protein head domains induces conformational changes in the tetrameric stalk that trigger F refolding.

Cleavage activation

As discussed previously, the precursor F0 molecule is biologically inactive, and cleavage of F0 to the disulfide-linked chains F1 and F2 activates the protein, rendering the molecule fusion-active and permitting viral infectivity. It is important to remember, however, that F2 and F1 are not separate domains in the atomic structure of F and thus are not individual parts of the protein. Cleavage of F0 is a candidate to be a key determinant for infectivity and pathogenicity, and for certain viruses, this appears to be the case. Proteolytic activation of F0 involves the sequential action of two enzymes, the host protease that cleaves at the carboxyl side of an arginine residue, and a host carboxypeptidase that removes the basic residues. The *Paramyxoviridae* can be divided into two groups: those that have F proteins with multibasic residues at the cleavage site and those with F proteins that have a single basic residue at the cleavage site (Table 12.5). Cleavage of F proteins containing multibasic residues at the cleavage site occurs intracellularly during transport of the protein through the *trans*-Golgi network.

Consensus sequence for furin protease cleavage is $\begin{matrix} & & \text{R} \\ \text{R-X—R}\downarrow & \text{or} & \\ \text{K} & & \end{matrix}$.[228]

Furin is a cellular protease localized to the *trans*-Golgi network, and its sequence specificity for cleavage is R-X-K/R-R. The available evidence suggests that furin, a subtilisin-like endoprotease, is the (or one of the) protease(s) that cleaves most F proteins intracellularly (Ref.[420]; reviewed in Ref.[275]).

Paramyxoviruses that have F proteins with single basic residues in the cleavage site (e.g., SeV) are not usually cleaved when grown in tissue culture, and, thus, only a single cycle of growth is obtained. However, the F0 precursor that is expressed at the cell surface and incorporated into released virions can be cleavage activated by the addition of exogenous protease,[519] leading to multiple rounds of replication. Purification of a protease from the allantoic fluid of embryonated chicken eggs has indicated that the endoprotease responsible for SeV activation is homologous to the blood clotting factor Xa, a member of the prothrombin family.[183,186] A protease with similar substrate specificity is secreted from Clara cells of the bronchial epithelium in rats and mice, and this enzyme is probably responsible for

activating paramyxoviruses in the respiratory tract. For NDV, the nature of the cleavage site correlates with virulence of the virus. Those strains with multibasic residues in the F0 cleavage site are virulent strains and readily disseminate through the host, whereas strains with F0 molecules having single basic residues are avirulent and tend to be restricted to the respiratory tracts where the necessary secreted protease can be found.[388]

A variation on the cleavage theme is found with HeV because its F protein does not contain a multibasic cleavage site. HeV F is cleaved in expressing cells at the sequence HDLVDGVK↓,[105] but the K residue is not essential for cleavage.[368] In the search for the cleavage enzyme, it was found that inhibition of cathepsin L blocks cleavage,[423] suggesting cleavage occurs in the endocytic pathway.[133,363]

Other Envelope Proteins

The *Rubulavirinae* such as PIV-5 and MuV and the Jeilongvirus paramyxoviruses contain a small gene located between F and HN designated SH.[1,214,215,308] The PIV-5 SH protein is a 44-residue, type II integral membrane protein that is expressed at the plasma membrane and is packaged in virions. The MuV SH protein is a 57-residue integral membrane protein orientated in the opposite direction from the PIV-5 SH protein with a C-terminal cytoplasmic domain.[151,580] Due to the variability in sequence among different strains of MuV, the *SH* gene sequence has been used as marker to identify MuV isolates.[579] PIV-5 lacking SH (rSV5deltaSH) grows as well as wild-type in tissue culture cells, but the virus is attenuated *in vivo*.[205] rSV5deltaSH induces apoptosis in L929 and MDCK cells (but not in HeLa cells) through a tumor necrosis factor alpha (TNFα)-mediated extrinsic apoptotic pathway.[206,314] *In vivo* virus attenuation and a comparable TNFα-mediated effect on pathogenesis were more recently reported for Jeilongviruses engineered to lack SH.[1] While the *SH* gene has been found in all strains of MuV, expression of the SH protein is also not required for MuV replication in tissue culture,[580] and in the Enders strain of MuV, a monocistronic mRNA encoding SH is not found. MuV SH may have a similar role as PIV-5 and *Jeilongvirus* SH.[635]

TM protein, the fourth integral membrane protein of members of the *Jeilongvirus* genus, has been found in association with F and G in

biochemical assays and was shown to stimulate cell-to-cell fusion activity in cell culture. However, TM was dispensable for growth of recombinant viruses in tissue culture.[308]

STAGES OF REPLICATION

General Aspects

Transient nuclear localization of the matrix protein has emerged as a recurring theme that may apply to all *Paramyxoviridae*, but all aspects of paramyxovirus genome transcription, replication, and virion assembly occur in the cytoplasm. A schematic overview of the paramyxovirus life cycle is provided in Figure 12.24, and an overview of transcription and replication is shown in Figure 12.25. In contrast to, for instance, the *Orthomyxoviridae*, paramyxovirus mRNA synthesis is insensitive to DNA-intercalating drugs such as actinomycin D (reviewed in Ref.[84]), and the *Paramyxoviridae* can replicate in enucleated cells.[450] In cell culture, single cycle growth curves are generally of 14 to 30 hours' duration, but virulent strains of NDV can complete a replication cycle in as little as 10 hours. The effect of viral replication on host macromolecular synthesis is quite variable, ranging from almost complete shutoff late in infection for NDV to no obvious effect in PIV-5–infected cells.

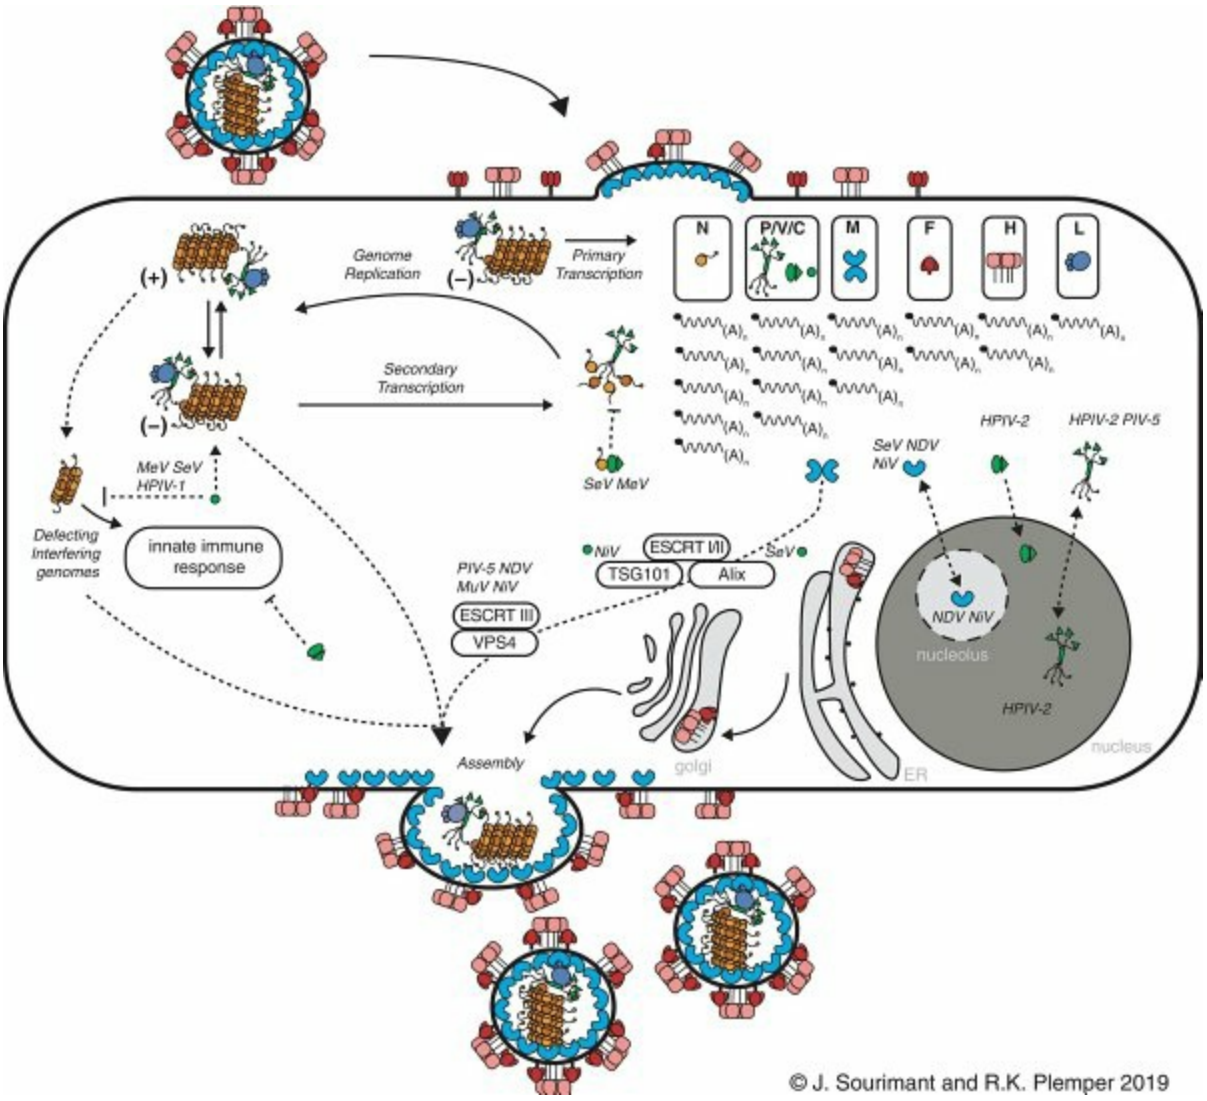

FIGURE 12.24 Schematic representation of the paramyxovirus life cycle. Incoming virions (*top*) fuse with the plasma membrane to release the (−) sense nucleocapsid into the cytoplasm. Viral mRNAs are represented by *zigzag lines*; 5′ mRNA caps are shown as filled *black circles* and 3′ poly-A tails by $(A)_n$. The transcription gradient is symbolized. The relative abundance of genomic and antigenomic RNPs is not shown. Primary and secondary transcription, stages of genome replication, and the role of P proteins in forming P-L polymerase and RNA-free N^0–P complexes are shown. The V protein has been observed to be able

to bind the nucleoprotein for MeV and SeV, although the N^0–V complex seems unable to form nucleocapsids. The newly synthesized RNPs are assembled into budding virions through interactions with the M protein. The polymerase can prematurely abort replication and release dsRNA structures that can trigger innate immune responses. The C proteins limit these phenomena by increasing polymerase fidelity, likely through direct binding to L. Nuclear transport of some M proteins and nucleolar localization are represented by a *dashed arrow*. Nuclear shuttling observed for some P proteins is represented by a *dashed arrow*. Integral envelope proteins are transported through the host cell secretory system. The proposed interactions of some M proteins with host cell ESCRT including TSG101 and Alix are represented by *dotted lines*, and recruitment of ESCRT-III and VPS4 to the budding site (*bottom*) proposed for some paramyxoviruses is shown. Release of progeny virions is thought to occur from the plasma membrane. (Images copyright © 2019 by Richard K. Plemper and Julien Sourimant.)

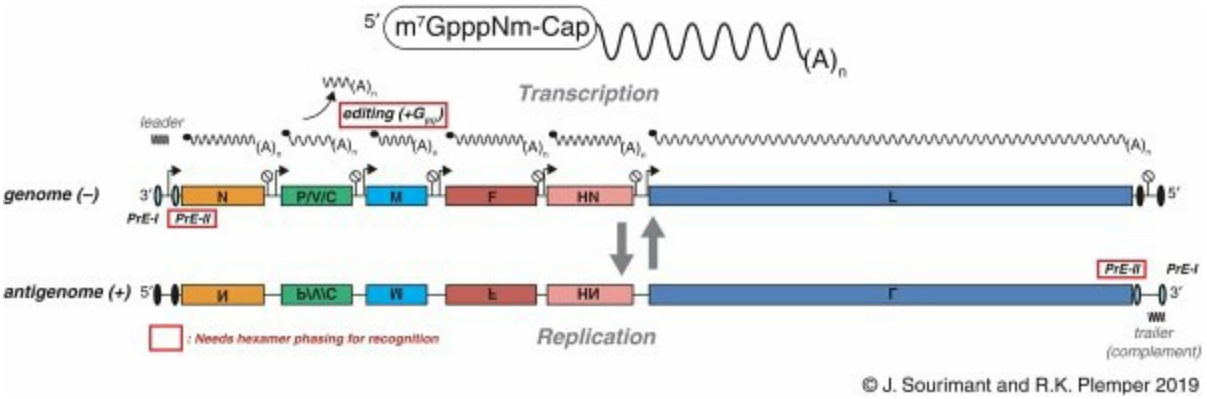

FIGURE 12.25 Schematic of the paramyxovirus negative-sense genomic and positive-sense antigenomic RNA. The locations of the 3′-end promoter element I (PrE-I) and internal promoter element II (PrE-II) are indicated by *blue oval circles*; color-coded areas refer

to transcribed sections. The 5′ end of the antigenome contains sequences that are the compliment to the genomic RNA promoter and are partially complimentary to the 3′ region of the antigenomic RNA. Transcription products are represented with *black zigzag lines* above the schematic genome, mRNAs are represented with a 5′ cap (*black dot*) and a poly-A tail: $(A)_n$. The 5′ cap of paramyxoviruses has a cap-1 structure typical of eukaryotic mRNAs. Guanine-7-methylation activity has been shown to be carried by the L protein of SeV, RPV and PPRV, and conserved motifs among mononegaviruses and MTases suggest that the L may also mediate ribose-2′O-methylation. PrE-II function and the P/V mRNA editing site are optimized for most paramyxoviruses based on their position relative to the RNP phase. (Images copyright © 2019 by Richard K. Plemper and Julien Sourimant.)

Virus Adsorption and Entry

It has long been accepted that molecules containing sialic acid (sialoglycoconjugates) serve as cell surface receptors for the respiroviruses and *Rubulavirinae*. This was originally based on the finding that sialidase of *Vibrio cholerae* acted as a "receptor-destroying enzyme" and protected the host cell from infection (reviewed in Ref.[340]). Sialic acid, the acyl derivative of neuraminic acid, is found on both glycoproteins and lipids (sialoglycolipids or gangliosides). For SeV, gangliosides function as both the attachment factor and the viral receptor.[341–343] As described above, the morbilliviruses and henipaviruses bind to proteinaceous receptors displayed on the target cell surface; cognate receptors for the morbilliviruses are the host species–specific homologues of human SLAM and nectin-4, while the zoonotic henipaviruses use highly conserved ephrin-B2 and ephrin-B3 for cell entry. Upon adsorption of the virus to the cellular receptor, the viral envelope fuses with the target membrane at neutral pH conditions, ultimately resulting in release of the helical nucleocapsids into the cytoplasm.

Cryo-ET–based reconstructions of paramyxovirus particles have revealed

numerous contacts between the M protein arrays and the nucleocapsid, necessitating the existence of a specific uncoating mechanism that allows separation of the nucleocapsid from the membrane-associated viral proteins after fusion of the envelope with cellular membranes. Unlike influenza virus, for instance, that encounters different environmental conditions at the assembly site (plasma membrane) and acidic uncoating compartment (endosomes), paramyxovirus self-assembly and disassembly are believed to both occur at the plasma membrane. Components of the host cell ESCRT machinery have been implicated in participating in the assembly and budding process, but the driving force for paramyxovirus uncoating is not known.

Viral RNA Synthesis

Paramyxoviruses control both the level and type of viral RNA that is synthesized at different stages of the infection cycle through the use of cis-acting RNA sequences and trans-acting proteins. The relationship between RNA sequences and the RdRP functions that they control is particularly complex because these cis-acting signals are only properly recognized when they are in the context of the nucleocapsid structure. Overlaying these RNA-encoded control elements are regulatory protein–protein interactions between components of the P-L polymerase and the RNP and trans-acting accessory proteins that govern specific activities of the RdRP. Because all RdRP functionalities are essential for completion of the viral replication cycle, synthetic minigenome systems using cDNA-derived viral components that allow the targeted assessment of individual activities of the viral polymerase machinery have been instrumental for the functional analysis of both cis-acting sequences and regulatory protein interactions.

The paramyxovirus genome expression and replication cycle can be divided into three major phases. Early after infection, before the synthesis of appreciable amounts of viral proteins (or in the presence of inhibitors such as cycloheximide that block protein synthesis), the RdRP, in the primary transcription phase, transcribes viral mRNAs from the incoming virus genome (Fig. 12.24). When a sufficiently large N protein pool has been synthesized to ensure encapsidation of full-length RNA genome copies, the RdRP in processive replicase mode generates (+)-sense antigenomes, which serve as templates to synthesize (−)-sense progeny genomes. Both antigenomic and genomic RNAs must be encapsidated cotranscriptionally.

The accumulating progeny genomes then serve as additional templates for viral mRNA synthesis in a secondary transcription phase, which yields the message required to produce the bulk of the viral proteins. Because of the increasing number of template genomes transcribed, viral mRNA copies present in the infected cell expand exponentially during secondary transcription, compared to linear accumulation during primary transcription.[460]

Paramyxovirus Promoter Organization

The paramyxovirus RdRP gains access to the viral genome and antigenome through single entry sites located at the 3′ ends. While the promoter present on antigenomes (hence termed the antigenomic promoter) only directs the synthesis of full-length genomic RNA, the promoter on genome RNA (termed the genomic promoter) is responsible for the generation of both mRNAs and antigenomes. Genomic RNA is present in higher copy numbers than antigenomic RNA in infected cells,[299] which was originally thought to reflect greater strength of the antigenomic than the genomic promoter. Using C protein–deficient recombinant SeV, however, it has more recently been demonstrated that the genomic promoter is in fact stronger than the antigenomic.[240] The greater relative abundance of genomic RNA is attributed rather to the C protein, which can interact with the L protein and regulate polymerase activity at the promoter.[189,223,239,240] The promoters of all paramyxoviruses have a bipartite organization, in which the first of two discontinuous promoter elements (PrE-I) is located at the 3´ end of the RNA strand and the second (PrE-II) between positions 73 and 96, depending on the virus,[217,339,365,381,587,618,619] placing the PrE-II sequence within the *N* or *L* gene for the genomic and antigenomic promoter, respectively (Fig. 12.26A). PrE-I sequences are highly conserved within the family, while the PrE-IIs feature three-time repetitions of one of two simple motifs, either $(CNNNNN)_3$ or $(NNNNGC)_3$.[217,339,365,381,587,618,619] Additional elements located between antigenomic PrE-I and PrE-II in PIV-5 (bases 51–66) and HPIV-3 (bases 13–55) are believed to act as nonessential enhancer of replication.[217,267]

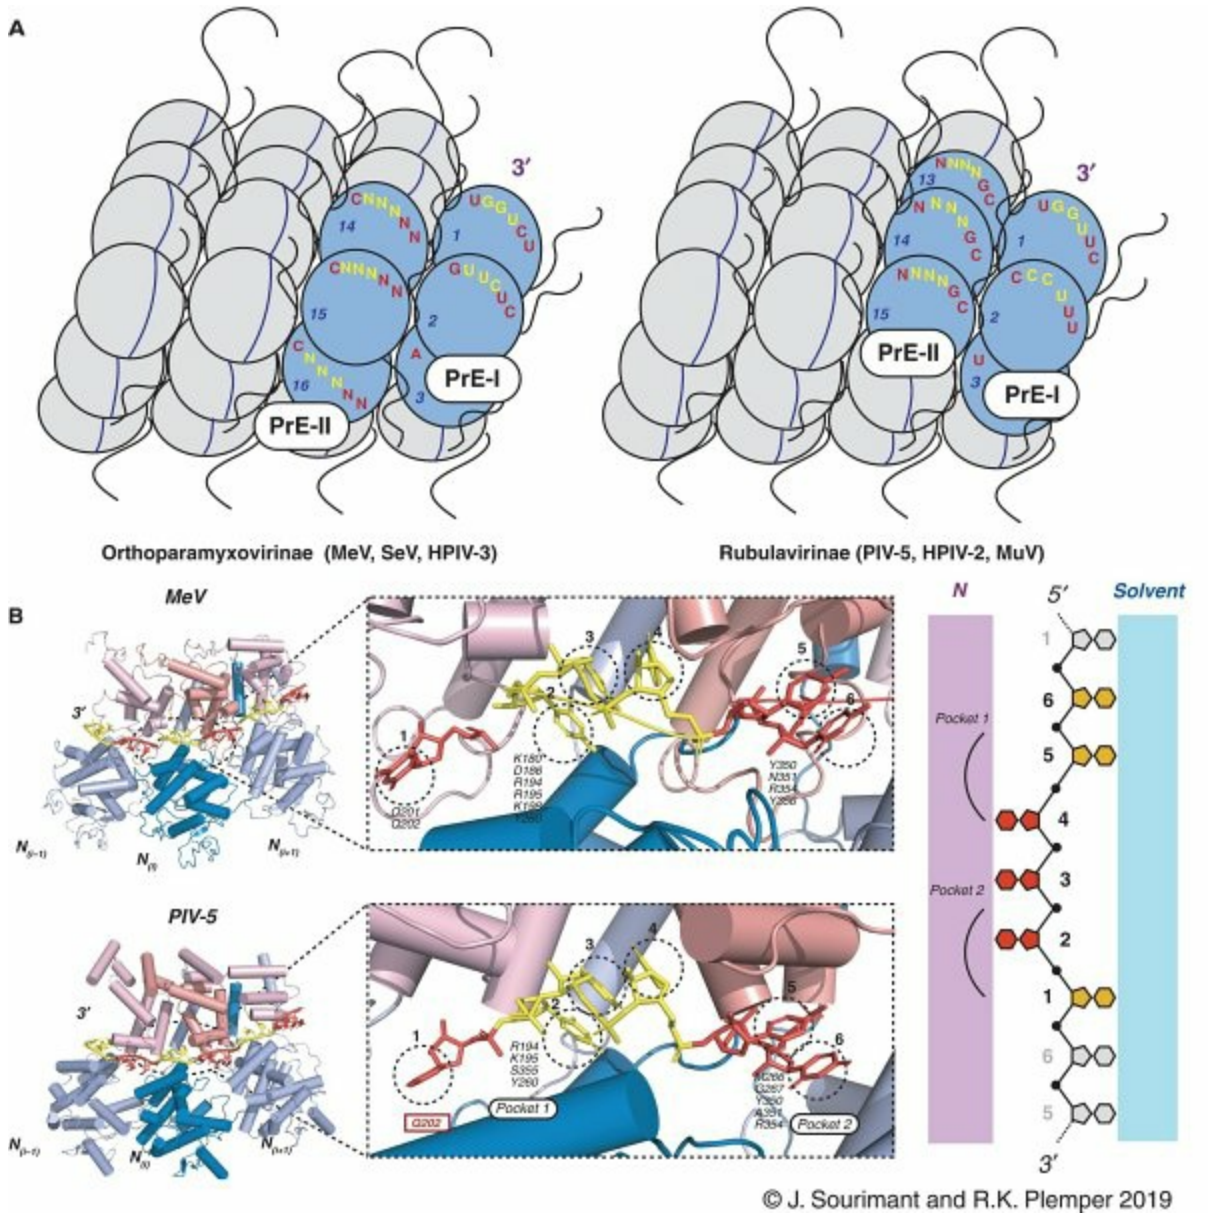

FIGURE 12.26 Nucleocapsid structure, hexamer phasing of nucleotide sequences, and the bipartite replication promoters of the *Paramyxoviridae*. **A:** Left-handed helix models of the SeV (*left*) and PIV-5 (*right*) nucleocapsid assemblies. Single N protein protomers (*gray spheres with black tail*) bind precisely six nucleotides, 13 N subunits per helix turn. Numbers refer to the position of each N subunit from the RNA 3′ end. The N protomers bound to the PrE-I and PrE-II elements are colored in *blue*. Both PrE-I and PrE-II of the bipartite replication promoter are found on

the same face of the helix. Bases oriented toward the solvent are colored in *yellow*, while bases oriented toward the nucleoprotein are represented in *red*. Note that for the internal PrE-II element, essential C residues are located in the first position of each hexamer for SeV, whereas GC residues are located in the fifth and sixth positions in the case of PIV-5. **B:** Cartoon representations of the structure of three successive protomers of the RNA-bound Ncore structures of MeV (*top left*) (PDB ID: 4UFT) and PIV-5 (*bottom left*) (PDBank ID: 4XJN). N-terminal domains are shown in *blue*, C-terminal domains in salmon. The central protomers (N_i) are colored with increased saturation; RNAs are shown as stick representations. Bases oriented toward the solvent are colored in *yellow*, while bases oriented toward the nucleoprotein are shown in *red*. *Center*: Magnification of the N–RNA interaction, circling and numbering the six bases defining a hexamer phase from 3′ to 5′. N residues defining the two RNA-binding pockets in PIV-5 RNPs and equivalents in MeV RNPs are marked. The residue Q202 of the *Orthorubulavirus* genus is the only residue demonstrated to directly interact with an RNA base. *Right*: 2D representation of the relative base orientation in a hexamer phase. The six bases bound to each protomer are numbered 3′ to 5′. The nucleoprotein surface is represented in *purple*; solvent is shown in *blue*. *Gray* bases are encapsidated by a preceding or subsequent N protomer. (Images copyright © 2019 by Richard K. Plemper and Julien Sourimant.)

As discussed above, precisely six nucleotides interact with each N protein protomer, and the phase of interaction determines the orientation of each base toward the outside or the nucleocapsid core.[64,193] Furthermore, each turn of the helical nucleocapsid assembly comprises on average approximately 12 to 13 N protein protomers. Mapping of the promoter elements onto the nucleocapsid structure has revealed that bases forming key sequence motifs are placed in phase positions facing outward and that the relative distance of

the two PrEs relative to each other posits them on the same face of the helix in immediate proximity of each other (Fig. 12.26A).[126,365,381,587,617,618] It is believed that the RdRP complex recognizes both promoter elements in conjunction, initiating loading onto the template RNA and allowing identification of the transcription start site. The correct initial positioning of the paramyxovirus polymerase appears to be independent of the 3′ end of the RNA itself, since relocation of the SeV bipartite promoter to an internal position did not abolish bioactivity, provided relative phase of the PrEs and distance to each other remained intact.[617] Experimental support for this promoter model comes from the observations that paramyxovirus promoter activity is governed by three factors: (a) the RNA sequence of promoter motifs, (b) the relative distance between the PrEs, and (c) the position of promoter motifs relative to the hexamer phase imprinted by N encapsidation of the RNA.

Specifically, mutational analyses of the PIV-5 and SeV antigenomic promoters have demonstrated that deletions or insertions in the RNA segment located between the promoter elements prevented RNA replication.[381,587] Furthermore, it was demonstrated that the overall length of a paramyxovirus N–RNA complex can affect the efficiency of RNA replication.[64] This RNA chain-length requirement was termed the “rule of six,” which entails that efficient replication of a paramyxovirus genomic or antigenomic RNA will only occur when the total number of nucleotides in the RNA is an even multiple of six. However, there is large variability in the stringency to which various groups of paramyxoviruses adhere to the rule of six requirements. RNA replication of SeV, all morbilliviruses, and the henipaviruses is strictly dependent on adherence to the rule of six. In contrast, the efficiency of PIV-5, NDV, and HPIV-3 RNA replication is boosted if genome lengths adhere to the rule of six, but this is not a stringent requirement.[144,339,383] It is currently believed that the rule of six reflects less a need for precise genome encapsidation without overhanging terminal nucleotides[617] but rather arises from imprinting the correct hexamer phase on the RNA,[449] orienting key bases of the promoter sequence outward and thereby recognizable by the polymerase complex (Fig. 12.26B).[277,300] Correct phase positioning is considered to be a prerequisite for efficient RNA editing in the *P* gene.[277,300] For HPIV-2, it has been demonstrated that a glutamine residue at position 202 of the N protein functions as a gatekeeper for PrE-II–dependent RdRP

initiation.[349] Gln202 is the only residue in the RNA-binding groove that directly contacts a nucleotide base and not the backbone in the N–RNA assembly and apparently ensures that only genomes imprinted with the correct hexameric phase of the mRNA editing site are replicated.

It should be noted that RNA synthesis can be promoted *in vitro* from an unencapsidated PrE-I,[253] suggesting that successful RdRP initiation on encapsidated template relies on (a) recognition of the promoter elements on the nucleocapsid and (b) direct contact of the unencapsidated PrE-I element by the polymerase. Since *in vivo* only N-encapsidated viral RNA can serve as template for paramyxovirus RNA synthesis, promoter binding by the incoming P-L polymerase complex must be followed by displacing of the N capsid and threading of the locally exposed RNA strand into the template channel of the RdRP complex. As discussed before, the viral RNA is positioned in the RNP assembly in the groove that is created by the parallel alignment of the NTD and CTD folding domains of neighboring N protomers. Comparison of PIV-5 N assemblies[6] with free NiV N[641] and direct comparisons of PIV-5[4] and MeV[192] N with N^0 drove the hypothesis that RNA release may result from deep-seated local conformational changes upon P-L binding that entail opening of the RNA groove through an outward rotation of the CTD.[6] Alternatively, it was suggested based on the overlay of a cryo-EM reconstruction of MuV nucleocapsids with the PIV-5 N crystal structure that P-L contacts with a loop–helix domain located adjacent to the central groove may be sufficient to unveil the sequestered RNA through a local conformational change, bypassing the need for major rearrangements of the tightly assembled N protein core.[536] While the precise molecular mechanism of local RNA release from the nucleocapsid remains unknown, the N protein core—stabilized by extensive side-to-side interactions between the protomers—is considered to be routed over the surface of the RdRP while the locally unveiled RNA passes through the RdRP complex, followed by re-encapsidation as the template RNA emerges from the template channel.[277]

RdRP Initiation

Different initiation mechanisms of RNA synthesis have been identified for paramyxoviruses compared to the pneumoviruses. Two distinct initiation sites, +3 for transcription and +1 for replication, have been proposed for

RSV, the archetype of the pneumovirus family,[406,601] although initiation at +3 likely represents the default and +1 may result from nontemplated preloading of the polymerase with a dinucleotide.[107,404,405] Paramyxovirus polymerase initiation sites have not been fully mapped yet, but several lines of evidence support templated initiation at +1 position[159]: (a) RdRPs preferentially initiate with purine (thus opposite a pyrimidine base),[409] but paramyxovirus promoters contain purines (G residues) at positions +2, +3, and in some cases—for instance, the *Ferlaviruses*—+4 (Fig. 12.27); (b) extension of primers representing SeV promoters did not reveal product populations derived from internal initiation sites[610]; and (c) unlike the experience with RSV polymerase, for instance, the amount of free N protein available is inversely correlated to transcription activity of MeV and SeV RdRP,[113,460] consistent with initiation of transcription and replication at position +1 by a single pool of polymerases. A current model of paramyxovirus RNA synthesis initiation proposes that polymerase alignment with the uridine tract in PrE-I drives initiation opposite the +1 position,[159] in all cases starting with pppApC.[406]

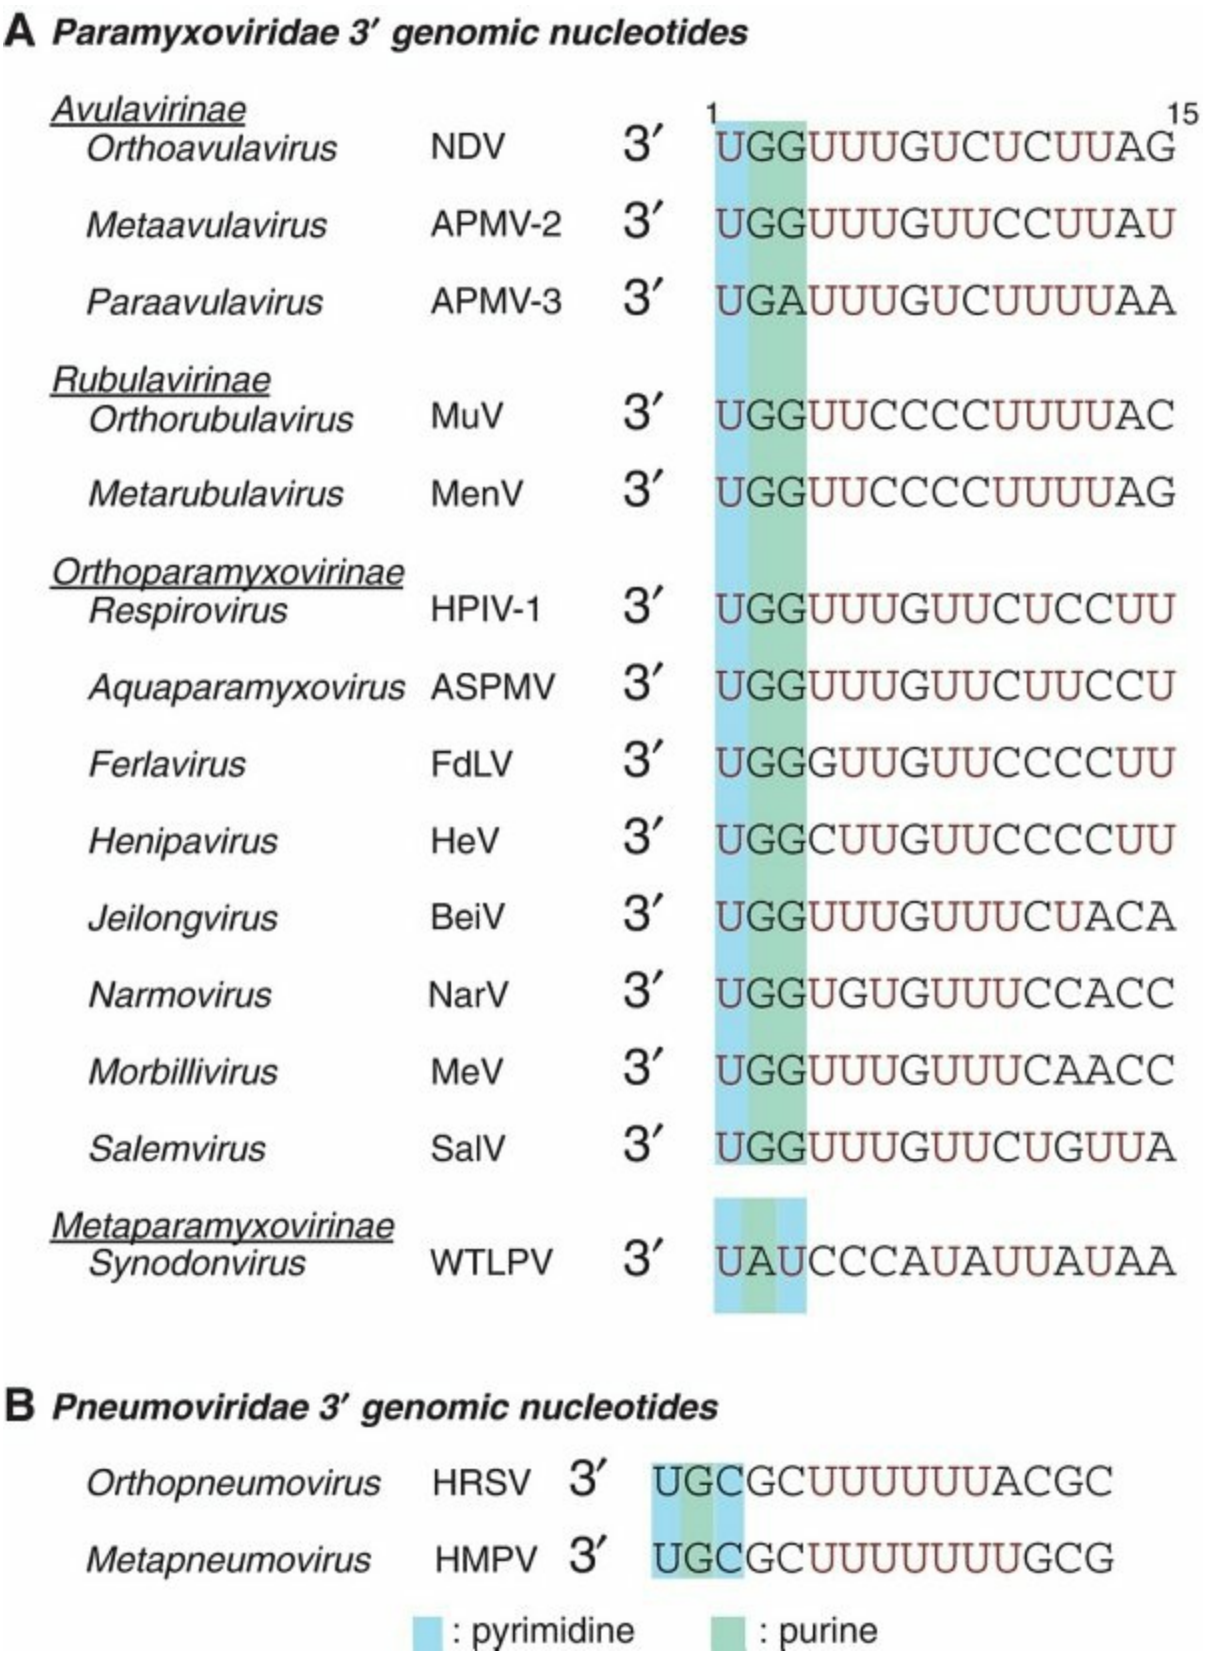

FIGURE 12.27 Selected 3′ termini sequences (nucleotides 1–15)

of the *Paramyxoviridae* and related *Pneumoviridae*.

A: Representative sequences from each genus of the *Paramyxoviridae*. The first three nucleotides are overlayed with *blue* for pyrimidines or *green* for purines; uracil bases are shown in *red*. Viruses of most *Paramyxoviridae* subfamilies but the *Synodonvirus* genus initiate with UGG (predominant) or UGA (pyrimidine–purine–pyrimidine), followed by uracil repeats. The newly proposed *Synodonvirus* WTLPV does not follow this pattern, but its first three nucleotides UAU (pyrimidine–purine–pyrimidine) are reminiscent of the *Pneumoviridae* 3′ termini, and the uracil-rich region is less defined.

B: 3′ termini sequences (nucleotides 1–15) of selected viruses from members of the *Pneumoviridae* family. Color-coding as in **(A)**. Characteristic are 3′ UGCGC (pyrimidine–purine–pyrimidine–purine–pyrimidine) initiation sequences, followed by uracil repeats.

Initiation of *de novo* RNA synthesis typically involves an aromatic residue in a priming loop that interacts with the incoming first ribonucleotide.[14,60,593] While the paramyxovirus priming loop is not yet fully defined due to lack of high-resolution native structural information, homology models of paramyxovirus L proteins based on the VSV L reconstruction have highlighted aromatic residues on the predicted priming loop[159] that, albeit not fully conserved in all paramyxoviruses, appear homologous to a critical tryptophan in the VSV priming loop[311,414] (Fig. 12.28). Transition of the polymerase complex from RNA synthesis initiation to elongation must entail significant reorganization of the reconstructed L structure, creating exit channels for both the template and transcript RNA strands. Support for a structural reorganization of mononegavirales polymerases at the transition from initiation to elongation comes from mechanistic studies with small-molecule inhibitors of the related RSV RNA polymerase that did not prevent initiation and extension by up to two nucleotides but blocked subsequent RNA elongation.[104,407] Resistance sites for one of these compounds were mapped to the L connector domain linking the polymerase subunit to the methyltransferase (MTase) and C-terminal domains. Mutations in the SeV L capping and MTase domains have furthermore been identified that are distant from the catalytic site for phosphodiester bond formation and do not affect L protein steady-state levels

but prevent RNA synthesis.[99,160,382] Although not experimentally validated yet, these data suggest that capping, MTase, and C-terminal domains relocate relative to the RdRP core domain of the polymerase complex, allowing egress of the nascent strand.

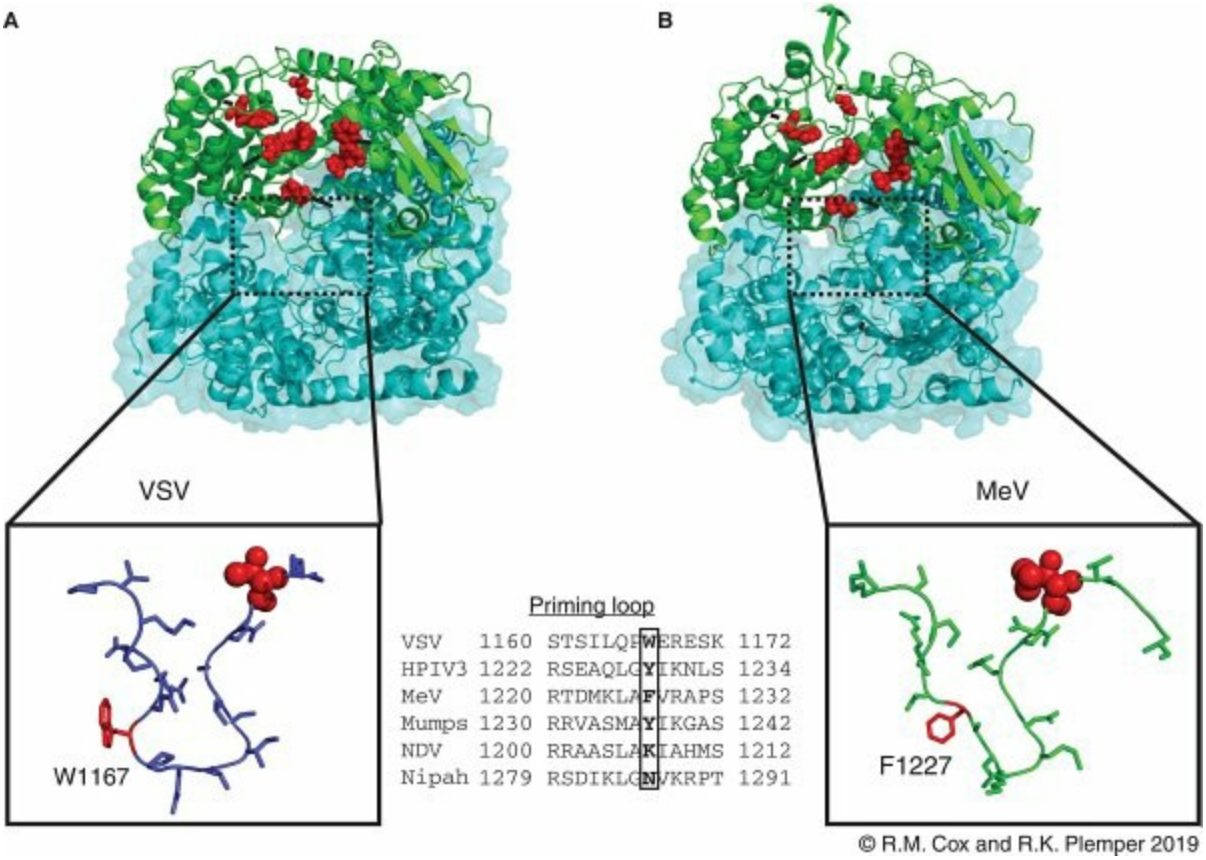

FIGURE 12.28 VSV and MeV RdRP priming loops. *Top*: 3D structural model of the RdRP (*cyan*) and PRNTase (*green*) domains of VSV L (PDB ID: 5A22)[311] **(A)**. Conserved motifs in the PRNTase domain are highlighted by *red spheres*. **B:** Corresponding domains in an MeV L homology model are shown in equivalent orientation. *Bottom inserts*: VSV L residue W1167 located in a priming loop facing the polymerase catalytic center is instrumental for RNA synthesis.[397,414] A homologous aromatic residue (F1227) in the predicted MeV L priming loop is highlighted. Sequence alignments of selected priming loop

structures are shown, but presence of an aromatic residue is not fully conserved. Sequence alignments were performed using Clustal Omega,[543] the MeV homology model was generated using the PHYRE2 homology modeling server.[268]

mRNA Synthesis

Following initiation of RNA synthesis at the 3′ promoter, the paramyxovirus polymerase generates a nontranslated short RNA copy of the leader (*le*) region of the viral genome. It is believed that encapsidation of this leader RNA, which depends on availability of free N^0–P complexes, serves as an important determinant for the switch of the paramyxovirus RdRP into replicase mode. If left unencapsidated, the leader RNA is typically released before the polymerase complex has reached the end of the *le* region[175,224,285,304,601,610] and the RdRP scans the template for the first gene-start (GS) signal, which in all paramyxoviruses is that of the *N* gene. Once the GS is located, RNA synthesis is reinitiated *de novo*.[601,610] All GS sequences in the genome resemble the genomic promoter, and initiation of mRNA synthesis is consistently with a purine (ATP),[406] suggesting a conserved underlying principle governing polymerase contact with the promoter and the GS and incoming ATP. In contrast to original initiation at +1 position, however, the scanning polymerase complex is preloaded with template RNA, requiring the presence of a fully formed exit channel and thus reducing the scope of conformational rearrangements at the switch from initiation to elongation. Nascent mRNA strands are expected to be released from the exit channel in proximity to the capping domain, enabling efficient capping and methylation (Fig. 12.29). Lack of capping results in the release of abortive RNA transcripts from VSV and RSV RdRPs of less than 40 or 50 nucleotides in length, respectively,[320,410,562] and a similar mechanism may prevent efficient elongation of uncapped paramyxovirus pre-mRNAs. SeV MTase expressed in isolation has been demonstrated to be able to methylate capped mRNAs in trans,[416] which is consistent with successful transcomplementation of distinct mutations in the N-terminal and C-terminal domains of SeV L, respectively,[550] and suggests that MTase recognizes a

specific RNA sequence for activity.

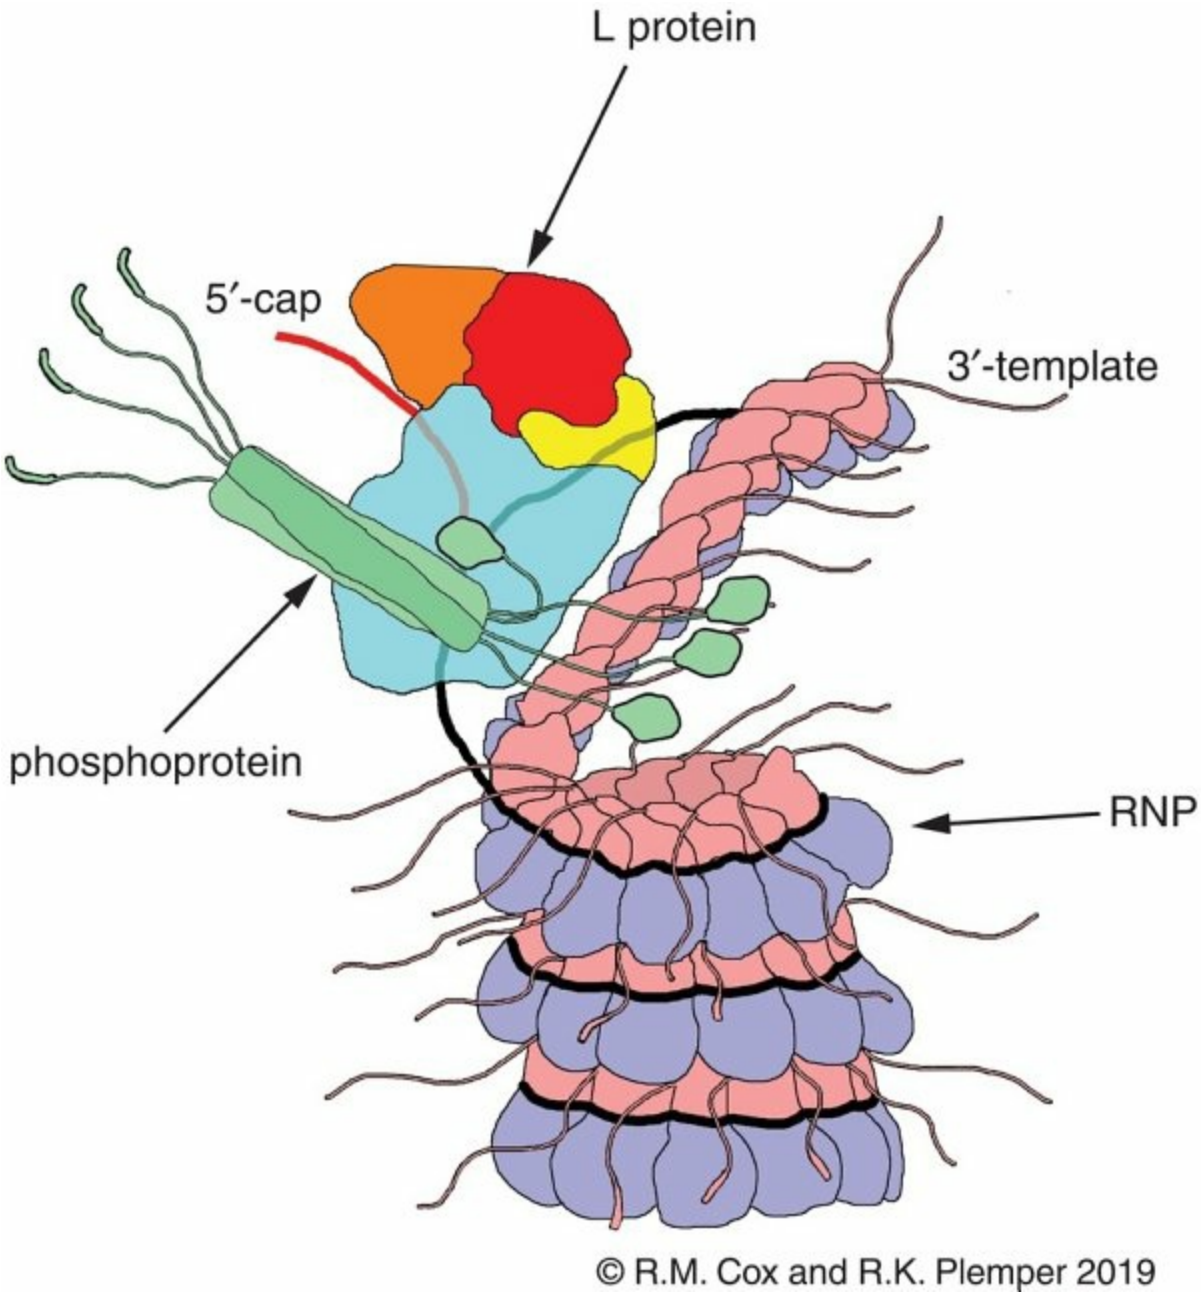

FIGURE 12.29 Model of the paramyxovirus transcriptase complex. The encapsidated viral genome serves as the template for the RdRP. The P protein acts as a bridge between the L polymerase and the RNP template, harboring binding sites for both the N and L proteins. The polymerase engages the template from the 3′ end of

the viral genome, routing the N protein chain over the surface of the RdRP after local release of the encapsidated RNA. Nascent mRNAs emerge from a proposed exit channel, located in close proximity to the capping domain.
(Images copyright © 2019 by Richard K. Plemper and Robert M. Cox.)

Starting with the intersection between the *N* and *P* gene, all paramyxovirus gene junctions comprise three distinct segments: a GE region at the 3′ end of the upstream gene, an IG region between the two genes that is normally not transcribed, and a gene-start (GS) region signaling reinitiation of transcription of the subsequent gene (Table 12.3). Located downstream of the stop codon of each viral gene, the GE sections are 10 to 13 nucleotides long and signal the advancing transcriptase complex to terminate RNA synthesis and add a poly-A tail at a stretch of four to seven uridine residues, the U tract. The resulting approximately 300- to 400-nucleotide–long poly-A tails are nontemplated, however, and are considered to be generated through reiterative backsliding of the polymerase complex in the U tract region,[277] followed by release of the newly synthesized *bona fide* mRNA molecule through an unknown trigger. Backsliding entails slippage of the nascent strand relative to the template RNA within the RdRP active site, although the molecular mechanism enabling this movement has not yet been elucidated. Shortening the length of the unstructured C-terminal Ntail domains or relocation of the P-binding MoRE domain from Ntail into Ncore has lowered the efficiency of GE signal recognition and instead caused the synthesis of multicistronic mRNAs with increased frequency.[102,594] These results suggest that the unstructured Ntail sections located upstream of the MoRE may allow structural flexibility between the P-L complex and the RNP template that enables efficient backsliding. In addition to protein–protein interactions between P-L and the N protein chain, GE sequences determine the frequency of readthrough transcription. Although generally infrequent, polymerases of HPIV-1 types 1 to 3, MeV, and PIV-5 generate bicistronic mRNAs most often at the M-F junction, where approximately 50% to 80% of the mRNA can be locked into M-F readthrough products.[42,71,481,559] This high readthrough frequency is a consequence of insertions[559] or substitutions[481] at the M GE, which modify termination efficiency. Conceivably, some paramyxoviruses experience a heightened selective pressure to increase

transcriptase access to the more 3′ distal genes (e.g., attachment protein and L), or frequent M-F readthrough may present a mechanism to selectively reduce F protein expression, since polycistronic paramyxovirus mRNAs do not contain internal ribosomal entry sites and the F ORF locked into a bicistronic M-F transcript would presumably not be translated.[260,481] F protein down-regulation has been demonstrated to be critically linked to virulence of some paramyxoviruses.[9]

After termination of transcription, the RdRP complex advances through the IG region, scanning for the next downstream GS site.[454] Paramyxovirus IG regions minimally consist of a conserved trinucleotide segment, but many are highly variable in length and sequence (Table 12.3).[290] In fact, paramyxoviruses can be divided based on the degree of variability of the GE and IG sequences. For instance, these regions are highly conserved in SeV, HPIV-1, and HPIV-3.[279] Each SeV GE sequence consists of a 3′-AUUCU$_5$-5′ motif, and the IG region is 3′-GAA-5′ (except the HN-L junction, which is 3′-GGG-5′). In contrast, the GE and IG regions of HPIV-2, MuV, and PIV-5 are highly diverse, providing an additional level of transcriptional control of individual viral genes.[199,482] Since the viral polymerase complex initiates exclusively at the 3′ leader promoter and is unable to mount the RNA template at internal GS sites, the template RNA must remain threaded through the template channel as the transcriptase scans the IG, displacing the N protein scaffold as the complexes advance. Despite this local separation of template RNA and N protein chain, some paramyxoviruses require correct positioning of the GS site relative to the encapsidation phase, suggesting that reinitiation of mRNA synthesis of at least some paramyxovirus transcriptases appears to be governed by both the RNA sequence and signals from the N protein.[277] Once the next downstream GS has been identified, mRNA synthesis reinitiates as described for the *N* gene GS, and this sequential "stop–start" mechanism of mRNA synthesis continues across the viral genome in a 3′ to 5′ direction. However, the frequency of reinitiation is not perfect, some RdRP complexes may advance along the template nonproductively or prematurely detach from the template RNA while negotiating an IG region, and the occasional readthrough transcription renders downstream ORFs locked in polycistronic mRNAs inaccessible to translation, resulting in a gradient of functional mRNA abundance that is inversely correlated to distance from the genome 3′ end, with functional N

mRNAs being found in far higher abundance than L mRNAs.[72]

P Gene mRNA Editing

mRNA editing, the pseudotemplated addition of nucleotides altering the ORF, is a mechanism to expand the coding capacity of a gene that for paramyxoviruses was first identified for PIV-5.[444,596] It is now known that most paramyxovirus *P* genes contain a functional editing site within the coding region of the *P* gene (Fig. 12.8). As described above, in addition to a faithful (unedited) mRNA, transcription across the *P*/*V*/*C* gene yields edited versions that contain variable numbers of inserted G residues. The number of G insertions can differ for each virus group and mirrors their requirements for mRNAs that encode the individual P/V/W/I/D proteins (Fig. 12.8). Mechanistically, mRNA editing is believed to be achieved through controlled cotranscriptional polymerase stuttering and backsliding relative to the RNA template[203,608] that is triggered by the sequence of the editing site and in principle is reminiscent of the stuttering and backsliding employed to generate poly-A tails. The efficiency of G insertion by the stuttering polymerase is furthermore influenced by the position of the editing site relative to the N-bound hexameric phase,[242] providing another example for control of RdRP activity by a combination of RNA sequence and N protein phase imprinted on the template.

Genome Replication

Replication of the paramyxovirus genetic information occurs through generation of single-stranded, N-encapsidated antigenome copies that serve as template for the synthesis of progeny genomic RNA. Antigenomes do not code for any known functional ORF or template mRNAs. However, the synthesis and release of a short SeV trailer complement have been shown to antagonize stress granule formation and apoptosis through specific interaction with cellular TIAR.[243] If protein biosynthesis is pharmaceutically blocked in infected cells, viral mRNA synthesis continues normally, but antigenome and genome synthesis are both aborted rapidly. This observation underscores that active protein synthesis is essential to sustain RdRP in replicase mode, in which the polymerase ignores all GE regions, polyadenylation signals, and editing sites and generates exact, full-length

copies of the viral genomic or antigenomic RNA, respectively.[190,353,610] Nascent transcripts of the replicase complex must be encapsidated cotranscriptionally[190] to generate bioactive antigenomes and genomes, mandating a continued supply of unassembled N proteins that are provided in the form of N^0–P complexes (approximately 2,600 N monomers are required per full-length RNA copy).[40] This coupling of genome assembly and synthesis establishes a self-regulatory system for controlling the relative levels of viral transcription and replication. As encapsidation of the leader RNA is critical for the switch of the RdRP complex into replicase mode, early during the growth cycle, when N^0–P complexes are limiting, leader RNA remains unencapsidated. The RdRP then acts predominantly in transcriptase mode, increasing the intracellular level of viral proteins until a sufficiently deep N^0–P pool has been generated. Similarly, the 3′ promoter of the antigenome directs synthesis of a short trailer RNA (also called [−] leader). Cotranscriptional encapsidation of this trailer RNA again serves as trigger for commitment of the polymerase to become fully processive and synthesize encapsidated minus-strand genomes. As shown in Figure 12.24, the progeny genomes can serve three distinct functions: they template the bulk of viral mRNA that is generated during secondary transcription; they can serve as template for additional antigenomes; and they can be incorporated into progeny virus particles during virion budding.

In vitro assembly of six-nucleotide RNA molecules with purified MeV N^0–P complexes resulted in spontaneous release of P and encapsidation of the discrete RNAs into a nucleocapsid, provided the RNA sequence corresponded to the 5′ end of the viral genome.[364] This study indicated that the initiation of the encapsidation process is sequence-dependent and that formation of helical RNP assemblies is a function solely of the N protein chain, not of a continuous RNA strand. However, the subsequent efficient cotranscriptional encapsidation of nascent genomic and antigenomic RNA transcripts is sequence independent, suggesting an interaction between the free N^0–P complexes and the P-L polymerase. Because there is no evidence for a direct interaction between L and N, the P protein presumably serves as a bridge facilitating both the P-L interaction with the RNP and, in case of P-L in replicase mode, the incoming N^0–P molecules. Substitutions have been described that specifically inhibit SeV L-mediated replication but not transcription.[160,551] Mapped onto the VSV L structure, the majority of these

mutations are located on the same face of L, potentially outlining residues that are involved in guiding the transfer of free N protein to the newly synthesized RNA for efficient encapsidation.[159] The paramyxovirus nonstructural proteins provide a second avenue to control replicase versus transcriptase function of the viral RdRP. SeV V is believed to sequester N protein in N^0–V complexes, inhibiting RNA replication by reducing the pool of bioactive unassembled N.[226] As discussed above, engineered paramyxoviruses unable to express the nonstructural C protein are viable in cell culture but produce abortive dsRNA transcripts in high frequency, highlighting a role of the C protein in controlling, among others, replicase fidelity.

Virion Assembly and Release

Paramyxovirus virions are generated through a budding process that entails the formation of buds from sites on the plasma membrane where viral components have assembled, followed by pinching off of progeny particles. This assembly is believed to require coordinated localization of multiple but distinct virus components, including viral glycoproteins, which are transported to the plasma membrane through the secretory system, and soluble viral components such as the RNP. This coordination appears to be accomplished through a series of protein–protein and protein–lipid interactions, many of which involve the viral matrix protein array that can interact with lipids, with the glycoproteins via their cytoplasmic tails, and with N proteins assembled in the RNPs. It furthermore appears to involve interactions between viral components and the host exocytotic machinery that allows bud formation and membrane fission. Paramyxoviruses with HN-type attachment proteins contain glycoproteins that lack sialic modification of their carbohydrate chains, and it is believed that the HN NA activity serves the same purpose as NA of influenza virus, to prevent self-binding and to prevent reattachment to the infected cell.

Assembly of the Nucleocapsid

Nucleocapsids assemble in the cytoplasm concomitant to RNA synthesis, through continuous encapsidation of the nascent genomic and antigenomic RNA copies by newly synthesized N proteins as the replicase complex advances. As discussed above, it is believed that specific interactions

between the L protein and free N^0–P complexes guide encapsidation. While this process ensures that only viral RNAs are efficiently encapsidated in infected cells, transient expression of N proteins in the absence of other viral components results in the spontaneous and random encapsidation of host RNAs into short nucleocapsid-like structures, suggesting that encapsidation can occur independent of specific RNA sequence elements,[97,153,524,558,568] although as discussed above RNA sequence can greatly influence efficiency of the process.[364] However, encapsidation is only initiated *de novo* during synthesis of the terminal 3′ leader RNA (and 3′ trailer RNA for antigenome templates), since once in transcriptase mode, reinitiation of RNA synthesis by the polymerase at downstream GS regions does not randomly prompt unproductive encapsidation of nascent mRNAs. To ensure that a new replication cycle can be started after infection, paramyxoviruses must package copies of the P-L polymerase complex, which are thought to associate with the helical RNP prior to particle assembly.[270] Packaging of one complete copy of the viral genome is sufficient for infectivity, but biochemical studies and particle reconstructions have revealed that paramyxoviruses can—in low frequency—incorporate multiple RNP copies in a single virion.[178,266,324,475] The RNP packaging efficiency is determined by RNP polarity, genome length,[98,278,375] and compatibility of the N and M proteins.

Virus Particle Assembly

Due to its ability to engage in multiple interprotein and protein–lipid contacts, the paramyxovirus M protein serves as the central virion assembly organizer. Matrix proteins are found stably attached to RNPs when purified from virions, they bind to lipid membranes both *in vitro* and in living cells, and they self-assemble into ordered structures as purified proteins *in vitro* and in virus-infected cells. As discussed above, specific, homotypic N and M interactions have been demonstrated for a range of paramyxoviruses spanning different subfamilies, and these interactions are thought to guide the RNP to the assembly sites at the plasma membrane where M arrays form.[98,245,266,525] However, live cell imaging studies with SeV and MeV outlined an active role also of the host cytoskeleton in RNP trafficking to the plasma membrane. Both SeV and MeV RNPs were found moving along microtubules in Rab11A transport vesicles.[75,392] In the case of MeV, virus budding from polarized

cells specifically appears to require Rab11A-dependent transport, whereas this association is important for efficient SeV assembly independent of whether or not host cells are polarized. Both SeV and NDV M proteins have furthermore been shown to interact with actin,[177] and a candidate actin binding site was located in SeV M that, when mutated, affected particle production, suggesting a requirement for SeV M interaction with the cytoskeleton for efficient particle assembly.[581] Consistent with this observation, major actin cytoskeleton reorganizations have been described after infection of cells with MeV, MuV, or NDV,[156] and MeV budding in particular requires uninhibited actin cytoskeleton dynamics.[560] NiV M has been found in proteomics studies in complex with AP3B1,[451,570] the beta subunit of the host cell AP-3 complex that facilitates vesicular budding from Golgi membranes and protein sorting in the late Golgi and endosomes. Disruption of NiV and HeV M interaction with AP3B1 blocked efficient virion production, suggesting that *Henipavirus* M relies on AP-3–directed vesicular trafficking for sorting from internal host membranes to the plasma membrane.[570]

Reconstructions of cryopreserved paramyxovirus particles have revealed that, once located at the assembly sites, the viral RNPs are arranged with the membrane-associated M lattice in high order. In NDV particles, the RNP helix was found in sync with the M protein dimers, placing the 7-nm pitch of the helical RNP along the diagonal 7-nm repeat of the matrix array.[23] Similarly, tomograms of both budding and cell-free MeV virions showed the viral RNP in register with the matrix array, the average 7.8-nm pitch of the RNP helix matching the 7.8 nm subunit spacing of the MeV M lattice.[266] Alternatively reported wrapping of MeV RNP into membrane-detached helical M tubes[313] was rare and restricted to structurally compromised virions.[266] Rather than representing a *bona fide* MeV assembly intermediate, coating of the viral RNP by an M-derived external helical structure may therefore likely result from M lattice reorganization during particle purification for imaging.

Driving efficient assembly of the viral envelope, multiple lines of evidence support specific interactions between the M protein layer and the cytoplasmic tails of the paramyxovirus envelope glycoproteins: (a) the M protein of SeV has been shown to specifically engage membranes individually expressing the F and HN glycoproteins, which implies an

interaction.[513,514] Engineered recombinant PIV-5 and MeV that lack glycoprotein cytoplasmic tails show a subcellular redistribution of the matrix protein,[69,521] and colocalization and mutational studies revealed an interaction between the NDV and MeV attachment and M proteins.[424,574] A recombinant SeV carrying an F protein mutant with altered cytoplasmic tail furthermore showed defects in particle assembly and viral subunit clustering at assembly sites, underscoring the importance of glycoprotein tail interactions with the M layer for coordinated virion formation.[154,563] (b) Coexpression of MeV or NiV M and envelope glycoproteins in polarized cells redirected intracellular sorting. While envelope glycoproteins expressed in isolation are targeted to basolateral membranes, the presence of apically sorted M proteins directed glycoproteins to the apical side,[293,331] consistent with apical budding of these viruses. (c) Cryo-ET reconstructions of budding MeV virions showed a coordinated two-layered fusion-M protein lattice at the budding site and in released particles (Fig. 12.30). In contrast, tomograms of NDV,[23] SeV,[324] and HPIV-3[191] particles did not reveal any appreciable organization of the fusion glycoprotein ectodomains, although the MeV matrix array itself resembled that of NDV. The co-organized arrangement of the fusion glycoprotein in a 2D array with a subunit spacing of approximately 11 nm provided structural evidence that the viral M protein drives particle assembly. Despite the biochemical evidence supporting an interaction between MeV M and H protein cytoplasmic tail, however, no obvious organization of the viral attachment protein was appreciable in the tomograms of MeV,[266] even when recombinant MeV particles were analyzed that expressed elongated attachment proteins, harboring an extension of the helical stalk domain by 41 residues[48] to reduce local electron density in the envelope glycoprotein layer.

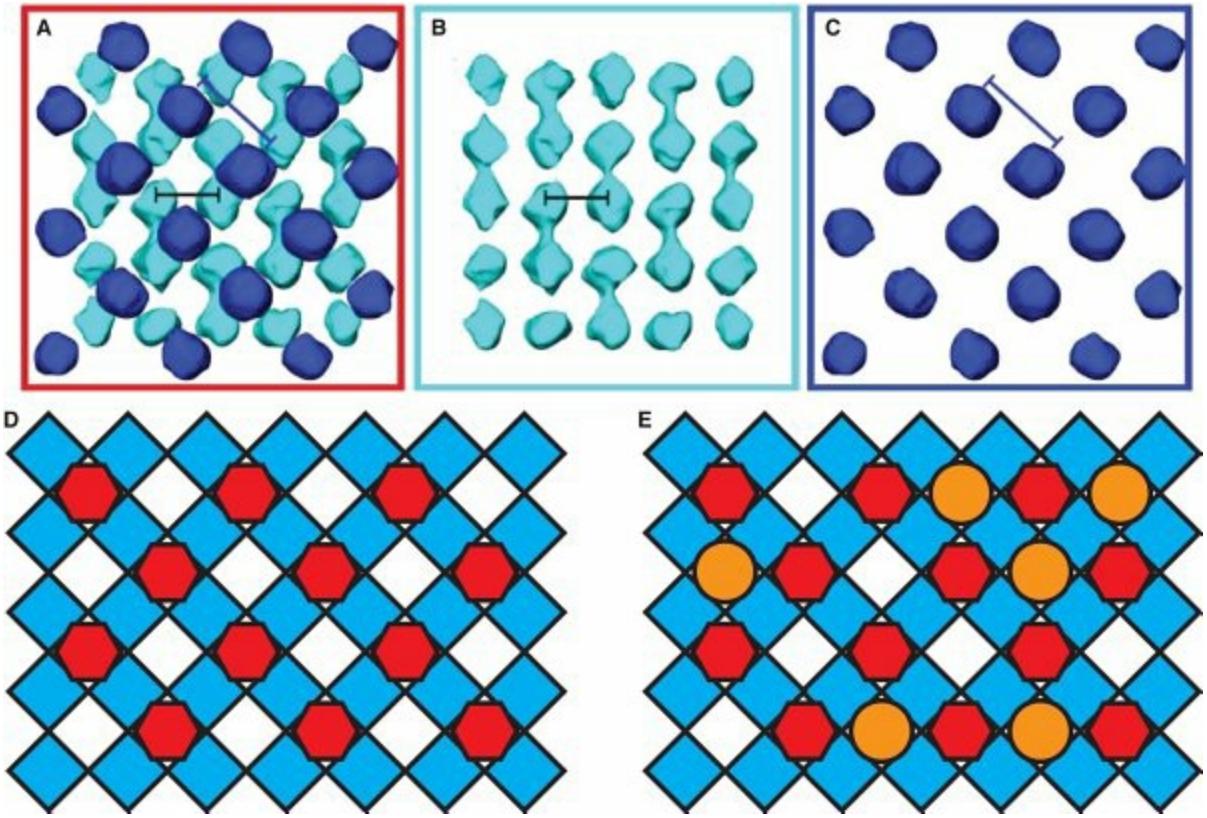

FIGURE 12.30 Symmetric arrangements of the F and M arrays observed in MeV particles. Cryoelectron tomography studies revealed a two-layered F–M lattice (EMDB entry: EMD-7591),[266] suggesting that M and F interact to facilitate efficient MeV assembly. **A–C:** Subtomogram averages of the MeV F–M lattice. The top layer of the averages reveals a regular array of F proteins (*dark blue*) **(A)**. The distance between F trimers is shown. Underlying the F layer, the M proteins (*cyan*) form a 2D array **(B)**. Distances between individual M dimers are shown. Overlay of the M and F lattices suggests coordination between the M and F protein arrangements **(C)**. **D:** Schematic of the F–M lattice displaying the organization of M (*blue*) and F (*red*) proteins above and below the viral envelope. **E:** The MeV H (*orange*) protein did not form regular arrays with the M or F proteins. However, the positions of the M and F proteins allow for variable distribution of H proteins above the M lattices. (Modified from Ke Z, Strauss JD,

Hampton CM, et al. Promotion of virus assembly and organization by the measles virus matrix protein. *Nat Commun* 2018;9(1): 1736, CC BY 4.0; http://creativecommons.org/licenses/by/4.0/)

Additional experimental confirmation for the instrumental role of matrix in proper virion assembly came from the analysis of paramyxoviruses with defective M proteins. A temperature-sensitive SeV strain has been isolated that is defective in proper virion assembly at the nonpermissive temperature due to mutations in its *M* gene.[651] This M protein variant is unstable at the nonpermissive temperature, indicating that low abundance of M prevents efficient virion assembly. In subsequent studies, engineered MeV and NiV mutants were recovered through reverse genetics techniques that lacked a functional *M* gene entirely.[68,134] These engineered viruses showed a dramatic reduction in progeny titers, infectivity remained essentially cell-associated, and virions were less stable, all consistent with a severe virion assembly and budding defect in the absence of the M protein. Moreover, in model systems of persistent SeV infection in culture in which the normally lytic infection is converted to a persistent one using DI particles, this change from lytic to persistent infection correlates mainly with M protein instability and an absence of virion assembly.[498]

Paramyxovirus Budding

While particle assembly entails the induction of local membrane curvature and the concentration of virus components in the nascent vesicular structures, budding—the release of cell-free progeny virions—requires an energy-demanding membrane fission event to pinch off the particle from the host cell membrane. An extensive list of enveloped viruses has been demonstrated to recruit components of the host cell vesicularization pathways to complete this final step in the replication cycle, and many others are thought to also follow this strategy.[81] Major experimental insight into the budding process was gained from the analysis of VLP systems. VLPs are nonreplication competent membrane-wrapped vesicles that contain only a subset of the viral structural proteins expressed from cloned cDNAs but lack genetic information. This section will assess minimal protein composition and protein–protein interaction requirements for paramyxovirus budding based on VLPs and

recombinant virions, followed by a discussion of a role of the host vesicularization machinery in paramyxovirus particle fission and the contribution of the lipid composition to bud zone selection.

VLP systems to identify viral proteins essential for budding

VLP systems have been established for a number of different paramyxoviruses and have revealed diverse, virus-specific protein requirements for budding. In the most basic scenario, expression of M proteins in isolation is sufficient for VLP formation, as has been described, for instance, for NDV and several *Orthoparamyxovirinae* such as SeV, HPIV-1, MeV, and NiV.[86,97,424,436,463,502,568,581] These studies confirmed that the M proteins of these viruses are inherently sufficient to interact with lipids, assemble into larger membrane-associated arrays that introduce local lipid curvature, and promote membrane fission. In contrast, PIV-5 M protein alone is unable to trigger efficient VLP formation, but coexpression with the N protein and either one of the viral glycoproteins induces budding with an efficiency approaching that observed in virus-infected cells.[524] M proteins of MuV, another member of the *Rubulavirinae* subfamily, also require coexpression with a viral glycoprotein for efficient budding, but a stimulatory effect is only observed when M is combined with the F and not the HN protein.[309,520,524] While the envelope glycoproteins of a number of *Orthoparamyxovirinae* subfamily members specifically engage the M protein layer as discussed above, these interactions do not impact virus budding in most cases. Accordingly, the ability to facilitate induction of local membrane curvature is a discrete function of some glycoproteins, rather than merely a consequence of M-mediated local glycoprotein concentration in discrete plasma membrane regions. However, VLP budding after expression of the M protein alone, for instance, becomes more efficient when SeV M is coexpressed with the F glycoprotein.[581] Efficient transport of the F–M complexes to the cell surface for budding depends on the integrity of a five-residue TYTLE motif in the SeV F cytoplasmic tail.[154] F mutants lacking this motif remained capable of interacting with SeV M but were retained in the ER, thus preventing transport of F–M complexes to particle assembly sites at the plasma membrane.

The VLP-based insight into particle assembly requirements has been largely corroborated by studies with engineered viruses. Recombinant MeV

expressing F proteins with truncated or modified cytoplasmic tails showed an increased cell-to-cell fusion rate of infected and uninfected, neighboring cells, indicating a redistribution of the envelope glycoproteins from bud sites to other plasma membrane regions.[69,370] Increased cell fusion activity is consistent with a shift of these recombinant viruses to a mode of virus propagation that is independent of budding. Recombinant PIV-5 was budding-impaired when the cytoplasmic tail was removed from the HN protein.[520] However, engineered PIV-5 similarly expressing tail-truncated F glycoprotein mutants remained capable of efficient replication and particle formation in cell culture.[624] Recombinant SeVs with F or HN cytoplasmic tail truncations reportedly showed an approximately 20- to 50-fold reduction in particle production,[164] and a follow-up study specifically confirmed the importance of the TYTLE motif in the F cytosolic tail for efficient production of progeny virions.[154]

Role of the host vesicularization machinery in membrane scission

Enveloped viruses of many different families are known to contain specific protein motifs that, when disrupted, cause defects late during budding, typically at the final stage of membrane fission.[81,122,173,187,250] These late (L) domains have been shown to engage host proteins of the cellular vacuolar protein sorting (VPS) pathway that is responsible for biogenesis of the multivesicular body (MVB). MVB formation is a key function of the cellular ESCRT machinery, a large network of cytoplasmic proteins that in its core consists of the ESCRT complexes I, II, and III, Alix and the VPS4 ATPase (reviews in Ref.[233,401,531,554]). Consistent with its central role in MVB formation, the hallmark of ESCRT activity is reverse-topology membrane scission, vesicularization away from the cytosol as opposed to, for instance, vesicle formation for intracellular vesicular transport or endocytotic pathways. Representing two distinct branches leading toward membrane fission, ESCRT-I, which forms a supercomplex with ESCRT-II when activated, and Alix recognize various protein interaction signals, triggering recruitment to cellular membranes and the induction of initial membrane curvature. Membrane-associated ESCRT-I–II or Alix then activates ESCRT-III polymerization in the nascent bud neck to high-energy dome-shaped spiral structures that cause membrane scission when VPS4 dependently resolved.[531]

Because the unique reverse-topology of ESCRT-mediated vesicularization is equivalent to that of virus budding into internal cellular compartments or the extracellular environment, ESCRT pathway components are likely candidates for exploitation by enveloped viruses. Viral L domains serve as the molecular adapters required to engage the ESCRT machinery, and at least one of three types of canonical L domain motifs can be found in, for instance, retroviruses, filoviruses, flaviviruses, rhabdoviruses, and herpesviruses: P(T/S)AP, $YP(x)_nL$, and PPxY.[616] Each of these sequences resembles a host cell protein interaction motif. For instance, P(T/S)AP-type L domains mediate binding to TSG101,[173,347] an ESCRT-I subunit, $YP(x)_nL$ recruits Alix[346,566,612,615] and the PPxY motif engages the WW domains of NEDD4 and similar HECT domain–containing E3 ubiquitin ligases.[200,269,599] Ubiquitin has been identified as the main pathway-specific signal in MVB biogenesis, and HIV Gag protein ubiquitination, for instance, promoting binding by TSG101 and Alix may be a major recruitment pathway for ESCRT components to bind Gag proteins.[539]

Although paramyxoviruses do not contain any of the canonical viral late domains, overexpression of a dominant-negative VPS4A ATPase mutant suppressed efficient budding of PIV-5,[523] NDV,[524] and MuV,[309] implicating the ESCRT machinery in particle release. Consistent with this observation, M proteins of these three paramyxoviruses contain a conserved, noncanonical FP(I/V)(I/V) motif that distantly resembles known viral L domains. In PIV-5, the core sequence of this motif is FPIV, which has been demonstrated to functionally compensate for lack of a PTAP L domain in budding HIV-1 VLPs.[523] The proline residue in this noncanonical motif emerged as critically important for bioactivity, since substitution in PIV-5 M protein resulted in poor VLP formation and failure of a corresponding recombinant PIV-5 to replicate normally. In addition, a screen for host factors interacting with PIV-5 M proteins identified AMOTL1, which itself contains three L/PPxY motifs and may in a novel host factor recruitment strategy serve as a bridge between a paramyxovirus M protein and NEDD4 ubiquitin ligases and the ESCRT machinery.[486] Consistent with a role of ubiquitination in engaging the PIV-5 budding machinery, formation of PIV-5 VLPs and virions was reduced by treatment of cells with the proteasome inhibitor MG-132,[523] which depletes the free ubiquitin pool in the cell by preventing recycling of ubiquitin after delivery of proteins marked for degradation to the proteasome.[613] Similar

effects of proteasome inhibitor treatment on virus budding have been observed for retroviruses such as HIV-1[532] and Rous sarcoma virus,[445] which contain PTAP and PPxY late domains for budding.[523]

Despite this experimental support for a possible role of the ESCRT machinery in paramyxovirus budding, the evidence is mixed, and it remains unclear whether paramyxoviruses in general rely on ESCRT components for virion release. The noncanonical paramyxovirus L domain candidate is not universally conserved in the family, no physical interaction between paramyxovirus M proteins and the ESCRT machinery has been demonstrated, and NiV VLP formation, SeV virion budding,[182] and both MeV VLP and progeny virion formation are apparently unaffected by dominant-negative VPS4A.[437,510] Although deletion of candidate L domains in NiV M abrogated VLP budding, this effect appeared to be due to unexpected relocation of the mutated M proteins to the nucleus.[86,437] Since nuclear localization is naturally incompatible with budding from the plasma membrane, these studies did not provide clear evidence that the budding arrest was due to impaired interaction with ESCRT components. In contrast to the indifference of NiV VLP formation to dominant-negative VPS4A, however, budding of NiV virions from infected cells has subsequently been demonstrated to depend on VPS4 activity,[431] indicating that VLP and virion budding can be mechanistically distinct. Apparently, this discrepancy is due to the presence of the nonstructural NiV C protein in infected cells, which can act as a molecular bridge between NiV M and the ESCRT-I component Tsg101. While *Henipavirus* C proteins lack L domains, they show homology to the Vps28 subunit of the ESCRT-I complex, suggesting that all members of this genus may employ a molecular mimicry strategy to engage the ESCRT pathway for virion release.[627]

This probudding effect of the NiV C protein through recruitment of ESCRT components is reminiscent of the demonstrated ability of SeV C to engage ESCRT-III/VPS4 through the Alix branch of the pathway.[238,568] In addition, a putative L domain, YLDL, was identified in SeV M that was attributed to engage Alix independent of the C protein.[241] Despite these links to the ESCRT pathway, neither suppression of Alix nor expression of dominant-negative VPS4A abrogated budding of SeV virions.[182] Also, VLP formation and virion budding by all members of the *Morbillivirus* genus appear to be independent of ESCRT, but it remains unclear whether these

viruses achieve membrane scission through noncanonical engagement of selected ESCRT components or through alternative fission mechanisms. As a structure-independent alternative strategy, local crowding of membrane-bound proteins at nascent fission sites has been proposed to generate sufficient steric pressure through lateral collisions to drive membrane vesiculation.[554]

Contribution of membrane subcompartments to paramyxovirus budding

Lipid molecules within the plasma membrane are not distributed homogenously in each leaflet of the bilayer but rather participate in lateral associations to form subcompartments within the membrane. These fluctuating nanoscale assemblies are enriched in sphingolipids, cholesterol, and a distinct set of membrane-bound proteins and can be stabilized into raft platforms by oligomerization.[544] Rafts were originally identified based on a simple assay, resistance to solubilization by some nonionic detergents such TX-100 at low temperature,[545] although these detergent-resistant membrane (DRM) extracts are unlikely to reflect the reality of a live cell.[67,131] Rafts are now recognized as highly dynamic structures that are involved, for instance, in cell signaling, assembly of many viruses,[24,66,495,576] and membrane trafficking. Rafts mediate lipid-based secretory sorting from the Golgi to the plasma membrane and in polarized cells locate predominantly to the apical site.[67,131] With the caveat of unclear physiological relevance of DRM extracts, a number of paramyxovirus proteins have been found enriched in detergent-insoluble membrane domains. For instance, MeV M, N, and F proteins[61,337,463,611]; SeV N, F, and HN proteins[182,512]; and NDV N, F, and HN proteins[136,287] are all selectively targeted to DRMs. MeV F targeting into rafts is apparently achieved through palmitoylation of two cysteine residues in the transmembrane domain of the protein.[24,61,66,495,576] Because functional MeV F and H protein complexes preassemble in the ER,[48,458] sorting of F into DRMs will pull H into the same subcompartment.[337] For some paramyxoviruses, lipid-mediated sorting may facilitate the local accumulation of envelope glycoproteins and matrix proteins, potentially resulting in the formation of viral assembly platforms.[329] However, engineered targeting of NiV M proteins into raft or nonraft domains did not affect VLP formation,[622]

suggesting that NiV particle budding does not depend on a specific lipid environment.

Polarized budding from epithelial cells

Association of viral envelope components with raft microdomains could provide an attractive mechanistic explanation for preferential virion budding from the apical side in polarized epithelial cells, which has been reported for a number of paramyxoviruses including SeV, MeV, PIV-5, and NiV.[293,331,492] Quite counterintuitively, however, the glycoproteins of MeV and NiV are trafficked to basolateral membranes when expressed on their own, which is determined by tyrosine-dependent sorting signals[331,369,628] and in the case of MeV F appears to override F targeting into DRM domains. These observations underscore that intrinsic trafficking signals of the envelope glycoproteins do not control the location of virion budding for these viruses. Rather, coexpression of the M protein as experienced in infected cells induces rerouting of the glycoproteins to the apical bud zones,[293,391,628] although no direct intracellular contacts between these M proteins and glycoproteins have been demonstrated yet.

Despite this mechanistic ambiguity, preferential apical virion budding and basolateral glycoprotein targeting are considered to be important contributors to viral pathogenesis. Budding from the apical surface could favor restriction of the infection to the epithelial cell layer, whereas budding from the basolateral surface allows viral access to underlying tissue and could favor development of a systemic infection. Consistent with this view, standard SeV and PIV-5 both produce localized infections of the respiratory tract *in vivo*, whereas a SeV mutant strain (F1-R) was described that is released bidirectionally and causes systemic infection.[590] In the case of MeV, redirecting the envelope glycoproteins away from basolateral membranes resulted in virus attenuation, coinciding with reduced lateral spread through cell-to-cell fusion in the respiratory epithelium.[371] The identification of SLAM and nectin-4 as cellular receptors for MeV has provided a solution to the conundrum of preferred apical release and efficient systemic dissemination of MeV. Mediated through SLAM-dependent cell entry, incoming MeV is considered to most likely initially infect respiratory macrophages and dendritic cells, using them as vehicle for homing to draining mediastinal lymph nodes where first centers of virus replication are

established.[118,362] Subsequently, primary viremia ensues that is carried by circulating, SLAM-positive lymphocytes. Infected lymphocytes and dendritic cells in the epithelial submucosa are considered to then transmit the virus late during infection to epithelial cells displaying nectin-4 on the basolateral side.[166,328] This infection of nectin-4–positive respiratory epithelial cells sets the stage for apical release into the mucus layer lining the lumen of the respiratory tract, enabling airborne viral transmission in aerosols through coughing and sneezing.

PARAMYXOVIRUS ACCESSORY GENES AND THEIR INTERFERENCE WITH THE CELLULAR ANTIVIRAL RESPONSE

Type I IFNs form a group of the most important antiviral cytokines that can be major determinants of tropism, pathogenesis, and viral dissemination.[108] As shown in Figure 12.31, the cellular IFN response involves two general phases: the induction of IFN synthesis in a primary transcriptional phase and signaling through IFN signaling pathways to activate in a positive feedback loop a secondary transcriptional phase of IFNs and greater than 300 ISGs, at least 51 of which directly contribute to host defense.[301,357] A large body of work has emerged on the role of paramyxovirus accessory proteins in counteracting the host cell IFN pathways at the level of both the induction of IFN synthesis and IFN-mediated signaling.[95,218,433] Albeit through different specific interactions, predominantly the paramyxovirus V/W proteins interfere with the cellular sensing pathways that trigger type I IFN transcription and IFN signaling, while C proteins can modulate the antiviral response by reducing the production of virus-specific signals that are recognized by these host cell sensors.

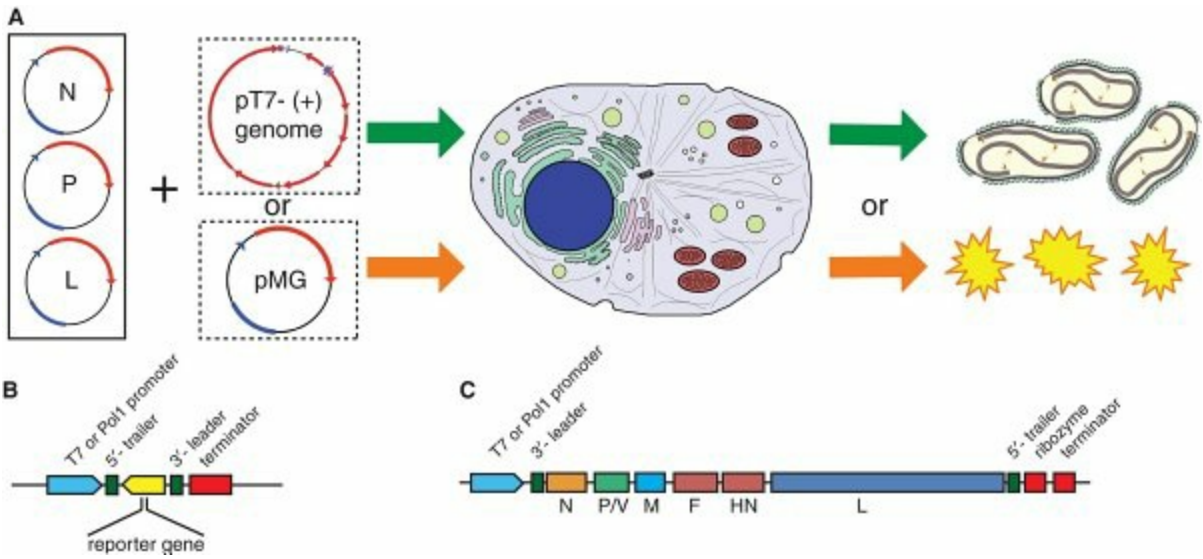

FIGURE 12.31 Minigenome reporter systems and recovery of recombinant paramyxoviruses from cloned cDNA. **A and B:** Paramyxovirus reverse genetics requires N, P, and L proteins provided *in trans* (plasmid-encoded or stable cell lines) and expression of viral genomic (minigenome) or antigenomic (minigenome, virus recovery) RNA, in most cases under the control of the T7 polymerase promoter. Ribozyme elements flanking the viral RNA ensure the generation of precise 3′ and 5′ ends. Minigenome reporter systems allow for quantitative assessment (i.e., luciferase reporter) of RdRP activity in the absence of viral replication. **C:** Schematic of a full-length viral genome expression cassette. Minigenomic or full-length viral RNAs are spontaneously encapsidated by the viral N protein, following RdRP-mediated transcription and amplification. (Images copyright © 2019 by Richard K. Plemper and Julien Sourimant.)

Antagonists of Interferon Synthesis

Providing the first line of defense against viruses and other microbial pathogens, the type I IFN response is triggered by pattern recognition receptors (PRRs) that detect pathogen-associated molecular patterns (PAMPs). PAMPs can be by-products of virus infection, for instance,

cytosolic dsRNA, other unique viral replication products, or capsid proteins, which all contain distinct features not normally present in the cell.[244] Major PRRs sensing RNA virus infections include the Toll-like receptor (TLR) family and the RIG-I–like receptor (RLR) RNA helicases. Sensing microbial RNAs, TLR3, TLR7, and TLR8 are associated with endosomal compartments,[7,212] while the RLR prototype retinoic acid–inducible gene I (RIG-I) and melanoma differentiation–associated gene 5 (MDA-5) represent the main cytosolic receptors responsible for the recognition of RNA.[234,516] Different downstream pathways and adapter proteins transduce the signal when these PRRs are triggered (Fig. 12.32), but most converge on activation of IFN regulatory factor (IRF) transcription factor family members IRF3 and IRF7 as the primary inducers of IFN-α and IFN-β expression.[582]

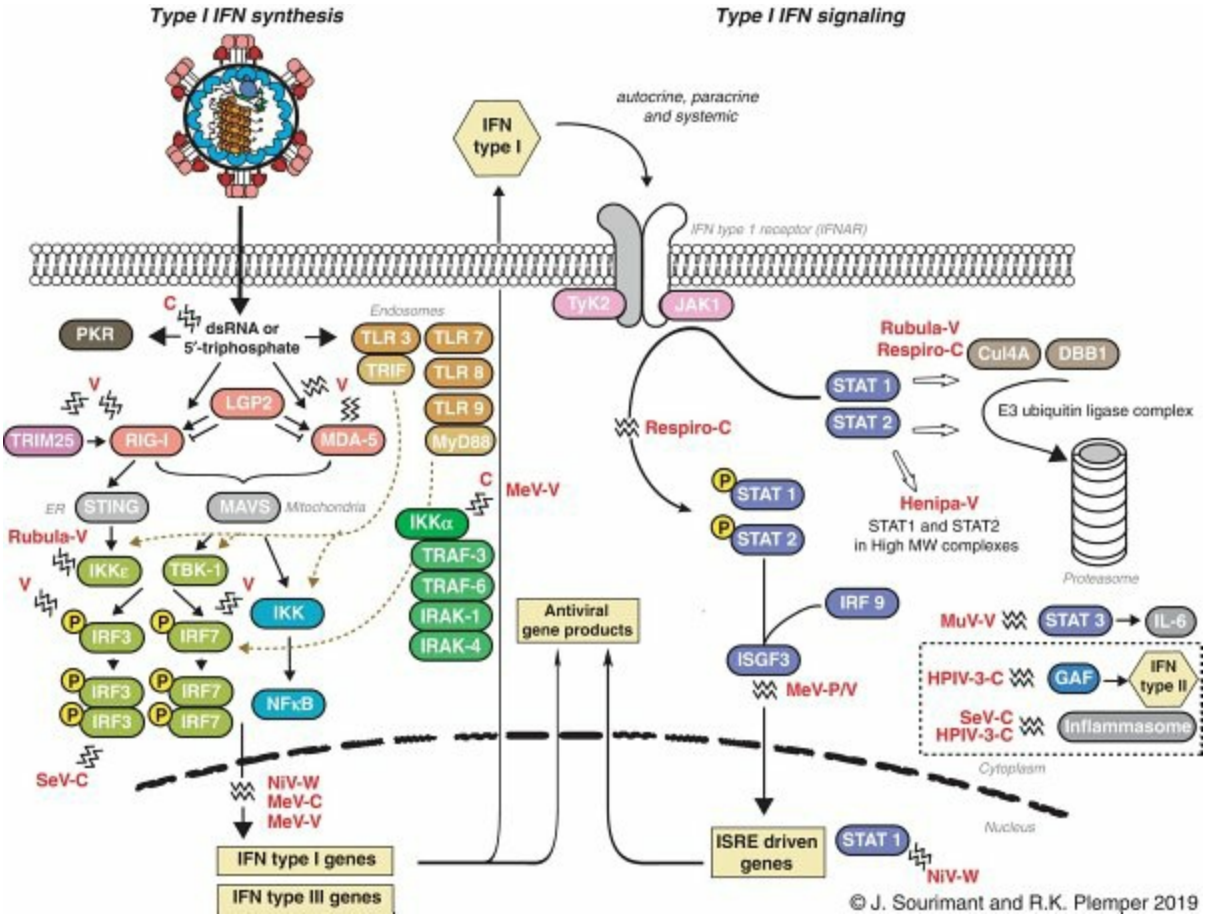

FIGURE 12.32 Type I IFN induction and signaling after paramyxovirus infection and viral strategies to antagonize the

innate antiviral response. Schematic overview of induction of IFN synthesis (*left*) and autocrine or paracrine IFN signaling (*right*) after infection. Currently known broad and paramyxovirus genus- or subfamily-specific interference pathways are specified.
(Images copyright © 2019 by Richard K. Plemper and Julien Sourimant.)

Results from transient transfection–based studies and the analysis of viruses that have been engineered to encode altered or deleted nonstructural protein genes have elucidated paramyxovirus antagonists of the cellular innate immune response. Most of these studies focused on pathogens of the *Morbillivirus*, *Respirovirus*, *Henipavirus*, and *Rubulavirus* genera. Common to all paramyxoviruses examined, the V proteins are instrumental for the suppression of type I IFN expression. Experimentally confirmed for many paramyxoviruses including, for instance, PIV-5, MeV, NiV, HPIV-2, and SeV,[10,83,116,336,376,425,479] the unique C-terminal zinc-finger domain of the V proteins associates with MDA-5 and also LGP2, the third member of the RLR family that lacks caspase recruitment domains (CARDs). Binding of paramyxovirus V to the helicase domain of MDA-5 has been shown to block association of MDA-5 with dsRNA, inhibiting MDA-5 association and signaling.[83] Originally, it was thought that paramyxovirus V proteins are incapable of interacting with the RLR prototype, RIG-I, itself. Subsequent reports were mixed, however, and recent work has suggested binding of a number of different paramyxovirus V proteins including those derived from NiV, MeV, SeV, and parainfluenza viruses to the RIG-I regulatory protein TRIM25 and to RIG-I as a novel mechanism to block type I IFN expression.[511] Although LGP2 lacks CARDs, LGP2 overexpression has been shown to impair both MDA-5 and RIG-I signaling,[281,496] mice deficient in LGP2 were more susceptible to viral infection, and coexpression of MDA-5 and LGP2 led to synergistic signal transduction.[516,607] Consistent with the notion that LGP2 facilitates MDA-5 and RIG-I mediated recognition of viral RNAs, binding of MeV and PIV-5 V proteins to LGP2 blocked LGP2-dependent promotion of MDA5 signaling.[489,490]

In addition to directly blocking RLR sensing, paramyxoviruses interrupt the downstream signaling cascade to prevent IFN expression. Rubulavirus V proteins have been proposed to compete with IRF3 for phosphorylation by

TBK1/IKKε kinase, preventing phosphorylation and nuclear translocation of the IRF3 transcription factor.[327] Similarly, MeV V protein has been shown to bind as a decoy substrate to IKK*α* kinase, competing with IRF7 for IKK*α*-mediated phosphorylation and thus blocking TLR7/9 signaling.[452] V proteins of MeV, HPIV-2, SeV, and NiV have furthermore been suggested to directly interact with IRF7, preventing its transcriptional activity.[274,452] MeV, SeV, and NDV V proteins have also been shown to directly associate with IRF3—in the case of SeV, V association takes place in the cytosol and prevents IRF3 nuclear translocation, while MeV V was proposed to associate with IRF3 after translocation—and block IRF3 transcription activation activity.[236] Likewise in the nucleus, NiV W but not V blocks IRF3-mediated IFN expression.[236,537]

Rather than interfering with the PAMP sensing pathways, several paramyxovirus C proteins appear to lower signal intensity through a regulatory effect on polymerase fidelity. For instance, cells infected with C-deficient recombinant SeV, HPIV-1, or MeV strains accumulated increased amounts of dsRNAs,[35,453,577] which triggered the RLR and protein kinase R (PKR)-mediated response pathways, stimulating type I IFN expression.[35,577] In the case of MeV, short virus-derived DI-RNAs with duplex structures were found in cells infected with a C protein–defective, but not standard, MeV, confirming a dsRNA-mediated effect.[453] *Henipavirus* C proteins likewise regulate viral RNA synthesis, lowering the impetus for type I IFN expression.[322,323,348,549] Constituting a second mechanism by which *Morbillivirus* C proteins inhibit IFN induction, a NLS was identified in MeV C, and the presence of *Morbillivirus* C in the nucleus was found to be associated with a block in IFN-*β* expression downstream of IRF3 activation.[46,556] Also *Respirovirus* C has been found to directly inhibit type I IFN expression, in this case by targeting IRF3 translocation into the nucleus.[237] One study in addition suggested a C-mediated suppression of IRF7 phosphorylation and consequently TLR7/9 signaling through direct binding to, and inhibition of, IKK*α* by C proteins of SeV, MeV, and NiV.[642]

Antagonists of Interferon Signaling Pathways

Once virus-sensing host cell PRRs are triggered, the ensuing first wave of type I IFN can result in autocrine, paracrine, or systemic stimulation,

activating multiple downstream signaling pathways through binding to the type I IFN receptor (IFNAR). The canonical response pathway involves formation of the signal transducer and activator of transcription 1 (STAT1)–STAT2–IRF9 signaling complex, also known as the IFN-stimulated gene factor 3 (ISGF3), which translocates to the nucleus and induces ISG expression through activation of IFN-stimulated response elements (ISREs) in gene promoters (Fig. 12.32).[357] ISGF3 formation is initiated by phosphorylation of STAT1 and STAT2 by the JAK kinases Tyk2 and Jak1. Major ISGs with effector activity against some or all negative-sense RNA viruses include, for instance, the myxovirus resistance (Mx) proteins, the IFN-induced protein with tetratricopeptide (IFIT) repeats and the IFN-inducible transmembrane (IFITM) families, members of the TRIM superfamily and the poly(ADP-ribose) polymerase (PARP) family, and the OAS/RNase L system.[108,526]

In addition to suppressing type I IFN synthesis, paramyxoviruses have developed a diverse range of strategies to interrupt IFN signaling that include the degradation of signaling pathway components and the sequestration of signaling complexes, and the V proteins again assume a central role in this activity. First demonstrated for PIV-5, rubulavirus V proteins directly induce the degradation of STAT proteins. PIV-5[12,132] and MuV V[283] both target STAT1 for degradation, while HPIV-2 V induces breakdown of STAT2.[427] Although STAT-specific, degradation requires the presence of both STAT1 and STAT2[428] and involves both the cysteine-rich C-terminal domain of V and residues located in the N-terminal section shared by P/V.[11,207,625] MuV V has furthermore been demonstrated to also induce STAT3 turnover, which results in an additional block in proinflammatory IL-6–mediated signaling.[605] Virulent MuV strains were found to bind STATs efficiently and limit the production of IL-6.[494,639] Mechanistically, these *Rubulavirinae* V proteins are thought to form a cytoplasmic V–dependent degradation complex that comprises STAT1, STAT2 and two components of a host cell E3 ubiquitin ligase, the UV-damaged DNA-binding protein DDB1, and the Cullin family of ubiquitin ligase subunit member Cullin 4A (Cul4A).[470,471,603] Assembly of this complex triggers polyubiquitination of the target protein, inducing its proteasomal degradation. PIV-5 V protein degradation of STAT1 occurs in human cells but not mouse cells, and PIV-5 growth in mouse cells is restricted.[132] However, efficient STAT1 degradation and higher PIV-5

replication levels can be restored in mouse cells engineered to express human STAT2.[426] Likewise, a single amino acid substitution in the PIV-5 V protein N-terminal domain is sufficient to allow targeted degradation of mouse STAT1 and block IFN signaling.[652] Thus, the ability to assemble specific STAT degradation complexes and disrupt IFN signaling may be a factor determining the host range of some paramyxoviruses such as PIV-5 and NDV,[426,429] which are restricted for growth in cells from particular species.

Rather than inducing breakdown of IFN signaling proteins, V proteins of a number of viruses of the *Orthoparamyxovirinae* subfamily have been shown to bind and sequester STATs in the cytosol, preventing shuttling into the nucleus and transcription activation. For instance, P/V proteins of MeV of the *Morbillivirus* genus target STAT1 through a tyrosine-based motif in the shared N-terminal domain[129,417,497] and STAT2 through nonconserved residues in the V protein C-terminal domain.[63,480,497] Binding prevents STAT protein nuclear import, and a recombinant MeV unable to target STAT1 specifically due to three point mutations in the shared N-terminal region of P/V was found to less efficiently control the proinflammatory response and experience reduced viremia titers in a rhesus monkey model of infection.[128] *Henipavirus* V proteins form high molecular weight aggregates with nonphosphorylated STAT1 and STAT2,[491] and a nuclear export signal in NiV V ensures localization in the cytosol.[488] In contrast, NiV W harbors a nuclear import signal in its short C-terminal unique region and forms nonfunctional complexes containing STAT1 in the nucleus.[87,538] Underscoring the importance of *Henipavirus* V and W for viral pathogenesis, the more recently identified low-pathogenic Cedar virus of the *Henipavirus* genus[344] does not express V or W, and Cedar virus P is unable to efficiently target STAT1 or STAT2 and therefore cannot effectively inhibit IFN signaling.[312]

C proteins of the respiroviruses, morbilliviruses, and henipaviruses have been proposed to interfere with IFN signaling, but in the case of *Morbillivirus* and *Henipavirus* C, these antisignaling effects were subsequently found to be minor.[162,322,323,348,394] In contrast, a number of studies have indicated that *Respirovirus* C proteins can interfere with IFN signaling pathways. HPIV-1 C proteins have been shown to bind STATs, prevent phosphorylation of STAT1 and STAT2, and retain STAT1 in perinuclear aggregates, preventing nuclear

translocation.[530] SeV and HPIV-3 C proteins have been found to alter STAT phosphorylation patterns,[185] were detected as interacting partners with STAT1,[169,333,578] and could induce ubiquitination and degradation of STAT1 in some mouse cells.[171] HPIV-3 C protein has also been shown to inhibit type II IFN signaling by blocking the formation of the gamma interferon activation factor (GAF) complex, and an N-terminal region of 25 amino acids was found to be involved in mediating both STAT1- and GAF-dependent antisignaling effects.[338] A recent study furthermore implicated HPIV-3 C in counteracting inflammasome activation in macrophages following HPIV-3 infection.[540] Inflammasomes are cytosolic multiprotein complexes that combat microbial infections by regulating production of proinflammatory IL-1β and IL-18, controlling the immune response and pathogen clearance.[165,483] They can be activated by a number of different viruses including SeV.[256,280,430,541] While the SeV V protein was suggested to antagonize inflammasome activity,[280] in the case of HPIV-3, the C protein was found to specifically block assembly of the NLRP3/ASC inflammasome by interaction with, and promotion of proteasomal degradation of, the NLRP3 protein.[540] These observations underscore that the mechanisms by which the paramyxovirus C proteins interfere with the host antiviral response depend on both host cell type and virus species.

ENGINEERED PARAMYXOVIRUS MINIGENOMES AND RECOMBINANT VIRUSES: REVERSE GENETICS

The study of viruses has benefited greatly from the ability to specifically modify viral genomes and recover the corresponding recombinant viruses, a technique known as reverse genetics.[631] For RNA viruses, the first recovery of a virus from a cloned cDNA copy has been described for the positive-sense RNA bacteriophage Qβ,[585] and many more positive polarity RNA viruses were recovered subsequently following this strategy. Adaptation of this approach to negative-strand RNA viruses was challenging, however, since synthetic genomic RNA copies are noninfectious. Only protein-encapsidated negative-strand RNA virus genomes and antigenomes are

biologically active, and exclusively, the viral polymerase machinery can productively interact with the RNPs. Instrumental for the development of *Mononegavirales* reverse genetics technology were shortened minigenome reporter systems, which minimally consist of a single reporter gene flanked by cDNA copies of the untranslated terminal regions of the viral genome (Fig. 12.32). Expressed under the control of a T7 RNA polymerase promoter and fused to a hepatitis delta virus–derived ribozyme to create precise 5′ and 3′ ends equivalent to those of genomic viral RNA, proof of concept was first established through successful replication of synthetic VSV-derived RNAs when plasmid-encoded VSV N, P, and L proteins were expressed in trans.[447]

Building on this strategy, rabies virus was the first infectious *Mononegavirales* to be recovered entirely from cloned cDNA,[528] followed several months later by VSV[298,633] and, as the first paramyxoviruses recovered, MeV and SeV.[172,474] In contrast to the first-generation minigenome reporter technology, which produced negative-strand RNAs, all of these initial full-length reverse genetics systems were engineered to express antigenomic, positive polarity RNA molecules (Fig. 12.32). Attempts to directly recover virions from direct expression of genomic RNAs were either unsuccessful or highly ineffective,[264] supposedly because simultaneous expression of negative polarity genomic RNA and positive polarity mRNAs in the same cell sets the stage for dsRNA formation through hybridization, triggering IFN-1 response pathways and preventing encapsidation.[528]

Although progress has been made to optimize the technology and many more paramyxoviruses have successfully been generated from cloned cDNAs (i.e., NDV,[493] NiV,[649] HeV,[345] CDV,[174] RPV,[21] MuV,[88] HPIV-1,[398] HPIV-2,[265] HPIV-3,[142,216] and PIV-5[208]), the frequency of virus recovery remains relatively low. Rate limiting remains the initial formation of bioactive antigenomes through inefficient, spontaneous encapsidation of the antigenomic RNA molecules expressed from the cloned full-length cDNAs by N protein provided in trans. Process improvements included the use of engineered cell lines stably expressing T7 polymerase[56] rather than the original superinfection of transfected cells with a recombinant vaccinia virus encoding T7 polymerase,[528] the use of helper plasmids encoding mammalian-cell codon-optimized versions of N, P, and L under the control of strong constitutive mammalian promoters, and the combination of a self-cleaving hammerhead ribozyme sequence preceding the viral antigenome RNA in

combination with overexpression of plasmid-encoded codon-optimized T7 polymerase.[25] In particular, the production of RNA transcripts with precise 3′ and 5′ ends of the viral genomes through inclusion of ribozyme elements has increased rescue efficiency dramatically, advancing from approximately 1 per 10^6 to 10^7 to 1 per 10^2 to 10^3 transfected cells. Based on the design of T7 polymerase–independent reverse genetics systems for influenza virus, *Mononegavirales* minigenome technology has also been developed that employs the cellular RNA polymerase I (Pol I) promoter.[643] Naturally responsible for the synthesis of ribosomal RNAs in higher eukaryotes, Pol I–driven systems, when combined with helper plasmids under the control of constitutive mammalian RNA polymerase II promoters, provide superior flexibility in the choice of host cell type while bypassing the need for transforming an additional, T7 polymerase–encoding plasmid or superinfecting with a T7 polymerase–expressing helper virus. However, Pol I–mediated RNA synthesis in the nucleus is less suitable for the synthesis of full-length viral RNAs and may require codon optimization of viral coding regions, making this technology most useful for minigenome reporter systems.

As discussed throughout this chapter, recombinant paramyxovirus viruses have been instrumental in elucidating the role of individual viral proteins and protein subdomains in the viral life cycle, better understanding the molecular interplay between the replicating virus and the host cell, and identifying determinants of viral pathogenesis. Reporter paramyxoviruses expressing, for instance, luciferases or fluorescent proteins from additional transcription units have elucidated host invasion pathways, increasingly in combination with noninvasive *in vivo* imaging technology. Reporter viruses have furthermore been game-changing for the identification and development of novel antiviral drug candidates through automated drug screening campaigns and the targeted engineering of next-generation vaccine candidates.

HISTORY

Hendra virus (HeV), the first known member of the genus *Henipavirus* in the family *Paramyxoviridae*, came to light in September 1994 as the causative agent of a sudden outbreak of acute respiratory disease in thoroughbred horses at a stable in Brisbane, Australia. A total of 21 horses and 2 humans (a horse trainer and a stable hand) became infected. The horse trainer and 14 horses died.[1,2] A virus was isolated, initially called *equine morbillivirus* but later renamed *Hendra virus* after the Brisbane suburb where the outbreak occurred. A second person died from HeV infection 13 months after the Brisbane outbreak, a farmer from Mackay, nearly 1,000 km north of Brisbane. Unlike the first case, however, the man succumbed to encephalitis caused by HeV infection 14 months after his initial mild meningitic illness.[3,4] After initial serologic evidence suggested that fruit bats (flying foxes) of the genus *Pteropus* in the suborder Yinpterochiroptera were the reservoir hosts,[5] HeV was isolated from two species of flying fox.[6] In total, there have been 60 recognized occurrences of HeV in Australia between 1994 and 2018, with at least 1 occurrence per year since 2006 (Table 13.1A).[7] Every occurrence of HeV has involved horses as the initial infected host, causing lethal respiratory disease and/or encephalitis, along with a total of seven human cases arising from exposure to infected horses, among which four have been fatal and the most recent in 2009 (Table 13.1B).[8]

Nipah virus (NiV), the second known member of the genus *Henipavirus*, emerged as the cause of an outbreak of disease in pigs and humans in Peninsular Malaysia in 1998 through 1999. The epidemic started in Perak State as clusters of cases of encephalitis among pig farmers. It was initially believed to be caused by Japanese encephalitis virus; however, various features of the outbreak, including a high proportion of cases in direct contact with pigs and illness and deaths in pigs, differed from those expected with

Japanese encephalitis.[9] Indeed, respiratory illness and encephalitis in pigs preceded human cases in the same district.[10] The epidemic spread south to the intensive pig farming areas of Negeri Sembilan in December 1998 and subsequently peaked between February and April 1999. More than 1 million pigs were destroyed to halt the spread of the epidemic, and by late May, 265 human cases of acute encephalitis with 105 deaths were recorded.[9,11] A cluster of 11 cases with 1 death occurred among abattoir workers in Singapore.[12] In early March 1999, a virus was isolated from the cerebrospinal fluid (CSF) of a patient with encephalitis and identified as the etiologic agent.[9,11] Named *Nipah virus* after the village from which the patient had come, it was shown to be closely related to HeV. NiV was subsequently isolated from the urine of Malaysian flying foxes.[13] A highly related NiV emerged in Bangladesh in 2001,[14] and outbreaks of NiV-related encephalitis have occurred in people from that country almost every year since, along with three reports of NiV encephalitis in India,[15,16] albeit in Bangladesh adjacent regions. However, the most recent outbreak of NiV occurred in 2018 in Kerala (India), more than 2,500 km southwest of NiV-endemic Bangladesh counties. This outbreak claimed 21 lives out of 23 infected human cases.[17] In 2014, an NiV outbreak occurred in the Province of Sultan Kudarat, the Philippines, which resulted in the death of 9 humans from 11, which showed an acute encephalitis syndrome.[18] The human case fatality rate of these NiV outbreaks averages around 60% (Table 13.1C). So far human NiV outbreaks have been documented in a total of five countries: Malaysia, Singapore, Bangladesh, India, and the Philippines. Seroepidemiological evidence for henipavirus spillover events from bats into high-risk human populations have also been reported in Cameroon.[19]

INFECTIOUS AGENT

Classification

When HeV was first isolated in 1994, partial sequencing of the matrix gene (M) revealed that it most closely resembled members of the genus *Morbillivirus* in the subfamily *Paramyxovirinae*.[2] Subsequent characterization of the full-length genome, however, revealed that many of the genetic features of HeV were unique among paramyxoviruses and that the virus did not fit within any of the existing genera at that time.[20,21] After the isolation of NiV in 1999, it was shown that sera raised against HeV were able

to neutralize NiV and vice versa and that both viruses shared a high degree of similarity in genome organization and protein size and sequence.[11,22, 23, 24] In 2002, the genus *Henipavirus* was created to accommodate these novel paramyxoviruses, and HeV was designated the type species.[25] Since 1994, there have been 38 isolations of HeV or NiV from humans, bats, horses, and pigs over a wide geographic area and spanning a period of approximately 20 years (Table 13.2). The susceptibility of humans, the virulence of the viruses, and absence of therapeutics and vaccines led to classification of HeV and NiV as biosafety level 4 (BSL4) pathogens. In the latest report from the paramyxovirus study group under the order Mononegavirales, the genus *Henipavirus* has been expanded to include three new species[26,27]; they are *Cedar henipavirus* (Cedar virus [CedV]) isolated from bats in Australia,[28] *Ghanaian bat henipavirus* (Ghana virus [GhV]) detected in bats from Ghana,[29] and *Mojiang henipavirus* (Mòjiāng [MojV]) detected in rats in China.[30] These three new species are highly divergent from NiV and HeV, and only CedV has been isolated. GhV and MojV are only known from sequence information. *Henipavirus* is now classified as one of the fourteen ICTV-approved genera in the family *Paramyxoviridae*.

Propagation in Cell Culture and Cytopathic Effect

The ultrastructural characteristics of henipavirus-infected cells resemble those found in cells infected by other members of the *Paramyxoviridae*. Shared features include generation of large syncytia and the presence of viral nucleocapsids in cytoplasmic inclusion bodies and underlying electron-dense

areas of the plasma membrane.[31,32] In Vero cells, NiV-induced syncytia are significantly larger than those generated by HeV, and nuclei and nucleocapsids are frequently located at the cell periphery, compared with HeV-induced syncytia, where they tend to be more centrally located or distributed randomly throughout the cytoplasm (Fig. 13.1). Henipavirus-infected cells also contain structures that are not seen with other paramyxoviruses—specifically a network of membrane-like reticular structures in the cytoplasm and long tubules that appear to be continuous with the plasma membrane in NiV-infected cells. Tubules can also be observed in NiV virions (Fig. 13.2A). *In situ* hybridization suggests that these reticular structures contain viral RNA and may play a role in viral transcription.[31]

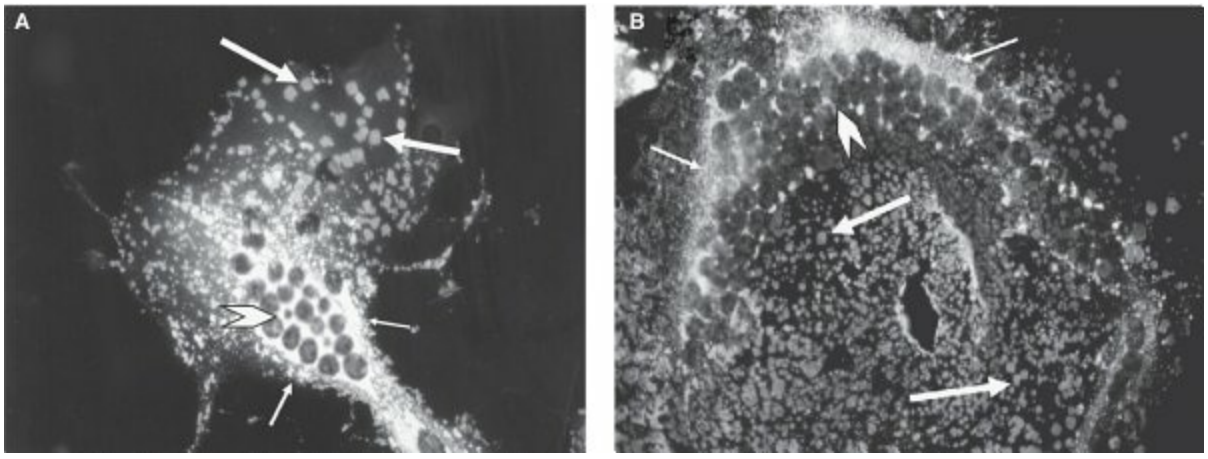

FIGURE 13.1 Syncytia induced in Vero cells 24 hours after infection by Hendra virus (HeV) **(A)** and Nipah virus (NiV) **(B)**. Methanol-fixed infected cells were labeled with rabbit monospecific antiserum to the HeV P protein and fluorescein-conjugated goat antirabbit immunoglobulin G. P protein is detected in extensive perinuclear ribonucleoprotein complexes (*small arrow*) and in discrete regularly shaped arrays (*large arrow*) distributed throughout the cytoplasm and believed to be sites of virus egress from the cell. Nuclei are indicated by *chevrons*.

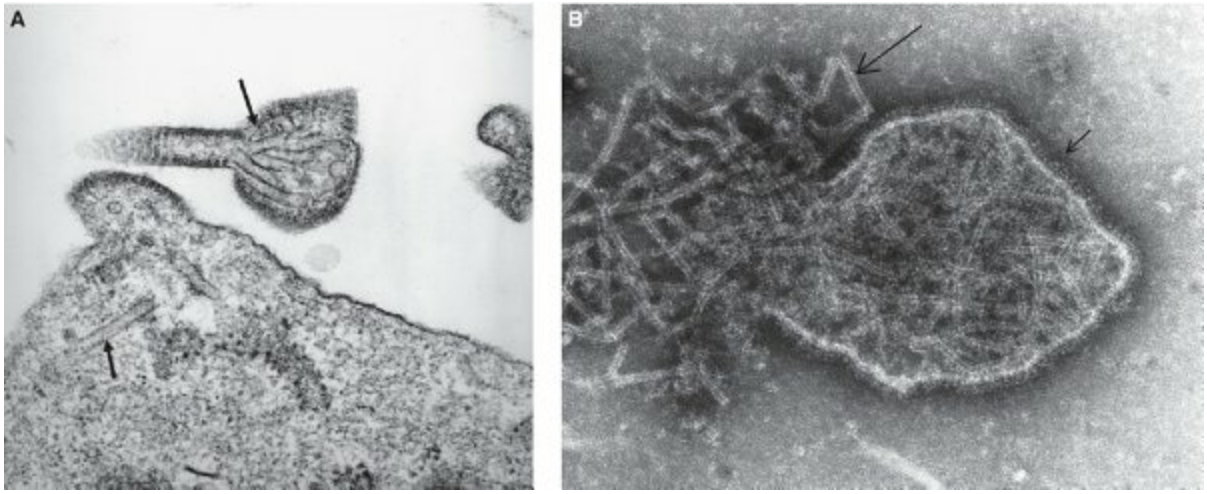

FIGURE 13.2 A: Electron micrograph of Nipah virus (NiV)–infected Vero cells showing tubule-like structures, both in the cytoplasm and in a maturing virus particle (*arrows*). **B:** Electron micrograph of negatively stained Hendra virus (HeV) displaying the double fringe at the virus envelope (*small arrow*) and the herringbone nucleocapsids (*large arrow*). (Courtesy of Dr. Alex Hyatt, CSIRO Australian Animal Health Laboratory.)

Virus Morphology

Henipavirus particles are pleomorphic, varying from spherical to filamentous and ranging in size from 40 to 1,900 nm.[2,31,32] Nucleocapsids have a diameter of 18 to 19 nm with an average pitch of 5 nm. When examined by electron microscopy (EM), HeV has a unique double-fringed appearance, caused by the presence of surface projections 15 ± 1 nm and 8 ± 1 nm in length (see Fig. 13.2B). Approximately 95% of virions contain the double fringe, and the remaining 5% display a uniform fringe length of 15 ± 1 nm. Unlike HeV, NiV possesses a single layer of surface projections with an average length of 17 ± 1 nm, and NiV particles released into the culture medium are difficult to image because they are routinely penetrated by negative stains. This suggests that the viruses may differ in the physical nature of their envelope.[32]

Genome Length and Organization

In the family *Paramyxoviridae*, the genome length of all characterized viruses is divisible by 6, an observation caused by the requirement of each N protein in the viral ribonucleoprotein to bind 6 nucleotide (nt) residues (see Chapter 12). This is also true for HeV and NiV despite their much larger genome sizes.[24] The genomes of the Malaysian (MY) and Bangladesh (BD) strains of NiV differ by 6 nt because of a 6-nt increase in the 3′-untranslated region of the *F* gene in NiV-BD.[33] A minigenome replicon study confirms that NiV complies with the rule of six.[34] When the complete genome sequence of HeV was determined, its length (18,234 nt) was more than 2,700 nt or 15% longer than the genomes of all other paramyxoviruses known at that time.[21] The size of NiV genomes at 18,246 nt to 18,252 nt is slightly larger than that of HeV.[22,23,33] These large genome sizes of greater than 18 kb are a conserved feature of henipaviruses as even the recently discovered and more divergent CedV, GhV, and MojV all have genomes between 18,162 nt (CedV) and approximately 18,430 nt (GhV). Given the caveat that there is wide variation among individual species of the other paramyxovirus genera, the extra length of the henipavirus genome is primarily due to the longer 3′ untranslated regions (3′ UTRs) at the end of several of its six genes and a larger *P* gene relative to the other paramyxovirus genera. A comparison of genome length and gene organization of representative members of the *Paramyxoviridae* is shown in Figure 13.3A. The nomenclature of each of the six major genes common to all paramyxoviruses has been updated to reflect the latest ICTV convention.[35] An analysis of the 3′ UTR lengths between extant henipaviruses and representative species from each paramyxovirus genera that infects mammals is presented in Figure 13.3B. The most significant differences are in the 3′ UTRs of *N*, *P*, and *RBP* genes even given the wide variance seen within each genus. The significance of long 3′ UTRs, especially in HeV and NiV, is generally unknown. However, the N gene 3′ UTR of NiV appears to play a role in the down-regulation of N mRNAs via specific interactions with hnRNP-D.[36]

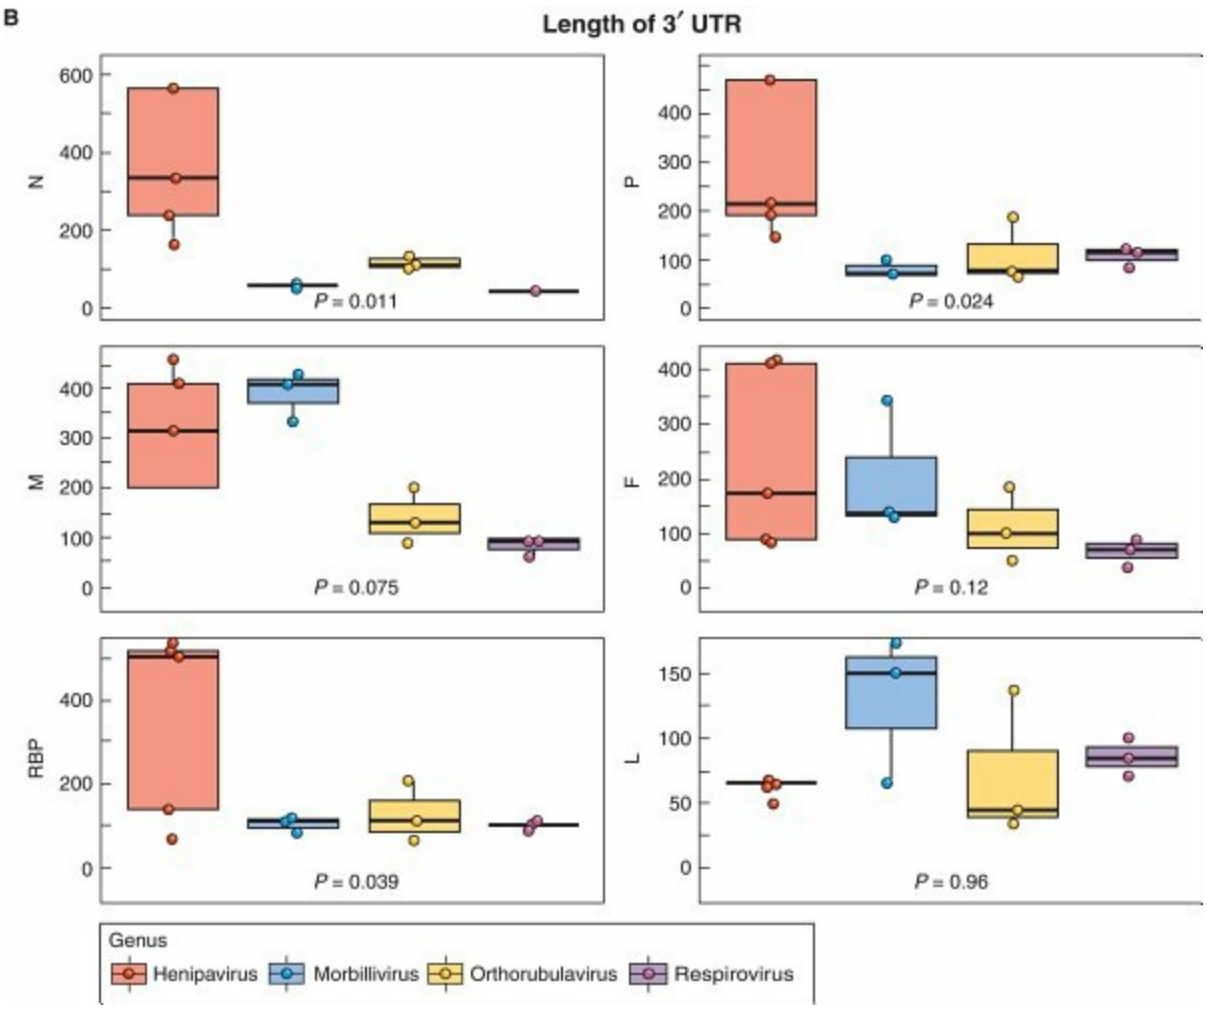

FIGURE 13.3 Genome size and organization of Hendra virus in comparison with the type species from representative genera genera in the family *Paramyxoviridae.* **A:** Genome length (in nucleotides) are given in brackets after each virus. Color coding: *blue*, N, P and L genes nucleocapsid responsible for replication and transcription; orange, M (Matrix); *purple*, envelope (F and RBP). **B:**3′ UTR of certain genes in henipaviruses (N, P, and G) are longer than their counterparts from representative members of paramyxovirus genera that infect mammals. The 3′ UTR length (number of nucleotides) of each gene from representative members of the indicated genera is compared separately in box-and-whisker plots (N, P, M, F, RBP, and L). P values are calculated based on one-tailed t-test (*Henipavirus* vs. all other genera); five virus

species from *Henipavirus* (HeV, NC_001906; NiV, NC_002728; CedV, NC_025351.1; GhV, NC_025256.1; MojV, NC_025352.1) and three each from *Morbillivirus* (MeV, NC_001498.1; CDV, NC_001921.1; FeMV, NC_039196.1), *Rubulavirus* (MuV, NC_002200.1; HPIV-2, NC_003443.1; PIV-5, NC_006430.1), and *Respirovirus* (SeV, NC_001552; HPIV-1, NC_003461; HPIV-3, NC_001796.2). (Courtesy of Satoshi Ikegame and Christian Stevens, Icahn School of Medicine at Mount Sinai, New York.)

The genome organization of henipaviruses resembles that in the genera *Respirovirus* and *Morbillivirus*, in that the first 12 nt of the 3′ and 5′ genomic terminal sequences of paramyxoviruses are highly conserved and complementary, containing promoter elements for replication and transcription (see Chapter 12). The first 3 nt of the henipavirus genome termini are 5′-ACC-3′—a sequence that is absolutely conserved in members of the family *Paramyxoviridae* and different from that found in the family *Pneumoviridae*.

Virus Proteins and Their Properties

Analysis of purified viruses by polyacrylamide gel electrophoresis reveals L, P, RBP (G), F_0, N, F_1, M, and F_2 proteins[20,24] where F_0 is the uncleaved and F_1 and F_2 are the cleaved products of the *F* gene (Fig. 13.4A). Interestingly, F_0 is more readily detected in HeV compared with other paramyxoviruses, including NiV,[24,37] which may suggest that HeV F is less efficiently cleaved. Overall, the proteins of henipaviruses are typical of those of *Paramyxoviridae*, with the exception of the P protein, which is significantly larger than cognate proteins in this virus family.[26] The P protein is translated from messenger RNA (mRNA) that is colinear with genomic RNA. For most henipaviruses, the *P* gene also encodes V and W proteins, produced from mRNA in which one and two nontemplated G residues, respectively, are inserted at the RNA editing site during transcription. The P, V, and W proteins, therefore, are identical for the first 405 amino acid residues of NiV and HeV. A C protein is encoded by the 5′ end of the gene in an overlapping reading frame and is produced by an internal translational initiation

mechanism, which is common to other members of *Paramyxoviridae*, except for rubulaviruses (see Chapter 12). The *P*-derived V, W, and C proteins are present in HeV-infected and/or NiV-infected cells.[24,38] It is worth noting that CedV lacks both the RNA editing and expression of the V protein.[28] Similar to other paramyxoviruses, P itself and its derived proteins (V, W, and C in the case of most henipaviruses), all antagonize innate immune responses via a diverse set of mechanisms.[39,40] The C protein also interacts with the host cell ESCRT machinery and the virus matrix (M) protein itself to facilitate virus budding (see Pathogenesis section for details on the function of these *P*-derived proteins).[41]

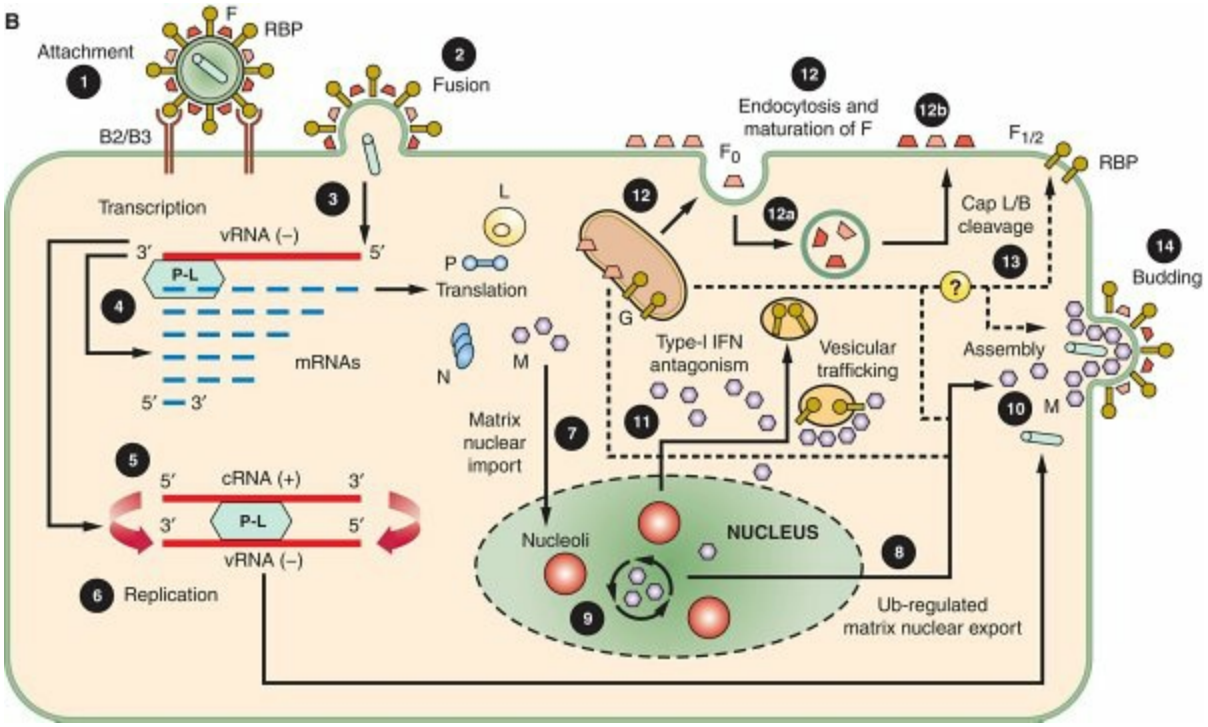

FIGURE 13.4 The major proteins of Hendra virus and Nipah virus and their roles in the henipavirus life cycle. **A:** Viruses were purified and analyzed as described in Wang et al.[20] Major virus proteins and the molecular weights of standard marker proteins are shown on the *right* and *left*, respectively. (Reproduced with permission from Wang LF, et al. Molecular biology of Hendra and Nipah viruses. *Microbes Infect* 2001;3:279–287.) **B:** Henipavirus replication cycle is depicted. The virus receptor–binding protein (RBP, *gold lollipops*) attaches the virus to the cell via its cognate receptor, typically ephrin-B2/ephrin-B3 (*1*) and triggers virus–cell membrane fusion mediated by the viral fusion protein (F, filled *orange trapezoids*) (*2*). Fusion delivers the nucleoprotein (N)–encapsidated negative-sense virus RNA genome (vRNA[−], *red*) to the cytosol (*3*). The vRNA(−) serves as template for viral transcripts made by the transcriptase complex comprised of the phosphoprotein (P) and the large RNA-dependent RNA polymerase (L) (P-L, *transparent hexagons*) (*4*). Viral transcripts are made

following a 3′ to 5′ attenuation gradient. The vRNA(−) is also the template for making full-length antigenomic cRNA(+) (*5*), which in turn is a template for vRNA(−) synthesis during virus genome replication (*6*). Henipavirus genome replication mediated by the N-P-L replicase complex is similar to the details described for the *Paramyxoviridae* in Chapter 12. However, some aspects of henipavirus assembly are relatively unique. The matrix protein (M, *purple octagons*) needs to transit through the nucleus (*7*) in a ubiquitin-regulated manner (*8*), in order to traffic properly to the plasma membrane. This nuclear sojourn involves shuttling through subnuclear compartments such as nucleoli (*9*). Proper trafficking is required for M to orchestrate the assembly of the viral RNPs with the viral envelope glycoproteins into budding infectious virions bearing the vRNA(−) (*10*). Matrix also has nonstructural functions such as antagonizing type I IFN responses (*11*); see Figure 13.9 and text for details. Additionally, in order for the henipavirus F protein to be cleaved and become fusion competent, it needs to access cathepsins L/B in the endosomal compartment. To do this, F first reaches the plasma membrane via the secretory pathway in an uncleaved form (*open beige* trapezoids) (*12*). Subsequent endocytosis and recycling back to the plasma membrane (*12a*) is required to form infectious virions where cleaved fusion-competent F (*filled orange trapezoids*) (*12b*) is complexed with the RBP in its proper oligomeric state. Where this occurs along the vesicular trafficking pathway and/or the plasma membrane is unresolved (*13*). F protein cleavage is seldom complete, and uncleaved F can be detected in budded virions (*14*). (Adapted from Aguilar HC, Lee B. Emerging paramyxoviruses: molecular mechanisms and antiviral strategies. Expert Rev Mol Med 2011;13:e6.)

Paramyxovirus N, P, and L proteins are necessary and sufficient for

replication of viral RNA both *in vitro* and *in vivo* as discussed in Chapter 12. This has been confirmed for henipaviruses by reverse genetics using a minigenome replicon containing leader and trailer sequences of the NiV genome with its entire coding region replaced with a reporter gene.[34,42] NiV N, P, and L proteins were also able to rescue an HeV minigenome, demonstrating the close genetic relationship between the viruses. Full-length recombinant NiV bearing the matrix (M), fusion (F), and receptor-binding protein (RBP) genes from HeV, singly or in combination, can also be functionally rescued. These chimeric but isogenic rNiVs replicate well in primary human endothelial and neuronal cells, further underscoring the genetic relatedness of NiV and HeV that allows for heterotypic complementation between their major structural proteins.[43] These henipavirus structural proteins contribute to unique aspects of the henipavirus life cycle (Fig. 13.4B) and play different roles in the spread and virulence of henipaviruses. Indeed, multiple groups have developed recombinant virus systems for NiV, HeV, and CedV bearing various reporters and/or relevant mutations.[43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 53] These additional tools have facilitated work toward understanding the virological and pathogenic similarities and differences among the henipaviruses (see Pathogenesis section for details).

The L protein of nonsegmented, negative-strand RNA (NNR) viruses in the order *Mononegavirales* contains a highly conserved GDNQ motif, believed to be important for polymerase activity.[54] Henipaviruses were the first NNR viruses in which GDNQ was replaced by GDNE. It was speculated that this motif might be unique to paramyxoviruses with relatively large genomes[21,24]; however, the GDNE motif has since been found in the L protein of Mossman virus that has a genome length of 16,650 nt.[55] Conversely, other henipaviruses of both Asiatic (CedV) and African lineages (GhV) also have the GDNQ motif that is common to most other NNR viruses. High-resolution cryo-EM structures of VSV-L (another NNR virus, family *Rhabdoviridae*) suggest that GDN is the truly conserved catalytic motif essential for the polymerase function of L.[56]

The receptor-binding proteins (RBPs) of the *Paramyxoviridae* display hemagglutination (H) and neuraminidase (N) activities in a predominantly genus-specific manner. Viruses in the genera *Respirovirus*, *Avulavirus*, and *Rubulavirus* possess both activities; hence their RBPs were formerly termed

HN proteins,[57] whereas viruses in the genus *Morbillivirus* do not behave uniformly and only some possess hemagglutination activity, but nonetheless their RBPs were formerly termed H.[58] This is an unfortunate misnomer. Paramyxoviruses with RBPs bearing HN activity genuinely use sialic acid–based receptors for entry, whereas "H" activity of some morbilliviruses arise from the ability of their RBPs to bind CD46 expressed on some nonhuman primate (NHP) red blood cells.[59] In contrast, henipavirus RBPs have neither of these activities[24,60]; rather, they utilize at least ephrin-B2, and in many cases, also ephrin-B3 expressed on host cell surfaces as attachment and entry receptors.[28,61, 62, 63, 64, 65] The exception is MojV, which does not appear to use any known paramyxovirus receptors.[66] Recent solution structures of various henipavirus RBPs alone and in complex with the ephrin-B2 and/or ephrin-B3 receptors have revealed the details of the virus–host cell binding process, distinguishing it from other paramyxoviruses' receptor-binding strategies[59,65, 66, 67, 68, 69] (Fig. 13.5).

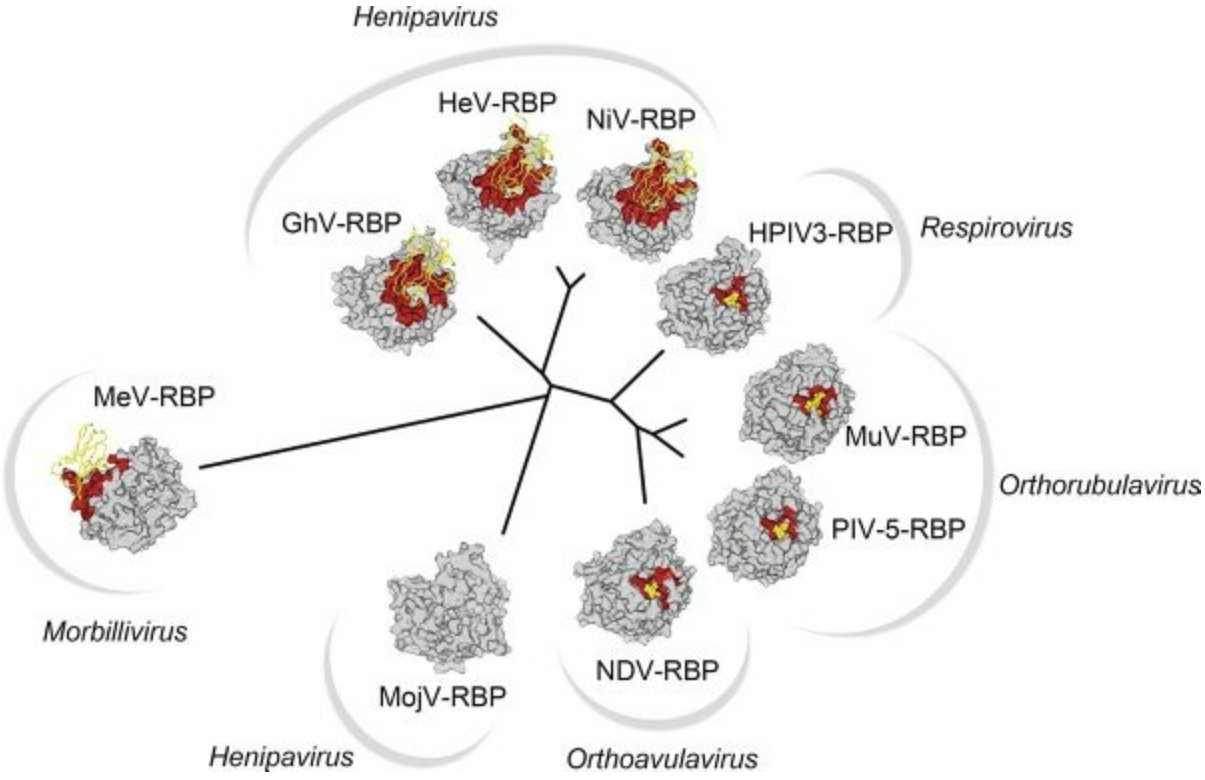

FIGURE 13.5 A structure-based phylogeny of paramyxoviral receptor-binding proteins. Structure-based phylogenetic analysis on

extant structures of henipavirus RBPs and representative RBPs from at least one virus in other paramyxovirus genera for which structural data are available. RBPs are shown besides the tree and are rendered as surface representation (*gray*). All receptor-binding proteins, with the exception of the MojV-G, are shown in complex with their respective receptor molecules (*yellow*), with the receptor-binding interface colored *red*. Analysis was performed and produced as described in Rissanen et al.[66] Paramyxoviral RBPs generally cluster according to their respective genera and cellular receptor usage with the exception MojV-RBP, which is almost equidistant to all structurally studied genera. (Courtesy of Dr. Thomas Bowden, University of Oxford, UK.)

Proteolytic processing of paramyxovirus F proteins is essential for the generation of a fusogenic form of the protein. For most paramyxoviruses that generate systemic infections, furin-like proteases in the secretory pathway cleave their F proteins at a multibasic cleavage site.[70] Surprisingly, henipavirus F proteins are cleaved without the involvement of furin and, although cleavage occurs at a single basic residue—lysine for HeV and arginine for NiV[37]—activation of the NiV F protein does not require a basic amino acid at the cleavage site.[71] Instead, endosomal/lysosomal cysteine proteases such as cathepsins L and B are responsible for the cleavage of henipavirus F proteins.[72], [73], [74], [75] To access cathepsins L/B, henipavirus F proteins are endocytosed upon initially reaching the cell surface in an uncleaved form and subsequently have to traffic back to the cell surface once they are cleaved into a fusion-competent form (Fig. 13.4B).[55,57] Classical endocytic YXXØ motifs[76,77] in the cytoplasmic tails of henipavirus F proteins and specific residues in the transmembrane domain of at least HeV F regulate this trafficking behavior through the early/sorting (S490) and recycling endosomal (Y498) compartments.[78] Henipavirus F proteins also have the ability to bud by themselves, forming F-only particles in the absence of M.[79,80]

The matrix protein (M) plays a major role in the efficient assembly and

budding of infectious paramyxoviruses.[81,82] M interacts specifically with N, the cytoplasmic tail of F, as well as cognate lipid ligands along the vesicular trafficking pathway. These orchestrated interactions help to coordinate the envelopment of encapsidated viral genomes (RNPs) and the budding of infectious virions bearing a relatively high density of viral envelope glycoprotein spikes. General details on the role that matrix plays in paramyxovirus assembly and budding are given in Chapter 12.

Henipavirus M exhibits some relatively unique behaviors and functions. For example, NiV and HeV M have classical nuclear localization and export sequences (NLS, NES) that when mutated give the relevant nuclear exclusion and nuclear retention phenotypes, respectively.[83] Time-course monitoring of M trafficking during live NiV and HeV infection indicates that M first appears in the nucleus and localizes to subnuclear compartments, including the nucleolus, before exiting into the cytoplasm and trafficking to the plasma membrane to coordinate virus assembly and budding (Fig. 13.4B).[83,84] This nuclear transit is regulated by ubiquitination and is critical for M to acquire its budding functionality.[83,85] Henipavirus M is multimono- and polyubiquitinated; a lysine to arginine mutation of a key residue in its bipartite NLS is sufficient to dysregulate ubiquitination of M and abrogate its budding function.[83,85] The latter is true not only in HeV and NiV but also in divergent henipaviruses (GhV, CedV, MojV), albeit to varying degrees.[86] Matrix interactome studies have identified many nuclear interacting factors, including importins and exportins, consistent with the nucleocytoplasmic trafficking phenotype of M.[85,87]

Host Range

For most paramyxoviruses, host range is limited and interspecies transmission is rare. In contrast, henipaviruses display a broad species tropism. In addition to a large number of bat hosts at various geographic locations (see more detail in Epidemiology section), NiV has naturally infected pigs, humans, dogs, horses, and cats,[10,11,88, 89, 90] whereas HeV infects all four Australian flying fox species and has naturally infected humans, horses, and dogs.[2,91, 92, 93] Confirmation of the wide host range of these henipaviruses and the identical cell tropism of HeV and NiV were obtained early using an *in vitro* cell fusion system that relies on vaccinia

virus–mediated cell surface expression of G and F glycoproteins.[94], [95], [96] Bats, guinea pigs, hamsters, ferrets, squirrel monkeys, and African green monkeys (AGMs) are also susceptible to experimental NiV infection.[97], [98], [99], [100], [101] Laboratory studies have added cats, guinea pigs, hamsters, ferrets, dogs, and AGMs to the list of HeV-susceptible species.[93,102], [103], [104], [105], [106] CedV, isolated from flying foxes (*Pteropus* sp.) in Cedar Grove, Australia, can establish transient but nonpathogenic infections in laboratory-challenged guinea pigs and ferrets.[28] GhV and MojV, known only from sequence information, were identified from bats[29] and rats,[30] respectively.

PATHOGENESIS AND PATHOLOGY

Entry Into the Host

Epidemiologic and experimental studies generally support an oronasal[8,107,108] or oropharyngeal[109], [110], [111] route of entry. This occurs directly or indirectly via saliva, urine, or oronasal secretions that are contaminated with relatively high levels of HeV or NiV.[93,105,107,112], [113], [114], [115], [116], [117], [118], [119], [120], [121], [122], [123] Figure 13.6 summarizes what is known about how NiV is transmitted to humans either directly from their pteropid reservoir hosts—fruit bats or flying foxes—or indirectly via a secondary amplifying host such as pigs, horses, and humans. Direct bat-to-human transmission has been associated with consuming contaminated fruit or liquid (e.g., date palm sap).[109], [110], [111] Human-to-human transmission of NiV has been well documented, especially in Bangladesh[117,124], [125], [126] and the most recent outbreak in Kerala (India).[17] However, all seven known cases of HeV infections in humans have resulted from contact with sick horses already exhibiting symptoms of respiratory distress,[127] likely after being exposed to food or water contaminated with saliva and urine/droppings from HeV-infected flying foxes.[128] While patients that succumb to henipavirus infections eventually die from encephalitic complications that often involve brainstem neuronal dysfunction,[108,129] there is diversity of clinical presentations.[130] For example, NiV-MY–infected patients in Malaysia present less often with respiratory involvement (~40%) than the vast majority of NiV-BD–infected patients in Bangladesh and India. A handful of HeV-infected humans have also presented with encephalitic

illness with or without a respiratory component (see Clinical Features section). To better understand the pathogenesis and pathology associated with henipavirus disease in humans, many relevant animal models have been developed that either represent natural amplifying hosts (pigs and horses) or reproduce well the respiratory and encephalitic disease seen in humans (hamsters, ferrets, and AGMs).[131,132] Despite the broad host range mentioned in the prior section, other animal challenge models (guinea pigs, cats, dogs) either do not represent the full spectrum of disease seen in humans or are relatively asymptomatic when challenged with NiV and/or HeV.[93,131]

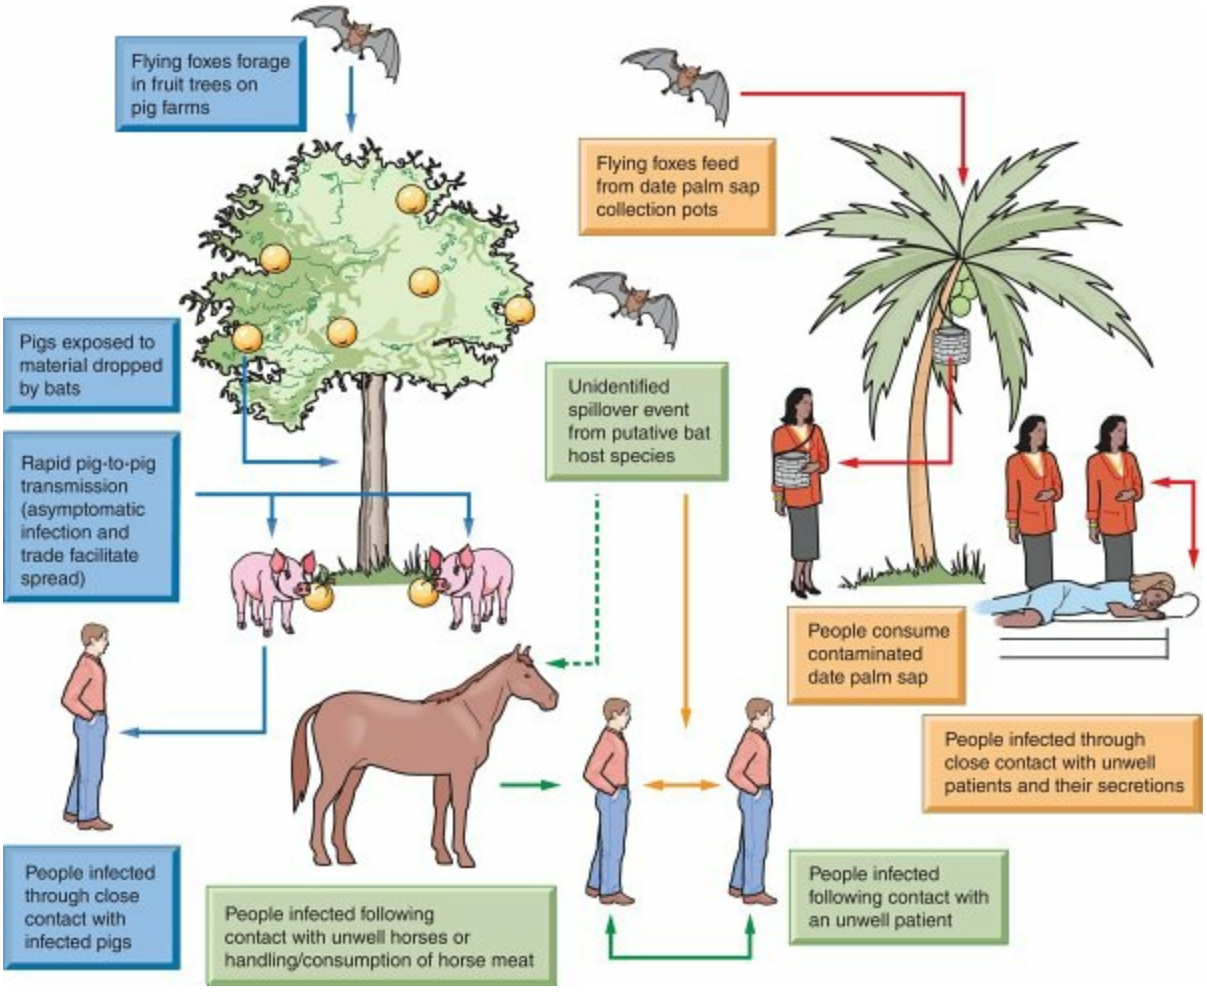

FIGURE 13.6 Nipah virus transmission. Major pathways of human Nipah virus infection are summarized for Malaysia (*blue arrows*), Bangladesh (*red arrows*), the Philippines (*green arrows*), and the latest outbreak in Kerala, India (*orange arrows*). (Adapted

Site of Primary Replication, Virus Spread, and Cell and Tissue Tropism

The clinical and pathological data from humans (see Clinical Features section), relevant animal models, and cell tropism studies (Table 13.3) indicate that the initial site of replication is within the respiratory system, likely involving cells lining the oro-/nasopharyngeal epithelium as well as bronchiolar epithelial cells, type I pneumocytes, alveolar macrophages, or pulmonary airway dendritic cells (DCs).[40,132, 133, 134, 135] The distribution and time of appearance of lesions throughout the vasculature and in the brain and lung in NiV encephalitis suggest that secondary infection probably arises via hematogenous spread of the virus, with secondary replication occurring in vascular endothelium.[136] Inflammation of blood vessels (vasculitis) occurs in most organs but is particularly prominent in the brain, lung, heart, kidney, and spleen.[9,136,137] Vasculitis is limited to small arteries, arterioles, and capillaries where NiV antigen is found in both endothelial cells and the smooth muscle of the tunica media. The pattern and time of appearance of vasculitis and viral antigen distribution are consistent with endothelial cell infection occurring before infection of the smooth muscle. The 5-day interval between maximal vasculitis in the brain and parenchymal infection in acute NiV encephalitis suggests that virus replication occurs first in endothelial cells, with infection of neurons occurring as a result of vascular damage and breakdown of the blood–brain barrier (BBB). In humans as well as in pigs and hamsters, viral antigen–positive brain microvascular endothelial cells can be observed in areas of compromised BBB integrity.[136,138,139] The presence of inclusion bodies and viral antigen in neurons, along with widespread histologic and radiologic lesions, suggests that neurologic impairment in NiV (and HeV) encephalitis may be caused by both the effects of ischemia and infarction and viral infection of neurons.[12,107,136]

[a]Expression inferred from (1) transcriptional data (microarray, next-generation sequencing, RT-PCR, etc.) provided in the cited references, or (2) independently verified through the Gene Expression Omnibus (GEO) database (https://www.ncbi.nlm.nih.gov/geo/), or (3) competition with soluble ephrin-B ligands or interference with cognate henipavirus receptor–binding proteins.

[b]For clarity and uniformity, only infection-permissive (not fusion-permissive) data are indicated; infection includes use of live virus and/or pseudotyped virus.

*c*References cited support expression, infection data, or cell-type origin where relevant and are representative, not comprehensive.

*d*Indicates greater than 10–100-fold below positive control when quantitative data are available. ND, not determined; (?), not specifically mentioned.

In addition to the systemic vasculitis, NiV antigen is clearly present in the parenchyma of multiple organs mentioned above. The same pathology has been reported for a fatal case of acute HeV encephalitis.[140] Similar widespread infection and multiorgan vasculopathy has been demonstrated in relevant animal models with the highest viral antigen load consistently seen in the lung and brain (Fig. 13.7).[131,132] Interestingly, intranasal inoculation in pigs, hamsters, and ferrets suggests that NiV can also directly invade the central nervous system (CNS) through the olfactory epithelium (OE). NiV antigen–positive neurons or olfactory nerves can be found extending through the cribriform plate or in the nasal turbinate into the olfactory bulb.[133,139,141] While primary human OE cells are susceptible to henipavirus infection,[142] the olfactory route is unlikely to be the major mode of CNS invasion in humans (and the AGM model). Primates have a relatively smaller area of OE

compared to hamsters, pigs, or ferrets where the majority of evidence regarding the olfactory route of entry has been gathered.[97,139,141] In addition, NiV antigen was not detected in the olfactory bulbs of at least nine infected patients from the autopsy series reported from the Malaysian outbreak.[136]

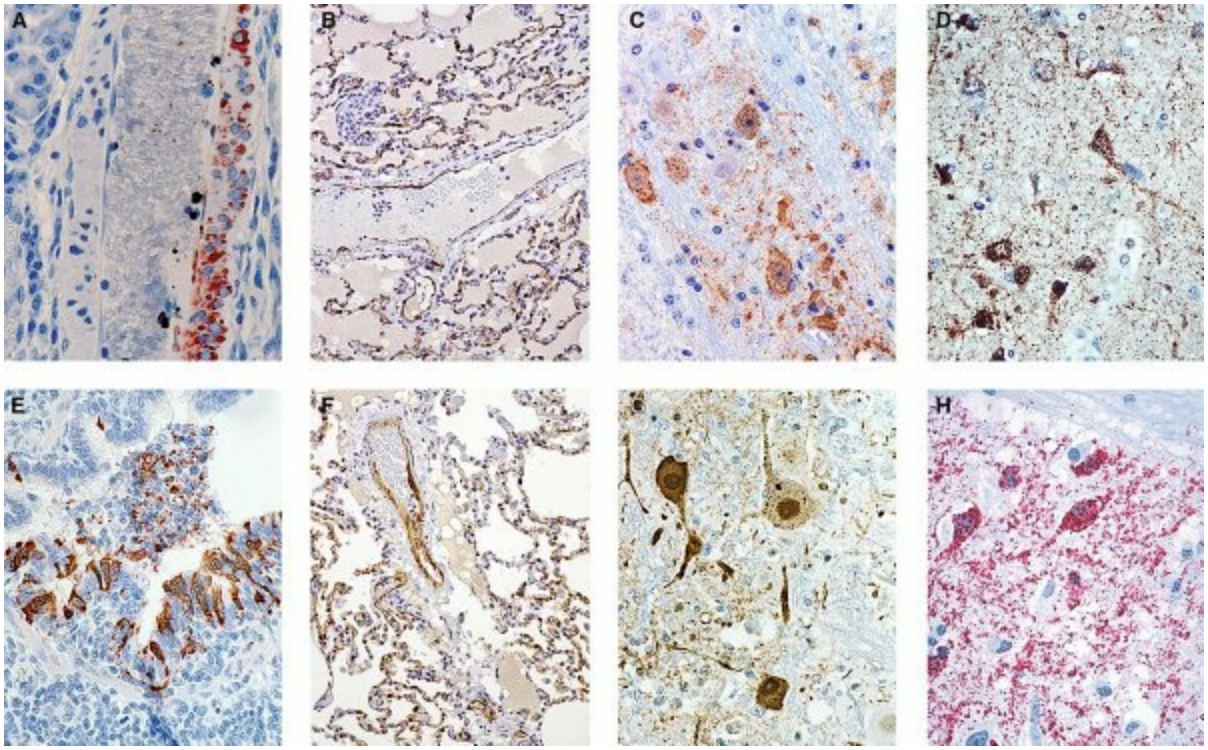

FIGURE 13.7 Immunohistochemistry detection of Nipah virus (NiV) and Hendra virus (HeV) antigen in henipavirus-infected tissues. **A–D:**Hendra virus–infected tissues. **A:** Staining of HeV antigen (N protein–specific rabbit antibody) within the wall of superficial arteriole in the submucosa of the nasal cavity in an HeV-infected horse. **B:** Immunolabeling (N protein–specific rabbit antibody) of the endothelium of medium-caliber vessels and alveolar septa in the lung of an HeV-infected African green monkey (AGM) (10×). **C:** Immunolabeling of HeV antigen (N protein–specific rabbit antibody) within neurons in the brainstem of an HeV-infected AGM (40×). **D:** Immunolabeling of HeV antigens (mouse anti-HeV polyclonal antibody) in neurons of acute HeV-

infected human case (40×). **E:** Positive immunolabeling (using anti–Nipah virus rabbit serum) within the lung of an NiV-infected pig. Involvement of bronchial epithelium and airway debris is noted. **F:** Immunolabeling (N protein–specific antibody) of the endothelium of medium-caliber vessels and alveolar septa in the lung of an NiV-infected AGM (20×). **G:** Immunolabeling of NiV antigen (N protein–specific antibody) within neurons in the brainstem of an NiV-infected AGM (40×). **H:** Immunolabeling of NiV antigens (hyperimmune anti-NiV mouse ascitic fluid) in the cytoplasm and nuclei of neurons and neuronal processes in the brain of acute NiV-infected human case (158×). Nipah virus infection: pathology and pathogenesis of an emerging paramyxoviral zoonosis. Am J Pathol 2002;161(6):2153–2167.)

The widespread cell and tissue tropism of NiV and HeV seen in humans and the various animal models is determined by the expression pattern of the henipavirus receptors, ephrin-B2 and ephrin-B3.[61], [62], [63], [64] The ephrin-B ligands and their cognate EphB receptors are both receptor tyrosine kinases that mediate bidirectional cell–cell signaling events upon engaging each other. They are critical modulators of cell remodeling events, especially within the nervous and vascular systems.[143,144] They are also highly conserved among vertebrates, which explains, at least in part, the unusually broad species tropism of henipaviruses. Ephrin-B2 is found in arteries, arterioles, and capillaries in multiple organs and is more broadly distributed across multiple tissues and cell types (Fig. 13.8), including neurons, arterial smooth muscle, and human bronchiolar epithelial cells,[143,145], [146], [147] but is absent from venous components of the vasculature.[148,149] In contrast, ephrin-B3 is essentially restricted to the brain[144] where it is expressed higher than

ephrin-B2 (Fig. 13.8). Its relative absence from organs such as the lung, kidney, and spleen, as well as from arterial endothelium, suggests that the systemic vasculitis, respiratory distress, and other end-organ pathologies seen in henipavirus infections are largely a consequence of ephrin-B2–mediated entry. Conversely, ephrin-B3–mediated entry may play a larger role in the spread of HeV and NiV within the CNS.

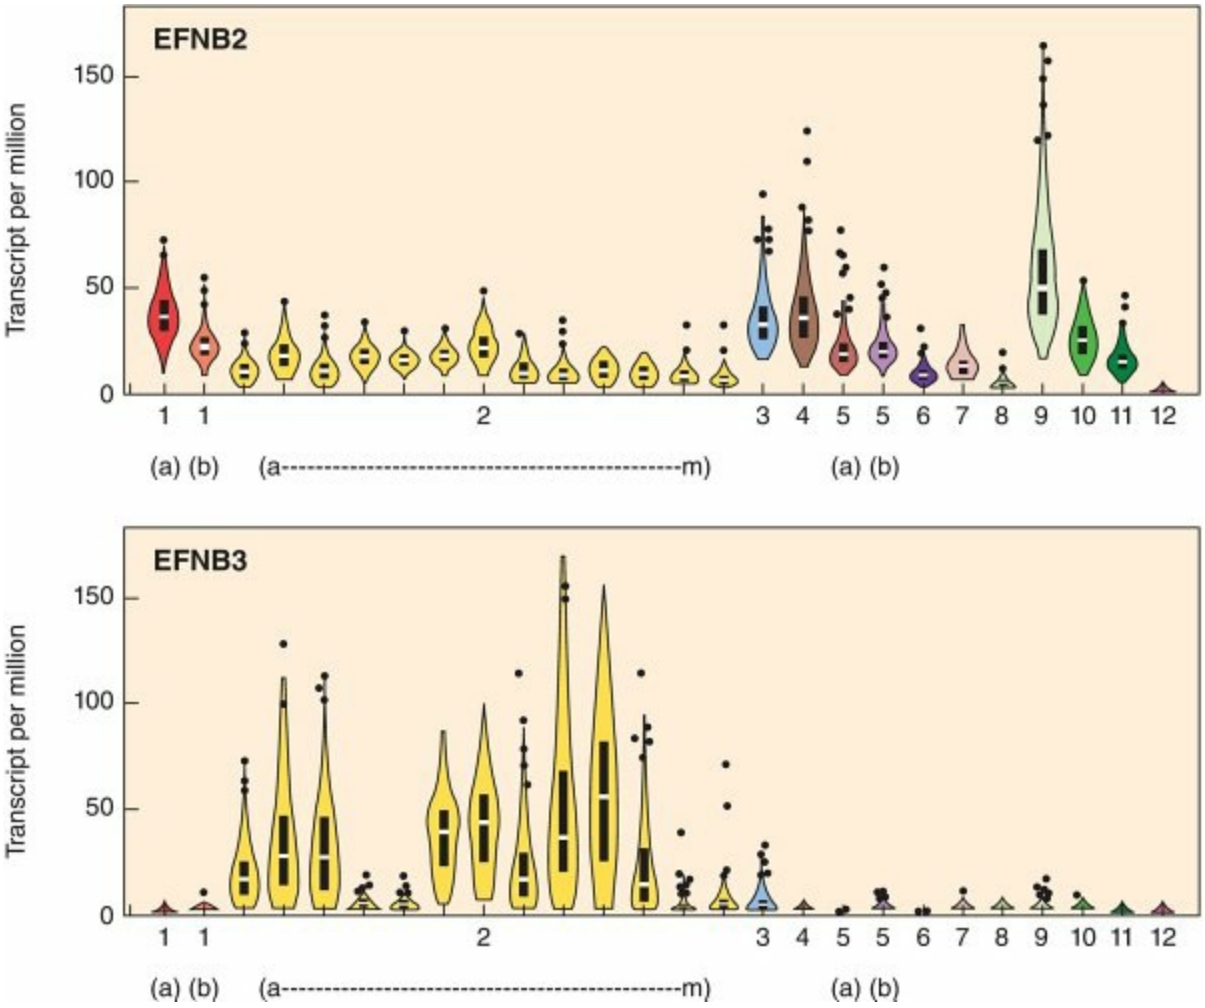

FIGURE 13.8 Ephrin-B2 and ephrin-B3 RNA-seq expression data across representative human nondisease tissues. Shown here are ephrin-B2 (*upper*) and ephrin-B3 (*lower*) expression data obtained from the Genotype-Tissue Expression (GTEx) Portal. The GTEx project is a public resource where up to 53 nondisease tissue sites obtained from nearly 1,000 individuals are subjected to RNA-seq

by next-generation sequencing among other assays. Details on datasets can be found on https://gtexportal.org. Data from all available brain regions are shown. The nonbrain tissues are chosen for illustrative purposes based on their relevance to henipavirus pathogenesis. Expression data in transcripts per million are plotted as *violin plots* with the medians and 25th and 75th percentiles shown; points are displayed as outliers if they are above or below 1.5 times the interquartile range. 1a Artery, aorta; 1b artery, coronary; 2a brain, amygdala; 2b brain, anterior cingulate cortex (BA24); 2c brain, caudate (basal ganglia); 2d brain, cerebellar hemisphere; 2e brain, cerebellum; 2f brain, cortex; 2g brain, frontal cortex (BA9); 2h brain, hippocampus; 2i brain, hypothalamus; 2j brain, nucleus accumbens (basal ganglia); 2k brain, putamen (basal ganglia); 2l brain, spinal cord (cervical c-1); 2m brain, substantia nigra; 3 breast, mammary tissue; 4 colon, transverse; 5 esophagus, gastroesophageal junction; esophagus, mucosa; 6 heart, left ventricle; 7 kidney, cortex; 8 liver; 9 lung; 10 minor salivary gland; 11 spleen; 12 whole blood.

Human lymphocytes (mainly T and B cells), and monocytes, despite being nonpermissive for NiV infection[150] or HeV F/RBP–induced fusion,[94] can bind and transfer NiV to permissive microvascular endothelial cells *in vitro*.[150] This transinfection phenotype, thought to be mediated by heparan sulfates,[151] may be an efficient form of hematogenous spread in addition to the free form viruses that make up the plasma viremia seen in acute NiV and HeV infections in humans. This acute but transient viremia appears about 4 to 7 days post onset of illness (POI) and, in survivors, is usually undetectable within 2 to 4 weeks POI depending on severity of the disease course.[17,152], [153], [154] A similar course of plasma viremia can also be detected in AGMs challenged intratracheally and orally with NiV.[98] The next section on the Immune Response will discuss possible mechanisms by which viremia is cleared in survivors.

Immune Response

Viral Antagonism of Innate Immune Responses

HeV and NiV have a broad host range that is uncommon in paramyxoviruses. This ability to replicate, spread, and cause acutely lethal disease among multiple species suggests that these viruses have evolved effective means to antagonize or evade innate antiviral responses that might otherwise keep them in check until adaptive immune responses develop. In henipaviruses, as in other paramyxoviruses,[40] the major anti-interferon (IFN) activities are encoded by the *P* gene, and *in vitro* studies indicate that *P* gene products inhibit both IFN induction and signaling (Fig. 13.9).[39] In IFN induction, various forms of viral double-stranded RNA (dsRNA) are detected by cytoplasmic RNA helicases[155], [156], [157] such as RIG-I and MDA5 and by toll-like receptor-3 (TLR3).[157,158] Both of these dsRNA signaling pathways, via a cascade of signaling events depicted in Figure 13.9 (left), lead to activation and nuclear translocation of interferon regulatory factor (IRF) 3, or if present, IRF7, and nuclear factor kappa B (NF-κB), transcription factors that induce the expression of IFN-α/β proteins. HeV and NiV inhibit dsRNA signaling via its V protein, which binds to MDA5 and prevents downstream signaling[155,159,160] but does not abrogate dsRNA signaling through TLR3.[161] Recent evidence suggests that NiV V also binds RIG-I and its regulator (TRIM25), disrupting downstream signaling.[162] In an additional strategy unique to henipaviruses, the W protein, by virtue of an NLS located in the unique carboxy-terminal, inhibits induction of IFN-α/β expression in the nucleus by targeting a process that is part of both helicase-dependent and TLR3-dependent signaling pathways.[163] Unexpectedly, the NiV M protein can also inhibit IFN-α/β induction by indirectly antagonizing the activity of IKKε, the kinase responsible for IRF3 activation.[51]

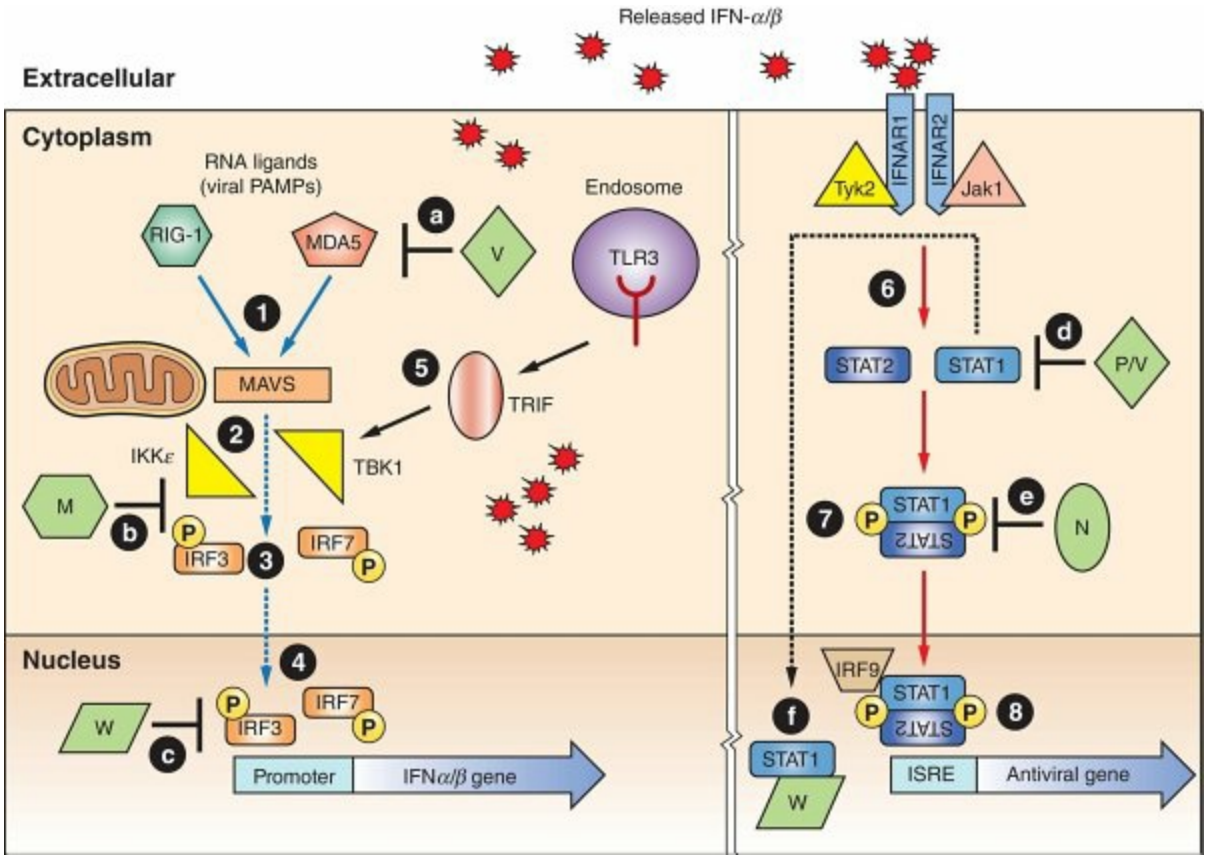

FIGURE 13.9 Innate immune evasion mechanisms of the Nipah virus N, P, V, W, and M proteins. **Left:** The V and W proteins (*green diamonds and trapezoids, respectively*) block IFN-*α*/*β* expression by different mechanisms. Depicted are simplified versions of the RIG-I–like receptor (RLR) signaling (*blue arrows*) and TLR3 signaling (*black arrows*) pathways. Both lead to activation of interferon regulatory factors 3 and 7 (IRF3 and IRF7) (*blue dashed arrow*). RIG-I, MDA5, and TLR3 can sense RNAs produced during viral infection. Activation of RIG-I or MDA5 leads to their interaction with the mitochondria-associated adapter protein MAVS (*1*). This leads to activation of the kinases IKK*ε* and/or TBK-1 (*2*), which phosphorylate and activate IRF3 and, when present, IRF7 (*3*). For clarity, MAVS activation of NF-*κ*B is not shown. Activated IRF3 and IRF7 translocate into and accumulate in the nucleus; both contribute to IFN-*α*/*β* gene

transcription (*4*). TLR3 signals through adaptor protein TRIF to activate IKK*ε*/TBK-1 (*5*). The cytoplasmic NiV and HeV V proteins interact with and inhibit MDA5, thereby inhibiting the induction of IFN-*α*/*β* expression early on in the pathway (*a*); however NiV V does not appear to inhibit TLR3 signaling. The nucleocytoplasmic shuttling NiV M protein (*green hexagon*), while it is in the cytoplasm, antagonizes induction of type I IFNs by blocking IKK*ε* activation (*b*). This prevents downstream phosphorylation and nuclear translocation of IRF3, which also leads to a failure of IFN-*α*/*β* induction. The nuclear W protein (*green trapezoid*) effectively blocks RLR and TLR3 activation of the IFN-*β* promoter by preventing the accumulation of phosphorylated IRF3 (*c*). This function requires the nuclear localization of W. **Right:** The Nipah virus N, P, V, and W proteins each block IFN signaling pathways at distinct steps (*red arrows*), ultimately leading to reduced expression of interferon- stimulated (antiviral) genes (ISGs). The P, V, and W proteins can each inhibit the phosphorylation and activation of STAT1 and STAT2 in response to IFN-*α*/*β* (6) and block the phosphorylation and activation of STAT1 in response to IFN*g*. The inhibition of the IFN-*α*/*β* signaling pathway is depicted. The cytoplasmic P and V proteins interact with and inhibit STAT1 (*d*). The V protein also interacts with STAT2, in a STAT1-dependent manner. P and V prevent nuclear accumulation of pSTAT1/pSTAT2 following IFN-*α*/*β* addition to cells and cause the STAT proteins to accumulate in a high molecular weight complex. The NiV and HeV N proteins (*green oval*) were recently reported to disrupt phospho-STAT1 complex formation (*7*), though not phosphorylation of STAT1 itself (*e*). Nonetheless, this N-mediated disruption of STAT complexes reduces nuclear accumulation of the activated STAT complexes required to stimulate ISG expression (*8*). The nuclear W protein relocalizes nonphosphorylated STAT1 from its typically

cytoplasmic localization to the nucleus (*f*). STAT1 relocalized to the nucleus by W remains unphosphorylated and does not activate transcription of ISGs in response to IFN-*α*/*β* addition. (Adapted from Basler CF. Nipah and Hendra virus interactions with the innate immune system. Curr Top Microbiol Immunol 2012;359:123–152.)

In the IFN signaling pathway (Fig. 13.9, right), IFN binds to the IFN-*α*/*β* receptor (IFNAR) on cells and initiates a signaling sequence that leads to activation of members of a family of proteins called *signal transducers and activators of transcription* (STAT).[164,165] Henipaviruses inhibit IFN signaling by sequestering STAT proteins in high molecular weight complexes and preventing their phosphoactivation.[166,167] The anti-IFN signaling activity is a property of the V protein, as has been observed for other paramyxoviruses, but also of the W and P proteins.[45,161,166,167] The P, V, and W proteins of henipaviruses have an N-terminal extension of 100 to 200 amino acids compared with cognate proteins in the subfamily,[20,23] and the STAT-binding domain of NiV V maps to this region.[161,168,169] The V and P proteins bind STAT in the cytoplasm, whereas the W protein, which is imported into the nucleus via specific interactions of its NLS with importin *α*-3,[170] likely sequesters unactivated STAT1 in the nucleus.[161,163] Recently, NiV and HeV N proteins were also found to antagonize IFN signaling by interfering with formation of activated phospho (p)-STAT1 complexes. This NiV N–mediated antagonism of pSTAT1 nuclear accumulation does *not* rely on direct binding to or inhibiting phosphorylation of STAT1 itself.[171] NiV C has also been demonstrated to interfere with IFN signaling.[47,172] However, its mechanism and true function remain unclear. Antagonizing IFN signaling is unlikely to be the main function of the C protein since recombinant C-deficient NiVs have an attenuated replication phenotype even in Vero cells,[41,45,46] which are genetically deficient in IFN production.

There is little doubt that inhibition of IFN-*α*/*β* production is one major contributor to the acute virulence of HeV and NiV *in vivo*. Daily administration of poly(I)–poly(C[12]U), a potent IFN inducer, results in greater than 80% survival in a lethal challenge hamster model for NiV

infections.[173] Most of the studies described previously were carried out *in vitro* using single-gene transfection expression systems. Understanding the true function(s) of these proteins requires assessing their impact in the context of a live virus infection or the phenotype of viruses deficient in the cognate protein(s). For example, IFN signaling apparently remains functional during live HeV and NiV infection of human cell lines, whereas IFN production was inhibited.[174] However, henipaviruses also clearly antagonize both IFN production and signaling in bat cells derived from *Pteropus* sp. that serve as their natural hosts.[175]

The diverse phenotypes observed in the various animal models when challenged with recombinant viruses deficient in the various *P*-derived accessory proteins make interpretation difficult. The clearest phenotype comes from rNiVs engineered to be V-deficient. rNiV-*Δ*V are extremely attenuated in both hamster and ferret challenge models.[46,50] Each model recapitulates the respiratory and neurological disease seen in human infections when infected with wt NiV, albeit in different ways and in a dose-dependent fashion.[103,131,176] However, challenge with V-deficient rNiV under conditions where their wt counterparts effectuate 100% mortality always results in 100% survival, and almost never results in any overt respiratory or neurological signs.[46,50] On the other hand, C-deficient rNiVs give a variety of phenotypes that range from strong attenuation in the hamster model[177] to 100% mortality in the ferret model, albeit with less severe histological lesions in the lung.[52] Similarly, W-deficient rNiVs did not show significant attenuation compared to their wild-type counterparts in both the hamster[46] and ferret models, although the disease symptomology appeared to be more neurologic in the latter.[50,52] Interestingly, an rNiV lacking both C and W still resulted in 60% mortality with reduced respiratory disease but markedly increased neurological disease.[52]

Adaptive Immune Responses

In patients with encephalitis, anti-NiV antibodies were observed more frequently in the serum than the CSF. Immunoglobulin M (IgM) antibodies occurred more frequently than immunoglobulin G (IgG) antibodies in both locations.[9,12,136] The appearance of specific IgM antibodies in serum preceded their appearance in the CSF, a sequence consistent with viremia

preceding central nervous system (CNS) infection. Anti-NiV antibodies were present in most patients with clinical NiV encephalitis; however, no difference was observed in clinical features, laboratory results, or mortality between seropositive and seronegative patients.[108,178] Seroconversion of IgG against HeV was seen in two human cases of HeV infection in 2008, with one progressing to fatal encephalitis.[8] From these cases, seroconversion in acute henipavirus disease may have diagnostic but no apparent prognostic value. Conversely, in the most recent NiV outbreak in Kerala involving 23 cases, careful monitoring of humoral and cellular immune responses in the 2 survivors revealed that there was a dramatic increase in activated (Ki67+) CD8+ T cells with an acute effector phenotype (CD38+/HLA-DR+/Granzyme B+/PD1+), suggesting that virus-specific naïve T cells were actively proliferating in response to the virus. Interestingly, clearance of viremia coincided with the peak of proliferating Ki67+ CD8+ T cells and occurred before peak IgG titers.[152] Increases in activated CD8+ T cells in lethal (NHP)[179] and nonlethal (swine) animal models of NiV infection have also been observed[180]; in the latter, prevention of virus shedding appears correlated with such T-cell responses. However, most animal studies do not monitor adaptive immune responses with the requisite precision and sophistication in order to make definitive statements regarding the relative importance of T- or B-cell responses in protective immunity against acute henipavirus infections.[181]

The high CFR associated with the acute nature of henipavirus infections already suggests that the virus interferes with the timely generation of effective T- or B-cell responses during the *natural* history of the disease in the majority of infected individuals. Indeed, although NiV replicates poorly in DCs (Table 13.3),[150,182] *in vitro* NiV-infected DCs induce an inflammatory proapoptotic milieu (TNF-α, IL-1β, IL-8) that leads not only to defective T-cell priming but apoptosis of cognate T cells and DCs.[182] This *in vitro* phenomenon, if recapitulated *in vivo* by NiV-infected DCs that traffic to lymph nodes, may account for the lymphoid depletion and lymphoid necrotic lesions seen in humans[136] and various relevant animal models.[50,183,184]

Release from Host and Transmission

Transmission is generally accepted to occur via the oronasal route[8,107,108] or

liquid/food (palm sap/fruit),[109], [110], [111] with transmissibility of HeV (horse–human or human-to-human)[185,186] being much less efficient than that of NiV transmission (pig-to-human or human-to-human).[9,15,17,108,115,117,126,187,188] Infectious NiV can be recovered from urine and the tracheal and nasopharyngeal secretions of infected patients in the early phase of their illness in the original Malaysian outbreak.[3,107,108] Nonetheless, human-to-human transmission in the Malaysian outbreak was extremely rare,[189] although it has been reported in the more recent outbreak in the Philippines. In contrast, person-to-person transmission in Bangladesh has been well documented and typically occurs during the final stages of disease in the index patient when not only symptoms of respiratory involvement are most prominent but also more frequent and closer contact with familial caretakers occurs.[125,187,188]

Replication in the respiratory epithelium and shedding in oronasal secretions is most likely responsible for virus release and transmission. Ferrets have been used to model the respiratory transmission of henipaviruses[112,184] as their respiratory symptoms (cough, serous nasal discharge, dyspnea) mimic the human disease.[97] Despite shedding relatively large amounts of virus in their oronasal secretions (4–5 log10 $TCID_{50}$ equivalents/mL at peak titers), passively cohoused naïve ferrets never got infected, regardless of whether the index ferrets were infected with HeV, NiV-MY, or NiV-BD.[112,184] However, following assisted or direct exposure to infectious oronasal fluids from the index ferrets, all the naïve ferrets developed acute infections, regardless of virus strain used.[112] Thus, the efficiency of NiV transmission appears low and likely requires direct and repeated oro- or nasomucosal exposure to infectious oronasal secretions. This is consistent with epidemiological investigations into the many recurrent outbreaks in Bangladesh where despite chains of person-to-person transmission, the estimated basic reproductive number R_0 of NiV-BD strains that have spilled over in Bangladesh have averaged 0.48.[187]

Virulence

Infection with HeV appears more severe than infection with NiV-MY and NiV-BD in the hamster[138,190] and AGM model.[191] The dose-dependent disease symptomology in the hamster model[138,192] makes it difficult to make

generalized statements about any intrinsic pathogenic difference between these three genetically distinct henipaviruses. However, the intratracheal and intranasal AGM challenge model appears to recapitulate the clinical pathologies seen in human patients more robustly.[98,103] Interestingly, it is also in this model that NiV-BD is shown to be more pathogenic than NiV-MY,[191] which reflects the observed differences in pathogenicity between NiV-MY and NiV-BD. Previous studies comparing NiV-MY and NiV-BD in hamsters[190] and in ferrets[112] gave conflicting and confusing results. But more careful comparisons of fully sequenced NiV-MY and NiV-BD strains in the AGM model provide support that NiV-BD is more pathogenic than NiV-MY,[191] consistent with the higher mortality rates associated with NiV-BD (see Table 13.1C). Under identical experimental conditions, not only is NiV-BD shown to be more pathogenic in terms of viral load in the lungs, spleen, and blood, but also the therapeutic window for postexposure prophylaxis using human monoclonal antibody (m102.4) is significantly shorter in NiV-BD–infected AGMs.[191] m102.4 is a potent neutralizing mAb previously shown to rescue NiV-MY– and HeV-infected AGMs even when administered up to 7 days postinfection.[193,194]

CedV lacks the editing site in the *P* gene and does not make the V protein,[28] a potent type I IFN antagonist required for henipavirus virulence *in vivo*.[39] Not surprisingly, CedV, which is naturally V-deficient, also does not induce any overt disease in ferrets and guinea pigs.[28] Reactive hyperplasia of oropharyngeal lymphoid tissues and detection of viral RNA in select bronchial associated lymphoid tissue (BALT) accompanied by increasing neutralizing Ab titers suggests that CedV likely replicates transiently in the upper and lower respiratory tracts of the challenged animals.[28] While recent evidence suggests that the CedV P protein itself is also a less efficient antagonizer of IFN-α signaling compared to HeV P,[195] whether CedV is truly nonpathogenic in humans or horses remains to be seen. Given the fact that CedV does not appear to use ephrin-B3 as receptor, one might also predict CedV to be less encephalopathic even in more susceptible animals.

Persistence

A small percentage of NiV-infected patients (3%–7%) experience late-onset or relapse encephalitis months to years after the initial NiV infection; the

former describes patients with initially mild or asymptomatic NiV infections, while the latter are survivors of acute NiV encephalitis.[108,129,196,197] One case of fatal late-onset HeV encephalitis has also been reported.[3,140] These cases suggest that NiV and HeV can persist in sanctuary sites like the brain especially since virus has never been isolated from oronasal secretions of relapsed encephalitis cases[9,107,136,196, 197, 198] (see Clinical Features section for details). There is one report of NiV RNA being detected in the semen of an NiV survivor 4 weeks POI, but this was gone 2 weeks later. Longitudinal studies on two HeV survivors show no evidence of viral shedding by RT-qPCR, up to 6 years postsymptom onset.[154] It is unlikely that NiV and HeV in humans can persist in infectious forms. Thus, relapse henipavirus encephalitis might resemble measles virus–associated subacute sclerosing panencephalitis, which can occur years after recovery from measles virus infection.[199,200]

EPIDEMIOLOGY

Age

The age of patients with encephalitis in the Malaysian outbreak ranged from 9 to 76 years, with almost 50% of cases occurring in those 40 to 44 years.[108,136,153,178,201] The male-to-female ratio was approximately 3:1, and more than 80% of the patients were Chinese, with statistics reflecting the increased risk to those working with infected pigs.[108,201] In Bangladesh, the age of patients ranged from 4 to 60 years, and males constituted 47% and 67% of the cases in the 2001 and 2003 outbreaks, respectively.[14,202] The outbreak in early 2011 in Bangladesh claimed at least 35 lives, including many children and infants, with ages ranging from 2 to 56 years.[127,203] Among the 18 suspected patients in the 2014 outbreak in the Philippines, the age distribution is between 21 and 60 years old.[18] In the most recent NiV outbreak in Kerala, India, the age distribution ranged from a 17-year-old male to a 75-year-old female among a total of 23 human cases.[17]

Morbidity and Mortality

In Malaysia, between September 1998 and June 1999, 256 patients who developed acute NiV encephalitis were admitted to Malaysian hospitals, and 105 died, a mortality rate of approximately 40%.[9,201] The rate of subclinical infection in households and farms where cases of NiV encephalitis occurred was calculated to be 8% and 11%, respectively.[196,201] In Singapore, where 11 patients were confirmed to have acute NiV encephalitis, a further 2 asymptomatic abattoir workers were serologically positive, representing a rate of subclinical infection of 15%.[204] Subsequently, 89 individuals were identified on the basis of positive serology as having experienced either an asymptomatic or mildly symptomatic NiV infection.[129] This increases the number of people infected with NiV to 345 and decreases the mortality rate to approximately 30%.[137] In Bangladesh, 98 of 135 patients died in 8 outbreaks from 2001 to 2008, giving a combined case fatality rate of 73%.[117,188,202] In the Philippines outbreak, the case mortality is 53% out of all the suspected cases or 81% for those with encephalitic clinical signs.[18] The case mortality is 94% for the 2018 Kerala outbreak in India.[17] There have only been seven known human cases of HeV infection in Australia in the past 16 years, four of which have been fatal (three acute and one case of relapsed encephalitis).[2,3,8]

Origin and Spread of Epidemics

Fruit bats (flying foxes) in the genus *Pteropus*, family Pteropodidae, and suborder Megachiroptera are main reservoir hosts of HeV and NiV.[5,6,13,89,205] In Australia, HeV has been shown to occur in all four flying fox species, with the crude seroprevalence of 47%, indicating an endemic pattern of infection throughout Australia.[91] Serologic tests show that NiV or NiV-related virus is widely dispersed in bats from Indonesia to the west border of Africa (Fig. 13.10). NiV was first isolated from the urine of island flying foxes and from the saliva on partially eaten fruit[13] and has since been isolated from Lyle's flying foxes (*Pteropus lylei*) in Cambodia[89] and *Pteropus medius* in Bangladesh.[206] The Indian flying fox (*Pteropus giganteus*) is the main pteropid species throughout Bangladesh and the Indian subcontinent with a high seroprevalence of henipavirus-specific antibody.[14,110,187,207] Additional serologic and limited nucleic acid evidence has suggested that related henipaviruses are circulating in other regions, including Thailand, Indonesia,

Vietnam, China, Madagascar, and several countries and regions in Africa (Fig. 13.10 and Table 13.4).

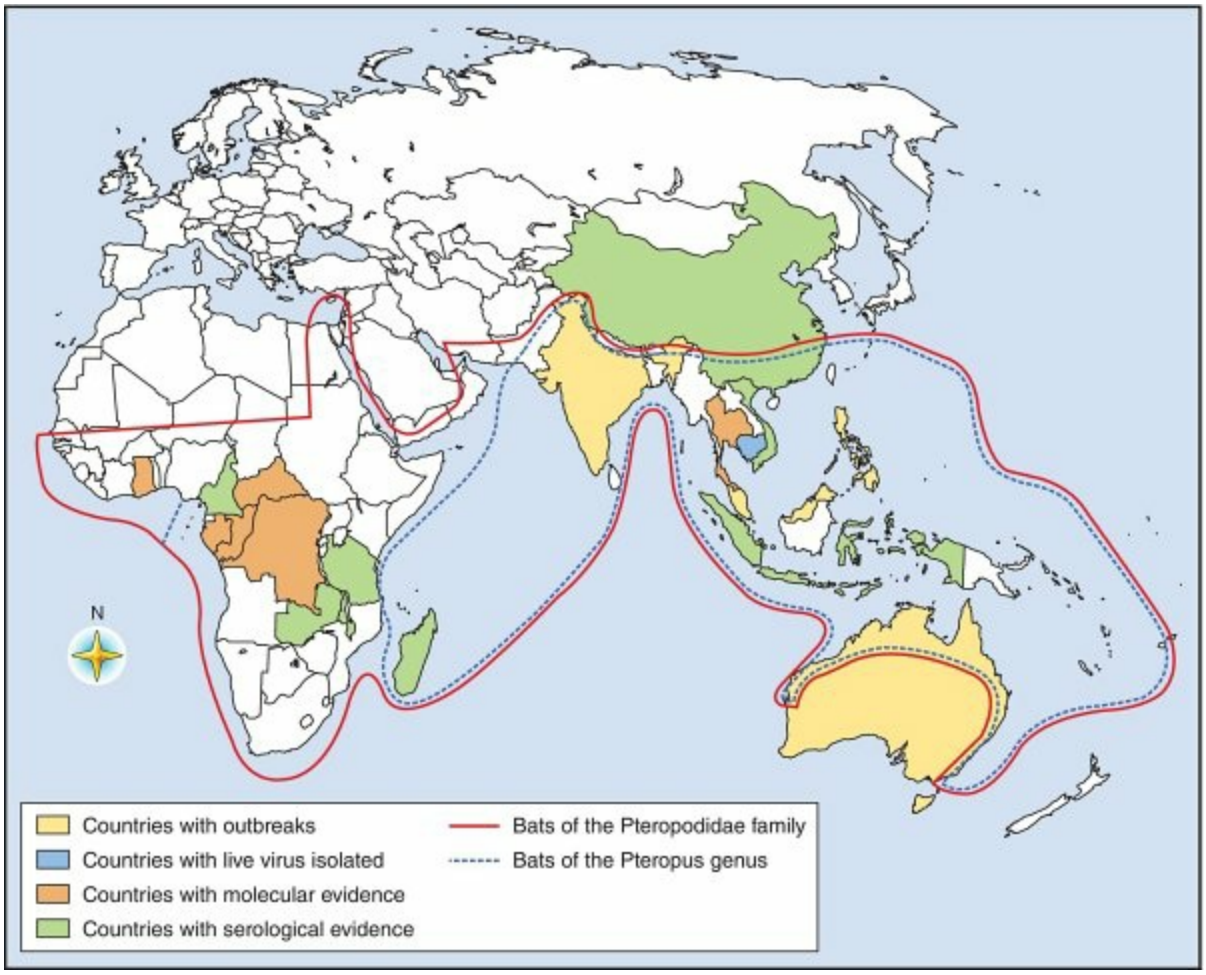

FIGURE 13.10 Distribution of frugivorous bats belonging to various genera in the Pteropodidae family where evidence of henipavirus presence have been detected. The presence of henipavirus is graded into four levels with known outbreak (yellow), virus isolation (blue), molecular detection (brown), and antibody detection (green).

TABLE 13.4 Detection of nipah or nipah-related virus infection in bats (geographic surveillance studies)

Bat Species	Method and Country of Detection			References
	Serology	PCR	Isolation	
Suborder: Yinpterochiroptera				
Cynopterus brachyotis	Malaysia			205
Cynopterus sphinx	Vietnam			292
Eidolon dupreanum	Madagascar			324
Eidolon helvum	Ghana, Zambia, Malawi, Tanzania, Uganda, Rio Muni, Bioko, Príncipe, São Tomé, Annobón, Cameroon	Ghana, Gabon, Democratic Republic of the Congo, Central African Republic		19,29,222,296,325
Eonycteris spelaea	Malaysia			205
Epomophorus gambianus	Ghana	Democratic Republic of the Congo, Gabon, Republic of the Congo		29,296
Hipposideros armiger	China			287
Hipposideros larvatus	Thailand	Thailand		286
Hipposideros pomona	China			287
Hypsignathus monstrosus	Ghana	Republic of the Congo, Central African Republic,		29,296
Myonycteris torquata		Democratic Republic of the Congo, Gabon, Republic of the Congo		29
Rhinolophus affinis	China			287
Rhinolophus sinicus	China			287
Rousettus leschenaulti	China, Vietnam			287,292
Rousettus aegyptiacus		Gabon		29
Pteropus giganteus	Bangladesh, India			207
Pteropus hypomelanus	Malaysia, Thailand	Thailand	Malaysia	205,221,326
Pteropus lylei	Cambodia, Thailand	Thailand	Cambodia	89,290,327
Pteropus medius		Bangladesh, India	Bangladesh	206,328,329
Pteropus rufus	Madagascar			324
Pteropus vampyrus	Malaysia, Thailand			205,286
Suborder: Yangochiroptera				
Carollia perspicillata		Costa Rica		29
Miniopterus spp.	China			287
Myotis daubentonii	China			287
Myotis ricketti	China			287
Pteronotus parnellii		Costa Rica		29
Scotophilus kuhlii	Malaysia			205

Neither HeV nor NiV appear to cause clinical disease in naturally infected bats.[91,202,205,208] Experimental infection with doses of HeV that are lethal in horses generates sporadic vasculitis in the lung, spleen, meninges, kidney, and gastrointestinal tract and, even then, only in a proportion of infected bats.[105] Viral antigen is detected in the tunica media rather than endothelial cells, a fact that may spare these bats from the clinical effects associated with vasculitis.[209] In infected pregnant fruit bats, antigen was observed in similar locations and in the placenta.[210] The mode of transmission between fruit bats is unknown. Transplacental transmission has also been observed experimentally without apparent harm to the fetus.[210] Experimental infection

of fruit bats with NiV produced a subclinical infection with a transient presence of virus within selected viscera along with periodic viral excretion in bat urine and seroconversion with neutralizing antibody present.[100]

The spillover and epidemic hosts of HeV and NiV were horses in Australia and the Philippines and pigs in Malaysia. All human infections with HeV in Australia and NiV in Malaysia have only occurred through transmission from these domestic animal hosts.[9,201] No evidence exists of direct transmission from pteropid bats to humans in Australia or Malaysia, despite many opportunities in Australia for transmission to bat carers.[196,211] In contrast, fruit bats apparently play a direct role in the transmission of NiV to humans in the many recent outbreaks of disease in Bangladesh, where epidemiologic evidence in support of a role for an intermediate host was lacking.[14,202] Three pathways of NiV transmission from bats to people have been identified based on epidemiologic investigations in Bangladesh.[117] Consumption of fresh date palm sap appears to be the predominant risk factor, and infrared camera studies have confirmed that *P. giganteus* bats frequently visit date palm sap trees and consume sap during collection.[212] In the 2005 NiV outbreak in Tangail District, Bangladesh, drinking raw date palm sap was the only activity significantly associated with illness (64% among cases vs. 18% among controls).[110] Another route of transmission for NiV from bats to people in Bangladesh could be via domestic animals. Contact with a sick cow in Meherpur, Bangladesh, in 2001 was strongly associated with NiV infection,[14] and contact with pigs and diseased goats has also been implicated in other occurrences of NiV in Bangladesh.[117] Although NiV has never been isolated in domestic livestock animals, serological evidence was reported for antibodies to NiV or NiV-related viruses in cattle, goats, and pigs in Bangladesh.[213] Transmission via direct contact with NiV-infected bat secretions also appears possible from evidence in the Goalando outbreak in 2004, where individuals who climbed trees were more likely to develop NiV infection than controls.[214]

The mode of transmission from bats to spillover hosts in Australia and Malaysia remains to be determined. Three principal hypotheses exist. One is that masticated pellets of virus-contaminated, residual fruit pulp spat out by flying foxes are ingested by horses or pigs.[205] The second is that urine from infected animals contaminates pastures or pigsties. The third is that infected

fetal tissues or fluids contaminate pastures or sties and are ingested. The latter is based largely on the fact that the HeV outbreaks have occurred during the birthing period of some species of flying fox and is supported by the isolation of virus from a pregnant flying fox and its fetus.[6]

HeV has been transmitted from horse to man on seven occasions from 1994 to 2009, twice during the initial outbreak in Brisbane,[1,2] twice during necropsy of horses that died in the field,[1,4] twice during either daily nasal cavity lavage or participating in a necropsy,[8] and once from performing an endoscopy on an infected horse.[8,215] HeV is rarely found in the bronchi or bronchioles of infected horses, which suggests that aerosol transmission to either man or horses is less likely[216] and horse-to-horse transmission of HeV has not been demonstrated.[105] The presence of HeV in equine saliva, however, suggests that close contact with infected horses, such as might occur during manual feeding of the animals, may facilitate horse-to-human transmission.[1] The presence of virus in a wide range of tissues and in the nasal discharge commonly found at the terminal stage of infection offers a range of sources for virus transmission during necropsy.[2,217] As shown in Figure 13.7, high level of viral antigen can be detected in the nasal cavity of HeV-infected horses.

In the Malaysian NiV outbreak, contact with pigs or fresh pig products was required for transmission of the virus to humans, with greater likelihood of transfer to those in direct contact with sick or dying pigs on farms or in abattoirs.[9,201] The presence of NiV in the respiratory epithelium of naturally and experimentally infected pigs (Fig. 13.7) indicated that virus probably spread to humans and within the pig population by aerosol or by direct contact with oropharyngeal or nasal secretions.[10,121,139] The presence of the virus in a wide range of organs indicates that humans may also have been infected during processes such as slaughtering or farrowing. In Bangladesh, pigs were excluded as potential sources of NiV on epidemiological grounds, and human-to-human transmission was observed.[126,188] The virus may have been transmitted to human index cases directly through contact with fruit bat secretions in contaminated fruit or date palm sap before circulation in the human population (Fig. 13.6).[13,14,117,202] Nosocomial transmission has been detected in some of the Bangladesh and India outbreaks.[15,117,218] In the Philippine NiV outbreak, of the 17 case patients, a total of 7 (41%) had

participated in horse slaughtering and horse meat consumption; 3 (18%) had only consumed horse meat but had no history of slaughtering or meat preparation; and 5 (29%) case patients had been exposed to other human case patients but not to any horses. So it is possible that both horse-to-human and human-to-human transmission might have occurred (Fig. 13.6).[18] For the Kerala NiV outbreak, while it remains undefined how the index case was exposed to NiV, it was evident that human-to-human transmission was the main driver for the spread of the virus in both family/community and hospital settings (Fig. 13.6).[17]

Genetic Diversity

Genome sequencing revealed that HeV isolated from equine and human sources during the outbreak in Brisbane appears identical and differs little from HeV isolated from flying foxes 2 years later.[2,6] Sequencing of five additional horse isolates from five different locations from the 2006 to 2008 HeV occurrences has also demonstrated a very high genetic similarity.[219] Similar observations were made in Malaysia, where it was demonstrated that NiV isolated from pigs at the height of the outbreak and at its geographic focus was essentially identical to human isolates made at that time and isolates obtained from flying foxes several years later.[13,22,23,220]

In Bangladesh, four human isolates obtained in 2004 demonstrate significant genetic heterogeneity, which might suggest multiple spillovers of NiV from flying foxes into the human population.[33] The NiV sequences detected from human patients in India from 2001 to 2018 were more related to NiV from Bangladesh than NiV from Malaysia.[15,17,218] A recently whole genome sequencing study of 10 NiV isolates obtained from bats in 2013 in Bangladesh at two different geographic locations revealed that the isolated viruses were very similar in sequences. This suggests that multiple strains were not cocirculating in the bat population at the time.[206] Furthermore, none of the bat NiV isolate sequences was identical with any previously detected human NiV isolate sequences, suggesting that NiV spillover into humans is a rare event and more intensive surveillance is required to appreciate the full genetic diversity of NiV in bats in an area with frequent spillover events into human populations.[206] NiV isolated from the flying fox *Pteropus lylei* in Cambodia[89] represents an evolutionary lineage that is separated from the

Malaysia or Bangladesh/India cluster. Partial *N* gene sequences detected in *Pteropus lylei* in Thailand indicate the circulation of at least two lineages of NiV—one related to the Bangladesh NiV and the other more related to the Malaysian NiV.[119] On the other hand, NiV sequences detected in *Pteropus hypomelanus* in Southern Thailand are clearly more related to the Malaysian NiV.[221] As the RNA-dependent RNA polymerase (RdRP), designated as the L protein, is the most highly conserved protein for paramyxoviruses, it has been used as a more reliable indicator of evolutionary relationship among different paramyxoviruses. Figure 13.11 shows an L-based phylogenetic tree of henipavirus species and strains, selected to represent major species origin, geographic location, and time of isolation. Prototype species from other genera in the family *Paramyxoviridae* are also shown for context and comparison.

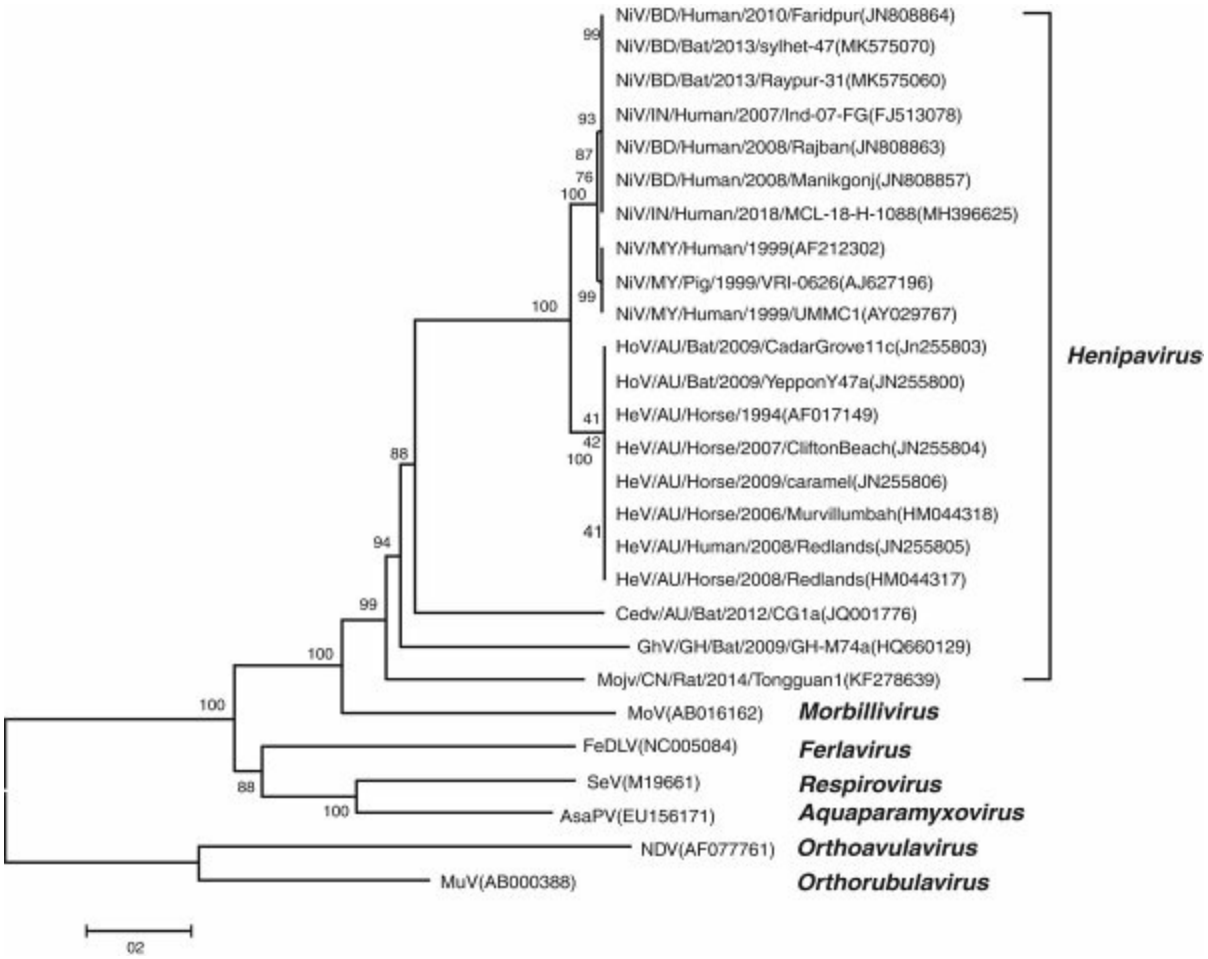

FIGURE 13.11 Phylogenetic tree based on RdRP proteins of

selected henipaviruses and prototype species of the other genera in the family *Paramyxoviridae*. Tree was constructed by using neighbor-joining approach with 1,000 bootstrap replicates. Numbers at the nodes represent bootstrap values. Scale bar indicates amino acid substitutions per site. Sequences are labeled with the following ordination when all relative information is available for any given genome sequence: Virus/Country/Host/Year/Strain (GenBank accession number). For example, NiV/BD/Human/2010/Faridpur(JN808864) represents a Nipah virus isolated in Bangladesh from humans in 2010 with Faridpur as its isolate name and JN808864 as its GenBank accession number.

The presence of henipavirus-reactive (but not neutralizing) antibodies and viral RNA in bats from other regions of the world (Fig. 13.10 and Table 13.4) indicates that a much greater genetic diversity of henipaviruses exists in different bat populations.[29,222,223] These divergent but yet to be characterized henipaviruses likely have different transmissibility, pathogenicity, and receptor usage patterns, as has already been shown for CedV,[28,53,195] GhV,[65,224,225] and MojV.[66] The latter is an outlier in many ways[41,66,86] and is currently the only henipavirus identified in rodents rather than bats.[30]

CLINICAL FEATURES

Incubation Period

Based on the time interval between the last exposure to pigs and onset of disease, the incubation period for NiV ranged from 2 to 45 days; however, for 90% of patients, it was 2 weeks or less.[108,153,178] An estimate of 2 to 3 weeks was made based on the time interval between importation of pigs from NiV-affected areas of Malaysia and development of human disease at a Singaporean abattoir.[204] A mean incubation period of 9.4 days was calculated for four patients who had a fixed period of exposure.[178] The NiV outbreak in

Kerala, India, 2018, revealed a median incubation period was 9.5 days among 23 cases, 22 of which were nosocomial.[17] In the occurrence of HeV in Australia in 2008, a detailed examination of exposure histories from two infected patients (one fatal) suggested a likely incubation period of 9 to 16 days, with exposure occurring some 3 days before the onset of symptoms of HeV infection in the horse.[8]

Acute Clinical Features

The first two patients infected with HeV presented with fever, myalgia, headaches, lethargy, and vertigo. One patient recovered; however, the other developed pneumonitis, respiratory failure, renal failure, and arterial thrombosis and died of cardiac arrest 7 days after admission to the hospital. Findings at autopsy were consistent with a viral infection; both lungs were congested, hemorrhagic, and filled with serous fluid, and the histology revealed focal necrotizing alveolitis with many giant cells, some syncytial formation, and viral inclusions.[1] Although the predominant clinical features of NiV encephalitis derived from CNS involvement in the initial Malaysian outbreak, a proportion (40%) of patients displayed pulmonary involvement, which presented as an atypical pneumonia with fever, cough, and headache.[12,108,136,178] In the Kerala, India, NiV outbreak, 19 cases (83%) presented with acute respiratory distress syndrome (ARDS) and shortness of breath, and 20 cases (87%) had respiratory symptoms.[17] The clinical presentation of NiV infections in Bangladesh also shows severe respiratory disease involvement.[226] A chest x-ray of an acute NiV-infected human case showing diffuse bilateral opacities of the lung fields consistent with ARDS (Fig. 13.12A) and a similar presentation were reported in the first fatal human HeV case.[1] Chest x-ray images of NiV- and HeV-infected AGMs have also demonstrated severe respiratory disease (Fig. 13.12B). Case definitions for suspected NiV infection in Bangladesh[226] and India[15,17] generally included individuals residing in an outbreak area who presented with fever, headache, vomiting, or altered mental status or with history of cough or shortness of breath and fever.

A novel model of lethal Hendra virus infection in African green monkeys and the effectiveness of ribavirin treatment. J Virol 2010;84(19):9831–9839, reproduced with permission.)

With NiV in Malaysia, most patients presented with acute encephalitis characterized by fever, headache, drowsiness, dizziness, myalgia, and vomiting, and more than 50% had a reduced level of consciousness.[9,12,108,178] The major clinical signs included drowsiness, areflexia, segmental myoclonus, tachycardia, hypertension, pinpoint pupils, and an abnormal doll's eye reflex. Such clinical features as these suggested involvement of the brainstem and upper cervical spinal cord and were observed more frequently in patients with a reduced level of consciousness.[108] In Kerala, India, 2018, NiV-infected patients presented with altered sensorium (74%), along with myalgia, headache, vomiting, and seizures.[17] Patients in the NiV-Malaysian outbreak who retained normal levels of consciousness throughout their illness recovered fully; however, only 15% with reduced levels of consciousness survived. Figure 13.13 shows magnetic resonance imaging (MRI) images of human cases of acute NiV encephalitis. Such neurological manifestations are consistent with vasculitis-induced thrombosis in the brain and the direct infection of neurons.[9,11,12,136] The multiple discrete lesions 1 to 5 mm in diameter in the cerebral white matter detected by MRI may be the site of such microinfarctions and are distinct from lesions caused by other viruses.[9,12,140,196,228] A third case of HeV infection presented first with meningitis and a 12-day history of sore throat, headache, drowsiness, vomiting, and neck stiffness. After an apparent full recovery, this patient developed fatal encephalitis 13 months later and was admitted to the hospital with a generalized tonic–clonic seizure after 2 weeks of irritable mood and low-back pain. Recurrent focal motor seizures occurred over the next 7 days,

as did secondarily generalized seizures and low-grade fever, followed by dense right hemiplegia, signs of brainstem involvement, and depressed consciousness requiring intubation. The patient remained comatose and died 25 days after admission.[3] Two patients in 2008[8] presented with initial influenza-like illness, although soon after apparent clinical improvement and an absence of fever, encephalitis developed in both. MRI revealed widespread cortical, subcortical, and deep white matter involvement, similar to the previous late-onset case of HeV encephalitis[3] and to NiV encephalitis cases (Fig. 13.13B).[108,196,229]

Outcome of Infection

Most patients who survived acute NiV encephalitis in Malaysia made a full recovery; however, approximately 20% had residual neurologic

deficits.[108,178,230] Neurologic sequelae included cognitive difficulties, tetraparesis, cerebellar signs, nerve palsies, and clinical depression. A few patients remained in a vegetative state. In patients with encephalitis who recovered, most brain lesions revealed by MRI disappeared or became smaller over a period of 12 to 18 months, although some remained unchanged.[230] Approximately 7.5% of patients who recovered from acute encephalitis and 3.4% of those who experienced nonencephalitic or asymptomatic infection developed late neurologic disease (Fig. 13.13).[108,129,196,197] Relapse encephalitis and late-onset encephalitis presented several months to 4 years after the initial infection, with the longest reported case 11 years after an initial acute infection.[231] Relapsed cases had elevated IgG, but not IgM, and no vasculitis, and unlike the situation in acute encephalitis, virus was not isolated from throat and nasal secretions.[9,107,136,196, 197, 198]

The clinical features associated with relapse and late-onset encephalitis resembled those found with acute NiV encephalitis, although decreased incidence was seen of fever, coma, segmental myoclonus, and meningism and an increased occurrence of seizures and focal cortical signs compared with the acute manifestation of the disease.[129] The clinical, radiologic, and pathological features of relapse NiV encephalitis resembled those of the patient who became infected with HeV; suffered mild, transient aseptic meningitis; and recovered but died of a fatal meningoencephalitis 13 months later.[3,140] Most patients with relapse and late-onset encephalitis had only one neurologic episode, although some patients experienced two episodes separated by a mean of 7.6 months (6 weeks–1 year).[129] The mortality rate associated with relapse and late-onset encephalitis at 18% was lower than that associated with acute encephalitis, at 30% to 40%. However, 61% of patients with relapse and late onset had further neurologic sequelae compared with 22% after acute encephalitis. Among NiV survivors in Bangladesh, some 30% have moderate to severe persistent neurologic dysfunction for years following acute infection.[196]

The demographics, clinical features, serology, and MRI of patients with relapsed and late-onset encephalitis were similar, suggesting that the two diseases have identical pathogenesis[129] and that the initial infection in late-onset encephalitis patients may not have been sufficiently severe to cause neurologic symptoms. MRI abnormalities similar to those observed in

patients with acute encephalitis were also seen in 16% of asymptomatic patients, although the lesions were fewer in number.[227] The involvement of the cortex in relapse and late-onset encephalitis suggests a different pathologic mechanism compared with acute encephalitis. Relapse and late-onset encephalitis are considered to be caused by the recrudescence and rapid replication of virus that had persisted following acute or asymptomatic NiV infection.[129] NiV, however, was not isolated from CSF and brain tissue of patients with relapse and late-onset encephalitis.[129]

The generalized understanding of the infection process along with the clinical features of human NiV and HeV infection is diagrammed in Figure 13.14. Transmission is likely via the oronasal route as described above (Pathogenesis section). The initial site of replication in humans is likely within the respiratory system, and disease onset is characterized by fever, myalgia, shortness of breath, and cough, which may progress to ARDS. Possible invasion into the CNS via the olfactory bulb has been demonstrated in nonprimate animal models.[133,139,141] Virus replication and hematogenous systemic spread occurs (cell-free or cell-associated viremia), and established infection is characterized by a widespread vasculitis with endothelial and smooth muscle cell tropism resulting in multinucleated syncytial cells.[136] CNS infection and encephalitis results in altered sensorium, headache, vomiting, and seizures along with fever and other systemic symptoms. Infection of other organs in addition to the lung and brain in human cases occurs and has been reported in the kidney, heart, spleen, and lymphoid tissues,[136] and similar widespread infection has been demonstrated in multiple animal models.[131]

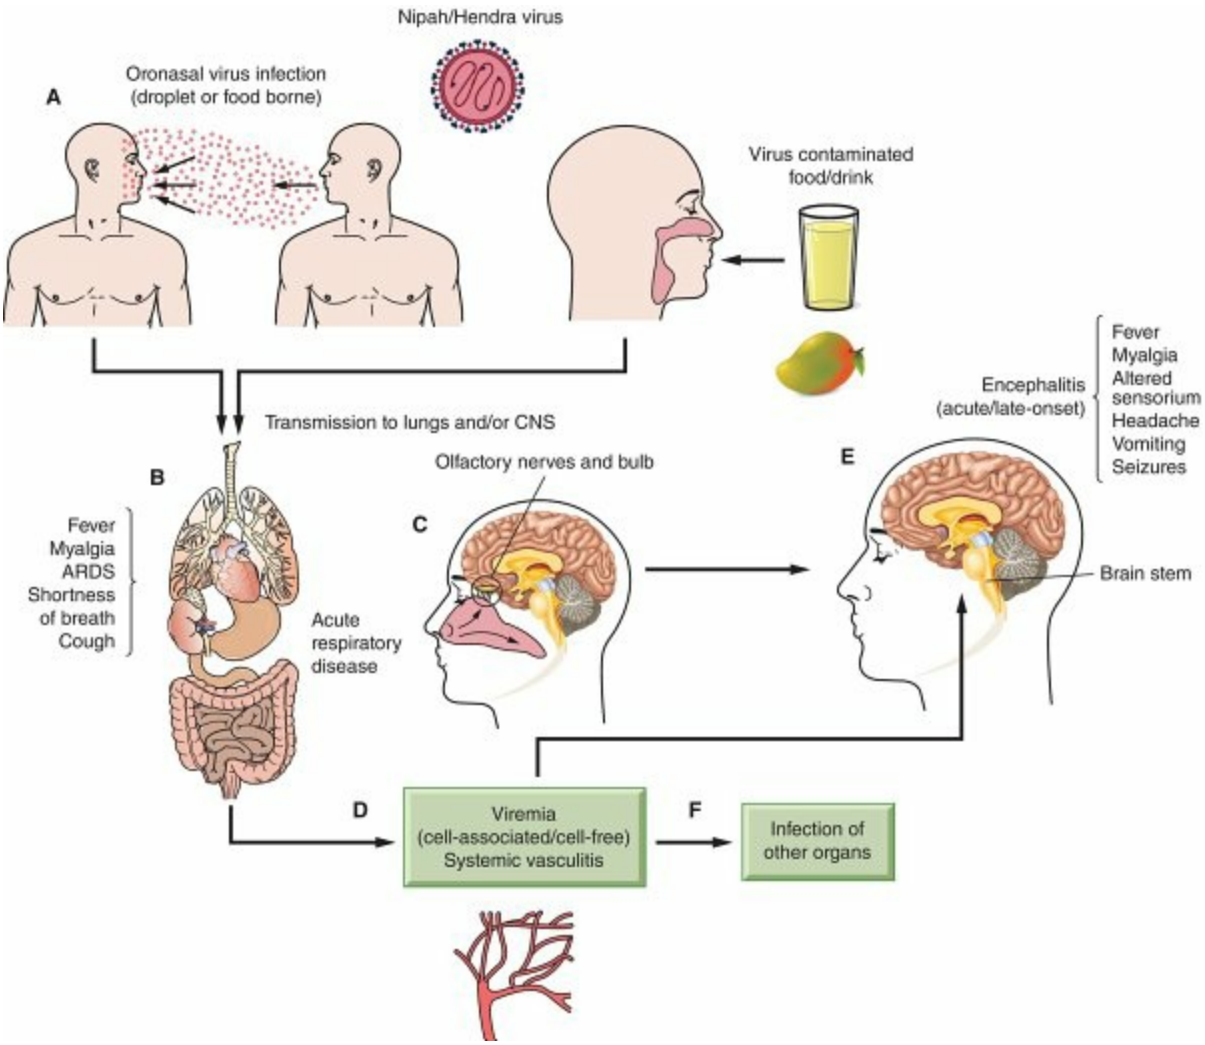

FIGURE 13.14 Generalized understanding of infection and clinical features of human Nipah virus (NiV) and Hendra virus (HeV) infection. **A:** Transmission is generally accepted to occur via the oronasal route presumably by virus-contaminated respiratory secretions or droplets from infected animals or people or liquid/food (palm sap/fruit). **B:** The initial site of replication in humans is ill-defined but is thought to occur within the respiratory system, and disease onset is characterized by fever, myalgia, shortness of breath, and cough, which may progress to an acute respiratory distress syndrome (ARDS). **C:** Possible invasion into the central nervous system (CNS) via the olfactory bulb has also been suggested and has been demonstrated in animal models. **D:**

Virus replication and hematogenous systemic spread occurs (cell-free or cell-associated viremia), and established infection is characterized by a widespread vasculitis with endothelial and smooth muscle cell tropism resulting in multinucleated syncytial cells. **E:** CNS infection and encephalitis results in altered sensorium, headache, vomiting, and seizures along with fever and other systemic symptoms. **F:** Infection of other organs in addition to lung and brain in human cases occurs and has been reported in kidney, heart, spleen, and lymphoid tissues, and similar widespread infection has been demonstrated in multiple animal models.

DIAGNOSIS

Virus isolation, EM, immuno-EM, immunohistochemistry (IHC), serology, and polymerase chain reaction (PCR) played key roles in the initial discovery of HeV[2] and NiV.[11] They remain essential elements in the repertoire of procedures for the rapid and specific diagnosis of henipavirus infections in humans and animals.

During investigation of a suspected disease outbreak, attempts to grow henipaviruses may be initiated in a BSL3 laboratory. However, if a cytopathic effect (CPE) is observed and the growth of henipavirus is confirmed by PCR or immunostaining, infected cultures need to be handled under BSL4 conditions and subsequent work with live virus restricted to BSL4. Both HeV and NiV replicate in various cell lines—a feature that contributed to the efficiency with which they were isolated during the initial disease outbreak investigations.[2,11] Vero cells are commonly used, generating titers of virus as high as 10^8 infectious virions per milliliter.[153,232] In fatal cases, attempts should be made to isolate virus from the brain, lung, kidney, and spleen.[232] For tissue specimens containing a high virus load, direct examination by immuno-EM and IHC can be very useful in providing early diagnosis. Various antibody reagents have been developed for this purpose, including polyclonal antisera, monospecific antibodies raised against recombinant antigens,[20] and monoclonal antibodies (mAb) raised against

whole virions or vaccinia virus–expressed viral proteins.[233], [234], [235], [236] Using HeV- or NiV-specific mAb, it is possible to differentiate between the two viruses.[235,236] Quantitative real-time PCR (TaqMan assay) has been the method of choice to detect viral materials in infected tissues because of its speed, specificity, and sensitivity. The first-generation henipavirus TaqMan assays are either HeV specific[237] or NiV specific.[238] Since then, several consensus henipavirus real-time PCR assays have been developed that target different conserved regions of the viral genome.[239] It should be cautioned that the current PCR tests may not work with new henipaviruses yet to be discovered, especially those from African bats, owing to expected greater genetic divergence than those detected in Australia and Asia.

For henipaviruses, serologic tests are important both during outbreak investigation and for disease surveillance. The virus neutralization test (VNT) is accepted as the reference standard.[232] Few laboratories, however, can conduct neutralization tests because of the requirement to handle live virus at BSL4. For surveillance and diagnostic purposes, three types of tests that do not require BSL4 containment have been developed:

1. *Enzyme-linked immunosorbent assay (ELISA):* Several ELISA-based tests have been reported for the detection of henipavirus antibodies.[232,240,241] For diagnosis of human infections, two different ELISA tests have been applied: an IgM capture ELISA for early diagnosis of infection and an indirect ELISA for detection of IgG antibodies.[232]
2. *Liquid protein array multiplex test:* A Luminex-based test based on recombinant soluble G proteins of HeV and NiV was developed that is capable of mimicking VNT with great sensitivity and differentiating between antibody responses of HeV and NiV infection.[242]
3. *Pseudotype virus:* Different pseudotype systems carrying the henipavirus F and G proteins have been developed as a surrogate VNT for detecting henipavirus-specific antibodies.[18,243], [244], [245] Incorporation of reporter genes in these systems resulted in greater sensitivity and reproducibility.

PREVENTION AND CONTROL

Drugs and Small Molecules

Ribavirin, which inhibits replication of HeV *in vitro*,[246] was used during the NiV outbreak in Malaysia in an open-label study in which 140 patients with encephalitis were given the drug and 54 patients who presented before ribavirin became available or who refused treatment acted as controls.[247] Mortality in the treated group was 32% compared with 54% in the control group, representing a 35% reduction ($P = 0.011$). Duration of ventilation and that of total hospital stay were both significantly shorter in the ribavirin group ($P = 0.0002$ and $P < 0.0001$, respectively). In the absence of other therapies, ribavirin may be an option for treatment of henipavirus infections. However, two HeV-infected patients in 2008[8] were given a high-dose intravenous regimen of ribavirin, although basal concentrations appeared inadequate given the results of *in vitro* susceptibility testing of HeV, and the efficacy of ribavirin as therapy or prophylaxis in people remains at best uncertain. Chloroquine, an antimalarial drug, was first demonstrated to block the critical proteolytic processing needed for HeV F maturation and function.[248] Not surprisingly, the drug was later shown to inhibit NiV and HeV infection in cell culture experiments.[249] Chloroquine was administered along with ribavirin to one HeV-infected individual in 2009[250] with no apparent clinical benefit. Remdesivir (GS-5734) is a nucleotide analog prodrug that showed therapeutic efficacy in a NHP model of Ebola virus infection.[251] GS-5734 has been administered under compassionate use to Ebola virus–infected patients and is currently in phase II clinical development for treatment of Ebola virus disease. The antiviral activities of GS-5734 have been demonstrated to be broad showing *in vitro* activity against viruses in the *Coronaviridae*, *Filoviridae*, and *Paramyxoviridae* including NiV and HeV.[252]

In vivo, ribavirin only delayed but did not prevent deaths caused by NiV and had no effect on HeV infection in a hamster model.[173,253] Ribavirin treatment also only delayed disease onset by 1 to 2 days in AGMs challenged with HeV with no significant benefit for disease progression or outcome.[103] Chloroquine administration, either alone or in combination with ribavirin, had no therapeutic benefit in ferrets challenged with NiV or hamsters challenged with either NiV or HeV.[253,254] Poly(I)–poly(C12U), which induces IFN-α and IFN-β production and can completely block NiV replication *in vitro*, displayed approximately 80% protective efficacy in the

hamster model of lethal NiV infection.[173]

Peptide Fusion Inhibitors

The first potential henipavirus-specific therapeutic was shown to be a heptad peptide–based fusion inhibitor,[95] analogous to HIV-1–specific peptide, enfuvirtide (Fuzeon) approved by the Food and Drug Administration (FDA) in March 2003. The henipavirus F_1 glycoprotein resembles other fusion glycoproteins in having α-helical heptad repeat (HR) domains proximal to both the fusion peptide at the amino (N) terminus and the transmembrane domain near the carboxy (C) terminus of the protein. The HR domains are involved in the formation of a trimer-of-hairpins structure during the membrane fusion and virus infection process. Addition of exogenous peptide from either HR domain blocks formation of the trimer-of-hairpins and abrogates membrane fusion and virus infection.[94,95,255] These observations were followed up with testing cholesterol tagged HR-derived peptides in the hamster model of NiV infection providing the first evidence of *in vivo* effectiveness of a fusion inhibiting peptide against NiV.[256]

Vaccines

A wide variety of immunization strategies have been developed for NiV and HeV prevention and include live-recombinant virus platforms, protein subunit, virus-like particles, and DNA vaccines; however, many of these approaches have only been examined for HeV- or NiV-specific neutralizing antibody induction.[257] A more limited number of vaccine candidates have been examined for both immune response and efficacy using a variety of animal challenge models (Table 13.5). Attenuated vaccinia virus strain NYVAC recombinants encoding either the NiV F or G glycoproteins used to immunize hamsters provided complete protection from NiV-mediated disease following challenge and demonstrated that an immune response to the viral envelope glycoproteins was an important immunogen in protection.[258] A second poxvirus-based approach was developed as a potential livestock vaccine using recombinant canarypox virus with the NiV F and G genes inserted into ALVAC vectors (Table 13.5). ALVAC vectors expressing either NiV F or NiV G were tested individually and in combination by vaccination of piglets, and animals were challenged intranasally with NiV. Piglets were

protected from NiV-mediated illness by either ALVAC vector alone or in combination, and immunized animals shed only low levels of nucleic acid detectable virus, and no recoverable virus was evident.[259] Three other viral vector-based NiV vaccines have been examined in animal challenge studies (Table 13.5). An adeno-associated virus (AAV) platform using the NiV G glycoprotein was tested in the hamster model using NiV challenge, showing complete protection against NiV, but only low level cross-protection (three of six animals) against an HeV challenge.[260] A recombinant measles virus vector encoding the NiV G glycoprotein was examined using two different vectors; the HL (rMV-HL-G) and Edmonston (rMV-Ed-G) measles virus strains[261] (Table 13.5). Here, complete protection from NiV disease was achievable in the hamster challenge model following vaccination with either rMV-HL-G or rMV-Ed-G, and the rMV-Ed-G was tested in the NHP model demonstrating two of two AGMs were protected against NiV challenge. Several groups have tested the vesicular stomatitis virus (VSV)–based platform using the NiV F or G glycoproteins (Table 13.5). In the ferret model, a single immunization with VSV encoding either NiV F or NiV G could afford complete protection from NiV challenge.[262] Similarly, NiV G or F glycoproteins in VSV vectors were successful in protection from NiV challenge in the hamster model,[263,264] and a single immunization of NiV G encoding VSV was protective in the AGM model.[265,266]

TABLE 13.5 Summary of advanced henipavirus vaccination development initiatives evaluated in animal challenge models

Platform	Viral Antigen Target or Immunogen	Animal Challenge Model
Active vaccination		
Recombinant vaccinia virus	Nipah F and/or G glycoprotein	Hamster[a] (NiV)
Recombinant canarypox virus	Nipah F and/or G glycoprotein	Pig[b] (NiV)
Recombinant VSV	Nipah F and/or G glycoprotein	Ferret[c] (NiV), hamster[d] (NiV), nonhuman primate[e] (NiV)
Recombinant AAV	Nipah G glycoprotein	Hamster[f] (NiV, HeV)
Recombinant measles virus	Nipah G glycoprotein	Hamster[g], nonhuman primate (NiV, HeV)
Recombinant subunit	Hendra virus soluble G glycoprotein	Cat[h] (NiV), Ferret[i] (HeV, NiV), nonhuman primate[j] (HeV, NiV), horse[k] (HeV)
VLP based	Purified virus-like particles made from NiV M, F, and G proteins	Hamster (NiV)[e]
Passive immunization		
Human monoclonal antibody m102.4	Hendra/Nipah G glycoprotein	Ferret[l] (NiV) Nonhuman primate[m] (HeV, NiV)

[a]Hamsters immunized with NiV F and/or G glycoprotein encoding recombinant vaccinia viruses were protected against disease following intraperitoneal challenge with 10^3 PFU of NiV.[258]

[b]Pigs immunized with NiV F and/or G glycoprotein encoding recombinant canarypox viruses were protected against intranasal challenge with 2.5×10^5 PFU of NiV.[259]

[c]Ferrets immunized with NiV F and/or G glycoprotein encoding recombinant vesicular stomatitis virus (VSV) vectors were protected against lethal intranasal challenge with 5×10^3 PFU of NiV.[262]

[d]Hamsters immunized with NiV F and/or G glycoprotein encoding recombinant vesicular stomatitis virus (VSV) vectors were protected against lethal intraperitoneal challenge with 10^5 $TCID_{50}$ of NiV[264] or 6.8×10^4 $TCID_{50}$ of NiV.[263]

[e]African green monkeys immunized with an NiV G encoding recombinant VSV vector were protected against lethal intratracheal challenge with 10^5 $TCID_{50}$ of NiV.[265,266]

[f]Hamsters immunized with an NiV G encoding recombinant adeno-associated virus (AAV) vector were protected against lethal intraperitoneal with 10^4 PFU of NiV.[260]

[g]Hamsters and African green monkeys immunized with an NiV G encoding recombinant measles virus vector were protected against lethal intraperitoneal challenge with 10^3 $TCID_{50}$ of NiV (hamsters) or 10^5 $TCID_{50}$ of NiV (AGMs).[261]

[h]Hendra virus soluble G glycoprotein (HeV-sG) used to immunize cats protects against lethal subcutaneous (500 $TCID_{50}$)[268] or oronasal (5×10^4 $TCID_{50}$) NiV challenge.[270]

[i]HeV-sG used to immunize ferrets protects against lethal oronasal challenge with 5×10^3 $TCID_{50}$ of HeV[106] or 5×10^3 $TCID_{50}$ of NiV challenge.[271]

[j]HeV-sG used to immunize African green monkeys protects against lethal intratracheal challenge with 10^5 $TCID_{50}$ of NiV[272] or 5×10^5 PFU of HeV.[273]

[k]HeV-sG used to immunize horses protects against lethal oronasal challenge with 2×10^6 $TCID_{50}$ of HeV.[274]

[l]An NiV and HeV cross-reactive G glycoprotein–specific neutralizing human mAb (m102.4) protects ferrets against lethal oronasal challenge with 5×10^3 $TCID_{50}$ of NiV[97] or 5×10^3 $TCID_{50}$ of HeV (J. Pallister and C. Broder, unpublished) by postexposure infusion.

[m]Human mAb m102.4 protects African green monkeys by postexposure infusion following lethal intratracheal challenge with 4×10^5 $TCID_{50}$ of HeV[193] or lethal intratracheal challenge with 5×10^5 PFU of NiV.[191,194]

[n]Hamsters immunized with VLPs (either one dose or three doses) composed of Nipah virus M, F, and G (RBP) proteins were completely protected against lethal intraperitoneal challenge with 1.6×10^4 pfu of NiV.[330]

The most extensively tested vaccine against NiV and HeV has been a recombinant protein subunit strategy because of the inherent safety of such an approach. Soluble, secreted, oligomeric forms of the G glycoprotein (sG)

from both NiV and HeV were developed and tested as possible vaccine candidates, and the HeV-sG was shown capable of eliciting a more potent cross-reactive polyclonal antibody response and also a better cross-protective response[267,268] (Table 13.5). HeV-sG is a soluble and secreted version of the molecule with a genetically deleted transmembrane and cytoplasmic tail that is produced in mammalian cell culture systems and is properly N-linked glycosylated[269] (Fig. 13.15). HeV-sG has been shown to retain many native characteristics including oligomerization and ability to bind ephrin receptors[62,267] and is capable of eliciting potent cross-reactive (HeV and NiV) neutralizing antibody responses in a variety of animals including mice, rabbits, cats, ferrets, monkeys, and horses.[257] The HeV-sG vaccine in the cat model provided complete protection against a lethal NiV challenge[268] and suggested a single subunit vaccine (HeV-sG) could be effective against both HeV and NiV. Further studies in the cat model revealed that antibody titers as low as 1:32 could protect against NiV-Malaysia challenge[270] (Table 13.5). Studies in the ferret model with low vaccine doses of HeV-sG formulated in CpG and Alhydrogel™ could completely protect against high-dose HeV challenge.[106] Immunization and challenge studies in ferrets with the NiV-Bangladesh strain also demonstrated complete protection.[271] In addition, good durable immunity was shown in other ferrets challenged 434 days postvaccination.[271] However, preliminary studies with HeV-sG as a vaccine in the pig model was less effective against HeV and unprotective against NiV, and both humoral and cellular immune responses were required for protection of swine against henipaviruses in that challenge model.[180]

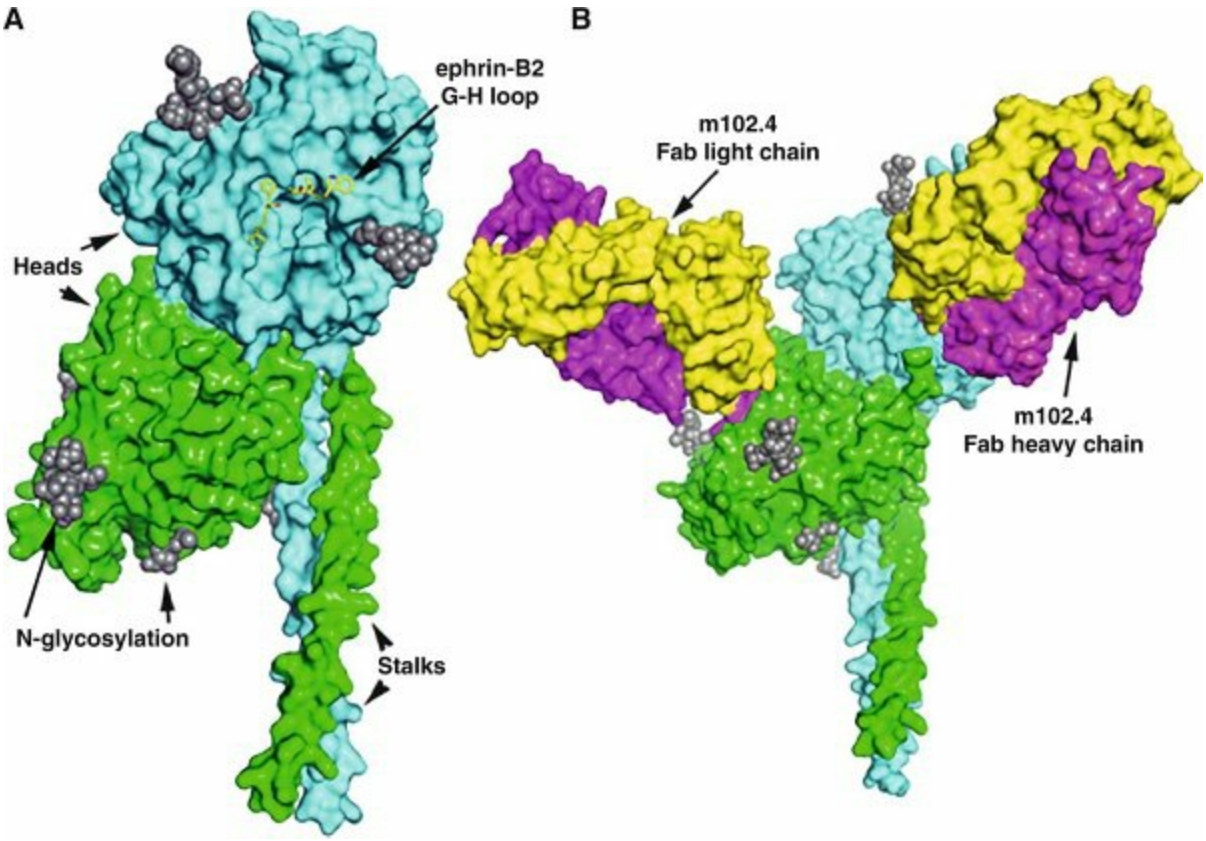

FIGURE 13.15 Model of the Hendra virus soluble G glycoprotein subunit vaccine (HeV-sG) and its complex with the Hendra and Nipah virus–neutralizing human monoclonal antibody m102.4. **A:** The HeV-sG glycoprotein subunit vaccine is composed of the entire ectodomain (amino acids 76–604) of the HeV G glycoprotein. HeV-sG is shown as dimer with one monomer colored *green* and the other *cyan*. The secondary structure elements of the two globular head domains are derived from the crystal structure of the HeV G head domain, the stalk regions of each G monomer (residues 77–136) are modeled, and N-linked glycosylation sites are shown as *gray spheres*. The ephrin-binding face of the *cyan* globular head is facing forward with an overlay of the interacting ephrin-B2 G-H loop residues in *yellow*. **B:** The HeV-sG dimer is modeled in complex with two m102.4 Fab antibody fragments. The two HeV-sG monomers are colored *green* and *cyan* as in **panel A** and rotated slightly to the right, and the two

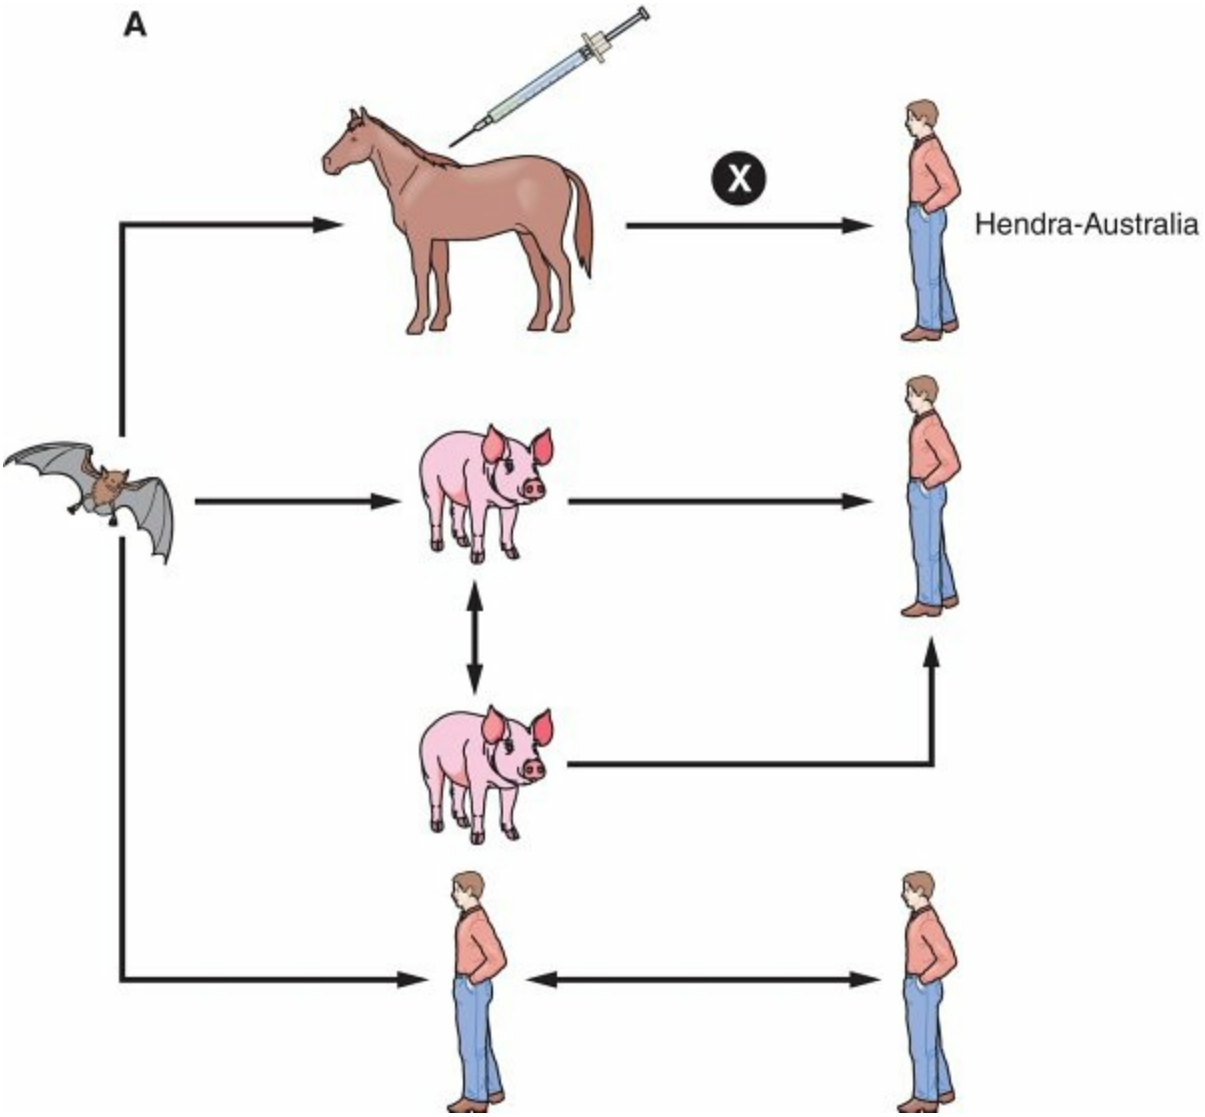
Fab molecules are shown with their heavy chains colored in *magenta* and light chain in *yellow*, each binding one globular head domains of G. (Modified from Broder CC, Xu K, Nikolov DB, et al. A treatment for and vaccine against the deadly Hendra and Nipah viruses. Antiviral Res 2013;100(1):8–13A.)

The HeV-sG vaccine has also been extensively evaluated in nonhuman primates (AGMs). Monkeys immunized with HeV-sG formulated in Alhydrogel™ and CpG were completely protected against intratracheal challenge with NiV-Malaysia, some with prechallenge neutralizing titers as low as 1:28, and no evidence of clinical disease, virus replication, or pathology was observed in any vaccinated monkeys.[272] Similarly, HeV-sG vaccination and protection from an HeV challenge in AGMs have also been shown, including HeV-sG formulated in Alhydrogel™ alone.[273] The inherent safety and effectiveness of the HeV-sG vaccine led to its development as an equine vaccine to prevent not only HeV infection of horses but also as the means to reduce the risk of HeV transmission to people (Fig. 13.16A). HeV-sG was licensed by Zoetis™ Inc., (formerly Pfizer Animal Health) and developed as an equine vaccine for use in Australia. Horse HeV-sG vaccination and HeV challenge studies were conducted at the BSL4 facilities of the Australian Animal Health Laboratory (AAHL) in Geelong[274] (Table 13.5). HeV-sG was formulated in an approved equine adjuvant (Zoetis, Inc.), and two initial efficacy studies in horses tested 50-*μ*g and 100-*μ*g doses of the same HeV-sG used in published animal studies were used to immunize horses. Additional studies used a 100-*μ*g dose of HeV-sG produced in CHO cells (Zoetis, Inc.). Immunizations were two doses given intramuscularly 3 weeks apart. All horses in these efficacy studies were challenged oronasally with 2×10^6 $TCID_{50}$ of HeV. Seven horses were challenged at 28 days, and three horses were challenged 194 days, after the second immunization. All vaccinated horses remained clinically healthy following challenge, demonstrating protection with prechallenge HeV neutralizing titers as low as 1:16.[274] There was no gross or histologic evidence of HeV infection in any of the vaccinated horses at study completion, and all tissues examined were negative for HeV antigen by IHC, with no viral genome detected in any tissue. In 9 of 10 vaccinated horses, HeV nucleic acid was not detected in

daily nasal, oral, or rectal swab specimens or from blood, urine, or fecal samples collected before euthanasia, and no recoverable virus was present.[274]



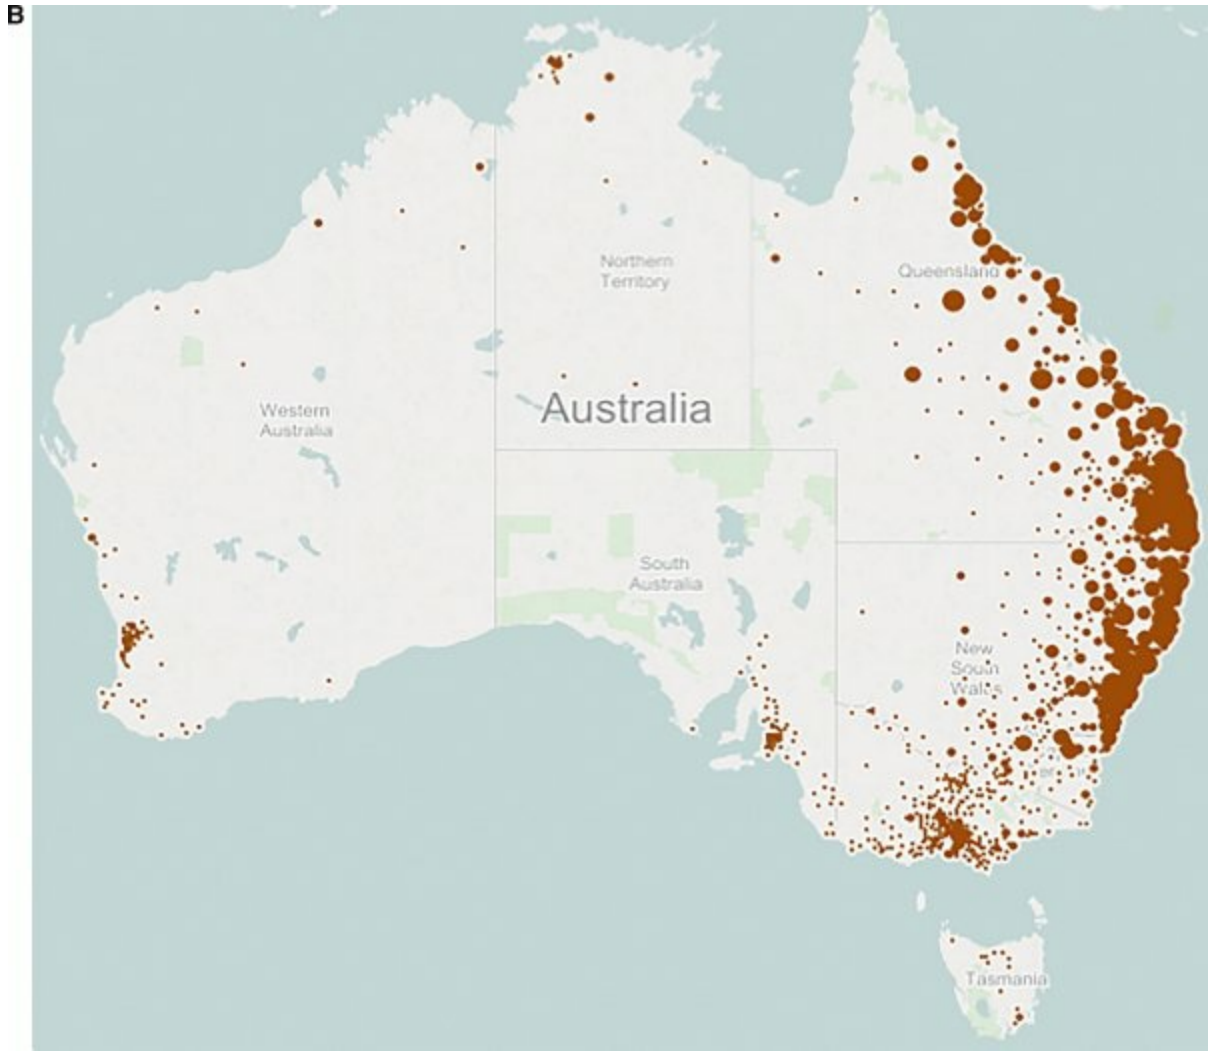


FIGURE 13.16 One Health vaccine strategy. **A:** The known modes of henipavirus transmission in different countries. In Australia, all seven human cases were infected via contacting infected horses. A One Health vaccine strategy was developed for immunization of horses with the dual purposes of saving horses from lethal Hendra virus infection and prevention of transmission from bats to humans via horses. **B:** Location densities of Equivac® HeV vaccine administered to horses around Australia. As of 2018, more than 700,000 doses of Equivac® HeV have been administered to horses around Australia, equating to more than 168,000 unique horses vaccinated. (Courtesy of Dr. Richard L'Estrange, Zoetis Inc.)

Equivac® HeV was launched in November 2012 on a Minor Use Permit by the regulatory authority, the Australian Pesticides and Veterinary Medicines Authority (APVMA), and is the first commercially developed and deployed vaccine against a BSL4 agent and is currently the only licensed antiviral approach for henipavirus infection. All vaccinated horses receive a microchip, and database is maintained, and in August 2015, Equivac® HeV received full registration by the APVMA. To date, more than 640,000 doses of Equivac® HeV vaccine have been administered to more than 153,000 unique horses (Fig. 13.16B). Since vaccine release, laboratory-confirmed HeV infections in horses (n = 21) have only occurred in unvaccinated horses. The HeV-sG recombinant subunit vaccine for NiV and HeV is now in clinical development with support from the Coalition for Epidemic Preparedness Innovations (CEPI),[275] and phase I clinical trials set to commence in 2019. Recent vaccination and challenge studies in NHPs have shown that a single immunizing dose of HeV-sG in Alhydrogel™ can protect against HeV and NiV-Bangladesh challenge (Geisbert and Broder, unpublished), and together with the results of recombinant VSV-based NiV vaccines, these findings highlight their potential usefulness in an emergency use or outbreak scenario.

Passive Immunization

Initial passive immunization studies using either NiV G– and F–specific polyclonal antiserums or mouse monoclonal antibodies (mAbs) specific for the NiV or HeV G or F glycoproteins were shown to be protective in the hamster model.[102,258,276] HeV- and NiV-neutralizing human mAbs reactive to the G glycoproteins of both HeV and NiV have been developed using recombinant antibody technology.[277] One mAb, m102.4, possessed strong cross-reactive neutralizing activity against HeV and NiV and was later produced in an IgG1 format in a CHO-K1 cell line.[278] The m102.4 mAb epitope maps to the receptor-binding site of G and engages G in a similar fashion as the ephrin receptors[279,302] (Fig. 13.5). The m102.4 mAb can neutralize all HeV and NiV isolates tested, including HeV-1994, HeV-Redlands, NiV-Malaysia, and NiV-Bangladesh.[97,280] NiV challenge experiments in the ferret demonstrated that complete protection was possible by a single dose of m102.4 mAb administered by intravenous infusion 10

hours following a lethal virus challenge.[97] The therapeutic efficacy of mAb m102.4 has also been examined in NHPs against both NiV and HeV challenge as a postexposure therapeutic reflective of a potential real-life virus exposure scenario[193,194] (Table 13.5). In one study, AGMs were challenged intratracheally with HeV, and following virus administration, they were infused twice with m102.4 (~15 mg/kg) beginning at 10 hours, 24 hours, or 72 hours postinfection followed by a the second infusion approximately 48 hours after the first. In this study, all subjects became infected following challenge, and all animals that received m102.4 survived, whereas all controls succumbed to severe systemic disease 8 days following virus challenge. Animals in a 72 hours treatment group did exhibit neurologic signs, but all recovered by day 16, but there was no evidence of HeV-specific pathology in any of the m102.4–treated animals, and no infectious HeV could be recovered from any tissues from any m102.4–treated subjects. A later study evaluated the efficacy of m102.4 against NiV-Malaysia challenge in AGMs, at several time points after virus exposure by intratracheal challenge including as late as the onset of clinical illness.[194] Here, animals were infused twice with m102.4 (15 mg/kg) beginning at either 1, 3, or 5 days following NiV-Malaysia challenge and again 48 hours after the first dose. All animals became infected following virus exposure, and again all subjects that received m102.4 therapy survived the infection, whereas the untreated control subjects succumbed to disease between days 8 and 10 following virus challenge. The m102.4 mAb was also shown to be effective in the NHP model against NiV-Bangladesh infection, although its therapeutic window was much shorter as compared to NiV-Malaysia–infected subjects.[191] Taken together, these studies have shown that m102.4 mAb therapy can prevent HeV or NiV lethal disease in exposed subjects is the only effective postexposure therapeutic tested *in vivo* in NHPs. The mAb m102.4 has since been used by emergency protocol in 13 people in Australia and one in the United States because of significant risk of HeV or NiV infection.[257] The m102.4 antibody has completed a phase I clinical trial in Australia and has recently been supplied to Government of India and included in an international Nipah treatment protocol sponsored by the Indian Council of Medical Research (ICMR) with support from the NIAID, NIH, USA.

PERSPECTIVE

Nipah and henipaviral diseases remain on the latest WHO list of Blueprint priority diseases (February 2018).[281] This acknowledges that NiV (or related virulent henipaviruses) is a major threat to global public health and calls for increased research and development into henipaviruses and their countermeasures, including surveillance and diagnostics. In addition, both NiV and HeV emergence and reemergence remain continuous infectious disease transboundary threats to economically important livestock throughout South Asia and Australia.[282] NiV is also one of the top three viral agents prioritized for vaccine development by the CEPI.[275,283] The high virulence of the henipaviruses and the requirement for BSL4 facilities have hampered investigations into the biology and pathogenesis of these novel paramyxoviruses. Nonetheless, the advent of reverse genetics for henipaviruses, coupled with the development of animal models that recapitulate the clinical features and pathology seen in virus-infected humans, has provided insights into the functions of many henipavirus proteins and the role they play in the pathogenesis of henipavirus disease. While the virulence of henipaviruses necessitates the initial functional characterization of henipavirus proteins from cloned genes, it is imperative that these functional characteristics be examined in the context of a live virus infection. Even then, it appears increasingly important to investigate why henipaviruses appear so much more virulent in many of their terrestrial hosts versus their chiropteran counterparts.[284]

Despite our expanded understanding of the henipaviruses, many questions relating to the ecology and biology of henipaviruses remain unanswered. *Pteropus* species of fruit bats are clearly the major reservoir host of these viruses,[202,207,208] but new studies have suggested that an even wider group of chiropteran species host not only the known henipaviruses but also multiple divergent clades of new henipavirus species.[29,222,285] Molecular or serologic evidence of henipaviruses can now be found in frugivorous and insectivorous bats that range from Australia and Austronesia to China, Southeast Asia, countries of the Indian subcontinent, Madagascar, sub-Saharan Africa, and even into the New World (Costa Rica and Brazil).[19,29,207,286, 287, 288, 289, 290, 291, 292, 293, 294, 295, 296, 297] The emergence of these and related viruses is probably associated with the destruction of the flying fox native habitats, driving the animals to seek food

from orchards and ornamental trees in urban and peri-urban areas. Continued deforestation and amplification of factors that drive zoonotic spillover from reservoir hosts will undoubtedly lead to further outbreaks of HeV, NiV, and novel related members of the genus.[298], [299], [300], [301] Continued surveillance coupled with identification and characterization of these putative new species of henipavirus is required to provide a proper assessment as to the countermeasures, such as the CEPI initiatives, that would be necessary to control or prevent future outbreaks and spillovers.

INTRODUCTION

Influenza viruses were possibly responsible for an epidemic disease in Athens in the in 5th century BC,[52] and thus they would have been with us for a long, long time. Influenza remains a major cause of morbidity and mortality worldwide, and large segments of the human population are affected every year. In addition, many animal species can be infected by influenza viruses, and some of these viruses may give rise to pandemic strains in humans, as in the case of the 2009 H1N1 pandemic. Most threatening is the possibility of another pandemic similar to that experienced in 1918, which is estimated to have caused on the order of 50 million deaths worldwide.[438]

CLASSIFICATION

The family of *Orthomyxoviridae* is defined by viruses that have a negative-sense, single-stranded, and segmented RNA genome. The definition of negative-sense RNA viruses came from work by David Baltimore, who showed that the packaged genome of this class of viruses is complementary to the messenger RNA (mRNA), which is defined as positive.[32] There are seven different genera in the family of *Orthomyxoviridae*: the *Thogotovirus*; *Alpha-*, *Beta-*, *Gamma-*, and *Deltainfluenzavirus* (*or Influenzavirus A, B, C, and D*); *Quaranjavirus*; *and Isavirus* (Fig. 14.1) (http://www.ictvonline.org/). Members belonging to any of the four different genera of influenza viruses can undergo genetic reassortment within the genus (see below) and thus readily exchange genetic information. However, reassortment between members of different genera (types) has never been reported. This absence of genetic exchange between viruses of different genera (types) is one manifestation of speciation as a result of evolutionary divergence. It is likely that many more members of the family *Orthomyxoviridae* will be discovered as more and more species and their viruses will be sequenced in the future.

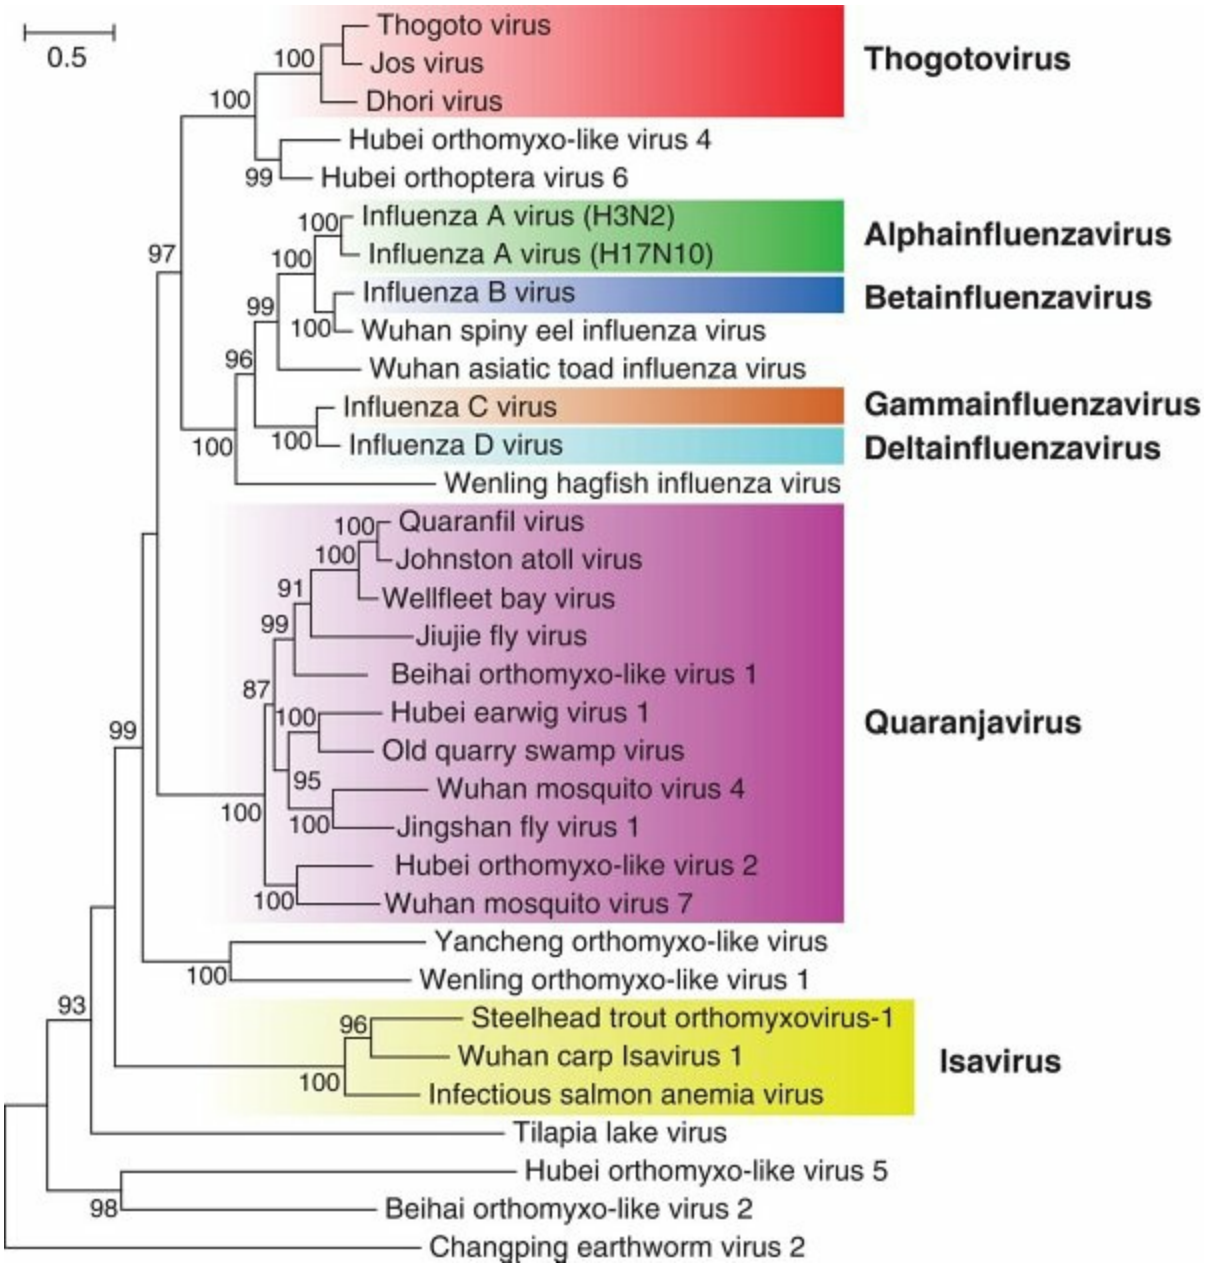

FIGURE 14.1 Phylogenetic relationships among members of the *Orthomyxoviridae*. Amino acid sequences of the polymerase basic 1 (PB1) protein were aligned using the MAFFT program,[456] with the phylogeny then inferred using the maximum likelihood algorithm implemented in PhyML.[328] The tree was midpoint rooted for clarity only and the support for individual nodes was assessed using an approximate likelihood ratio test (aLRT). The

scale bar represents the number of amino acid substitutions per site. (Figure was kindly provided by Edward C. Holmes and Mang Shi.)

Different influenza virus strains are named according to their genus (type), the species from which the virus was isolated (omitted if human), the location of the isolate, the number of the isolate, the year of isolation, and, in the case of the influenza A viruses, the hemagglutinin (H) and neuraminidase (N) subtypes. For example, the 220th isolate of an influenza virus isolated from a chicken in Hong Kong in 1997 is designated as influenza A/chicken/Hong Kong/220/97(H5N1) virus. There are now 18 different hemagglutinin (H1–H16 and hemagglutinin-like proteins H17 and H18) subtypes and 11 different neuraminidase (N1–N9 and neuraminidase-like proteins N10 and N11) subtypes for influenza A viruses, while there are no influenza B virus hemagglutinin and neuraminidase subtypes (Fig. 14.2).

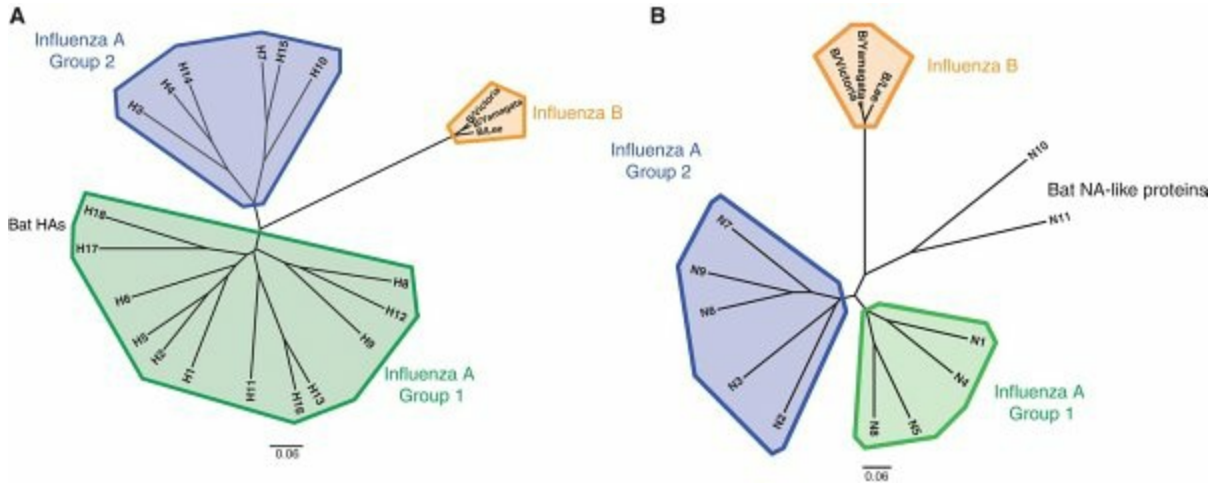

FIGURE 14.2 *Phylogeny of influenza A and B virus hemagglutinins (HAs) and neuraminidases (NAs).* Unrooted, radial phylogenetic trees based on amino acid sequences of the HA **(A)** and NA **(B)** proteins from representative influenza A and B viruses. Representative viruses were selected from the Global Initiative on Sharing All Influenza Data (GISAID) and aligned using ClustalW. Phylogenetic trees were visualized using FigTree (v1.4.3). The scale bars represent an amino acid change of 6%. (Courtesy of

Ericka Kirkpatrick.)

VIRION STRUCTURE

Influenza A viruses have a complex structure and possess a lipid membrane derived from the host cell (Fig. 14.3A). This envelope harbors the hemagglutinin (HA) and the neuraminidase (NA) that project from the surface of the virus and the membrane integral M2 ion channel. The matrix (M1) protein lies just beneath the envelope, and the core of the virus particle is made up of the RNP (**r**ibo**n**ucleo**p**rotein) complex, consisting of the viral RNA (vRNA) segments, the polymerase proteins (PB1 [**p**olymerase **b**asic 1], PB2 [**p**olymerase **b**asic 2], and PA [**p**olymerase **a**cid]), and the nucleoprotein (NP).[486] The NEP (**n**uclear **e**xport **p**rotein) protein is also present in purified viral preparations.[747] The overall composition of virus particles is about 1% RNA, 5% to 8% carbohydrate, 20% lipid, and approximately 70% protein.[3,162,265] Specifically, it is important to get quantitative data on the presence of individual viral components as well as cellular components that are packaged into the virus.[414,808] Excellent analyses have already been performed using electron microscopy (EM) of negatively stained or frozen-hydrated (cryoelectron microscopy) particles and tomographic reconstructions.[20,106,270,352,354,664,905,946] The morphology of influenza A virus particles is characterized by distinctive spikes that are readily observable in electron micrographs of negatively stained virus particles (Fig. 14.3B). These spikes, made up of HA and NA, have lengths of approximately 10 to 14 nm, with an approximate ratio of four HA trimers to one NA tetramer. Influenza viruses are pleomorphic. The spherical particles have a diameter of about 100 nm, but filamentous particles with elongated viral structures (more than 300 nm) have frequently been observed, particularly in fresh clinical isolates[176] and in preparations of viruses with specific M1, M2, or NP proteins (Fig. 14.4).[54,73,100,107,176,226,227,768]

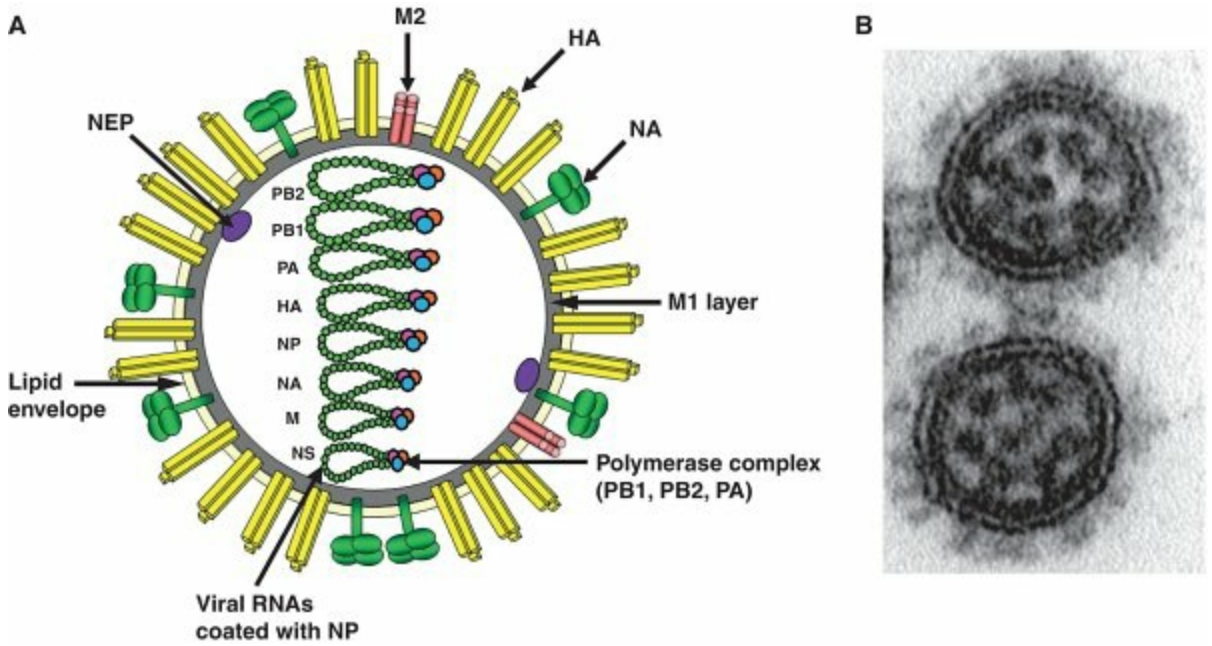

FIGURE 14.3 Schematic diagram and electron micrograph of influenza virus particles. A: The hemagglutinin (HA), neuraminidase (NA), and M2 proteins are inserted into the host-derived lipid envelope. HA is found as a trimer and NA and M2 both as tetramers. The matrix (M1) protein underlies the lipid envelope. A nuclear export protein (NEP) is also associated with the virus. The viral RNA segments are coated with nucleoprotein and are bound by the polymerase complex. Of note, this is a schematic representation and does not represent the actual architecture of the different viral components. **B:** Electron micrograph thin-section image of influenza virus particles (diameter ~100 nm) with the HA and NA spikes visible on the surface and the eight ribonucleoprotein (RNP) segments visible in the interior of each particle. (Courtesy of Yi-ying Chou.)

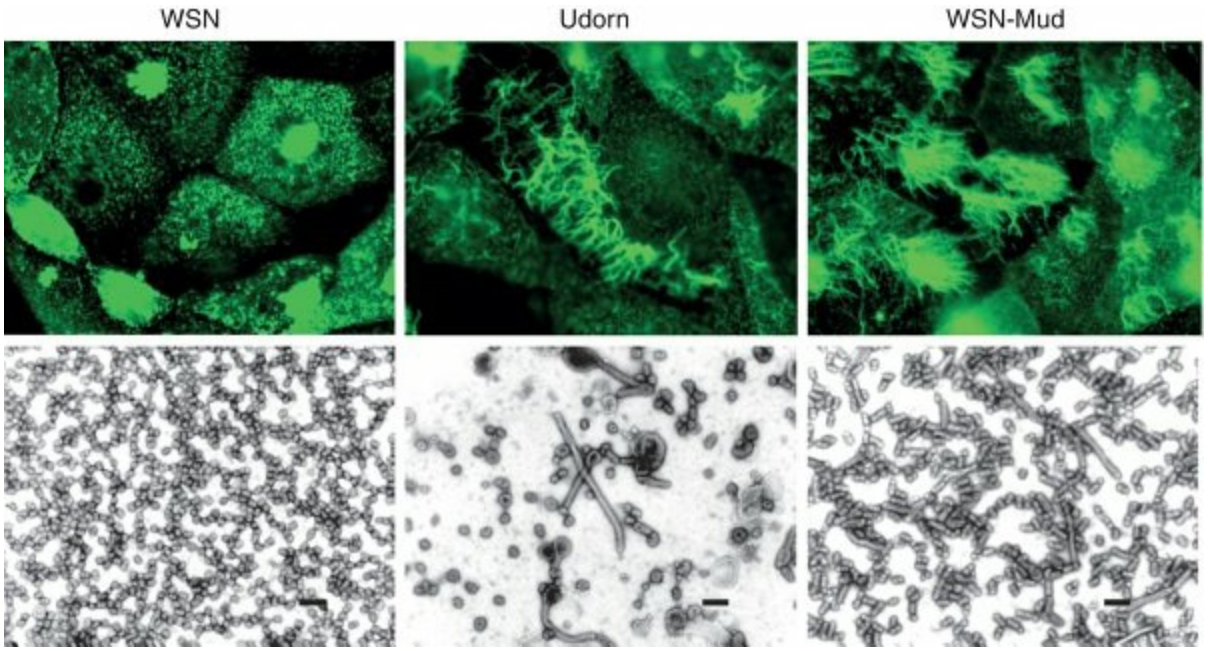

FIGURE 14.4 The filamentous phenotype depends on the M segment. Indirect immunofluorescence of viral antigens on the surfaces of infected cells (*top panels*) and electron microscopy images of negatively stained virus preparations (*bottom panels*). Particles of influenza A/WSN/33 virus are spherical, whereas those of influenza A/Udorn/72 virus are filamentous. Substitution of the WSN M segment with that of Udorn (WSN-Mud) results in a recombinant/reassortant virus with a filamentous phenotype. Calibration bar represents 300 nm. For details, see Ref.[73] (Courtesy of Adolfo García-Sastre and Svetlana Bourmakina.)

Less is known about the internal structures of influenza viruses. However, the underlying M1 layer can be visualized and reveals a helical superstructure.[106,774,776] The RNP complexes were first separated by Duesberg[207] on sucrose gradients and were visualized by EM using positive staining with uranyl acetate.[161] These RNP structures appear to consist of a strand that is folded back on itself to form a double-helical arrangement covered by NP and affixed to a trimeric polymerase with one open end and a loop on the other end.[161,632,723] Most recently, RNPs or individual RNA segments have been visualized by EM of thin-section virus particles and

cryotomography.[20,606,664,665,858]

Influenza B viruses are mostly indistinguishable from the A viruses by EM. They have four proteins inserted in their lipid envelopes: the HA, NA, NB, and BM2.[53,81,671,1021] The M1 and the RNP complexes make up the interior of the particle. It has also been shown that the influenza B virus NEP is associated with purified virus preparations.[420]

Influenza C and D viruses have been found to possess hexagonal reticular (net-like) structures on the surface[15,642] and to form unusually long (500 μm) cord-like structures on the surface of infected cells (which seem to be more prevalent in influenza C than influenza D viruses).[628,642,659] Influenza C and D viruses also contain a core of three polymerase proteins and the NP, which are associated with seven RNA segments. The influenza C and D virus M1 appears to have a similar role to those of influenza A and B viruses. The major glycoprotein, HEF (**h**emagglutinin-**e**sterase **f**usion), combines the functions of the HA and NA (and thus influenza C and D viruses contain one less RNA segment than do the A and B viruses).[379] The HEF of influenza C and D viruses is inserted into the lipid membrane, as are the glycosylated CM2 and DM2, which are analogous to the M2 of influenza A viruses and the BM2 of influenza B viruses.[460,636,704,834]

GENOME STRUCTURE AND ORGANIZATION

Influenza Viruses

All A- and B-type influenza viruses possess eight RNA segments, whereas influenza C and D viruses only have seven different RNAs (Figs. 14.5–14.7). This genome assignment for influenza A viruses was first shown by using polyacrylamide gel electrophoresis of isolated RNAs from two parent influenza A virus strains and their reassortants. Identifying the derivation of an RNA segment (by gel electrophoresis) in a reassortant and simultaneous protein analysis (by serologic or gel analysis) allowed the assignment of individual RNAs to specific viral proteins[687] (Figs. 14.5–14.7). Interestingly, influenza A viruses increase the coding capacity of their genomes via both

splicing and use of alternative open reading frames (ORFs). The M and NS genes each give rise to a spliced mRNA encoding the M2 and the NEP (formerly NEP/NS2) proteins, respectively.[501,502] The PB1-F2 is expressed from an alternative ORF within the *PB1* gene, while PB1-N40 is an N-terminal truncation produced by the use of a downstream AUG and leaky scanning[122,970] (Fig. 14.5), although not all influenza A virus strains encode these proteins, making them true accessory proteins. Recently, a frameshift product, termed PA-X, was identified comprising the endonuclease domain of the viral PA protein with a C-terminal domain encoded by the X-ORF[433] (Fig. 14.5). PA-X can function to repress cellular gene expression,[433] and mutations in the PA-X gene have the potential to improve the hemagglutinin yield of vaccine viruses.[413] The PA-X protein, like the NS1 protein, is multifunctional and has effects on the innate immune response of the host.[668] Each viral segment contains noncoding regions at both the 5′ and 3′ ends. The extreme ends are highly conserved among all segments of influenza A viruses, and they are followed by less conserved segment-specific noncoding regions.

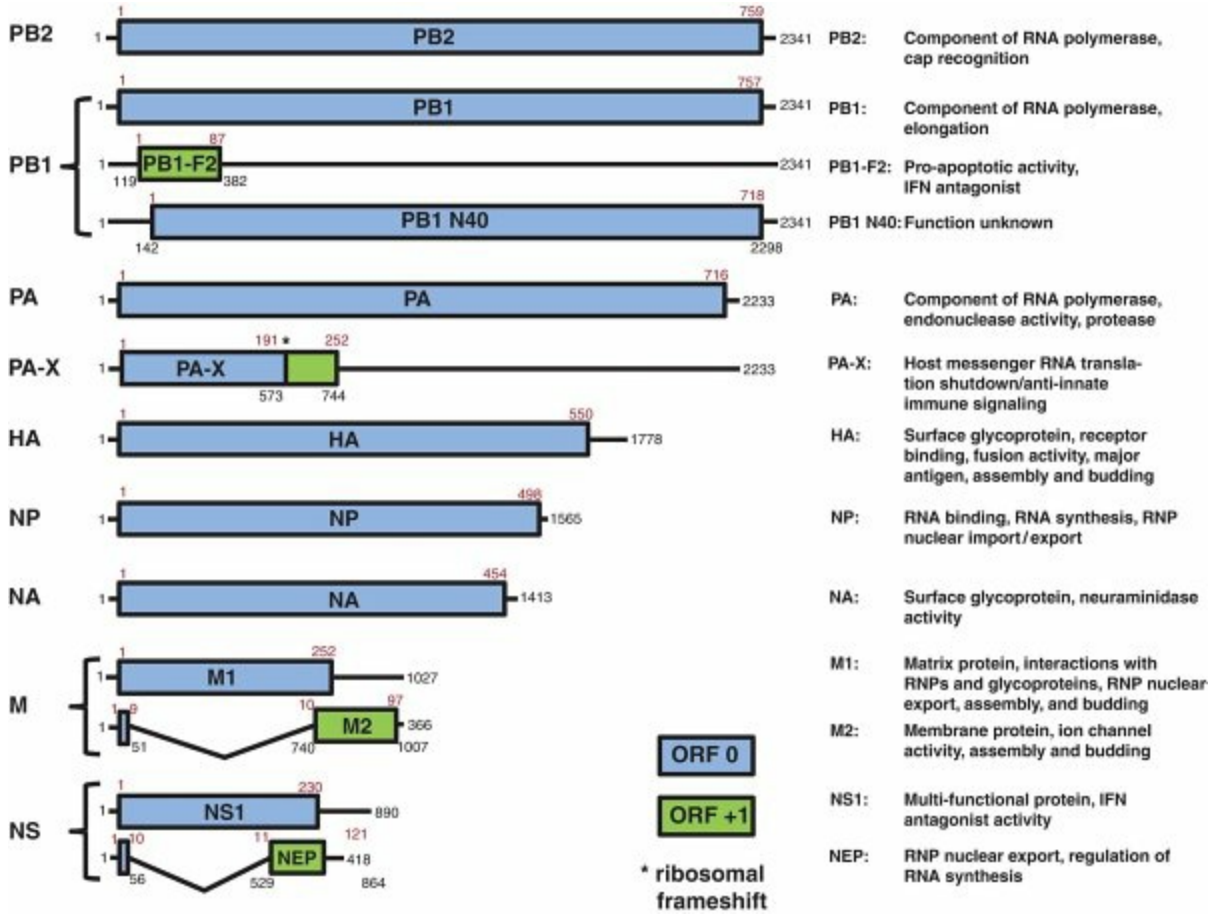

FIGURE 14.5 Genome structure of influenza A/Puerto Rico/8/34 virus. RNA segments (nucleotides in *black*) shown in positive sense and their encoded proteins (amino acids in *red*). The *lines* at the 5′ and 3′ termini represent the noncoding regions. The polymerase basic 1 (PB1) protein segment contains a second open reading frame (ORF) in the +1 frame resulting in the PB1-F2 protein and a third ORF in the 0 frame resulting in the PB1-N40 protein. The PA segment contains codes for a second protein that consist of the N-terminus of PA and a novel C-terminal sequence that is added after a frameshift to +1 at the codon for amino acid 191. The M2 and nuclear export protein (NEP) proteins are encoded by spliced messenger RNAs (mRNAs) (the introns are indicated by the *V-shaped lines*). Additional accessory proteins are not shown but discussed in the main text. (Courtesy of Heinrich

Hoffmann.)

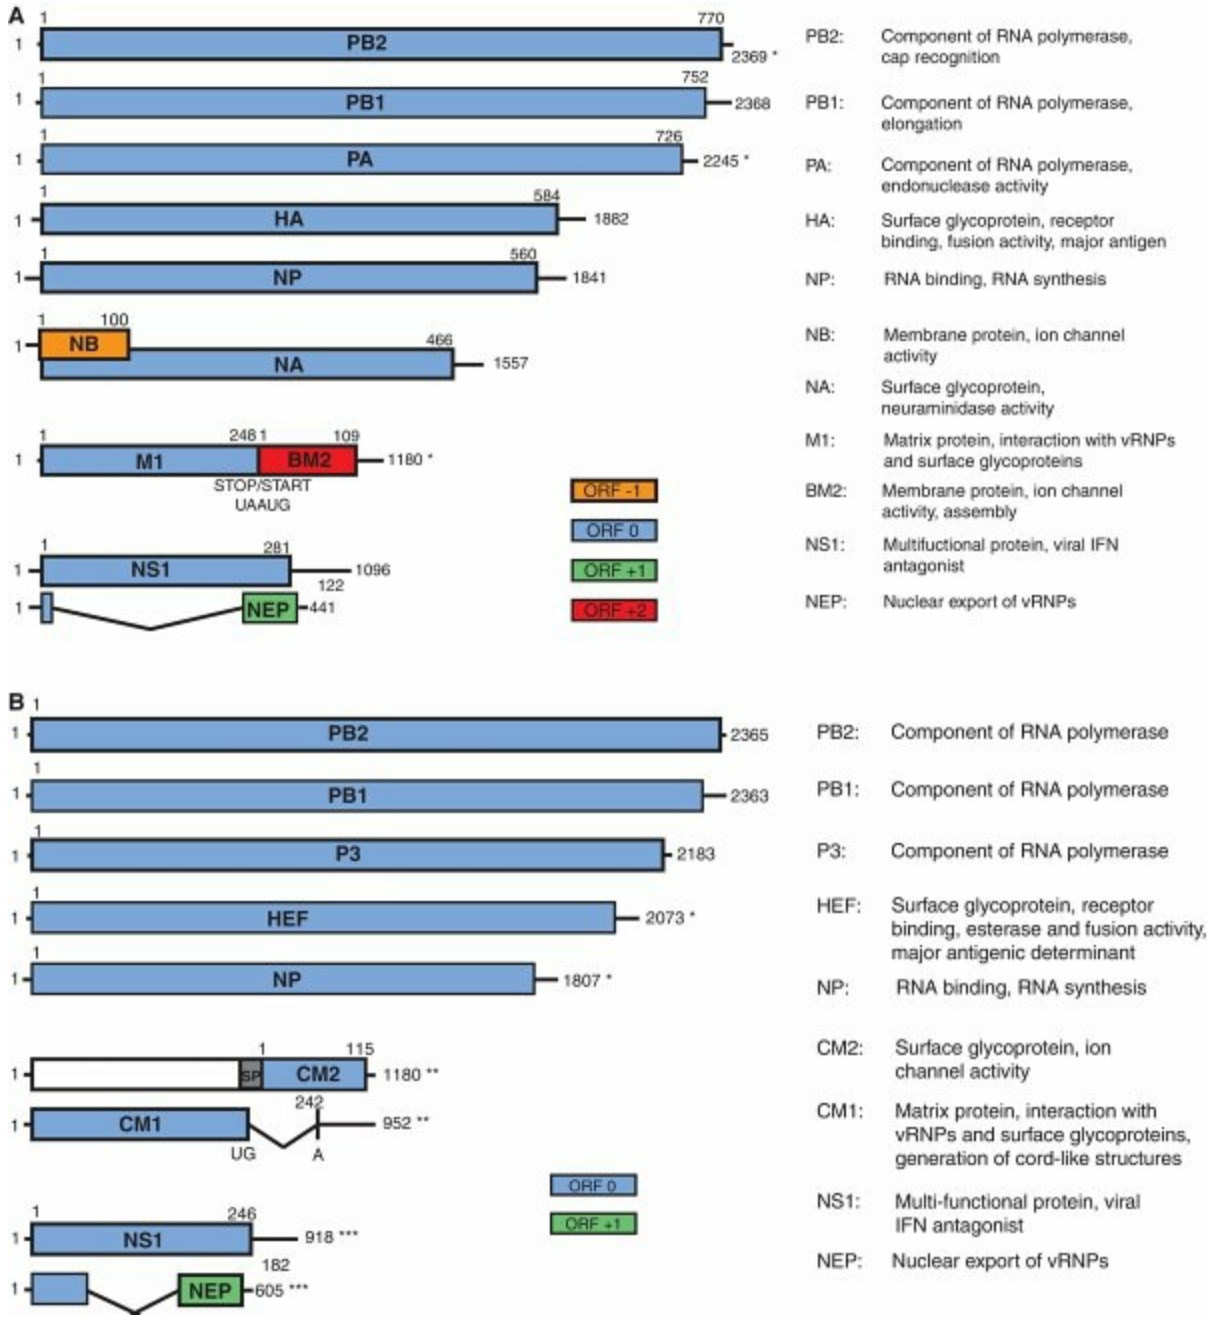

FIGURE 14.6 A: Genome structure of influenza B/Lee/40 virus. RNA segments (in nucleotides) shown in positive sense and their encoded proteins (in amino acids). The *lines* at the 5′ and 3′ termini represent the noncoding regions. The NA segment contains an

additional open reading frame (ORF) in the −1 frame starting four nucleotides upstream of the NA start codon, resulting in the NB protein. The M segment encodes the M1 and the BM2 protein. The M1 termination codon UAA overlaps with the BM2 initiation codon AUG in a translational stop-and-start pentanucleotide UAAUG (shown in *capital letters*). The NS segment codes for NS1 and NEP. NS1 is a translation product of a colinear messenger RNA (mRNA), whereas NEP is a product of spliced mRNA (intron is shown by the *V-shaped line*). Asterisks indicate that RNA segments are from influenza B/Memphis/97/12 virus. **B:** Genome structure of influenza C virus. RNA segments (in nucleotides) shown in positive sense and their encoded proteins (in amino acids). The lines at the 5′ and 3′ termini represent the noncoding regions. The M segment encodes the CM1 and CM2 proteins. The CM2 protein is derived from a colinear messenger RNA (mRNA). The p42 precursor contains a signal peptide (SP) that becomes cleaved and releases CM2. CM1 is the product of a spliced mRNA in which the stop codon UGA (shown in *capital letters*) is introduced by mRNA splicing. The NS segment codes for NS1 by a colinear mRNA and for NEP by a spliced mRNA (intron is shown by the *V-shaped line*). (PB2, PB1, and P3 are derived from C/JJ/50 virus; HEF* is derived from C/JHB/1/66 virus; NP** and M** are derived from C/AnnArbor/1/50 virus; and NS*** is derived from C/Yamagata/1/88 virus.) (Courtesy of Heinrich Hoffmann.)

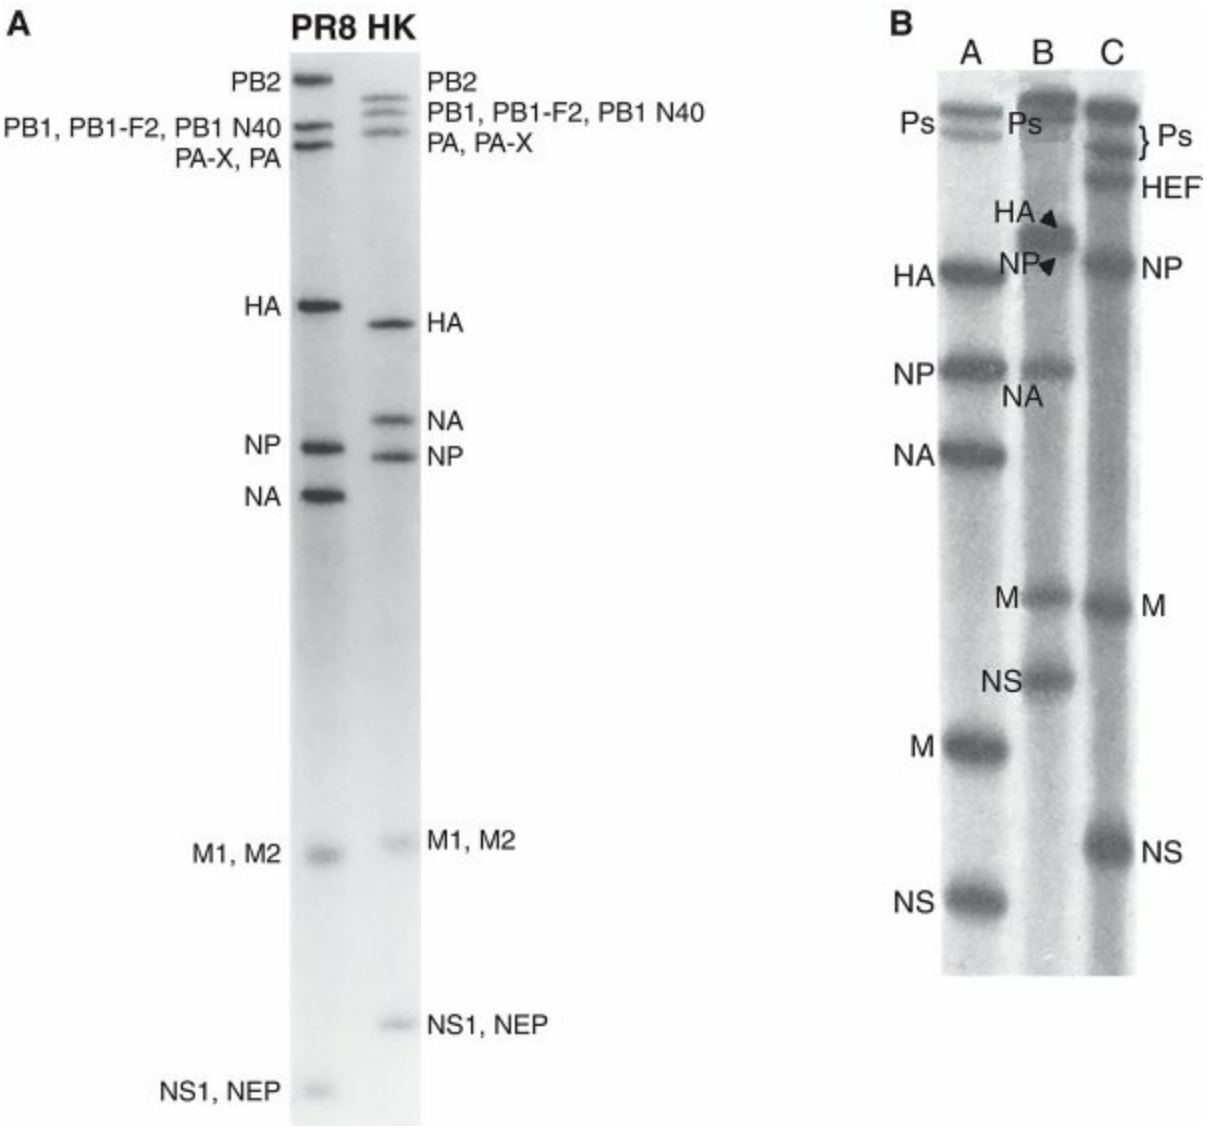

FIGURE 14.7 A: RNA segments of influenza A/Puerto Rico/8/34 (H1N1) and A/Hong Kong/8/68 (H3N2) viruses. The viral RNAs are separated on a polyacrylamide gel and the proteins encoded by the RNAs are indicated. (Adapted from Palese P. The genes of influenza virus. *Cell* 1977;10(1):1–10.) **B:** Separation of RNAs from influenza A, B, and C viruses on a polyacrylamide gel. The ^{32}P-labeled RNAs of influenza A/PR/8/34 virus (*lane 1*), influenza B/Lee/40 virus (*lane 2*), and influenza C/JHB/1/66 virus (*lane 3*) were isolated from purified virus preparations. The RNAs were treated with glyoxal for complete denaturation and separated by

polyacrylamide gel electrophoresis. (Adapted from Palese P, Racaniello VR, Desselberger U, et al. Genetic structure and genetic variation of influenza viruses [and Discussion]. *Philos Trans R Soc Lond Ser B Biol Sci* 1980;288(1029):299–305, Ref. [691])

The influenza B virus genome is similar to that of influenza A virus (Fig. 14.6A). Again, eight RNA segments code for one or more viral proteins with the three largest RNAs coding for the polymerase proteins, the fourth RNA for the HA, and the fifth and sixth RNAs for the NP and NA, respectively.[738] The NA gene codes for the NB protein as well as for the NA. The NB protein is encoded by a −1 ORF seven nucleotides upstream (…AUGAACAAUG…) of the NA coding frame.[806] The seventh RNA codes for the M1 protein (248 amino acids in length). Its termination codon (…UAAUG) overlaps with the initiation codon (UAAUG…) for the BM2 (109 amino acids in length), which allows for a "stop–start" translation mechanism.[400] The eighth RNA codes for the NS1 as well as for the NEP protein, the latter via a spliced mRNA. Cognate PB1-F2, PB1-N40, and PA-X proteins have not yet been identified in influenza B viruses. The noncoding regions of the influenza B virus genome are longer than those in influenza A virus.

The genome of influenza C viruses has only seven RNA segments, with the three largest RNAs each coding for one of the polymerase proteins (Fig. 14.6B). The PB1 and PB2 proteins are homologous to the corresponding influenza A and B virus proteins. The third influenza C virus polymerase protein is named P3 because it does not display acid charge features at neutral pH, as do the corresponding PA proteins of influenza A and B viruses.[995] The fourth RNA codes for the HEF protein,[379] combining the hemagglutinin, receptor-destroying, and fusion activities. The NP is encoded by the fifth RNA. The sixth RNA codes for the M protein, which is expressed from a spliced mRNA, and from the unspliced mRNA a long precursor is translated (p42), which is then processed by signal peptide cleavage into CM2. This 115–amino acid (aa)-long protein consists of an amino-terminal extracellular domain (with a carbohydrate chain), a hydrophobic transmembrane domain (TMD), and an intracellular cytoplasmic tail.[703,704,995] Finally, RNA 7 codes for the NS1 protein (246 amino acids)[637] and, via a spliced mRNA, for the

NEP protein (182 amino acids).[5,394] The genome structure of influenza D virus seems to be very similar to that of influenza C virus.[855]

Evolutionarily, influenza A, B, C, and D viruses have a common precursor, and it is also likely that influenza A and B viruses diverged from each other more recently than did influenza C and D viruses. Based on comparative sequencing studies using the hemagglutinin molecules, it has been postulated that the influenza A viruses diverged about 2,000 years ago and the influenza B and C viruses about 4,000 and 8,000 years ago, respectively.[867] Clearly, these numbers are based on a series of unprovable assumptions, including a steady rate of evolution over time, and therefore must be taken *cum grano salis*. Interestingly, influenza C[152,359,646] viruses have only seven distinct RNA segments, but scanning transmission electron microscopic tomography suggests that the majority of their virus particles package 7+1 viral RNPs,[642] similar to what is observed with influenza A and B viruses (the latter each having eight different RNA segments).

Thogoto Virus

The genomes of Thogoto viruses, including Bourbon virus, possess only six single-stranded RNA segments of negative polarity, with a total coding capacity for seven proteins.[220,508] As with the influenza viruses, three proteins make up the RNA-dependent RNA polymerase complex. The NP, the glycoprotein (G), the matrix protein (M), and one nonessential accessory protein (ML) are coded for by the remaining three RNAs. The M and ML proteins are both encoded by the shortest RNA, with the M protein being derived from a spliced mRNA.[336,474] The 304-aa-long ML protein has been shown to possess interferon antagonist activity[92,333,336,434] and is virion associated.[336]

Quaranjavirus

The genomes of viruses in the *Quaranjavirus* genus consist of six or seven negative-sense, single-stranded RNA segments.[7,708] The ends of each segment are conserved and partially complementary. Segments 1, 2, and 3 encode the PB2, PA, and PB1 polymerase subunits, respectively, while segment 5 codes for a protein that is distantly related to the Thogoto virus glycoprotein and the gp64 surface glycoprotein of baculoviruses and thus is

likely the attachment protein.[7,731]

Isavirus (Infectious Salmon Anemia Virus)

The genome of infectious salmon anemia virus consists of eight negative-sense, single-stranded RNA segments similar to those of influenza A and B viruses,[167,604] and an important reverse genetics system has been established.[893,894] Segment 6 encodes the hemagglutinin-esterase (HE) protein, which is also present on the viral surface and whose function is to bind sialic acid residues of the cellular receptor.[372] The HE protein also presents receptor-destroying enzyme (RDE) activity that favors the release of new viral particles that emerge from the cellular membrane.[623] This activity is similar to the binding and RDE activities previously observed for the HEF protein of influenza C viruses and the HE glycoprotein of coronaviruses.[372,379,918,919] Segment 8 encodes two proteins of 27.6 and 22 kD, the larger of which has interferon antagonist activity.[167,295]

STAGES OF VIRAL REPLICATION

An overview of the influenza virus life cycle is illustrated in Figure 14.8, and in the following pages, we will discuss each stage of this life cycle in order.

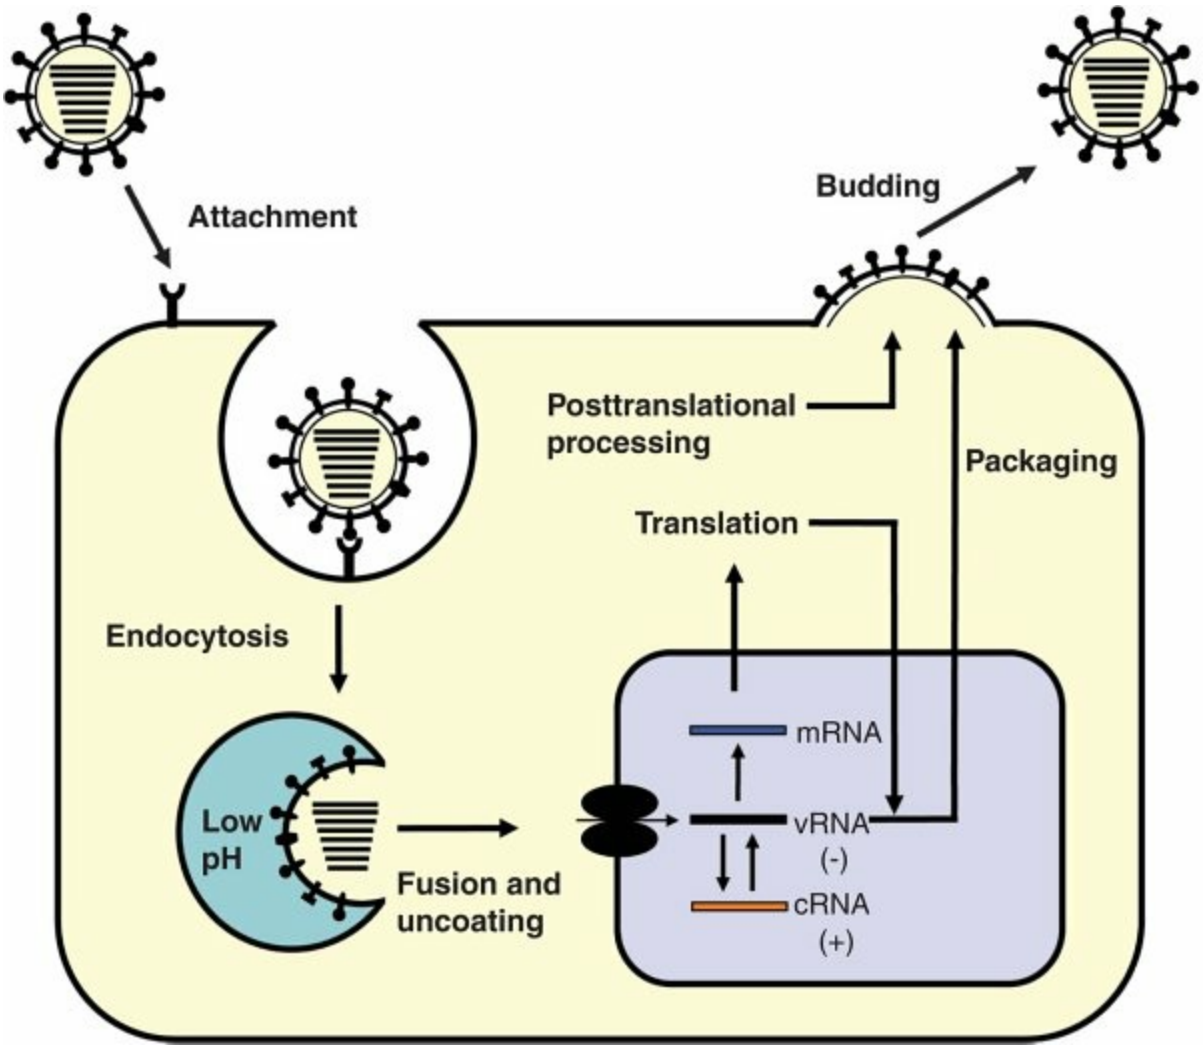

FIGURE 14.8 Illustration of the influenza virus replication cycle. Upon binding at the cell surface, the virus is internalized by receptor-mediated endocytosis. The low pH in the endosome triggers fusion of the viral and endosomal membranes, releasing the viral ribonucleoproteins (vRNPs) into the cytoplasm. vRNPs are imported into the nucleus where they serve as the template for transcription. New proteins are synthesized from viral mRNA. The viral genome (vRNA) is replicated through a positive-sense intermediate (complementary RNA [cRNA]). Newly synthesized viral RNPs are exported from the nucleus to the assembly site at the apical plasma membrane, where virus particles bud and are released.

Mechanism of Attachment

Influenza viruses bind to neuraminic acids (sialic acids) on the surface of cells to initiate infection and replication. The interaction of influenza viruses with a ubiquitous molecule such as sialic acid is constrained by the fact that the HAs (Fig. 14.9) of viruses that replicate in different species show specificity toward sialic acids with different linkages.

The five predicted antigenic sites (Ca2, Sb, Sa, Ca1, and Cb) surround the sialic acid receptor–binding site. Toward the membrane-proximal end (*bottom*) is the fusion peptide and helices A and B are indicated. For details, see Ref.[847] (Courtesy of James Stevens and Ian A. Wilson.)

Human viruses preferentially bind to *N*-acetylneuraminic acid attached to the penultimate galactose sugar by an *α*2,6 linkage (SA*α*2,6Gal), whereas avian viruses mostly bind to sialic acid with an *α*2,3 linkage[165,765,957] (Fig. 14.10). In agreement with this finding is the fact that human tracheal epithelial cells contain mostly SA*α*2,6Gal, while the gut epithelium from ducks possesses mostly SA*α*2,3Gal sugar moieties.[168,424] It should be noted, however, that this viral specificity is not absolute and that avian and human cells can contain both neuraminic acid linkages (2,3 as well as 2,6). Studies have shown that sialylated proteins with *α*2,3 linkages are present on cells in the human airways and that these cells can be infected with avian influenza viruses.[582,819,931] Furthermore, the relevant glycan structure consists of more than just the terminal sialic acid linkage, and evidence suggests that factors such as the type of backbone, chain length, and branching pattern as well as sulfation and fucosylation may also influence the interactions with HA.[137,837,846,931] In fact, studies have shown that recent human H3N2 viruses have evolved to bind to branched human-type receptors with extended poly-*N*-acetyl-lactosamine chains.[706] Glycan microarrays that contain a wide spectrum of glycan structures are now being used as tools to better understand the specificity of receptor binding.[845] Also, when viruses are passaged in a particular host, they can adapt to that host by mutating the receptor-binding site in the viral HA.[284,605] In a study of the A/New York/1/1918 virus HA, it was shown that the binding specificity can be changed by a single amino acid mutation (D190E) to a preference for *α*2,3-linked sialic acids. It is thus hypothesized that the HA gene of the 1918 influenza virus has its origin in avian influenza viruses and that a single amino acid change (E190D) allowed the hemagglutinin to recognize the *α*2,6-

linked sialic acids prevalent in human cells.[307,844] Similar changes in binding phenotype based on a small number of mutations have now been shown for many virus subtypes.[182] The interactions between HA and sialic acid are relatively well understood, but it is less clear if influenza viruses bind to N-linked glycans attached to specific surface proteins or if there is no specificity in terms of the protein carrying the glycan. Interestingly, it has been shown that the HA-like proteins of the H17N10 and H18N11 subtypes do not bind to sialic acid but can use MHC II as receptor.[450,865,892,1048]

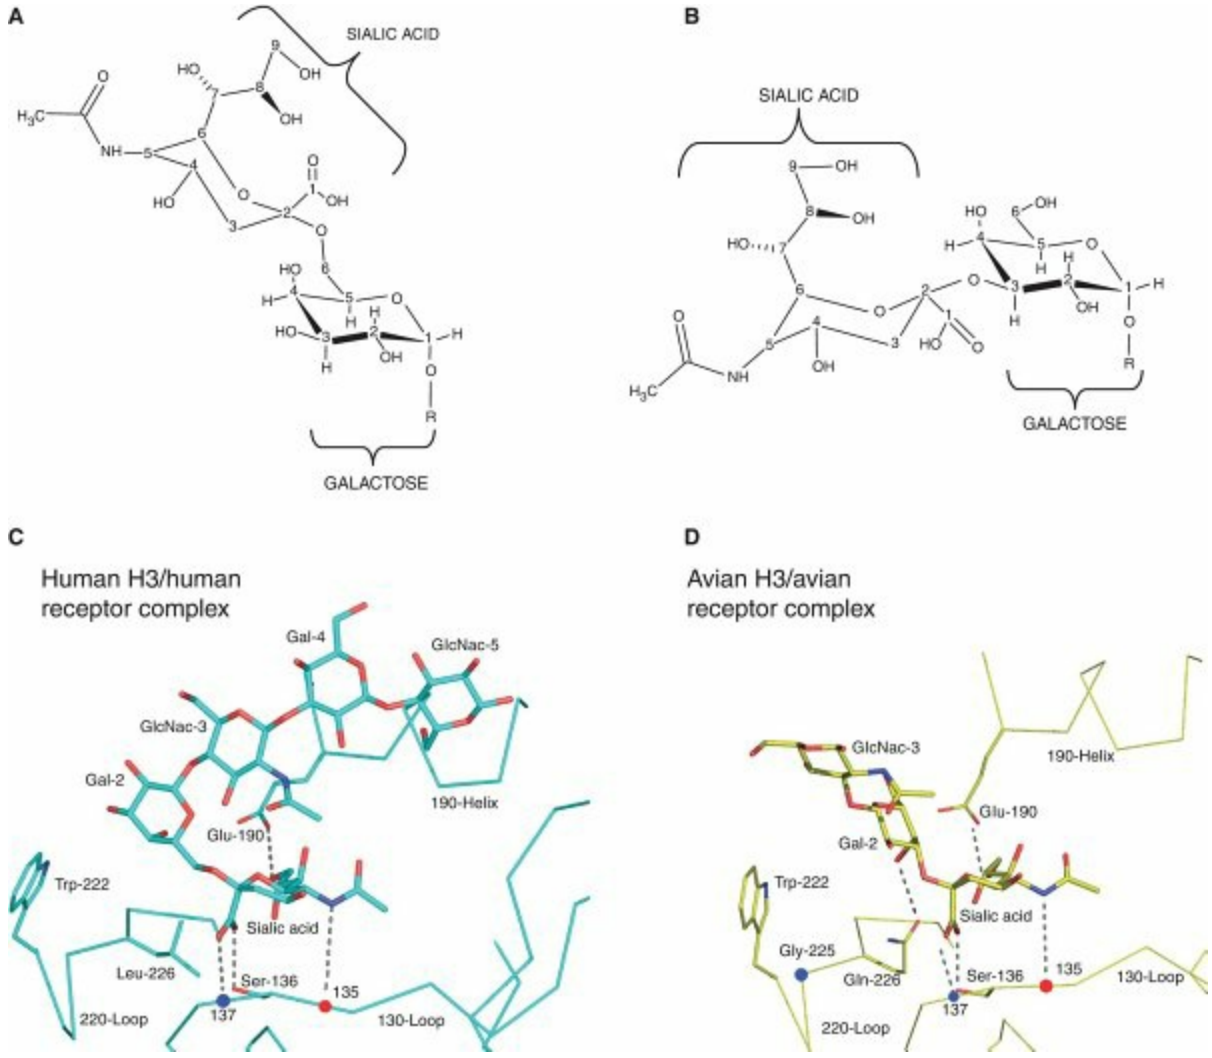

FIGURE 14.10 Sialic acid linkages preferred by human or avian influenza viruses.

galactose molecule via its C atom 2.

B:*α*2,3-linkage (avian): The sialic acid is attached by its C atom 2 to the three positions (C atom 3) of the penultimate sugar, galactose. These different linkages result in receptor molecules with different steric configurations. (Courtesy of Laurel Glaser.) Conformational differences in the receptor-binding sites of the H3 avian and H3 human hemagglutinins (HAs).

Interactions of human subtype 3 HA with a human receptor analog **(C)** and avian H3 HA with an avian receptor analog **(D)**. The three secondary structure components (190-helix, 130-loop, 220-loop) of the binding site are labeled in this backbone representation together with some of the most relevant side chains. The broken lines indicate potential hydrogen bond interactions between the HA and the receptor. Residues making interactions via main chain carbonyl groups are shown as red spheres, while those interacting via main chain nitrogens are shown as blue spheres. In the pentasaccharide ligand model, the galactose molecule is bound to sialic acid in an *α*2,6 or an *α*2,3 linkage (**C** and **D**, respectively). The human HA is from A/Aichi/68 (H3) virus and the avian HA is from A/duck/Ukraine/63 (H3) virus. For details, see Ref.[332]

Mechanism of Entry

While some viruses (e.g., paramyxoviruses and herpes viruses) can enter cells directly through the plasma membrane by a pH-independent fusion process, influenza viruses require a low pH to initiate fusion and are therefore internalized by endocytic compartments. There are several internalization mechanisms including clathrin-coated pits, via caveolae, through macropinocytosis and through alternative mechanisms.[211,371,600,997] Clathrin-mediated endocytosis has traditionally been the model for influenza virus entry.[581] However, a nonclathrin, non–caveolae-mediated internalization mechanism has also been described for influenza viruses.[821] The latter pathway is dependent on low pH and trafficking to late endosomes, as it requires protein kinase C, Rab5, and Rab7 functions.[820] More recently, through the use of specific inhibitors and RNA interference (RNAi), it has been shown that in addition to entering via a dynamin-dependent, clathrin-

driven pathway, influenza viruses can also enter via a dynamin-independent pathway that is characteristic of macropinocytosis.[184] This mechanism has specifically been implicated for entry of filamentous influenza virions.[771] Potential differences in the entry pathways defined in polarized versus nonpolarized cells should also be appreciated, as, for example, the actin cytoskeleton appears to be critical for uptake of influenza viruses into polarized cells but not nonpolarized cells.[866] Of note, it is still unclear if binding of virus particles to sialylated glycans is sufficient or if additional interactions are needed to trigger/initiate efficient entry. A number of proteins have been identified to be of importance in influenza virus entry. Epsin 1 has been shown to be specifically required for clathrin-mediated uptake of influenza virus.[131] The epidermal growth factor receptor (EGFR) has also been demonstrated to play a role during influenza virus entry,[217] and it is thought that virus attachment to the cell stimulates EGFR, which leads to activation of signaling cascades such as phosphatidylinositol 3-kinase (PI3K) signaling, which is known to promote influenza virus entry.[214] Additional proteins including phospholipase D, the sialylated voltage-dependent Ca^{2+} channel $Ca_v1.2$, cell-surface nucleolin, prolidase, and fibronectin have been identified as factors important for influenza virus entry.[115,269,527,672,722] There are also questions over whether sialic acid is the only attachment molecule. Lec-1 cells, which are deficient in N-linked glycosylation (but still contain sialylated proteins), are unable to internalize influenza viruses.[143] Similarly, cells deficient in sialic acid can be made to support influenza virus entry if they express one of the C-type lectins, DC-SIGN or L-SIGN.[382,549,655]

Mechanism of Fusion and Uncoating

Influenza viruses and other enveloped viruses (including rhabdo-, flavi-, bunya-, and filoviruses) require low pH to fuse with endosomal membranes. After binding to the target cell surface and endocytosis, the low pH of the endosome activates fusion of the viral membrane with that of the endosome. This fusion activity is induced by a structural change in the HA of influenza viruses (Fig. 14.11), but in order for this to occur, the HA0 precursor must first be cleaved into two subunits, HA1 and HA2 (which typically occurs after release of new virions/before attachment; for details, see the following section on Hemagglutinin). Once in the acidic environment of the endosome,

the cleaved HA molecule undergoes a conformational change, and this exposes the fusion peptide at the N-terminus of the HA2 subunit, enabling it to interact with the membrane of the endosome[66,355,963,980] (for details, see the following section on Hemagglutinin). The transmembrane domain (TMD) of the HA2 (inserted into the viral membrane) and the fusion peptide (inserted into the endosomal membrane) are in juxtaposition in the low pH–induced HA structure. The concerted structural change of several hemagglutinin molecules then opens up a pore, which releases the contents of the virion (i.e., viral RNPs) into the cytoplasm of the cell (Fig. 14.12). The precise timing and the location of uncoating depend on the pH-mediated transition of the specific HA molecule involved.[282]

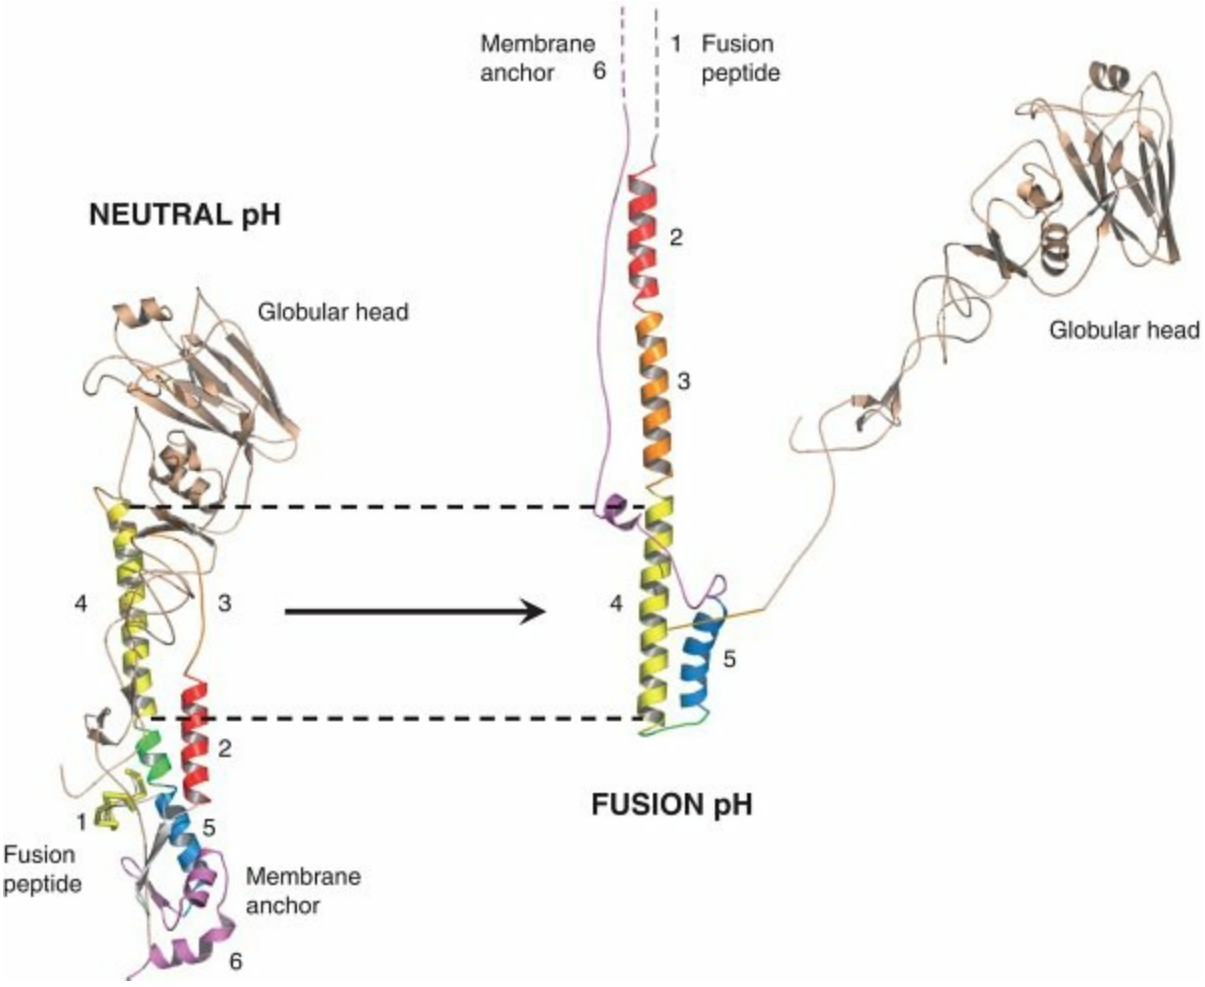

FIGURE 14.11 Ribbon representation of the structural changes that occur in hemagglutinin (HA) at low pH. Bromelain-treated

HA monomer with regions of HA2 undergoing conformational changes at low pH as indicated by numbered domains (*left*). The domains, starting at the fusion peptide (domain 1), are numbered sequentially until the membrane anchor is reached (domain 6). The structure and the position of the region comprising residues 75 to 106 (domain 4) are the same before and after the conformational change (denoted by the *dotted lines*). The globular head domains retain their structures but detrimerize (falling to the right, away from the HA2 portion). For details, see Refs.[127,825] (Courtesy of John Skehel and Rupert Russell.)

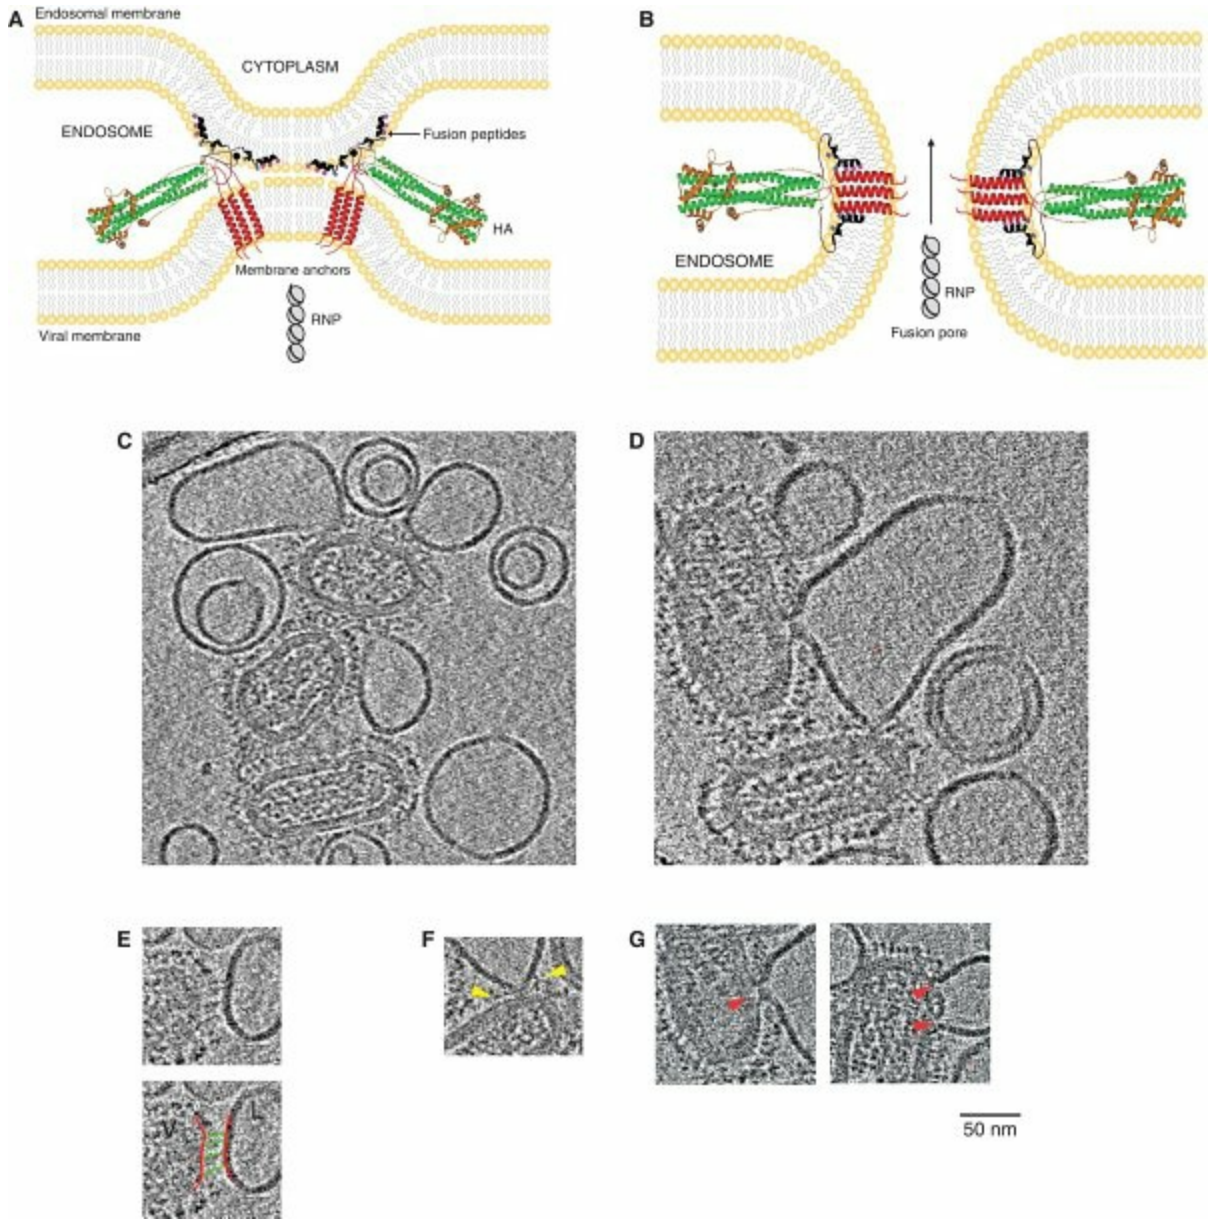

FIGURE 14.12 Model for juxtaposition of viral and endosomal membranes resulting in formation of a fusion pore and release of ribonucleoproteins (RNPs). Structures of influenza virus hemagglutinins in their postfusion state modeled into a possible fusion intermediate **(A)** and into a fusion pore **(B)**. The fusion peptides are shown inserted into the endosomal membrane, while the transmembrane domains remain anchored in the viral membrane. Note the large conformational changes of the ecto- and fusion domains when compared to their prefusion structures (see

Figs. 14.9 and 14.11). The small spheres (*pink*) on the fusion peptide denote glycines that may mediate helix interactions, and the small squares (*blue*) denote glutamates that may be responsible for the pH dependence of the fusion peptide penetration into lipid bilayers. Following the formation of a pore, the RNPs are released from the interior of the virus particle into the cytoplasm, completing the uncoating process. (Courtesy of Lukas Tamm.) The uncoating of influenza viruses is blocked by changes in pH caused by weak bases (e.g., ammonium chloride or chloroquine) or ionophores (e.g., monensin).[573] Effective uncoating is also dependent on the presence of the M2 protein, which has ion channel activity.[567,716] Early on, it was recognized that amantadine and rimantadine inhibit replication immediately following virus infection.[826] Later, it was found that the virus-associated M2 protein allows the influx of H^+ ions from the endosome into the virus particle, which disrupts protein–protein interactions and results in the release of RNP free of the M1 protein.[567,581,1037] Amantadine and rimantadine have been shown to block the ion channel activity of the M2 protein and thus uncoating.[138,391,716,862,942] The HA-mediated fusion of the viral membrane

with the endosomal membrane and the M2-mediated release of the RNP result in the appearance of free RNP complexes in the cytoplasm. This completes the uncoating process.[575] Cellular factors like Itch, transportin 1, and the cellular aggresome have been shown to play important roles in this process.[34,603,736,853] The time frame for the uncoating process was examined by inhibiting virus penetration with ammonium chloride. The majority of virus particles showed a half-time for penetration of about 25 minutes (after adsorption). Barely 10 minutes later (half-time of 34 minutes after adsorption), RNP complexes are found in the nucleus.[575] The following uptake of RNP molecules through nuclear pores is an active process, involving the nucleocytoplasmic trafficking machinery of the host cell (for details, see Nuclear Import of RNPs).

Much less is known about the uptake and uncoating of influenza B, C, and D viruses. Influenza B viruses are more like influenza A viruses as both recognize *N*-acetylneuraminic acid as receptors, while influenza C and D viruses bind to 9-*O*-acetylated neuraminic acid derivatives.[380,834] Like influenza A viruses, the B- and C-type viruses go through an endosome-mediated uncoating process, which requires proteolytic activation (cleavage) of the HA or HEF proteins and subsequent fusion of the viral and endosomal membranes. Although the viral glycoproteins of both HA and HEF are dependent on a low pH–triggered fusion process, the influenza C virus HEF-mediated fusion/uncoating may occur at a higher pH in early endosomes.[257,1037] The opposite seems to be true for the HEF protein of influenza D virus, which has been shown to be relatively acid stable leaving a question mark about its specific entry mechanism.[1014] At this point, the role of CM2 and DM2 in uncoating of influenza C and D viruses is less well established than that of the BM2 protein of influenza B viruses, which is the homolog of the influenza A virus M2 protein.[273,358,393,460,620,940,945] The NB ion channel of influenza B viruses does not seem to be required for virus infectivity *in vitro* and *in vivo*.[225,358]

The Hemagglutinin

Structural features

Much is known about the HA molecule, and excellent reviews are

available.[66,286,355,777,984,985] In fact, the influenza virus HA has become a model for studies of protein folding and trafficking, protein quality control, membrane fusion, protein–receptor interactions, and antigen–antibody complexes and, last but not least, for investigating how the immune system reacts to a foreign protein. The major functions of the HA are the receptor-binding and fusion activities, but there may also be a structural role for the HA in budding and particle formation. The HA is a trimeric rod-shaped molecule with the carboxy-terminus inserted into the viral membrane and the hydrophilic end projecting as a spike away from the viral surface (i.e., a type I integral membrane protein). Early on, it was shown that (a) posttranslational modifications of the precursor molecule (i.e., glycosylation and palmitoylation), (b) cleavage of the signal peptide in the endoplasmic reticulum (ER), and (c) cleavage of the HA0 precursor into HA1 and HA2 subunits are required for the full activity of the molecule.[469,513,727] During human infections, HA is cleaved when expressed on the cell surface or virus surface by airway proteases potentially including matriptase, transmembrane protease, serine 2 (TMPRSS2), and human airway trypsin-like protease (HAT).[46,70,282,347] HAs with a polybasic cleavage site, for example from specific H5 and H7 strains, can also be cleaved in the Golgi apparatus by furin/furin-like proteases.[849] In cell culture, tosyl phenylalanyl chloromethyl ketone (TPCK)-treated trypsin is usually added to culture medium to facilitate cleavage. The attachment of N-linked glycans is also a very important posttranslational modification for the viral HA. N-linked glycosylation sites in the stalk domain are conserved within groups/subtypes and contribute to protein folding and stability. Glycosylation of the head domain is more variable between strains and subtypes and plays an important role in immune evasion and pathogenicity.[592]

The first x-ray crystallographic structure of an HA (the ectodomain released from the virus by bromelain treatment) was resolved in 1981 by Wilson et al.[969] At that time, the HA (from A/Aichi/68 [H3N2] virus) was the largest biological molecule for which a structure had been resolved, and it started an unprecedented drive to study the structure/function relationships of biologically important molecules, which continues unabated to this day. The structures of numerous HAs have now been resolved, including the subtype 1 HA molecules of the 1918 and 2009 pandemic influenza viruses[285,847,989] and that of an H2 subtype HA (Fig. 14.9).[990] Remarkably, even though the

overall amino acid sequence identity can be less than 50%, the structure and functions of these HAs are highly conserved. This represents a case of evolution and sequence variation proceeding to an extreme level while structure and function have remained conserved. Even more surprising is that the structure of the influenza B virus HA is similar to that of influenza A virus HA despite sharing only approximately 25% sequence identity.[934,944]

The crystallographic structure of the uncleaved influenza A virus HA is superimposable onto that of the cleaved HA1 and HA2, with the exception of the amino acids adjacent to the cleavage site. The major features of the structure are (a) a long fibrous stem, which is made up of a triple-stranded coiled coil of α-helices derived from the ectodomain of the three HA2 parts of the molecule (helix A and helix B; Fig. 14.9) and the N-terminal and C-terminal portions of HA1, and (b) the globular head, which is also made up of three identical domains whose sequences are derived from the central region (C52–C277 in H3 numbering) of the HA1 of the three monomers.

A major function of HA is binding to receptors and the receptor-binding site lies within the globular head of the molecule. This site has been defined through crystallization and structure analysis of HA–receptor complexes, as well as by mutational analysis. In the H3-subtype viruses, it appears that within the receptor-binding pocket of an avian HA, a glutamine in position 226 and a glycine in position 228 preferentially accommodate the 2,3-linked sialic acid, whereas leucine and serine in these positions in human H3 HAs preferentially accommodate the 2,6-linked sialic acid (Fig. 14.10).[165,332] (See the previous section on Attachment for more details.) Similar receptor-specificity defining amino acids have been characterized for many influenza A HA subtypes.

The second major function of the HA is acid pH–triggered fusion, which is required for the uncoating process. Low pH treatment changes the structure of the HA dramatically. The molecule becomes susceptible to protease digestion, and the disulfide bond linking the HA1 and HA2 subunits becomes susceptible to mercaptoethanol.[320,824] However, the important feature of the acid pH–mediated change is that the fusion peptide becomes aligned antiparallel to the membrane anchor of the HA2 (Fig. 14.11). The end result is that the fusion peptide brings the endosomal membrane into juxtaposition with the viral membrane, leading to fusion. The presence of more than one hemagglutinin then leads to the formation of a fusion pore through which the

RNPs can enter the cytoplasm (Fig. 14.12). Structures of the postfusion HA as well as an early fusion intermediate have helped to reveal the molecular details of the changes that occur during the transition from pre- to postfusion state.[98,991] The dynamics of the fusion process have recently been further elucidated using cryoelectronmicroscopy, cryotomography, and single-molecule FRET.[105,178] Structures of the fusion peptide in lipid environments have been resolved by nuclear magnetic resonance (NMR) and show that the peptide forms a tight helical hairpin structure that angles back on itself.[348,497,551,980] This hook structure may help to pull the endosomal membrane close to the viral membrane, resulting in the initiation of the actual fusion process.

Another important structural element (c) of the HA is the TMD, which is relatively conserved and consists of a trimeric helical bundle. The TMD is connected to the ectodomain by a short, flexible linker, which allows the HA ectodomain to tilt more than 25 degrees, which is likely needed to facilitate structural rearrangements during fusion.[51]

The last major structural element of the HA, the cytoplasmic tail (d), is highly conserved among all subtypes. There are three cysteines that are palmitoylated (with one of them located in the TMD). The role of this cytoplasmic tail (and the palmitates attached to the cysteines) is not entirely clear due to subtype- and cell/host-specific differences.[128,437,928,1049]

Antigenic determinants

In addition to having an important role in receptor binding, fusion, and assembly, the influenza virus HA is also the *major determinant* recognized by the adaptive immune system of the host. Following infection and replication, a vigorous immune response is induced, which usually results in the formation of neutralizing antibodies.[483] These antibodies then lead to the selection of “antibody escape” variants. The amino acids undergoing change are almost exclusively on the globular head domain (and on the outside of the molecule). Many of these changes get fixed (accumulate over time), defining the antigenic drift of influenza viruses. Using insertion and mutagenesis libraries as well as evolutionary analysis, it has also been shown that the head domain of influenza A virus HA is highly plastic as compared to the conserved stalk domain and tolerates drastic changes enabling fast antigenic

drift (Fig. 14.13).[202,369,465] Using the same methods, the influenza B virus HA head domain was shown to be less tolerant to changes than its A counterpart.[272,465]

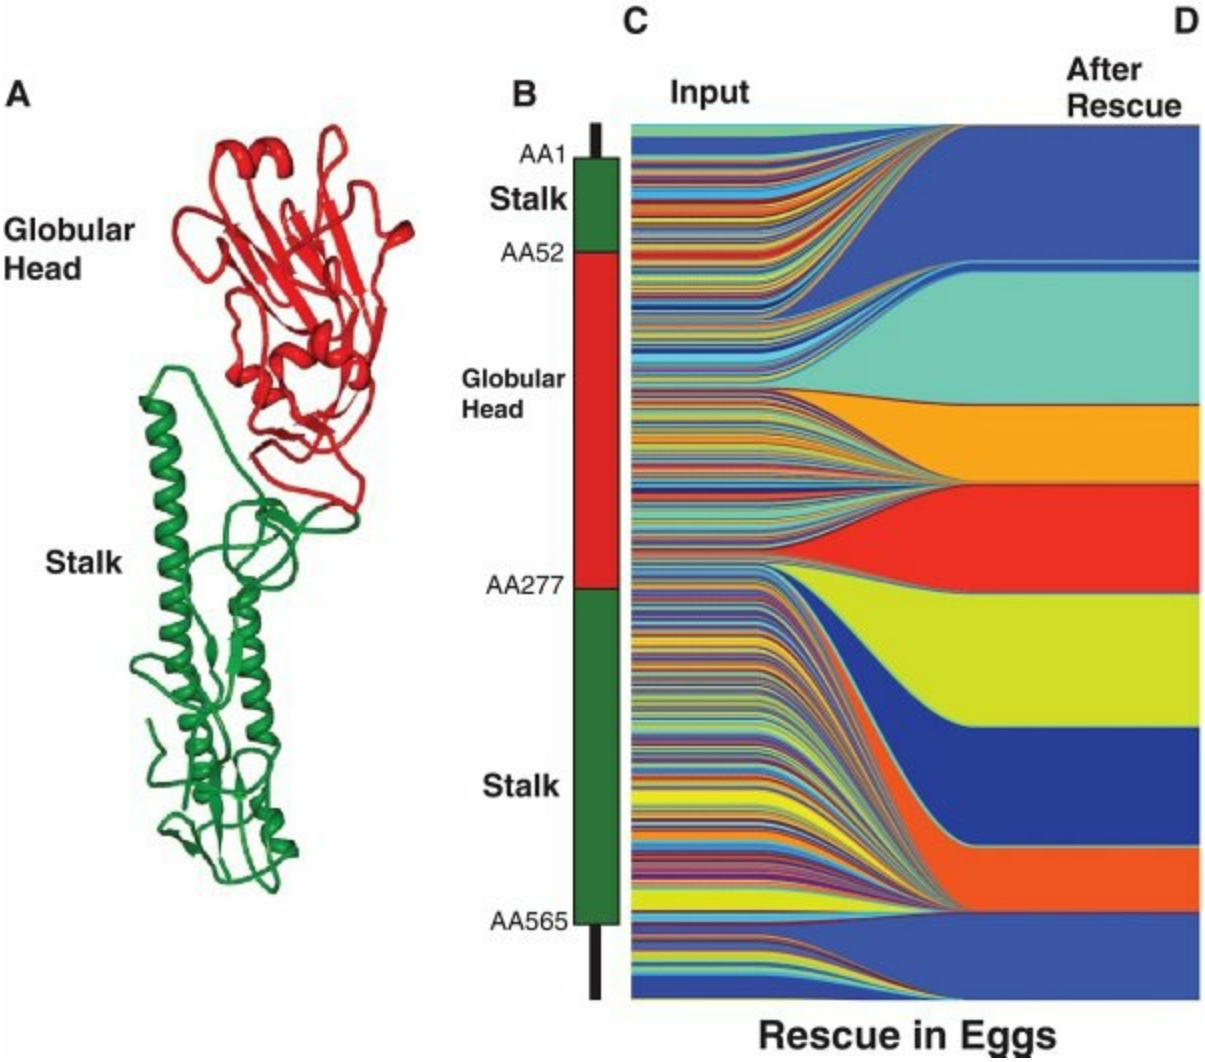

FIGURE 14.13 Relative tolerance to insertions in the head (*red*) of the influenza A virus hemagglutinin versus the stalk (*green*) **(A and B)**. Plots represent individual insertion sites. Individual insertions in the input **(C)** and after rescue **(D)** of viruses are represented by different colors; the thickness of the lines is representative of the proportion in the population. (The figure was kindly provided by Drs. Nicholas Heaton and Peter Palese.) For

details, see Ref.[369]

Fab antibody fragments have been shown to bind to different regions of the HA head (Fig. 14.14) and, interestingly, not in all cases do three Fabs bind to one trimeric spike (3:1 ratio). Examples have been found where only one Fab molecule binds to one HA spike (1:1 ratio) or where just two Fab molecules bind to a trimeric spike (2:1 ratio) (Fig. 14.14).[471] In the latter case, the two Fab fragments cross-link two monomers so that the HA molecule cannot undergo an acid pH–induced conformational change.[471] Attempts have also been made to measure antigenic evolution of influenza virus strains by pairwise comparison of hemagglutination inhibition assay titers.[256,259]

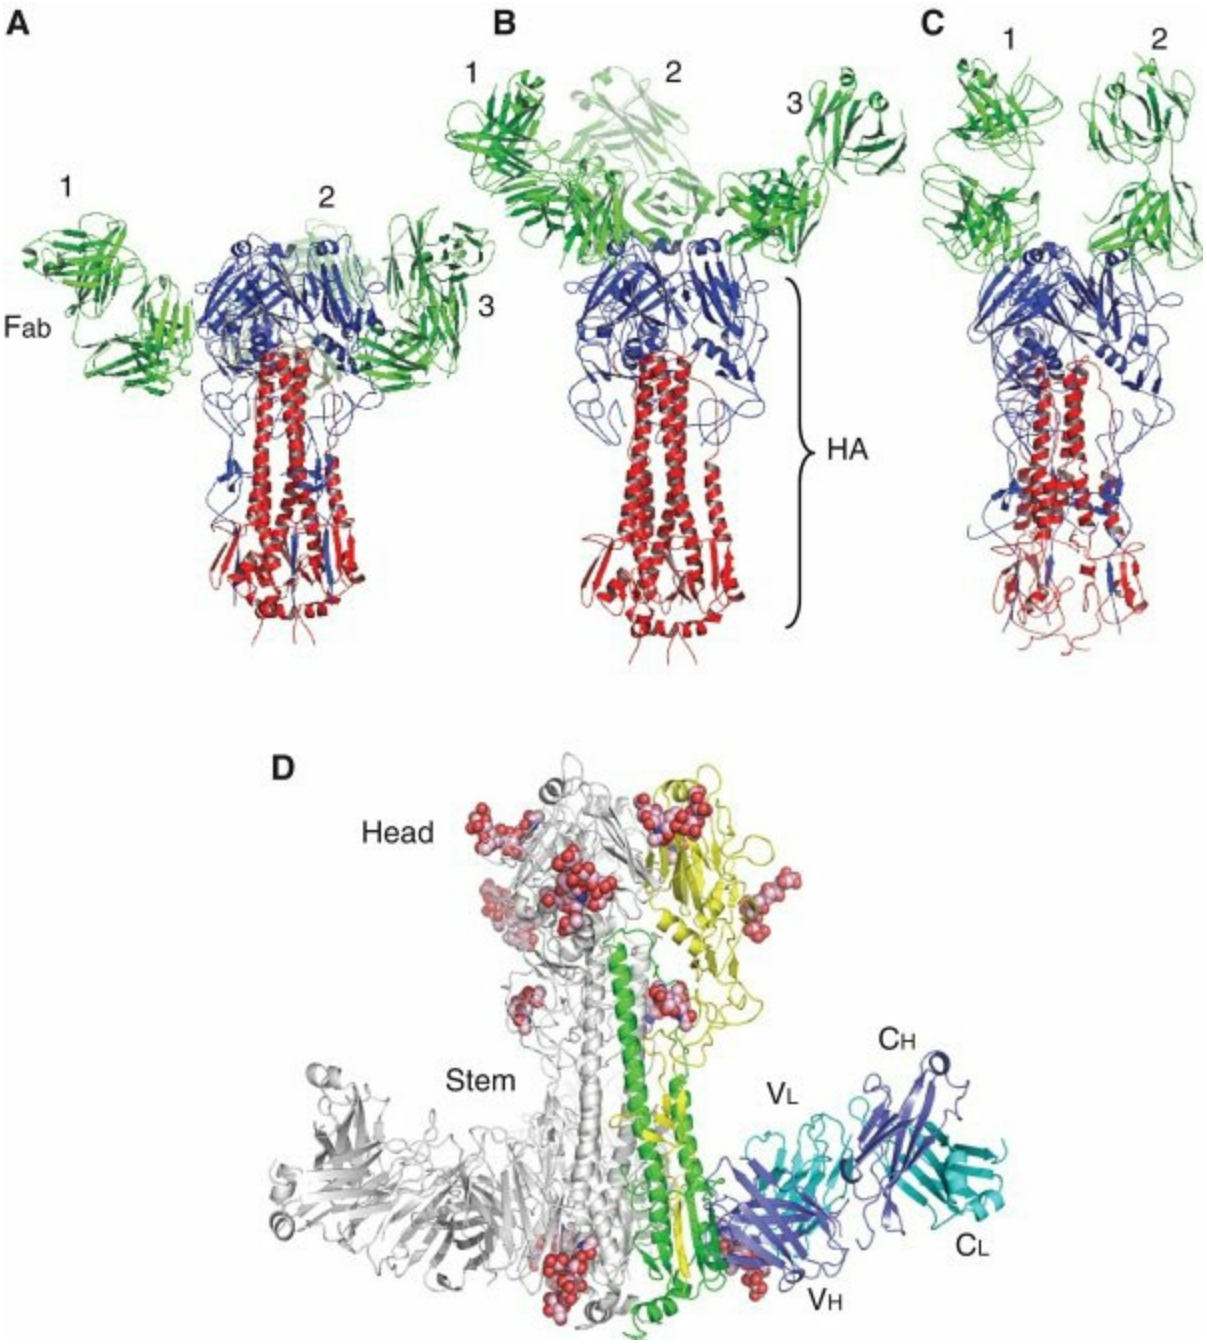

FIGURE 14.14 Ribbon diagram of H3 hemagglutinin (HA) in complex with Fab molecules. **A and B:**The first two complexes are examples where three Fab molecules (shown in *green*) are bound per HA trimer (i.e., one per HA monomer). **C:** The third complex has only two Fab molecules bound as the third is blocked by steric hindrance. For details, see Ref.[471] (Courtesy of John

Skehel and Rupert Russell.) **D:** Crystal structure of antibody CR8020 bound to the H3 hemagglutinin. CR8020 binds an epitope on the hemagglutinin (HA) stem and has broad neutralizing activity against multiple group 2 influenza A viruses, including H3, H7, and H10. One monomer from the HA trimer is depicted in yellow and green (HA1 and HA2 subunits, respectively) and CR8020 is colored *blue* and *cyan* (heavy chain and light chain, respectively). N-linked carbohydrates are represented as pink van der Waals spheres. See for details Ref.[222] (Courtesy of Damian Ekiert and Ian A. Wilson.)

Unexpectedly, broadly cross-reactive monoclonal antibodies have been identified, which do not bind to the tip of the HA molecules but also have neutralizing activity. These antibodies are directed against the conserved stalk region of the HA spike and recognize the membrane-proximal part of HA1 in combination with HA2 or the HA2 alone (Fig. 14.14). In general, these antibodies recognize HAs within either group 1[221,455,678,863,873,885] or group 2.[223,264,943] However, very rare cross-group monoclonal antibodies[14,166,376,444,982] and one monoclonal antibody that binds to influenza A and B virus HA have also been isolated.[203] These cross-reactive antistalk antibodies protect from influenza virus infection via several mechanisms including by blocking conformational rearrangements associated with membrane fusion (antifusion vs. hemagglutination inhibition activity), by blocking viral egress, by blocking the function of the viral NA via steric hindrance, and by inhibiting the cleavage of HA0 and, importantly, via Fc–Fc receptor–mediated effector functions.[79,193,874,972] A number of antibodies that broadly bind to the head domain of HA have been isolated as well. These antibodies target the conserved sialic acid–binding site or a conserved area at the trimer interface of the head domain.[223,517,985] Antihead cross-reactive antibodies seem to be more prevalent for influenza B HA than for A HA, likely due to the higher conservation of influenza B virus HA.[872] Universal influenza virus vaccine approaches that target conserved epitopes in the stalk and/or head domain are currently being tested in preclinical and early clinical trials.[485,634,635]

The HEF of Influenza C and D Viruses

In contrast to the HA of influenza A and B viruses, the major glycoprotein of the C and D viruses has receptor-destroying activity. This is mediated by HEF's esterase activity, which cleaves off an acetyl group at position 9 of the neuraminic (sialic) acid receptor, eliminating the ligand.[851] This activity is important for entry of the virus, implying a role in releasing the incoming virus from the receptor so that the uncoating process can begin.[834,920] Thus, in addition to receptor-binding (**h**emagglutination) and **f**usion activities, the molecule also has **e**sterase activity, hence the name HEF.[380] Although there is only about a 12% sequence identity between HAs and HEF, the overall structure of the molecule is similar, as was shown by x-ray crystallographic analysis.[766,834] Even more surprising are structural and sequence similarities between influenza virus HEF and some coronavirus esterases.[1022]

The M2 Protein

The M2 protein of influenza A viruses is a tetrameric type III (lacking a signal peptide sequence) integral membrane protein. It has a short ectodomain, a TMD, and a cytoplasmic domain with palmitate and phosphate modifications.[567,717,794] M2 has been shown to possess ion channel activity, and its major role is thought to be that of conducting protons from the acidified endosomes into the interior of the virus to dissociate the RNP complexes from the rest of the viral components, thus facilitating the uncoating process (see earlier section on Fusion and Uncoating). The structural and genetic analyses of the M2 protein have revealed that the ion channel is acid gated (but not voltage gated) and highly selective for H^+ and K^+ ions.[121,138,618,619,660,840] The structures of the transmembrane regions of M2 and of those that include the cytoplasmic sequences reveal a good understanding of the mechanism of proton conductance, which is controlled by the histidine-37 and tryptophan-41 cluster.[1,104,405,657,790,803,850,883] The transmembrane region, when viewed from the top, shows four helices that sit at an angle in the lipid bilayer, forming a pore (Fig. 14.15). Structural studies on M2 in complex with adamantine drugs indicate two potential sites of interaction. In the x-ray structure, a single drug molecule binds to the core of the pore.[850] In contrast, the NMR structure shows four drug molecules binding to the lipid-exposed surface of the channel close to the cytoplasmic

ends of the helices.[790] More recent data confirm the existence of these two interaction sites and propose that both drug-binding mechanisms may have physiologic significance.[104,482] The structure and the precise function of the extracellular portion of the M2 protein remain to be resolved. This external portion of M2 has been considered as the basis of a universal influenza virus vaccine approach because the M2 protein maintains a relatively conserved sequence over long periods of time.[786]

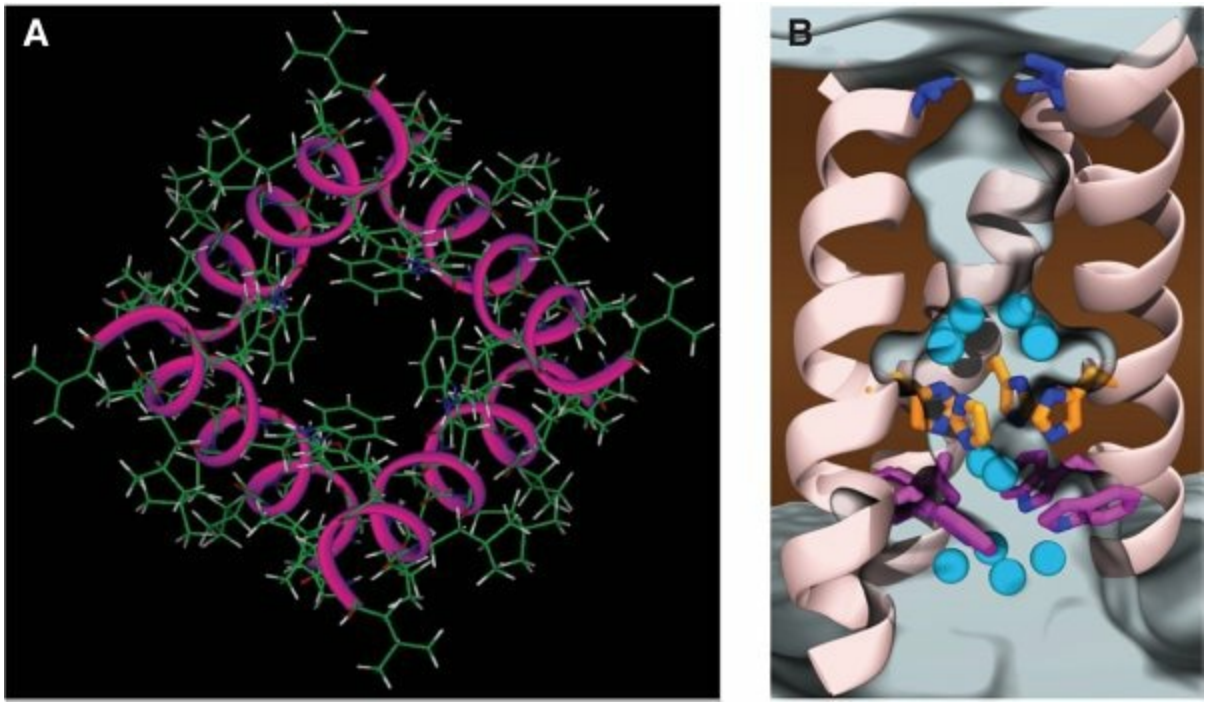

FIGURE 14.15 Structure of the tetrameric M2 ion channel. A: As seen from the top, four helices sit at an angle in the lipid membrane forming a pore. The backbone structure was determined by solid-state nuclear magnetic resonance (NMR) spectroscopy of the aligned bilayers. The histidine-37 and the tryptophan-41 side chains form the bottom of the pore in the closed state at neutral pH. For details, see Ref.[660] (Courtesy of Tim Cross.) **B:** X-ray structure of the transmembrane section of the M2 proton channel. The protein backbone is shown as a cartoon, viewed from across the viral membrane (lipid molecules and one of the monomers are

not shown). Cyan spheres represent crystallographically resolved water molecules, which are stepping stones in possible proton conduction pathways. The three most important groups of side chains (the Val27-valve [*blue*], the His37-box [*orange*], and the Trp41-basket [*magenta*]) are shown in sticks. The three-dimensional density of water at 37°C, calculated from molecular dynamics simulations, is drawn as a gray contour. See Ref.[1] for details. (Courtesy of Giacomo Fiorin.)

The ion channel activity of M2 has also been implicated in stabilizing HAs from premature low pH transitions in the trans-Golgi network, but this second function may only come into play for viruses carrying highly acid-sensitive HAs.[146] This is the case for some strains of H5 and H7 HAs, which have a multibasic cleavage site that can be cleaved by ubiquitous proteases and are therefore more susceptible to a premature low pH–induced conformational change. Further functions attributed to the M2 protein include roles in particle morphology,[319,427,756,757,768] genome packaging,[319,427,587] membrane scission[579,757,769] (see Assembly and Release), and inhibition of autophagy.[287] M2 expression also activates the inflammasome via the NLRP3 pathway.[244,418]

Influenza Virus Transcription and Replication

Overview

After uncoating, the viral ribonucleoproteins (vRNPs) are transported into the nucleus, and the incoming negative-sense vRNAs are transcribed into mRNA by a primer-dependent mechanism. These mRNA products are incomplete copies of the vRNA templates and are capped and polyadenylated, unlike vRNA. Replication occurs via a two-step process. A full-length, positive-sense copy of the vRNA is first made, which is referred to as complementary RNA (cRNA), and is in turn used as a template to produce more vRNA.

Nuclear Import of Ribonucleoproteins

One of the characteristics of the influenza virus life cycle is its dependence on nuclear functions. All vRNA synthesis occurs in the nucleus, and the trafficking of the viral genome into and out of the nucleus is a tightly regulated process.[72,173] The eight influenza virus genome segments never exist as naked RNAs but are associated with four viral proteins to form vRNP complexes. The major viral protein in the RNP complex is the nucleoprotein (NP), which coats the RNA. The remaining proteins are the three polymerase proteins (PB1, PB2, and PA), which bind to the partially complementary ends of the vRNA. RNPs (10–20 nm wide)[577] are considered too large to allow for passive diffusion into the nucleus, and therefore they must rely on an active nuclear import mechanism. All proteins in the RNP complex possess nuclear localization signals (NLSs), which mediate their interaction with the nuclear import machinery.[440,622,644,830,939,956] However, the signals on NP have been shown to be both sufficient and necessary for the import of vRNA.[96,172,639,669,682]

NP interactions with importin-α

The transport of proteins across the nuclear membrane is an energy-driven process that is initiated upon recognition of an NLS-containing cargo protein by members of the importin-*α* (also called karyopherin-*α*) family. Importin-*α* binds directly to the NLS and then recruits importin-*β* into a trimeric complex, which docks at the nuclear pore (Fig. 14.16A). Interestingly, the NP NLS-binding site on importin-*α* is distinct from that of classical NLS-containing proteins and relies on a low affinity–high avidity interaction with the nuclear import machinery.[172,595,639,890] One could postulate that this serves to avoid competition for importin-*α* binding with host proteins and may explain the use of an unconventional NLS. There is also evidence that differential interactions with human versus avian importin-*α* proteins may determine species specificity of influenza viruses.[278,279]

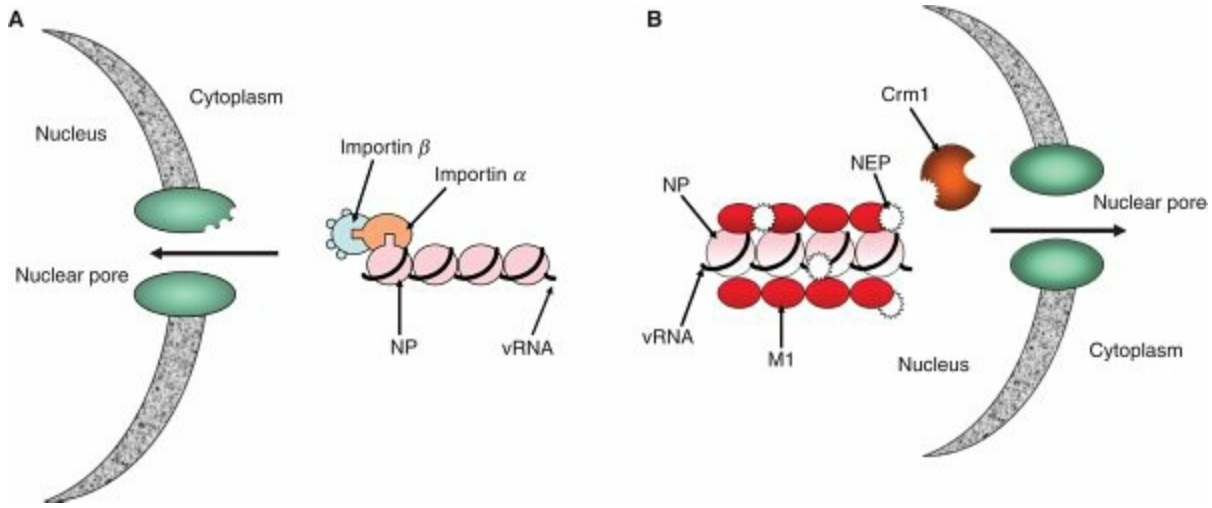

FIGURE 14.16

A: Illustration of influenza viral ribonucleoprotein (RNP) nuclear import. Viral RNPs (shown as viral RNA [vRNA] wrapped around nucleoprotein [NP]) are imported into the nucleus by an energy-dependent process, requiring interactions with soluble host factors. NP interacts with importin-*α* via its nuclear localization signals. Importin-*α* binds to importin-*β*, which mediates the interaction with proteins of the nuclear pore. For details, see Ref.[173]

B:Illustration of influenza viral ribonucleoprotein (RNP) nuclear export. The nuclear export of newly synthesized viral RNP complexes is mediated by the viral nuclear export protein (NEP). NEP interacts with a cellular export factor, Crm1, and with the viral RNPs via the M1 protein. This interaction with the cellular export machinery facilitates the transport of the viral genome through the nuclear pore and into the cytoplasm.

The Viral Ribonucleoprotein Template

Each vRNA segment exists as an RNP complex in which the RNA is coated with NP and forms a helical hairpin that is bound on one end by the heterotrimeric polymerase complex.[713,745] NP is an arginine-rich protein and has a net positive charge (at pH 6.5), which reflects its RNA-binding activity and its primary role in encapsidation.[726] The RNA/NP interaction is thought to be mediated by the positively charged residues on NP and the negatively charged phosphate backbone of the RNA, and thus there is no apparent

sequence specificity to the interaction.[40,228] The RNA within the influenza virus RNP also remains sensitive to digestion with RNase and chemical modifications,[207,470] supporting the model that the bases are exposed so that they can be accessed by the polymerase without disrupting the RNP structure.[40] Approximately 24 nucleotides of RNA are bound by each NP monomer,[681] and NP also has homo-oligomerization properties,[734] which adds structure to the RNP complex. This is maintained even in the absence of RNA[207,723,775] and has been shown to be crucial for maintaining the RNP in a transcriptionally active form.[116,229] Crystal structures of NP show that it is composed of a head domain and body domain and that a flexible tail loop mediates oligomerization.[656,1005] A potential RNA-binding groove, which is highly positively charged, has been identified between the head and body domains.[1005] Structural data based on EM also provide evidence that NP makes direct contact with the bound polymerase complex on the RNP,[19,159,577] which may reflect the previously reported interaction of free NP with both PB1 and PB2.[57] Mutagenesis and mapping of conserved residues in NP indicate the regions that are involved in genome replication/transcription and also genome packaging.[23,521,539,615,967]

The RNA Polymerase Complex

The influenza virus RNA-dependent RNA polymerase is a 270-kD complex of three proteins: PB1, PB2, and PA.[77] Three-dimensional images of the complex obtained by EM and x-ray analyses indicate that the three subunits are tightly associated to form a compact structure (Fig. 14.17).[19,374,712,713,743,895]

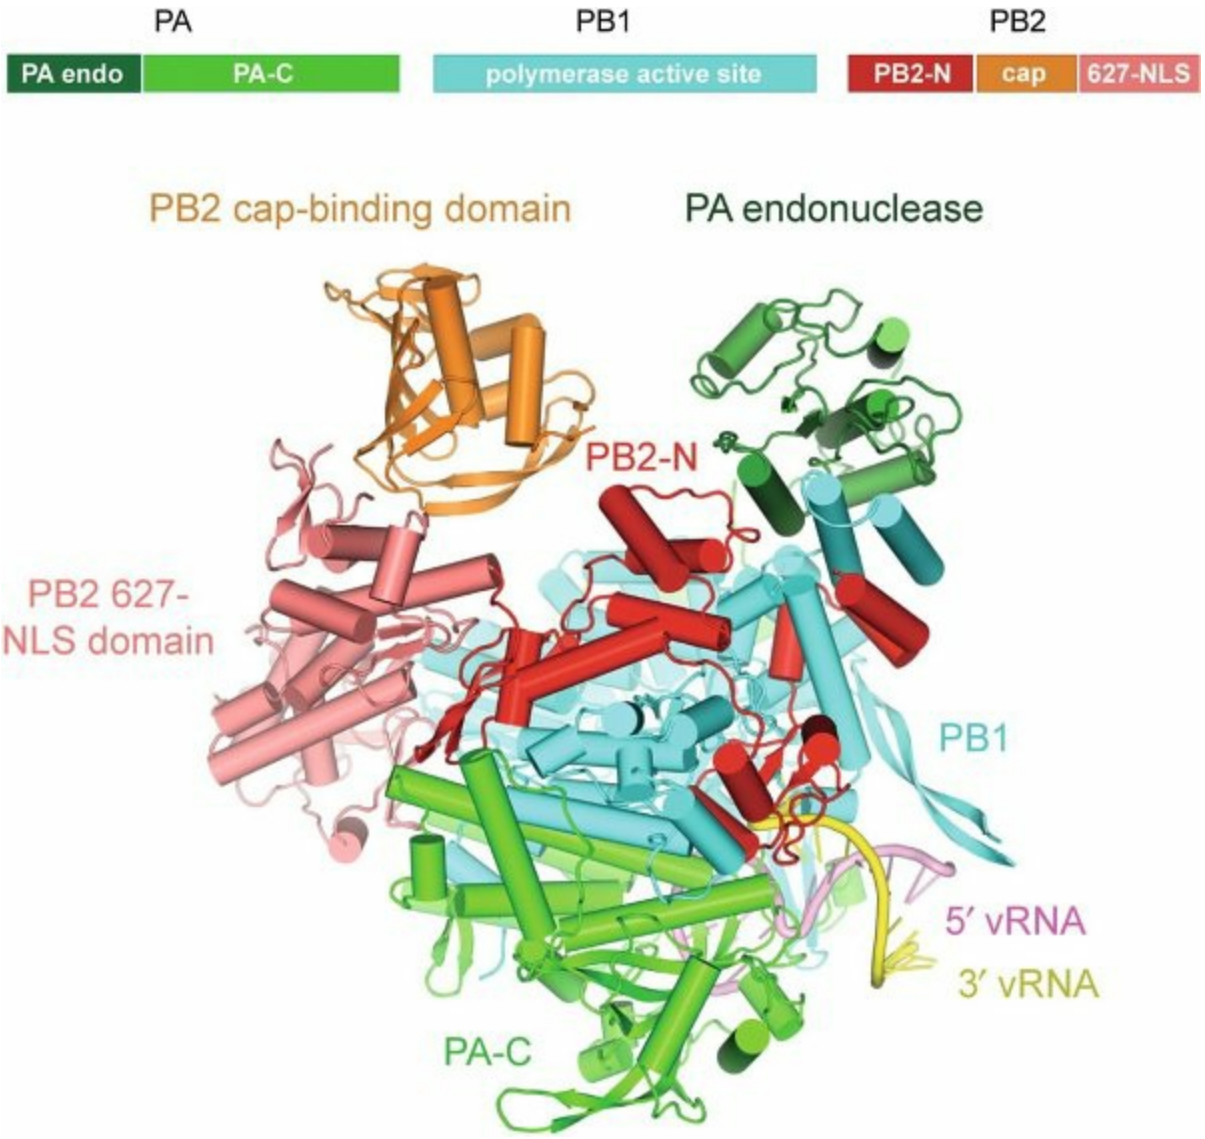

FIGURE 14.17 Structure of the heterotrimeric influenza polymerase, bound to the viral RNA promotor (ribbon representation, color-coded according to the scheme above). The 3′ end of the promotor is shown in *yellow* and the 5′ end in *pink*. The domain organization of the subunits is shown above. (Courtesy of Maria Lukarska and Stephen Cusack, European Molecular Biology Laboratory.)

The PB1 proteinThe PB1 protein catalyzes the sequential addition of nucleotides during RNA chain elongation[77] and contains the conserved

motifs characteristic of RNA-dependent RNA polymerases.[58] The active site for the polymerization activity is an S–D–D motif at positions 444 to 446.[58] The PB1, or more precisely the polymerase core, consisting of the PB1, the C-terminal domain of PA (PA-C), and the N-terminal domain of PB2 (PB2-N), is also responsible for binding to the terminal ends of both vRNA[312,537] and cRNA[313] for initiation of transcription and replication (Fig. 14.18).[712,743]

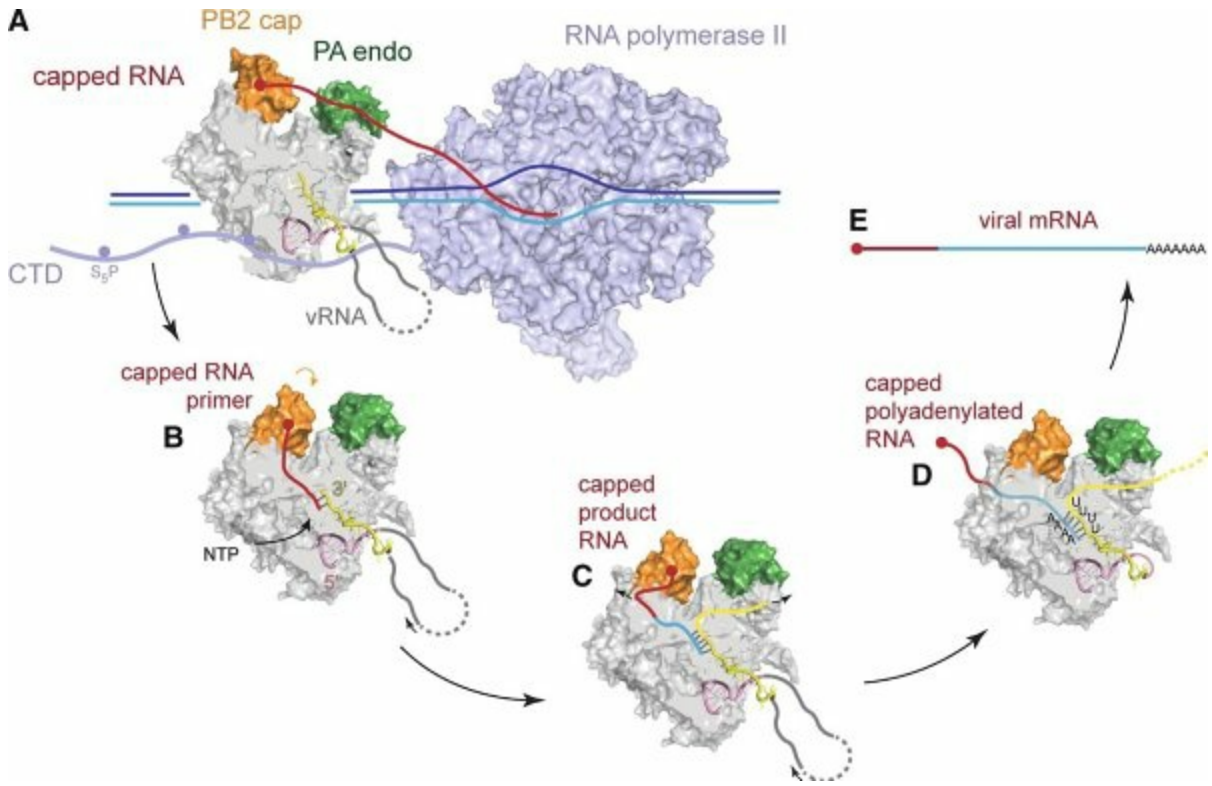

FIGURE 14.18 Schematic representation of the transcription cycle of influenza polymerase. A: Cap snatching: association with the Ser5-phosphorylated C-terminal domain of RNA polymerase II brings the influenza virus polymerase in proximity to the nascent capped transcript, which is recognized by the PB2 cap-binding site and cleaved by the endonuclease activity around 10 to 15 nucleotides after the cap. The conserved ends of the viral RNA are bound to the polymerase (*pink* and *yellow* for 5′ and 3′ end, respectively). **B:Transcription initiation:** the cap-binding domain rotates by about 70 degrees to direct the capped RNA primer into

the active site of the polymerase, where it serves to initiate transcription of the vRNA segment at the 3′ end of the template (*yellow*). **C: Elongation:** incorporation of NTPs leads to elongation of the capped transcript and translocation of the template. **D: Termination/polyadenylation:** near the end of the template, the polymerase stutters over a oligouridine stretch, while the 5′ hook remains tightly bound to the polymerase, producing a poly(A) tail. **E:** The product of the transcription cycle is a hybrid RNA, containing a cap and a host-derived sequence at its 5′ end (*red*), the coding sequence of the viral segment (*blue*) and poly(A) tail. (Courtesy of Maria Lukarska and Stephen Cusack, European Molecular Biology Laboratory.)

The PB2 protein

The PB2 protein plays a critical role in the initiation of transcription as it is responsible for binding the cap on host pre-mRNA molecules (Figs. 14.17 and 14.18).[60,713,904] Despite earlier discrepancy in the position of the binding site, it has now been shown that a domain encompassing PB2 residues 318 to 483 is sufficient for cap binding[327] and confirms the findings of a mutagenesis study that identified two aromatic residues (F363 and F404) as being important for the interaction.[240] PB2 has also been shown to localize to mitochondria, and this is determined by an N-terminal mitochondrial-targeting signal.[112] However, avian influenza viruses have a polymorphism in this signal, so it appears that mitochondrial localization of PB2 is unique to human influenza viruses.[317] Finally, as well as interacting with PB1 via its N-terminus,[860] the PB2 is also reported to interact with PA.[373] The PB2 also participates in genome replication as mutations affecting this activity but not transcription have been reported.[299]

The PA protein

Until several years ago, the specific function of PA was unknown, but crystal structures of the N-terminal domain revealed that the endonuclease activity of

the polymerase, which is required to generate the capped primer, resides in the PA protein (Figs. 14.17 and 14.18).[191,712,1017] Previous work had mistakenly attributed this function to the PB1 protein. In the structure, the fold and position of the active site identify the PA endonuclease as a member of the PD-(D/E)XK family of nucleases. The catalytic site involves residues His 41, Glu 80, Asp 108, Glu 119, and Lys 134 and harbors two $Mn^{(2+)}$ ions.[170,191] Mutation of these residues abolishes the transcriptional activity of the trimeric polymerase, but replication activity is unaffected, confirming the specific role of the endonuclease in viral transcription.[170,1017] PA does, however, participate in genome replication as mutations affecting this process have been described.[252,410] In addition to encoding nuclease function, the N-terminus of PA (aa 1–100) is also involved in an interaction with PB2,[373] while the C-terminus makes contact with PB1.[713]

The vRNA Promoter

All influenza virus RNA segments contain noncoding sequences at their 5′ and 3′ ends, which flank the coding region. Some of this sequence is segment specific,[1036] but the terminal ends are highly conserved between all segments in all influenza viruses. These conserved 13 nucleotides at the 5′ end and 12 nucleotides at the 3′ end display partial and inverted complementarity, which led to the proposal of a panhandle structure created by base pairing of the 5′ and 3′ ends.[189,758] This is supported by cross-linking experiments that demonstrated a circular configuration for virion RNAs[402] as well as by more recent structural analyses.[29,577] The panhandle model was refined to incorporate a fork model and a corkscrew style conformation.[249] Studies using *in vitro* transcription of model RNA templates or reporter gene expression *in vivo* have shown that both 5′- and 3′-terminal ends are necessary for promoter activity and that base pairing is required.[250,649] Furthermore, it has been demonstrated that the polymerase can interact with both 5′ and 3′ ends and that the binding affinity decreases when the duplex is disrupted.[254,312,334,520,887] A full understanding of the promoter has been obtained following the successful x-ray analysis of the bat influenza virus polymerase complex by S. Cusack and his group (Fig. 14.19).[693,743,753,891] These data define the vRNA promoter as an element that features a double-stranded region created by pairing between 5′ and 3′ ends, forking of ssRNA

for the 5′ end and a hairpin on the 5′ end making a partial corkscrew.[662,712,743]

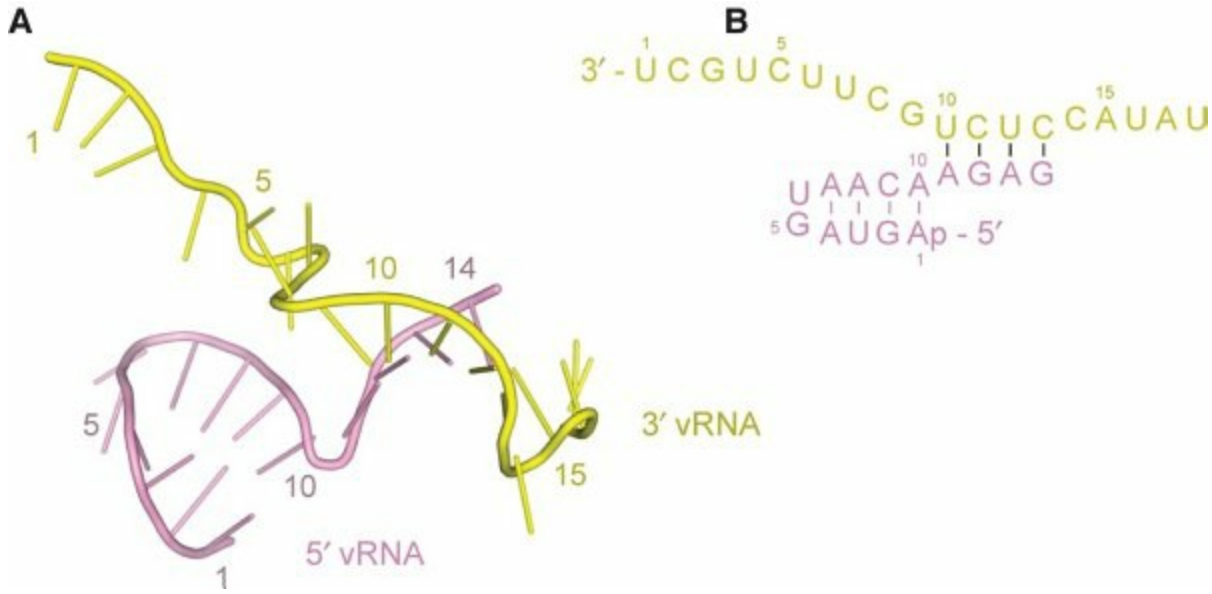

FIGURE 14.19 A: Structure of the vRNA promotor, bound to the polymerase, showing the 5′ hook and the distal base-pairing region between the 5′ and 3′ ends. **B:**Schematic diagram of the 5′ and 3′ end of the vRNA promotor, with base pairing indicated with lines. (Courtesy of Maria Lukarska and Stephen Cusack, European Molecular Biology Laboratory.)

While the need for base pairing of the 5′ and 3′ ends is clear, the stem–loop structures are also involved in binding and stabilizing the polymerase complex.[85]

Initiation of Messenger RNA Synthesis

Influenza virus mRNA synthesis is dependent on cellular RNA polymerase II activity. This is because it requires a 5′-capped primer, which it steals from host pre-mRNA transcripts, to initiate its own mRNA synthesis.[721] This process is known as cap snatching and involves the cap-binding function of the PB2 protein and endonuclease function of the PA protein. The initiation

of transcription commences with binding of the 5′ end of the vRNA to the PB1 subunit (Fig. 14.18). This induces an allosteric change in the polymerase, which allows the PB2 protein to recognize and bind the cap structure on host pre-mRNAs.[148,239,537,713] This structural change in the polymerase also increases its affinity for the 3′ vRNA end, which is bound by PB1. Endonuclease activation leads to cleavage of the bound mRNAs and small nuclear RNAs.[322,479] This occurs approximately 10 to 14 nucleotides from their 5′ caps, usually after a purine residue.[44,721] Transcription is then initiated by the addition of a "G" residue to the primer, directed by the penultimate "C" nucleotide at the 3′ end of the vRNA template,[44] although in some instances the incorporation of a "C" that is directed by the "G" at position 3 in the vRNA has also been observed.[255] Unlike influenza viruses, Thogoto viruses lack host-derived sequences at the 5′ end of their capped mRNAs.[955] RNA chain elongation is catalyzed by the polymerase function of PB1 and continues until a stretch of uridine residues is encountered approximately 16 nucleotides before the 5′ end of the vRNA.[535,557,759] This is the signal for polyadenylation (Fig. 14.18).[713]

Polyadenylation

Unlike host cells, which use a specific poly(A) polymerase for generating the poly(A) tail on mRNA transcripts, polyadenylation of influenza virus mRNAs is catalyzed by the same polymerase that is used for transcription. This activity is dependent on an uninterrupted stretch of five to seven "U" residues and the adjacent double-stranded region of the vRNA promoter.[535,557,759] The current model proposes that the 5′ end of the vRNA remains bound to the polymerase during elongation while the template is threaded through in a 3′ to 5′ direction (Fig. 14.18).[713] In support of this model, mutations introduced into the 5′ end of the vRNA that prevent or weaken polymerase binding have been shown to also inhibit polyadenylation.[253,725,732,733] The polyadenylation signal is vital for gene expression as replacement of the uridines with adenosines has been shown to result in transcripts with poly(U) tails, which fail to be properly exported from the nucleus.[724]

Splicing

Members of the *Orthomyxovirus* family can extend the coding capacity of their genomes by producing two proteins from one gene via an alternative splicing mechanism. *Orthomyxovirus* genome segments that encode proteins from both spliced and unspliced mRNA transcripts include segments 7 and 8 of influenza A virus,[504,507] segment 8 of influenza B virus,[82] segments 6 and 7 of influenza C virus,[638,994] segment 6 of Thogoto virus,[474] and segment 7 of isavirus[56] (see Genome Structure and Organization section). The primary transcripts from these segments have 5′ and 3′ splice sites, which (more or less) fit the consensus sequence for the exon/intron boundaries of cellular transcripts. This, combined with the fact that splicing can be demonstrated in the absence of any viral proteins,[505,506] indicates that the virus is using the cellular splicing machinery. However, unlike cellular splicing, which is extremely efficient, splicing of viral mRNA has to be relatively inefficient because proteins must be expressed from both spliced and unspliced mRNAs. In influenza virus–infected cells, splicing is tightly regulated such that the steady-state level of spliced viral transcripts is only 10% that of the unspliced viral transcripts.[503,507] These control mechanisms may act on several different levels. The rate of nuclear export of the unspliced transcript is certainly crucial as this determines its availability for splicing. It has been proposed that the NS1 protein inhibits both the splicing and nuclear export of NS1 transcripts via negative feedback,[9,293] but contradictory reports[751] suggest that alternative mechanisms may exist for regulating splicing of viral transcripts. Potentially, these may involve *cis*-acting sequences in the NS1 transcript that negatively control the rate of splicing.[8,648] Strangely, the influenza C virus NS1 protein (C/NS1) has been reported to up-regulate viral mRNA splicing.[625] Splicing of the influenza A virus M1 transcript is controlled by the aforementioned rate of nuclear export[906] as well as by the viral polymerase and a cellular splicing factor, SF2/ASF. The polymerase determines the time at which splicing (and hence production of M2) occurs and SF2/ASF is required to activate splicing.[811,813] Other host proteins have also been shown to modulate splicing of influenza virus RNAs.[260,884,899]

Replication Products: cRNA and vRNA

Full-length copies of the incoming vRNAs have to be made, and these positive-sense cRNAs serve as templates for the synthesis of new negative-

sense genomic vRNAs. The cRNA promoter is complementary to the vRNA promoter and has also been reported to assume a corkscrew configuration, albeit with subtle differences.[28,174,697,753,1036] This variation has been implicated in determining whether or not the endonuclease function of the polymerase is activated and therefore may play an important regulatory role.[515]

The Switch from Transcription to Replication

The vRNA serves as a template for both mRNA and cRNA synthesis, and yet the means of initiation and termination for the generation of these two molecules are quite different. In contrast to the primer-dependent mechanism of initiation of mRNA synthesis, initiation of cRNA synthesis occurs without a capped primer, and cRNA molecules are full-length copies of the vRNA and thus are not prematurely terminated and polyadenylated as are mRNAs. The different initiation and termination reactions therefore have to be coordinated, but exactly how the polymerase switches between these two modes is still not well understood. It has been proposed that the transcription-competent polymerase is structurally different from the replication-competent polymerase. Support comes from evidence that different domains of PB1 are involved in binding vRNA versus cRNA and that PA is more critical for binding the cRNA than the vRNA promoter.[313,374,564,877,882] One obvious difference is that the cap-binding and endonuclease functions of PB2 and PA, respectively, are not required when the polymerase is in replication mode.

In contrast to mRNAs, newly synthesized cRNAs and vRNAs are encapsidated. It has been proposed that the availability of soluble NP (i.e., not associated with RNPs) controls the switch between mRNA and cRNA synthesis. This hypothesis arose from the observation that replication is dependent on *de novo* protein synthesis, which means that the incoming RNPs are only capable of transcription.[360] Indeed, free NP has been shown to be required for production of full-length cRNA (antitermination),[45] and this is consistent with data from temperature-sensitive (ts) NP mutants,[489,591,802] which show that cRNA but not mRNA synthesis is affected at the nonpermissive temperature. However, this model has been challenged by a report demonstrating that overexpressed NP does not promote replication.[624] Another study disputes the existence of a switch, instead suggesting a

stabilization role for NP and the polymerase.[926] This model claims that the incoming polymerase is able to synthesize both mRNA and cRNA,[922] but until there is a sufficient pool of polymerase and NP to encapsidate the cRNA, it is degraded and therefore at early times postinfection there is a bias toward mRNA accumulation. Also, requirements for higher nucleotide concentrations to initiate cRNA synthesis may determine the timing of transcription versus replication.[925] Furthermore, the accumulation of NEP is associated with a decrease in transcription and an increase in replication, suggesting a regulatory role.[97,752] Interestingly, NEP is also required for the generation of small viral RNAs (svRNAs), which have been implicated in the initiation of vRNA synthesis.[709] The svRNAs are 22 to 27 nt in length and correspond to the 5′ end of each vRNA segment. These segment-specific svRNAs are needed for vRNA but not cRNA synthesis, so according to this model the polymerase is in replication mode when these svRNAs are present. It has also been proposed that the switch from transcription to replication is the result of accumulation of a newly synthesized free polymerase complex, which enhances cRNA to vRNA synthesis (and vice versa) over mRNA synthesis.[441] The role of host factors in regulating influenza virus replication, including posttranslational modification of viral proteins, should also be considered.[69,132,442,542,584,607,609,611,612]

Regulation of Viral Gene Expression

Early studies have provided evidence for temporal regulation of viral gene expression,[360,829] but the mechanism(s) is (are) still unresolved. Disproportionate accumulation of mRNAs from the different segments has been observed, but whether this represents specific up-regulation of transcription for these segments[232,357] or reflects different rates of vRNA synthesis[801,829] or RNA stability is unclear. Regardless, the synthesis of NP and NS1 mRNAs and protein is favored at early stages, whereas the synthesis of HA, NA, and particularly M1 mRNAs and proteins is delayed.[357,360,801,829] This differential expression is mirrored by the roles these proteins play at different points in the virus life cycle. As discussed earlier, NP is required for replication and NS1 plays a crucial role in combating the host immune response; thus, both of these proteins are needed early in the virus life cycle. M1 has been found to inhibit viral transcription,[707,947] which demands its

delayed expression, and at later stages, M1 accumulation probably dictates the arrest of viral mRNA synthesis. M1 is also involved in the export of RNPs from the nucleus,[576] which must only occur once replication is complete.

Another control mechanism for differential gene expression resides in the vRNA promoter. A natural variation is found at position 4 from the 3′ vRNA end in an otherwise totally conserved region. The PB1, PB2, and PA RNA segments have a “C” at this position, while the remaining segments usually have a “U.” The C4-containing promoter is associated with a down-regulation in transcription and an up-regulation in replication compared to the U4 promoter,[523] which correlates with the lower amounts of polymerase mRNAs and proteins found in infected cells.[360,829] A structural analysis of the C4 and U4 promoters has revealed differences that may alter their interaction with the polymerase and thereby regulate gene expression.[516]

As observed with many other viruses, influenza virus gene expression is also controlled at the level of translation. This is achieved via numerous mechanisms and results in the selective translation of viral genes and suppression of host protein synthesis.[281,924,1003] These mechanisms include (a) degradation of host pre-mRNAs following cleavage (due to cap snatching), (b) inhibition of host mRNA processing, (c) degradation of cellular RNA polymerase II, and (d) preferential translation of viral mRNA transcripts. Several of these processes involve the influenza virus NS1 and PA-X proteins. The NS1-mediated and PA-X–mediated effects on mRNA processing are discussed in a later section (see below). NS1 is also involved in the specific translational enhancement of viral mRNAs through its association with the 5′ noncoding region of viral mRNA transcripts and with cellular proteins involved in translation initiation.[16,99,698] These include the translation initiation factor eIF4GI and poly(A)-binding protein 1, and it has been proposed that this protein complex acts to specifically recruit ribosomes to the 5′ end of viral mRNA transcript. Another cellular protein that may play a role is GRSF-1, an RNA-binding protein that has been reported to interact with the 5′ end of the NP transcript and to stimulate the specific translation of a template driven by the NP 5′ noncoding region in a cell-free translation system.[454,699] Whether this interaction is relevant *in vivo* remains to be determined.

An interesting model explaining the selective translation of viral mRNAs has been proposed suggesting that the viral polymerase complex remains associated with the viral mRNA transcript in the cytoplasm. It is thought that this interaction eliminates the need for complex formation with eIF4E. Since eIF4E is inactivated in influenza virus–infected cells,[241] this would explain the selective translation of viral transcripts over cellular transcripts. Other components of the translation machinery, such as eIF4A and eIF4G, are required for influenza viral protein translation.[1001] Although this model is compelling in its simplicity, this mechanism is questioned by the finding that viral mRNAs in the cytoplasm are devoid of viral polymerase but are associated with cellular cap-binding proteins, including eIF4E.[55] Clearly, further investigation is required to explain the selective translation of viral transcripts in infected cells.

An additional host shutoff mechanism is controlled by the viral polymerase at the level of host transcription. It has been shown that the influenza virus polymerase interacts with the C-terminal domain of the large subunit of cellular RNA polymerase II[235] and that this interaction mediates the degradation of RNA polymerase II at late times postinfection.[763,923] This shutoff mechanism may play a role in viral pathogenicity because attenuated influenza viruses have been shown not to induce RNA polymerase II degradation.[762] Another mechanism involves the reduction of free RNA polymerase II due termination defects.[42,1034]

Virus Assembly and ReleaseNuclear Export of RibonucleoproteinsAssociation of RNP complexes with M1

Following virus replication, newly formed RNP complexes are assembled in the nucleus from which they are then exported into the cytoplasm. Two viral proteins, the matrix (M1) protein and the NEP, are involved in directing the nuclear export of RNPs[72,173,416,499] in a proposed daisy chain model in which M1 binds to the RNP complexes and NEP then binds to M1.[499] Our present understanding of this process indicates that M1 associates with RNPs in the nucleus, a process potentially facilitated by the host protein clustered mitochondria homolog (CLUH).[13] This association may actually promote the

formation of RNP complexes.[409] M1 makes contact with both the vRNA and NP,[41,173,645,1006] and evidence that M1 also binds to nucleosomes[294,1039] has led to the hypothesis that M1 interactions cause the dissociation of RNP from the nuclear matrix. This agrees with the significant finding that nuclear import of M1 is required for subsequent export of RNP complexes.[96,576] Furthermore, at high temperatures, heat shock protein 70 is found bound to RNP, which prevents association with M1 and results in a block in RNP export.[384,780] It has been reported that sumoylation of M1 is essential for its nuclear export function.[983] An alternative to the daisy chain model has also recently been proposed in which the C-terminal part of NEP interacts with both PB2 and PB1 and facilitates binding of M1 to NP and vRNA.[88] In this model, the N-terminal part of NEP then interacts with Crm1. This model is attractive since it has recently been shown that the polymerase complex can assume different conformations when bound to cRNPs and vRNPs.[499] Selective binding of NEP to the vRNP polymerase conformation in this model might regulate the export of vRNP versus cRNPs.

NEP interacts with the cellular export machinery

Initial data suggested that M1 alone could control RNP export, but as is the case for import, nuclear export of large molecules involves direct interactions with the cellular export machinery and no such interactions with M1 had initially been demonstrated. However, NEP has been found to interact with the export receptor Crm1[651] and several nucleoporins.[123,670] NEP also associates with M1,[4,816,1004] so the current model proposes that an RNP–M1–NEP complex is formed in the nucleus and that NEP is responsible for recruiting the export machinery and directing export of the complex (Fig. 14.16B). In support of this role, it has been shown that injection of anti-NEP antibodies into the nucleus of infected cells inhibits RNP export,[670] which is also seen in a system using recombinant virus-like particles (VLPs) lacking NEP.[651] A methionine/leucine-rich and a leucine-rich nuclear export signal (NES), NES1 and NES2, respectively, have been identified in the N-terminus of NEP[407,670] and shown to be critical for RNP export and virus growth.[407,426,651] NES2 potentially interacts directly with Crm1, while NES1's contribution might be indirect by involving host factor chromodomain–helicase–DNA-binding protein 3 (CHD3) since it does not

interact with Crm1.[403,407,651] Treatment with leptomycin B, a Crm1 inhibitor, completely inhibits RNP export in infected cells, which indicates that export does occur in a Crm1-dependent manner.[230,426,952] Interactions between Crm1 and the RNP–M1–NEP complex have been shown to occur at chromatin structures rich in Ran nucleotide exchange factor Rcc1, a protein that generates Ran-GTP, which in turn activates Crm1.[119,878]

Another viral protein, NP, has also been shown to bind to Crm1 and to the NTF2-related export protein 1 (NXT1)[145,230] and therefore is proposed to play a role in export as well as import. Both this study and another also revealed that RNPs are localized to the periphery of the nucleus after leptomycin B treatment but that M1 and NEP retain diffuse nuclear staining.[230,561] The RNPs were shown to colocalize with nuclear lamins just beneath the nuclear pore complex, which may represent an intermediate step prior to export through the pore.[561] The roles of M1 and NEP are obviously called into question by their differing staining pattern compared to RNPs,[230,561] but this could be explained if only a fraction of the total M1 and NEP pool was used for export. In addition to potential involvement of NP in nuclear export of vRNPs, an NES on M1 has been identified recently as well. Removal of this NES impaired export of RNPs and suggests that M1 might have a more active role in nuclear export than previously thought.[109] These findings raise the possibility that redundant export mechanisms may exist. Already in the nucleus, the RNP–M1–NEP complexes associate with Y-box–binding protein 1 (YB-1), which is coexported from the nucleus and likely facilitates interactions with microtubules at microtubule-organizing centers (MTOCs). There, the RNPs are thought to be delivered to Rab11a-positive recycling endosomes.[457]

Regulation of RNP export

As discussed earlier, the late expression of M1 determines that export takes place only after a full round of replication has occurred, therefore preventing premature exit of RNPs from the nucleus. The process is also controlled by a number of other mechanisms including the enlargement of nuclear pores by caspases induced by virus replication and the slow accumulation of NEP in the nucleus due to inefficient splicing.[144,621] Similarly, control mechanisms must also exist to stop the re-entry of RNPs into the nucleus following

export. Studies with a temperature-sensitive virus (ts51) showed that when grown at the nonpermissive temperature, this virus is unable to retain its RNPs in the cytoplasm following export.[965] This defect mapped to M1,[966] once again demonstrating the vital role of this protein in regulating the nucleocytoplasmic transport of RNPs. It is interesting to note that the canonical NEP-binding site on M1 maps to the M1 NLS,[4] which suggests that NEP may act to mask the NLS on M1 and therefore prevent the complex from re-entering the nucleus. NP is also proposed to cause the cytoplasmic retention of RNPs by binding to filamentous actin and thereby anchoring the RNPs in the cytoplasm.[192] All these processes are likely to be regulated at some level, and protein modification by phosphorylation is probably involved as several studies have reported alterations in M1, NEP, and NP trafficking in the presence of kinase inhibitors.[93–95,594,720,744,966]

RNP export in influenza B and C viruses

Few studies concerning export in influenza B and C viruses have been performed, but it has been shown that as with influenza A viruses, the NEP proteins possess nuclear export activities.[696] They both have been shown to interact with Crm1 (and a subset of nucleoporins), and NES motifs have been defined for each protein. Similar to that of influenza A viruses, the influenza C virus NES is composed of two separate leucine-rich domains, both of which are required for full activity.[696] In contrast to influenza A virus where M1 acts as a bridge between NEP and the RNP complex, the influenza B NEP has been proposed to bind directly to the RNP as well as to M1,[420] which suggests that the model for export of influenza B virus RNPs may be slightly different than the canonical model for influenza A virus. Interestingly, the influenza B virus M1 protein also contains two NES motifs that could be involved in export of RNPs.[108] Not much information is available for RNP export of influenza D virus, but it can be assumed—based on the genome structure and the presence of an M1 and NEP protein—that the mechanisms are likely similar to those for influenza C virus.[855]

The Site of Virus Assembly and Budding

Influenza viruses assemble and bud from the apical plasma membrane of polarized cells (e.g., lung epithelial cells of the infected host)[477,761,770] (Fig.

14.20). This asymmetrical process (i.e., apical vs. basolateral) is thought to have an important role in viral pathogenesis and tissue tropism. Viruses that bud from the internal cell surface (e.g., Marburg virus) tend to cause systemic disease, whereas viruses, such as influenza virus, that bud from the external cell surface generally have a more restricted tissue tropism.[242] The influenza virus HA, NA, and M2 have all been shown to localize to the apical surface of polarized cells when expressed alone,[411,439,772] and apical sorting signals have been identified within the TMDs of HA and NA. The vRNPs are thought to arrive at the site of virus assembly and budding in a Rab11-dependent manner although the exact mechanism is still unclear.[499]

The M1 protein

M1 is the most abundant virion protein and lies just beneath the lipid envelope where it is believed to make contact with the cytoplasmic tails of the glycoproteins and with the RNPs, thereby forming a bridge between the

inner core components and the membrane proteins.[770] Structural analyses indicate that the M1 protein consists of two globular helical domains that are linked by a protease-sensitive region.[21,353,799] Rods (6 nm in length) corresponding to M1 monomers have been observed by negative-stain EM of virions with one end in contact with the membrane and the other end pointing toward the interior of the particle.[4] These rods form an ordered structure consistent with the homo-oligomerization properties of M1[106,1030,1032] and are arranged such that the positive and negatively charged residues are on opposite sides of the oligomer.[21,353] Several reports have documented the ability of M1 to associate with lipid membranes,[231,383,774,1026] and as mentioned previously (see section on Nuclear Export of Ribonucleoproteins), M1 interacts with both RNPs and NEP. M1 also interacts with the cytoplasmic tail of M2.[124] Therefore, it is proposed that M1 plays a vital role in assembly by recruiting the viral components to the site of assembly at the plasma membrane.

Assembly of Viral Components

Following synthesis on membrane-bound ribosomes, the three integral membrane proteins, HA, NA, and M2, enter the ER where they are folded and HA and NA are glycosylated. There, it is traditionally believed that the HA is assembled into a trimer, assisted by membrane protein translocator SEC61, and NA and M2 are assembled into tetramers.[196,368] However, it has recently also been shown that trimer assembly for HA might occur at a later stage in the Golgi network.[563] Of note, M2 associates with the E3 ubiquitin–protein ligase UBR4 in the ER. UBR4 has been shown to be required for effective shuttling of M2 to the plasma membrane as is ubiquitination of M2 (but not by UBR4).[857,898] Lack of UBR4 or ubiquitination leads to transport of M2 to the autophagosome.[857,898] HA, NA, and M2 are subsequently transported to the Golgi apparatus where cysteine residues on HA and M2 are palmitoylated in the *cis*-Golgi network and M2 is acetylated.[842,861,913–915] For those HAs that have a multibasic cleavage site (e.g., some H5 and H7 subtypes), furin cleavage of HA into HA1 and HA2 subunits may occur in the *trans*-Golgi network.[849] From here, HA, NA, and M2 are all directed to the virus assembly site on the apical plasma membrane via their apical sorting signals. The signals for HA and NA have been described to reside in their

TMDs.[36,495,544,976] The TMDs of HA and NA also contain the determinants for association with lipid rafts.[35,36,544] Lipid rafts are proposed to be nonionic detergent-resistant lipid microdomains within the plasma membrane that are rich in sphingolipids and cholesterol. The significance of lipid rafts/transient lipid nanodomains for virus budding is still controversial and an area of ongoing research.[311,528,798,835] However, the lipid raft model is helpful in explaining influenza virus assembly and budding, and examination of the lipid content of purified virus particles indicates that influenza virus might bud preferentially from these domains.[784,1028] HA and NA individually also selectively accumulate at and are incorporated into rafts.[495,785] Also, it has been shown that reduction of cholesterol levels in the plasma membrane impacts negatively on titers of progeny virus, while increases in cholesterol levels positively affect titers.[633] The signals for apical sorting and raft association both lie within the TMD and are not mutually exclusive.[35,183,645] Raft association of HA has been shown to be essential for efficient virus replication.[869] This is thought to be because of a requirement for concentrated "patches" of HA at the plasma membrane, which governs the level of HA incorporation into budding particles and subsequently affects fusion. A similar scenario holds for raft association of NA, as an optimal amount of NA must be incorporated to allow for efficient virus release.[35] Coexpression of HA and NA seems to induce raft clustering leading to acceleration of their apical transport.[673] It is important to mention that a recent study using high-resolution secondary ion mass spectroscopy in fibroblasts found that there was no enrichment of cholesterol or sphingolipids in HA clusters on the cell membrane, which questions the significance of lipid rafts for influenza virus assembly and budding.[968] While not mutually exclusive with lipid raft–based mechanisms, clustering of HA has recently also been associated with actin-rich membrane regions (ARMRs) that lacked cofilin providing an alternative mechanism for the formation of HA nanoclusters.[326] In contrast to HA and NA, the majority of M2 protein is excluded from lipid rafts,[1028] which may reflect its low abundance in virus particles. M2 has been shown to bind cholesterol, and this property is suggested to target M2 to the raft periphery where it may act to bridge several raft domains.[791] Mutation of the cholesterol recognition/interaction amino acid consensus (CRAC) motif in M2 is reported to affect membrane targeting but not raft association,[879–881] and in the context of infection, it is shown to attenuate the virus *in vivo* but

not in tissue culture.[848] There is also evidence that M2 is involved in capturing the RNPs at the assembly site. Experimental evidence for this mechanism was first demonstrated with an influenza B virus that lacked BM2 expression and produced particles devoid of RNPs.[419] Subsequently, mutation or truncation of the influenza A virus M2 cytoplasmic tail has been shown to correspond with decreased incorporation of genome segments into virions.[319,427,587,588,857]

In comparison to the integral membrane proteins, less is known about how the remaining viral components reach the assembly site. A long-standing hypothesis is that M1 acts as the master recruiter dictated by its position between the viral envelope and the RNP core. This is supported by evidence that the availability of M1 affects the timing of assembly and maturation, as seen with a virus engineered to express reduced levels of protein from the M segment.[74] This virus showed no defects in virion protein composition but displayed delayed growth kinetics, suggesting that a minimum amount of M1 protein must accumulate before assembly can begin. The association of M1 with the RNP–NEP complex is well described (see section on Nuclear Export of Ribonucleoproteins), but the specific interaction of M1 with the membrane-bound glycoproteins has been difficult to prove because of M1's intrinsic membrane-binding properties, which has resulted in some conflicting reports.[231,487,1026] However, it was noted that in influenza virus–infected cells, M1 becomes resistant to extraction with Triton X-100 (a marker for lipid raft association), whereas M1 expressed alone remains soluble.[6,1026] This suggested a role for other viral proteins, and indeed, coexpression of HA and NA together with M1 has been shown to promote raft association of M1.[6] This requires the TMDs and cytoplasmic tails of HA and NA,[6,1028] and in the absence of the cytoplasmic tails of these two proteins, virus particles have been found to be grossly distorted, which perhaps indicates reduced M1 association.[436] A recent study using EM, electron tomography, and cryoelectron tomography also showed that, while expression of HA, NA, or HA and NA led to the formation of particles, only coexpression of the M proteins clustered the glycoproteins together into filamentous membrane protrusions and led to the formation of particles with characteristics similar to authentic budding virus.[139]

The hypothetical model for transport of M1 to the plasma membrane proposes that M1 becomes associated with the glycoproteins during their

passage through the exocytic pathway and “hitches a ride” to raft domains in the apical membrane. The initial model also proposed that M1 was taking the RNP–NEP complex with it. However, the current working hypothesis is that the vRNPs use the cytoskeleton to reach the virus assembly site. This is based on the finding that RNPs can interact with cytoskeletal components and Rab11.[12,25,86,141,218,610] In this model, vRNP–M1–NEP complexes delivered to microtubules at MTOCs by YB-1 (as described above) lead to an interaction between PB2 and Rab11.[12,26,457] Interactions between human immunodeficiency virus Rev-binding protein (HRB) and potentially between NP and actin might also play a role early in this process.[25,192,219] It is unclear if M1 and NEP disassemble from the RNPs at this point or if they stay attached. While costaining of RNPs and Rab11 has been observed, interactions with M1 have not been detected in the cytoplasm, although M1 can interact with cytoskeletal components.[12,25,610] Rab11 proteins are small GTPases that are involved in transport of recycling endosomes. These Rab11a-containing recycling endosomes can be transported along microtubules or along actin filaments.[907] This might provide an explanation why inhibition of microtubules[12,608] or actin filaments[18,492,755,823] on their own does not drastically impact influenza virus replication. It remains controversial if Rab11-based RNP transport is mainly microtubule-[12,26,608] or actin filament–dependent.[18,492] However, an intact cytoskeleton has only been found to be necessary for the production of filamentous virus particles,[755,823] so a specific role in assembly remains to be confirmed. Interestingly, a recent report suggested that the RNPs are transported in a Rab11a-dependent manner on infection-induced irregular coated vesicles associated with a reorganized tubulated endoplasmatic reticulum that stretches throughout the cell to the plasma membrane.[181] Independent of the transport mechanism, it has been observed using fluorescent *in situ* hybridization that different RNPs start to colocalize in the cytoplasm. This colocalization is associated with Rab11 and suggests that Rab11-positive vesicles facilitate association of different RNPs.[141,500] It was recently suggested that RNPs could then be transferred from Rab11-positive vesicles to the plasma membrane by interaction of NP with phosphatidylinositol 4,5-bisphosphate, a component of lipid rafts.[447] Finally, there is evidence that NP alone is intrinsically targeted to the apical plasma membrane and associates with lipid rafts in a cholesterol-dependent manner, which suggests that RNPs

could reach the assembly site independently of the cytoskeleton.[113] How exactly the RNPs reach the plasma membrane is an ongoing area of research and future studies will bring more clarity.[11]

Packaging of Eight RNA Segments

Correct assembly and packaging of a full complement of RNA genome segments is a requirement for a fully infectious virion. The precise mechanism of packaging of the eight vRNA segments is still not well understood, although different models have been proposed. The first model, *the random incorporation model*, assumes that a common structural feature is present on all vRNAs (vRNPs), which enables them to be randomly incorporated into budding virions. This model is supported by evidence that virions may possess more than eight vRNPs, ensuring the presence of a full complement of eight vRNPs in a significant percentage of virus particles.[33,234,290] Mathematical analysis of packaging suggests that if eight RNA segments were randomly packaged into budding virions, only 0.24% of released virus particles would be infectious.[234] However, if a greater number of RNA segments were randomly packaged, then the percentage of infectious particles increases.[84,160,197]

The second model, *the selective incorporation model*, suggests that each vRNA segment acts independently, allowing each segment to be packaged selectively. A similar model has been reported for the packaging of the 3 double-stranded RNA (dsRNA) segments of bacteriophage-ϕ6[602] and for the packaging of the 11 dsRNA segments of rotavirus (RV).[589] This model suggests that each vRNA segment contains a unique “packaging signal” and predicts that every virion possesses a full complement of the eight vRNP segments. There is increasing evidence to support this model. The precise number of vRNPs packaged in a single virion has been determined by imaging of serially sectioned budding virions using EM and electron tomography.[261,262,643,663,664] The vast majority of virions from influenza A and B viruses appear to contain exactly eight vRNPs organized in a distinct pattern: one in the center and seven in the surrounding positions (1+7 configuration).[663] The eight vRNPs are oriented perpendicular to the budding tip. These findings were also corroborated by multicolor single-molecule fluorescent *in situ* hybridization.[142] In addition, the existence of packaging

signals within the noncoding and coding regions at both the 5′ and 3′ ends of the genomic RNAs has been confirmed (Fig. 14.21).[574] Coding regions of the NA[267]; HA[954]; NS[266]; PB2, PB1, and PA[150,540,630]; NP[682]; and M[684] segments have all been demonstrated to increase the ability of a reporter sequence to be incorporated within assembling virions. Similar sequence features have been shown to govern packaging in influenza B viruses.[809] Goto and colleagues proposed that the 5′ and 3′ noncoding regions act as virus incorporation signals, while the sequences in the coding regions act as bundling signals bringing the eight segments together.[315] Both the coding and noncoding regions of the packaging signals are relatively conserved compared to other parts of the sequences.[275,309] Mutations introduced into the packaging signal region of one segment can result in a decrease in packaging efficiency of the segment itself and of other segments,[415,417,541,572,574] suggesting the existence of specific interactions among genomic segments. Interestingly, data also show that efficient packaging of the NA or NS segment does not absolutely require the original sequences of the packaging signal, while this is required for efficient HA segment packaging.[268,962] In addition, it has been shown that certain segments are preferentially interacting with each other, a mechanism that might play a role in governing the position of each segment in the 1+7 configuration.[150,289,306] Segment-specific packaging is hypothesized to occur via specific RNA–RNA or protein–RNA interactions, but exactly how the packaging signals participate during the genome packaging process is yet to be determined. Another piece of evidence supporting the specific packaging model is the generation of a rewired influenza virus carrying the HA packaging signal on the NS segment and the NS packaging signal on the HA segment.[291] The modified virus grew well; however, it lost its ability to independently reassort its rewired HA or NS segment with a wild-type (WT) virus, indicating that only viruses containing a full complement of all eight packaging signals will grow to high yields. This model is also supported by data showing specific interference of deleted RNA segments with packaging of the corresponding WT RNA segment but not with any other genome segment.[208,209] Furthermore, segments carrying two different reporter genes but the same packaging signals compete with each other for incorporation into virions and produce viruses that express only one or the other reporter but not both.[421] It has now also been demonstrated that packaging signals, specifically the portions in

coding regions, can have a strain-specific component that can limit reassortment and can impact on viral fitness of reassortant viruses.[236,961,962] Recently, a novel hypothesis regarding the concerted packaging of eight distinct genomic segments has emerged. While it was thought that the vRNA interacts uniformly with NP in a beads-on-a-string manner, it has recently been shown using high-throughput sequencing techniques that this binding is relatively heterogeneous leaving loops of RNA free of NP.[521,967] These loops are vulnerable to RNAse digestion in an experimental setting, and loops from different RNPs can freely interact with each other. Sequence-specific interactions between these loops from different RNPs (kissing loops) have been proposed to govern the packaging of eight distinct genomic segments (Fig. 14.21).[300,521,967] These regions include some of the previously identified more canonical packaging sequences.[967] However, since these loops include regions of low genetic conservation, this hypothesis might provide an explanation for reassortment incompatibility between viruses or fitness loss after reassortment.[521,961,967] This model also leaves room for a more active role of NP in determining packaging specificity and may explain why specific NP sequences or mutations may affect reassortment and packaging.[63,83,615] It will be interesting to define the precise sequences, structures, and mechanisms that determine the specific packaging of each segment. Such conserved features must also be compatible with the divergent sequences observed among influenza viruses. Taken together, there is now good evidence for selective packaging of eight distinct genomic segments per virion mediated by packaging/bundling sequences in the 5′ and 3′ noncoding regions as well as the coding regions of the genomic segments.

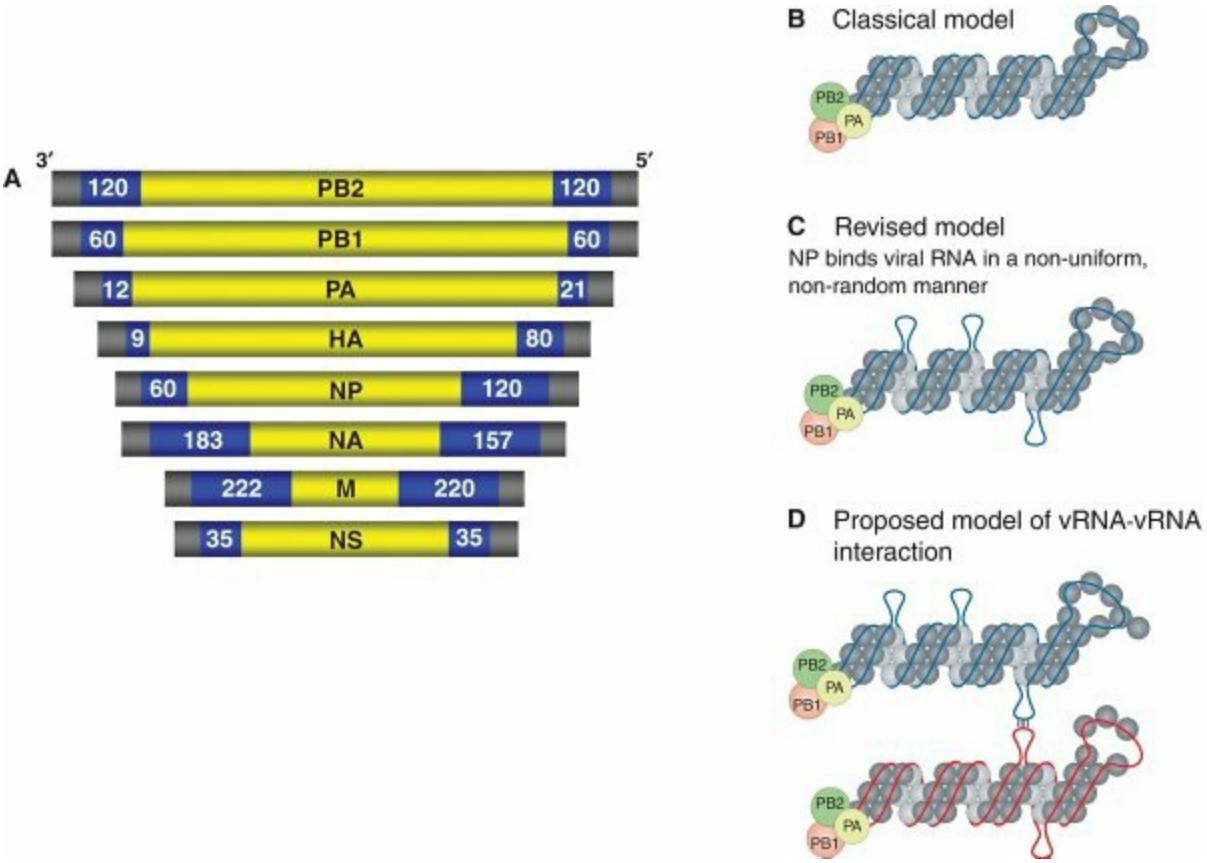

FIGURE 14.21 A: Schematic diagram of the packaging signals on each RNA segment. Each influenza virus RNA segment is depicted with the conserved noncoding regions on both 3′ and 5′ ends. The adjacent numbered domains indicate the number of nucleotides in the coding regions required for effective incorporation of viral RNA (vRNA) into virions. For details, see Refs.[266,267,540,630,682,684,954] (Courtesy of Yoshihiro Kawaoka and updated by Qinshan Gao.) **B:** Model of vRNP structure. The classical model of vRNP is a uniform association of NP to viral RNA. **C:** Recent work[514,521,967] supports a revised model where NP binds viral RNA in a nonuniform manner unique to each viral RNA segment. The nonuniform binding produces regions of viral RNA free of NP and accessible for putative RNA–RNA interactions. **D:** Proposed strategy for intersegmental viral RNA interactions, which likely occur at NP-free sites. The Budding Process

Initiation of bud formation requires outward curvature of the plasma membrane (Fig. 14.20). The virus bud is then extruded until the inner core is enveloped. The budding process is completed when the membranes fuse at the base of the bud and the enveloped virus particle is released following fission from the cell membrane.[770,787] It is likely that several of the influenza virus structural proteins contribute to the budding process. HA, NA, and M2, when expressed alone in transfected cells, are all capable of forming VLPs[125,496,1012] although only in the presence of M proteins are HA and NA brought together in filamentous membrane protrusions that resemble budding virus.[139] Although M1 obviously participates in the formation of virus particles from infected cells, unlike other viral matrix proteins, it does not appear to possess a late domain sequence that mediates interaction with the cellular ESCRT pathway.[87,769,949] It has initially been demonstrated that in the absence of other viral proteins, M1 does not associate with membranes.[935] More recent data suggest that M1 does associate with membranes on its own.[383,526] It is likely a concerted action of all structural components of the virus as well as host factors that brings the components together and initiates budding of authentic virus particles.[526] The extent to which the membrane is extruded before pinching off occurs will affect the size and shape of the virus particle. Generally, influenza virus particles are either spherical or filamentous, and this characteristic morphology is genetically linked to the M segment (Fig. 14.4).[73,226,756,828] It has been further shown that the determinants for a particular filamentous isolate (A/Udorn/72[H3N2]) map to two residues (R95 and E204) in the M1 protein,[73] although other residues in M1 as well as in the cytoplasmic tail of M2 are also involved in regulating morphology.[319,756,757,768,900] Host factors such as polarization and an intact actin cytoskeleton also play a critical role in determining the morphology of virus particles.[492,755,823] The final step of the budding process is membrane

scission, which may be facilitated by both viral and cellular factors. The amphipathic helix in the cytoplasmic tail of M2 has been demonstrated to mediate membrane curvature and scission.[579,757,769] Also, the small guanosine triphosphate (GTP)-binding protein, Rab11, has been implicated in this process.[86]

Release

Influenza virus particles have to be actively released after the viral envelope has separated from the cell membrane during the completion of budding. This is because the HA anchors the virus to the cell by binding to sialic acid–containing receptors on the cell surface. The enzymatic activity of the NA protein is required to remove the sialic acid and thereby releases the virus from its host cell. NA activity is also required to remove sialic acid from the carbohydrates present on the viral glycoproteins themselves so that the individual virus particles do not aggregate. The essential function of NA in particle release has been demonstrated through the use of NA inhibitors,[558,688] temperature-sensitive (ts) NA mutant viruses,[688] and NA-deficient viruses.[546] In all cases, the absence of NA enzymatic activity was seen to cause viral particles to amass in clumps at the cell surface (Fig. 14.22), resulting in a loss in infectivity that could be restored by addition of exogenous sialidase. Virions released from infected cells can, as described above, be spherical or filamentous, but often have a pleomorphic character. Recently, it was proposed that morphologically different particles released during infection might be a strategy to survive different environments that fluctuate over different replication cycles.[905]

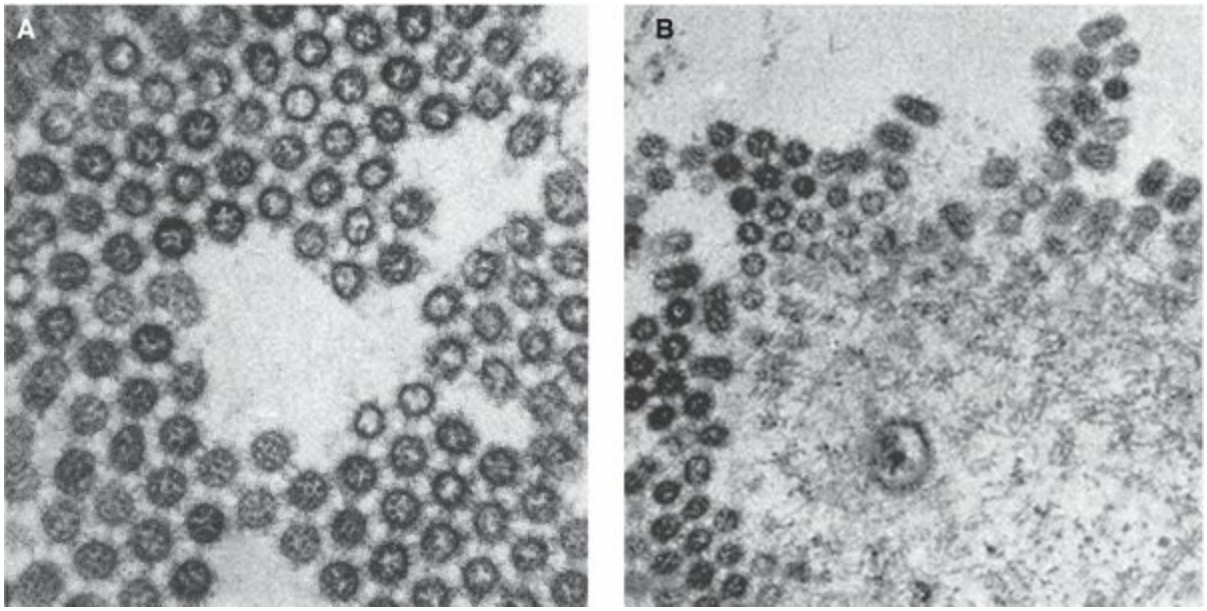

FIGURE 14.22 Aggregate formation of influenza virus particles in the absence of neuraminidase activity. Electron micrograph thin-section images showing aggregates of temperature-sensitive neuraminidase (NA) mutant influenza virus grown at nonpermissive temperature **(A)** or grown in the presence of the neuraminidase inhibitor FANA **(B)**. For details, see Refs.[688,693]

Due to the fact that both HA and NA recognize the same molecule (sialic acid) but have opposing effects (receptor binding vs. receptor destroying), a delicate balance exists between the HA and NA functions.[929] This is optimized for individual viruses but if disturbed can result in attenuation.[103,301,1008]

The neuraminidase

The NA is the second major glycoprotein of influenza A and B viruses and is a type II integral membrane protein with its N-terminus oriented toward the interior of the virus (Fig. 14.23).[154,512,973] The nine subtypes of the A virus NA fall into two major groups (N1, N4, N5, N8 and N2, N3, N6, N7, N9) based on sequence comparisons (Fig. 14.2).[973] In addition, the NA-like

proteins from H17N10 and H18N11 viruses do not possess NA activity despite their structural similarity with authentic NAs.[263,892,1047] No subtypes have been found for the NAs of B viruses, possibly because these viruses do not have an animal reservoir. The influenza A virus NAs have a highly conserved short cytoplasmic tail and a hydrophobic transmembrane region, which provides the anchor for the stalk and the head domains. The purified head domain of an N2 NA (obtained by pronase treatment of whole virus) was first crystallized by Graeme Laver, and its x-ray crystallographic structure was solved by Peter Colman.[158] The structure of the N1 NA from the 1918 pandemic virus and of several other NA subtypes has also been determined.[992] The head of the NA is a homotetramer, each monomer of which is composed of six topologically identical *β*-sheets arranged in a propeller formation. The structure of the influenza B virus neuraminidase, similar to that of the A virus, is characterized by the interaction of the sialic acid ligand with nine conserved active site residues.[101] The enzymatic activity of NA was first recognized by George Hirst, who found that red blood cells treated with virus were refractory to reagglutination by another virus preparation.[385] The enzyme was also found to cleave ketosidically bound sugars of alcohols (at position 2 of neuraminic acid).[90] Neuraminidases from different subtypes are described to have different substrate specificities.[531,728] Transition state inhibitors such as 2-deoxy-2,3-dehydro-*N*-trifluoroacetylneuraminic acid, which mimic the enzymatic substrate, were shown early on to inhibit influenza virus replication,[692] and compounds with the same mechanism of action were later developed for use as highly effective antivirals in humans.[43,195,430,658] Early work had also elucidated the function of the NA in virus replication. Cells infected by temperature-sensitive mutants with defects in the NA were shown by EM to have large aggregates of intact virus particles accumulating near the cell surface (Fig. 14.22). This finding was interpreted to mean that the viral NA must remove the sialic/neuraminic acid receptor from the surface of the cell as well as from the virus particles to prevent recognition by the HA of the virus. The NA thus has a role in releasing the virus from the infected cell and in cleansing the environment (e.g., mucus and cell surfaces in the respiratory tract) of sialic acid receptors to allow for virus spread.[688,693] In addition, it has been shown that the viral NA may also play a role early in infection, possibly facilitating entry of the virus[151,583,674,1000] and/or modulating late

endosome/lysosome trafficking.[445,868] A role in immunomodulation by interaction with TGF-β has also been proposed.[111,484,793] As described earlier (see Budding Process), the NA can also mediate virus budding[496,1012] and the cellular restriction factor, tetherin, can influence this step.[950,1012] Another function for at least one NA subtype has also been reported. In the case of an N9 NA, a hemadsorption activity was found to be associated with the purified molecule, and x-ray structure analysis revealed a second independent binding site for sialic acid.[910] A similar site has been described for N1 as well,[205] but its relevance in human influenza virus strains remains unclear[903] Of note, mutations in the regular enzymatic site of NA can lead to receptor-binding activity as well, which in some instances can completely replace the receptor-binding activity of HA (but not its fusion mechanism).[395,396,1046]

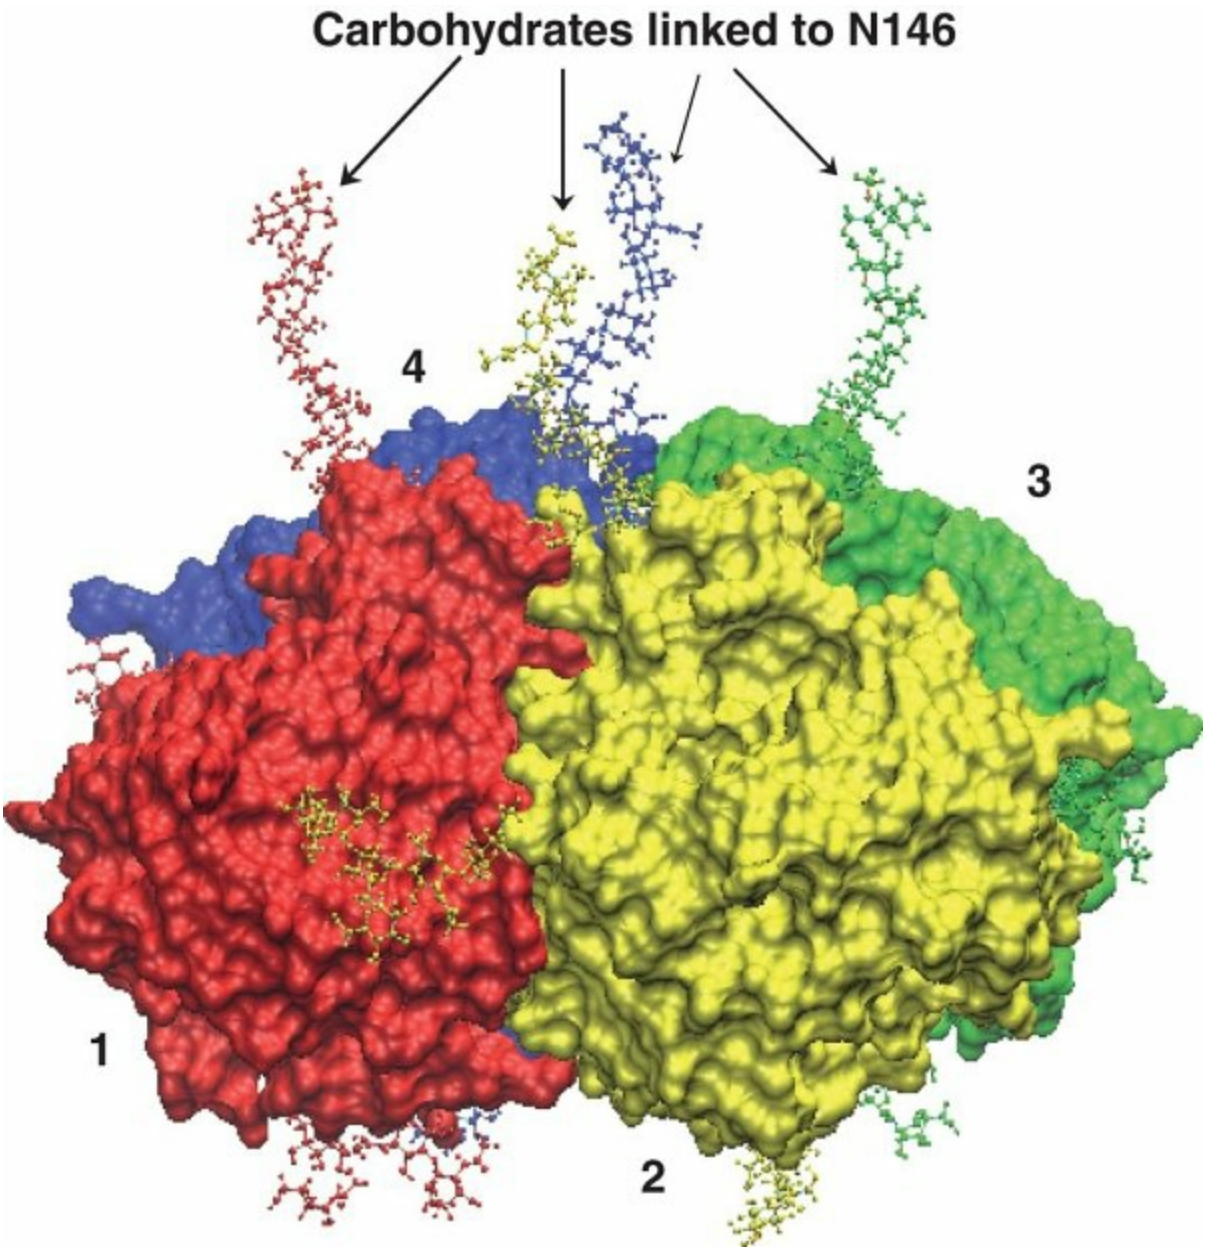

FIGURE 14.23 Molecular surface drawing of the x-ray structure of an N2 neuraminidase head. The neuraminidase is a tetramer made up of a bulky head attached to a slender stalk. A side-on view of the head only is shown consisting of four identical monomers (from this perspective, the two rear monomers, *blue and green*, are mostly hidden). The carbohydrates attached to asparagine residue 146 of each monomer are shown in ball-and-stick model and form antennae-like structures rising from the top of

the molecule. For details, see Ref.[911] (Courtesy of Peter Colman.)

It is assumed that the function of the influenza B virus NA is similar, if not identical, to that of the A virus NA.[304,559,739] Additionally, the active sites of influenza A and B virus NAs are conserved, which allows for broad-spectrum activity of NA inhibitors. In influenza C and D viruses, the receptor-destroying role of the NA is played by the esterase activity of the viral HEF. By removing the acetyl group from 9-*O*-acetylneuraminic acid, the HEF facilitates the release and spread of virus from infected cells. In addition, it appears that the enzyme is needed for virus entry, suggesting release of the HEF from cell receptors during the endosomal uptake and fusion/uncoating process.[920]

Like the HA, NA molecules are antigenic and variants are selected in nature.[782] Antibodies directed against the NA are usually not neutralizing, but can be broadly protective in animals and humans.[130,169,216,484,614,975] Immunization with NA preparations has been proposed as an infection-permissive, disease-preventing vaccine approach against influenza, and NA has recently re-emerged as an attractive vaccine antigen.[216,463,484,973,974]

Interactions of Influenza Virus with the Host Cell

Cellular Functions Required for Influenza Virus Replication

A virus with a small coding capacity, such as influenza virus, relies on numerous host cell functions in order to complete its replication cycle. In comparison to our understanding of the role of each viral protein in the influenza virus life cycle, we know relatively little about the contribution of host cell proteins. Some well-characterized interactions between viral and host proteins are noted in the sections covering specific viral proteins (e.g., NP and importin-*α*, NEP and Crm1, NS1 and CPSF30), but these probably represent only a small fraction of the molecular interactions that occur between influenza virus and its host cell during the viral life cycle. Initial efforts to expand our knowledge of these cellular binding partners have involved a yeast two-hybrid analysis of 10 influenza virus proteins (all except

PB1-F2 and PA-X), which identified interactions with 87 human proteins.[800] These interactions exist in a tightly connected network, as 24 of the human proteins interact with two or more viral proteins and there are 51 known interactions occurring between the 87 human proteins. Other studies have examined interacting partners of viral protein complexes rather than individual proteins and particularly those that retain functionality such as the RNP or trimeric polymerase complexes. Forty-one human proteins were reported to interact with the viral RNP complex of influenza A/WSN/33 (H1N1) virus, and 10 interacting proteins were identified in another study using the polymerase complex.[442,584] A large-scale proteomic analysis of an H5N1 influenza virus polymerase complex has revealed an astonishing 859 human proteins that are associated with either the full polymerase complex or PA-containing subcomponents thereof.[78] In their analyses, the authors also distinguished between those interactions that are dependent on RNA and those that are not. In summary, 166 PA interacting proteins, 23 that bind to the PB1-PA dimer and 10 that associate with the full polymerase, were identified irrespective of the presence of RNA. Using RNAi, 31 proteins known for interacting with the vRNP or polymerase complex were assessed for their role in polymerase activity.[69] Eighteen were shown to facilitate the activities of both H1N1 and H5N1 polymerases, while two antagonized both polymerases, supporting the idea that interacting proteins are likely to play functional roles. Recent large-scale studies queried additional interactions between individual viral proteins and the host.[368,746,948]

Completion of the analysis of the human genome and the discovery of RNAi have made it possible to query the participation of each human gene product in functional assays using genome-wide small interfering ribonucleic acid (siRNA) libraries. Using this powerful tool, genome-wide RNAi screens have been performed on influenza virus–infected cells to identify those genes that are required for efficient virus growth.[843,953] These five studies[80,350,451,478,800] identified a total of 1,077 unique genes that when targeted by siRNAs lead to decreased influenza virus replication. Each study employed different assay conditions, and this likely contributes to the finding that only 85 genes were common to two or more of the screens. However, a greater degree of concordance is seen when one analyzes the results at the level of cellular function rather than gene name.[804,843,953] Following these initial studies, many different screens using different technologies including

RNAi screens,[49,133,194,201,853] CRISPR screens,[349,366] transcriptomics profiling,[377,788] proteomic screening,[368,543,746,948,1013] kinase profiling,[24,611,832,1002] radiation hybrid mapping,[550] and meta-analysis/network analysis of existing screening data[2,120,898] have been performed. These and many other studies have identified a large number of host and restriction factors that play significant roles in influenza virus interactions with the host cell. Host factors involved in attachment and internalization,[131,184,217,224,269,349,773,1045] endosome trafficking,[321,498,722,749,820,822,996] fusion, uncoating and nuclear import,[34,39,70,212,329,365,519,568,603,669,710,853,1002] transcription and replication,[110,194,235,260,451,509,571,764,812,856,859,899,916,1027] protein synthesis, nuclear export[13,22,145,274,292,403,651,720,730,797,878,951,986] and transport to the bud zone,[12,219,368,457,864,898,937] and packaging, assembling, and budding[187,314,365] have been described above and/or are depicted in Figure 14.24. In addition, important restriction factors including interferon-inducible transmembrane (IFITM) proteins were identified in this manner.[80,237,729,741,1044]

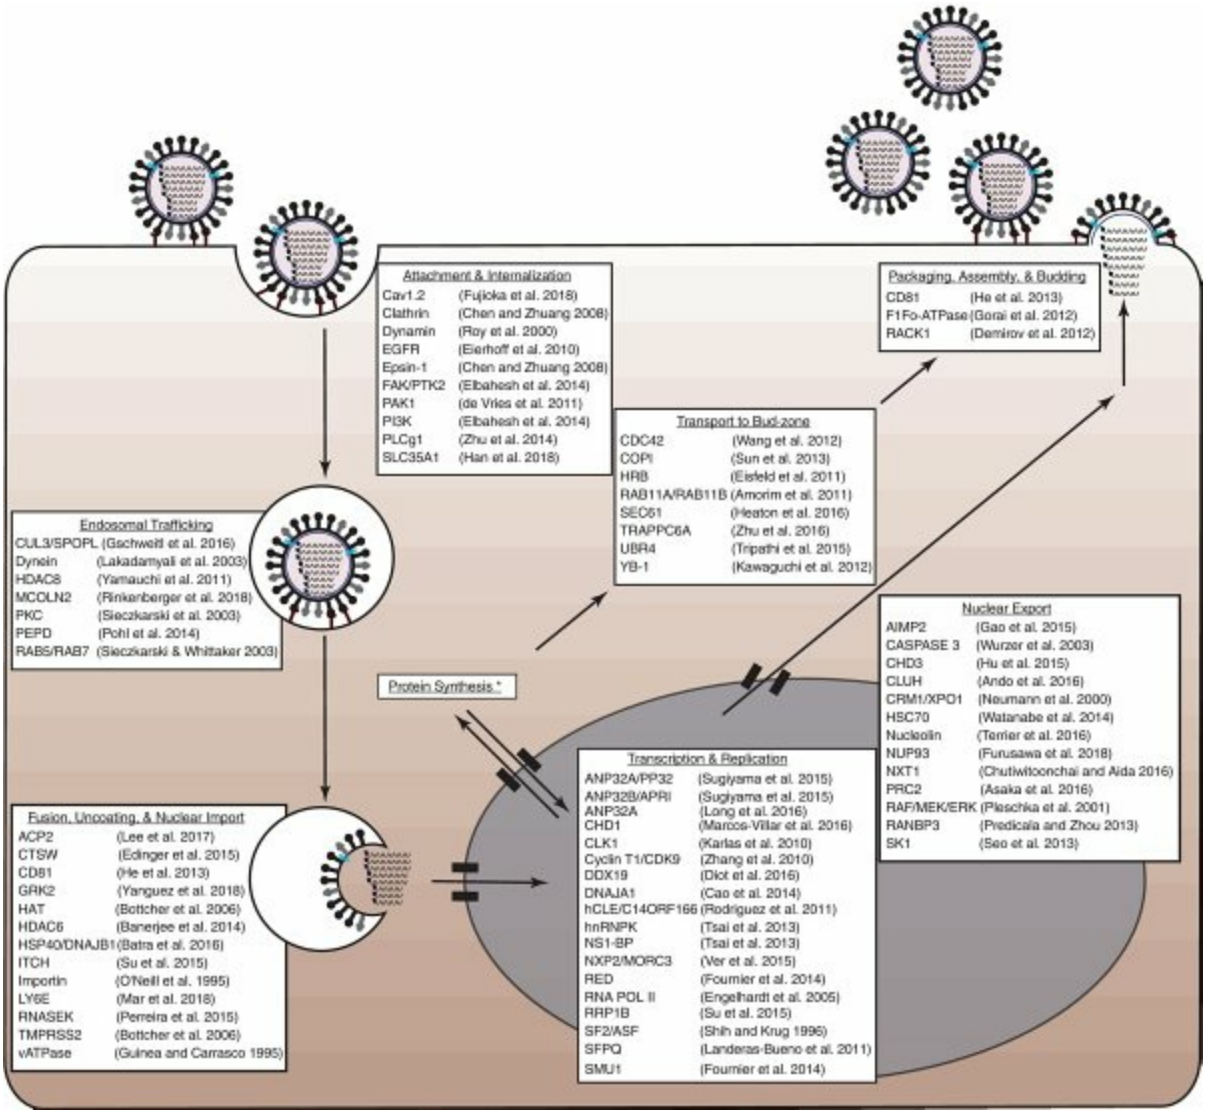

FIGURE 14.24 Host factors of influenza A virus. Shown are a subset of identified host factors required by influenza A virus during different stages of the viral life cycle. Of the depicted cellular proteins, experimental evidence exists indicating that influenza A virus is dependent on the expression/function of the respective protein for productive infection. The listed host factors are categorized based on individual stages of the influenza A virus life cycle during which they exhibit their proviral function: (1) attachment and internalization; (2) endosomal trafficking, fusion, uncoating, and nuclear import; (3) transcription and replication; (4) protein synthesis*; (5) nuclear export; (6) transport to bud zone;

and (7) packaging, assembly, and budding. See Ref.[807] for more details. *Influenza A virus depends on a large variety of cellular proteins during viral protein synthesis. However, current screening methodologies for the identification of host factors of IAV involve manipulation of host gene expression. Therefore, proteins crucial for host cell viability, such as proteins involved in translation and protein expression, are usually not identified in such screening efforts. (Courtesy of Silke Stertz, Marie Pohl, and Eva Spieler.)

Future progress in this area will depend on integrating the data obtained from these global approaches (e.g., proteomics, RNAi, microarray, CRISPR, etc.) to build a clearer picture of the cellular networks that govern efficient influenza virus growth. Such information may address questions concerning species specificity and also provide new avenues to explore for drug discovery (see section on Inhibition of Cellular Factors).

The Actions of the NS1 Protein

When a virus infects a cell, it has to contend with the rapid onset of the host innate immune response, whose mission it is to establish an antiviral state within the cell and prevent virus replication. A critical component of this response is type I interferon (IFN-α/β), which is secreted from virus-infected cells. A characteristic feature of all orthomyxoviruses is their sensitivity to the inhibitory effect of IFN-inducible Mx GTPases.[346] In fact, IFN was first described as a factor induced by heat-inactivated influenza virus,[422] although interestingly, live influenza virus was found to inhibit the induction of IFN by inactivated virus.[545] The reason for this observation did not become clear until almost 40 years later when, with the benefit of reverse genetics technology, it was possible to engineer an influenza A virus that lacked the *NS1* gene (delNS1).[297] This virus displayed unusual growth properties as it was severely attenuated in IFN-competent systems but grew well in IFN-deficient systems such as Vero cells and 6-day-old embryonated eggs and was lethal in STAT1$^{-/-}$ mice (Fig. 14.25).[297,871] Thus, in the absence of an IFN response, NS1 appears to be dispensable, whereas in the context of an immunocompetent host, it is essential. Microarray analysis has demonstrated

that infection with delNS1 virus leads to enhanced expression of IFN and IFN-regulated genes compared to WT influenza virus infection,[303] and NS1 is therefore termed an *IFN antagonist* because it acts to suppress the virus-induced host IFN response.[340,977] These findings have given rise to a new concept for the design of live attenuated vaccines based on mutations in the NS1 gene.[689,690,748,871] Studies on viruses expressing truncated forms of NS1 have shown that the level of attenuation is determined by the amount of IFN induced by the virus (i.e., highly attenuated viruses induce larger quantities of IFN),[37,243,737,833,871] and immunization with these mutant viruses produced protective immunity in mice, chickens, swine, horses, and macaques.[667,748]

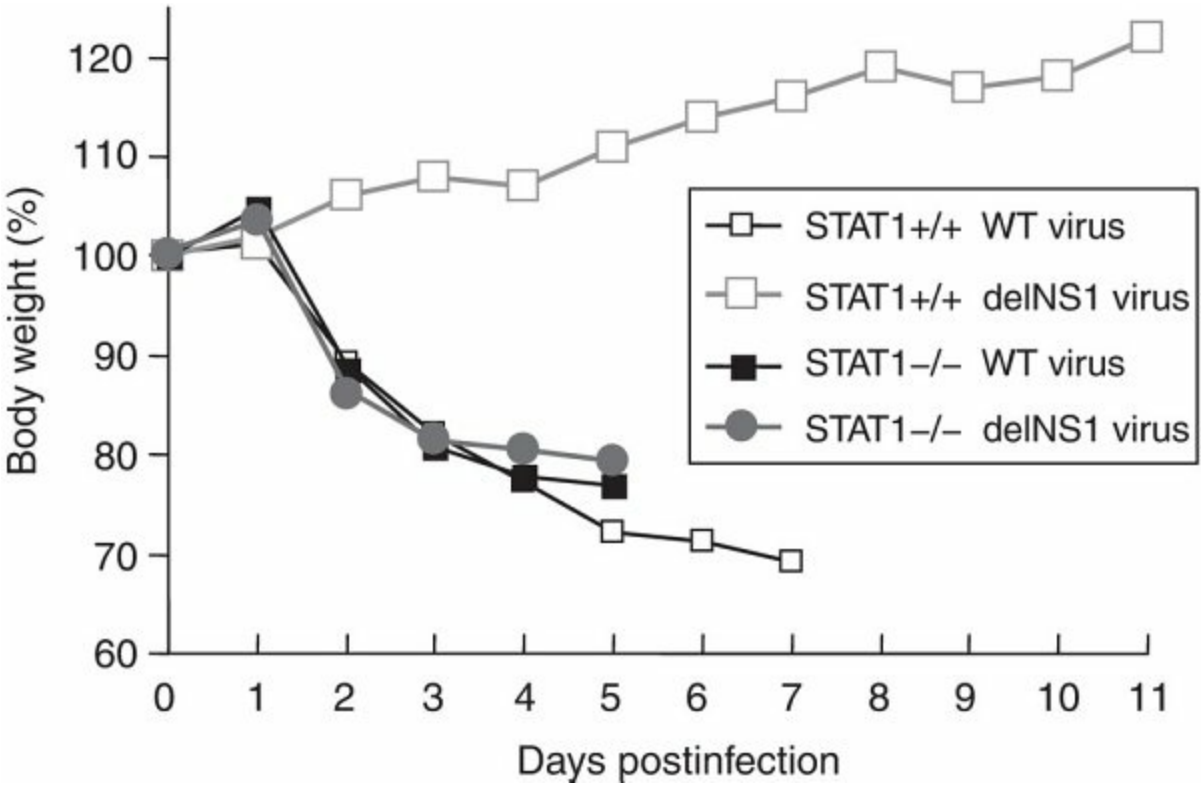

FIGURE 14.25 Pathogenicity of influenza A virus lacking NS1 expression in STAT1−/− mice. Wild-type (STAT1+/+) or STAT1−/− mice were infected with either wild-type (WT) or delNS1 viruses as indicated. DelNS1 virus is apathogenic in STAT1+/+ mice; however, the weight loss (shown in percentage) of delNS1 virus–infected STAT1−/− mice is comparable to that of

WT virus–infected mice. DelNS1 and WT virus are equally lethal in STAT1−/− mice. (For details, see Ref.[297]; courtesy of Adolfo García-Sastre.)

Structural features of the NS1 protein

NS1 is a nuclear, dimeric protein that is highly expressed in infected cells and has a dsRNA-binding domain, an effector domain, and a disordered tail.[345,668] The RNA-binding domain lies within the N-terminal 73 amino acids,[735] for which both NMR and crystal structures have been obtained.[134,135,548,1009] These data indicate that the NS1 RNA-binding domain forms a symmetric homodimer with a six-helical fold and that conserved tracks consisting of basic and hydrophilic residues on each monomer mediate interactions with dsRNA. Mutational analysis has further demonstrated that dimer formation is crucial for RNA binding as are residues R38, R35, and R46.[134,941] Residue K41 strongly enhances the binding affinity[941] and residues S42 and T49 also participate in dsRNA binding.[134] It is suggested that the basic residues make contact with the phosphate backbone of the RNA via electrostatic interactions,[136,941,1009] which is consistent with the observed lack of sequence specificity.[356,735] Structural data indicate that the NS1 dimer spans the major groove of canonical A-form dsRNA in a length-independent mode.[134] Structures of the influenza B virus NS1 RNA-binding domain indicate a similar binding mode.[1009]

The remaining portion of NS1 has been termed the effector domain and includes binding sites for several host factors (Fig. 14.26).[345] Crystallographic structures of the NS1 effector domain have been determined for several influenza A virus strains. While the monomer conformation is very similar, different dimer interfaces have been determined, specifically one that is mediated by a helix–helix interaction[17,341,458,987] and another mediated by a strand–strand interaction.[67,459] The helix–helix interaction is dependent on residue W187 in each monomer,[341,988] and it has been proposed that the monomer interface can twist and therefore the dimer can exist in both open and closed conformations.[458] Finally, one structure of a full-length NS1 protein has been reported.[68] Strikingly, instead of individual

dimers, NS1 is shown to form a chain with alternating interactions occurring via the dsRNA-binding and effector domains. Moreover, three of these chains are shown to interact with one another to form a tubular structure that can accommodate dsRNA in its center. This chain-like structure opens up questions regarding how interactions between NS1 and its cellular partners can be accommodated, but models for how this may occur in the context of an individual NS1 dimer have been proposed.[458]

FIGURE 14.26 Schematic diagram of the multiple functions of NS1 within infected cells. A: Pretranscriptional limitation of interferon-*β* (IFN-*β*) induction. **B:** Inhibition of the antiviral properties of protein kinase R (PKR) and 2′-5′-oligoadenylate synthetase (OAS)/RNase L. **C:** Posttranscriptional block to processing and nuclear export of all cellular messenger RNAs (mRNAs). **D:** Enhancement of viral mRNA translation. **E:** Activation of phosphatidylinositol 3-kinase (PI3K). Some other interactions that have been characterized are detailed in the *lower box*. See Refs.[27,345,468,570,668] for details (Adapted from Hale BG, Randall RE, Ortin J, et al. The multifunctional NS1 protein of influenza A viruses. *J Gen Virol* 2008;89(Pt 10):2359–2376; courtesy of Ben Hale.). **F:** Schematic representation of the influenza A virus NS1 protein, together with its known interactors. The influenza A virus NS1 protein (*yellow*) is 202 to 237 amino acids long depending on the strain. The N-terminal 73 amino acids form a functional RNA-binding domain, while the effector domain predominantly mediates interactions with host cell proteins. The final C-terminal approximately 20 amino acids appear to be natively unstructured. NS1 contains two nuclear localization sequences (NLS1 and NLS2) and a nuclear export signal (NES). A nucleolar localization sequence (NoLS) has been reported for some strains and is concomitant with NLS2. The interaction of NS1 with itself to form homomultimers via both the RNA-binding domain and effector domain (W187) is important for function. Residues involved in RNA binding (Arg-38 [R38] and Lys-41 [K41]) are implicated in the inhibition of 2′-5′-oligoadenylate synthetase/RNase L, Jun N-terminal kinase, and RIG-I/TRIM25. Additionally, NS1 contains binding sites for poly(A)-binding protein I (PABPI), p85*β*, importin-*α*, nucleolin, NS1-BP, eIF4GI, hStaufen, NS1-I, PKR, PACT, hnRNP-F, Ubc9, CPSF30, poly(A)-

binding protein II (PABPII), Crk/CrkL, PDZ domain–containing proteins (e.g., Scribble, Dlg-1, PDlim2, and the MAGIs), the viral polymerase/nucleoprotein, and components of the cellular messenger RNA (mRNA) nuclear export machinery (E1B-AP5, p15, NXF1, and Rae1). Several posttranslational modifications to NS1 have also been described: ISG15 modification (*red*) by the interferon (IFN)-inducible Herc5 protein mediates negative effects on NS1 function, while phosphorylation and sumoylation (*green*) appear to enhance NS1 function. See Refs.[27,345,468,570,668] for details. (Adapted from Hale BG, Randall RE, Ortin J, et al. The multifunctional NS1 protein of influenza A viruses. *J Gen Virol* 2008;89(Pt 10):2359–2376; courtesy of Ben Hale.)

Inhibition of the interferon synthesis

WT influenza virus infection induces far less IFN than does delNS1 virus, and this difference lies at the level of mRNA molecules.[303,870,938] This implies that NS1 either acts to prevent the synthesis of IFN mRNA or destabilizes IFN mRNA (Figs. 14.25 and 14.26). The transcriptional activation of IFN-β in response to virus infection is regulated by transcription factors including interferon-regulatory factor-3 (IRF3), nuclear factor-κB (NF-κB), and activator protein-1 (AP-1).[668] Each one of these transcription factors has been shown to be activated in delNS1 virus–infected cells but not in WT virus–infected cells,[554,870,938] which corresponds with the differential induction of IFN-β by these viruses. Moreover, expression of NS1 alone inhibits the activation of the IFN-β promoter in response to infection with a heterologous virus or even delNS1 virus.[554,938] Substantial progress has been made to understand the precise mechanism by which NS1 suppresses IFN synthesis[340,345] (Fig. 14.26). First, dsRNA binding is important as expression of the RNA-binding domain alone is sufficient to block virus induction of IFN.[938] However, a virus expressing only the first 73 residues is still attenuated in mice (with a phenotype intermediate to that of delNS1 and WT virus), pointing to a role for the effector domain *in vivo*.[243,871,932] Alanine substitution of the residues involved in RNA binding (R38 and K41) was

found to significantly reduce the ability of NS1 to inhibit IRF3 and NF-κB activation[870,938] and, hence, IFN-β synthesis.[198] In the context of a virus, lack of NS1 resulted in increased IFN-β production and, therefore, an attenuated phenotype in mice (Fig. 14.25).[198] Second, NS1 is found in complex with the cytoplasmic sensor RIG-I and acts to prevent RIG-I signaling and IFN-β production.[330,601,680,715] This interaction appears to depend on the same residues implicated in dsRNA binding, indicating that it is potentially mediated by RNA.[715] Third, NS1 interacts with TRIM25 via residues E96 and E97.[280] TRIM25 is responsible for ubiquitinating and activating RIG-I and the presence of NS1 blocks this activity (Fig. 14.26). However, *in vivo*, different influenza viruses show different patterns of interferon inhibition,[740] which are difficult to reconcile based on the known mechanism of action in tissue culture.[488] Dozens of different host factors involved in the suppression of the IFN response by NS1 have been identified.[668]

Inhibition of host mRNA processing

Influenza virus–infected cells harbor pre-mRNAs in their nuclei that do not undergo efficient 3′-end processing and therefore cannot be exported.[126,815] This is thought to be an NS1-mediated effect that occurs via interaction of the NS1 effector domain with two components of the 3′-end processing machinery: the 30-kD subunit of the cleavage and polyadenylation specificity factor (CPSF)[179,473,647] and the poly(A)-binding protein II (PABII).[126,340,345,490] The NS1 interaction effectively inhibits these processing factors and results in pre-mRNAs that either remain uncleaved[647,815] or only acquire short poly(A) tails.[126] NS1 also inhibits splicing of pre-mRNAs, which also results in their retention in the nucleus,[258,552] and evidence for the requirement of CPSF in splicing suggests that both of these mRNA-processing defects in influenza virus–infected cells may be related to the inhibition of CPSF (Fig. 14.26).[532] NS1 also interferes with mRNA export via complex formation with several components of the nuclear export machinery.[783] As the induction of the host antiviral response relies so heavily on transcriptional up-regulation of genes, this global posttranscriptional inhibition may aid in aborting or at least delaying the onset of this response. This is reflected in data from a CPSF-binding mutant virus, which is attenuated in tissue culture and which causes an earlier

induction of antiviral gene products compared to WT virus.[661] It should be noted, however, that the delNS1 virus shows shutoff of host protein synthesis at levels similar to that of WT virus in an A/PR/8/34 background (which cannot bind to CPSF40).[781] This suggests that other (or additional) factors may be responsible for inhibition of general gene expression.[675,930]

Additional NS1 interactions with host cell factors

The influenza A virus NS1 protein binds directly to the p85*β* regulatory subunit of PI3K via its C-terminal effector domain, and NS1 expression is sufficient to activate PI3K signaling.[215,343,818] Specifically, residues Y89, M93, P164, P167, L141, and E142 in the NS1 protein, which are located in predicted src homology 2 (SH2)- and SH3-binding motifs, have been implicated in the interaction with p85*β*.[343,530,817,818] The NS1-binding site on p85*β* is located in an inter-SH2 domain,[342] and a cocrystal of the NS1 effector domain in complex with this region of p85*β* shows that residues Y89 and P167 of NS1 are at the binding interface.[344] Furthermore, a model of a heterotrimeric complex consisting of NS1–p85*β*–p110 predicts that the presence of NS1 would disrupt the inhibitory contact between p85*β* and p110.[344] This explains the PI3K-activating properties of NS1, which theoretically serve to delay apoptosis at late stages of infection.[213] However, recombinant viruses expressing NS1 proteins that fail to activate PI3K were not seen to induce any more apoptosis than WT virus, so the biological significance of NS1-mediated PI3K activation remains unclear.[432] It also should be noted that a proapoptotic activity of NS1 has been reported.[792]

NS1 has also been reported to interact with several other host factors (Fig. 14.26), including the eukaryotic translation initiation factor 4GI, poly(A)-binding protein I, Staufen, NS1-I and NS1-BP, nucleolin, hnRNP-F, E1B-AP5, Herc5, PABII, importin-*α*, CrkL, Scribble, Dlg1, PDLim2, p15, NXF1, Rae1, PACT, Ubc9, and others.[16,99,126,238,310,370,401,547,596,631,783,789,875,978,979,1015,1029,1033] It has been shown that disruption of the Staufen-1/NS1 interaction inhibits influenza virus replication, indicating that this virus–host interaction is required for optimal virus growth.[522] Furthermore, it has been shown that NS1 can act like a histone mimic.[569]

Anti-interferon proteins of influenza B, C, and D viruses; thogoto virus; and isavirus

Like its A virus counterpart, the NS1 protein of influenza B virus (B/NS1) exists as a dimer and has RNA-binding activity in its N-terminal domain (residues 1–93).[199,936,1016] A virus lacking B/NS1 has also been demonstrated to induce larger amounts of IFN than WT virus,[180] and the B/NS1 protein can complement the growth of influenza A delNS1 virus,[199] indicating that A/NS1 and B/NS1 are functional equivalents. Therefore, as described for influenza A virus, recombinant influenza B viruses either lacking NS1 or expressing truncated NS1 proteins have been proposed as vaccine candidates.[338,981] Expression of B/NS1 has been shown to inhibit virus activation of the IFN-β promoter,[180,199] but interestingly, both N- and C-terminal domains of the protein encode this inhibitory activity, and hence RNA binding was found not to be essential for inhibition of IFN-β synthesis.[199] However, in the context of expression of the N-terminal domain alone, RNA binding was required. Similarly, both portions of B/NS1 were shown to independently inhibit virus activation of the transcription factor, IRF3.[199] B/NS1 is also an inhibitor of PKR, but unlike A/NS1, it does not interfere with mRNA processing.[936] B/NS1 does possess the unique ability to bind to *ISG15* (an IFN-inducible gene) and prevent its conjugation to target proteins,[1018] which it does through its N-terminal domain independently of RNA binding.[435,1016,1035] Structural analysis shows that a dimer of the B/NS1 N-terminal domain interacts with two ISG15 molecules, with each ISG15 molecule binding distinct regions of each NS1 monomer.[323] ISG15 conjugation or ISGylation has been shown to regulate the IFN signaling pathway and to be critical for host antiviral defense.[565,750,1031] Interestingly, B/NS1 inhibits ISGylation in a species-specific manner, binding only to human and nonhuman primate ISG15 proteins.[836,917] This likely contributes to the fact that influenza B infections are restricted to humans. The influenza B virus NS1 protein may also have a role in virus replication as the virus lacking B/NS1 grows to lower titers, even in IFN-deficient cells.[180] It has also been shown that B/NS1 associates with nuclear speckles and that this is linked to residues in its N-terminal region.[789]

The C/NS1 has been shown to inhibit RIG-I–mediated activation of the

IFN-β promoter through a region located in its C-terminus.[686] C/NS1 has also been shown to up-regulate splicing of viral mRNAs.[625] While no data are available, similar mechanisms are probably used by influenza D virus since it expresses a D/NS1 protein.[855]

Unlike the influenza viruses, Thogoto virus has no NS segment and instead, its anti-IFN activity is encoded by the M segment.[336] The M segment produces the M protein from a spliced transcript and the ML protein from an unspliced transcript, of which the latter has been shown to be an IFN antagonist protein.[336,474] As seen with the delNS1 influenza virus, a recombinant Thogoto virus lacking the ML protein was shown to induce far greater levels of IFN in infected cells than WT virus[336] and was remarkably attenuated in mice expressing functional Mx1 (an IFN-inducible protein that protects against orthomyxovirus infection).[714] ML has also been demonstrated to inhibit virus-induced activation of IRF3 but in a manner distinct from that of NS1.[434] Another striking difference between ML and NS1 is that ML is a structural protein.[335] Because expression of ML is controlled by the same promoter as that of the M protein (which is expressed late in infection), this strategy ensures that ML is present (as part of the incoming virion) at the initial stages of virus infection when it can most effectively exert its effect on the host immune response.[335]

The isavirus IFN antagonist proteins are expressed from the unspliced transcript of RNA segment 7 and the larger ORF of RNA segment 8.[167,295,886]

The Actions of the PB1-F2 Protein

Influenza A viruses can express an 11th protein, PB1-F2, which is encoded by the +1 alternate ORF in the *PB1* gene.[122,448,480] PB1-F2 is 87 to 90 aa long, depending on the virus strain, and is expressed by most human H3N2 viruses, while a large number of human H1N1 isolates have a premature stop codon in the PB1-F2 ORF. Of note, the pandemics that occurred in 1918, 1957, and 1968 were all caused by influenza viruses that express full-length PB1-F2 and so do many zoonotic influenza viruses.[10] The protein has been shown to contribute to influenza virus pathogenicity through several mechanisms. Initially, a proapoptotic function was described for PB1-F2. It was found to localize to the mitochondria and disturb the mitochondrial

membrane potential, leading to the efflux of cytochrome c into the cytoplasm.[122,305] The induction of apoptosis by PB1-F2 is thought to occur specifically in immune cells in a strain-dependent manner and, thus, contribute to immune evasion by influenza viruses.[91,122,585,1020] It was demonstrated that PB1-F2 triggers an apoptotic response by interacting with the mitochondrial adenine nucleotide translocase 3 (ANT3) and voltage-dependent anion channel 1 (VDAC1) proteins[1019] and/or forms pores via self-oligomerization (Fig. 14.27).[89,117,375]

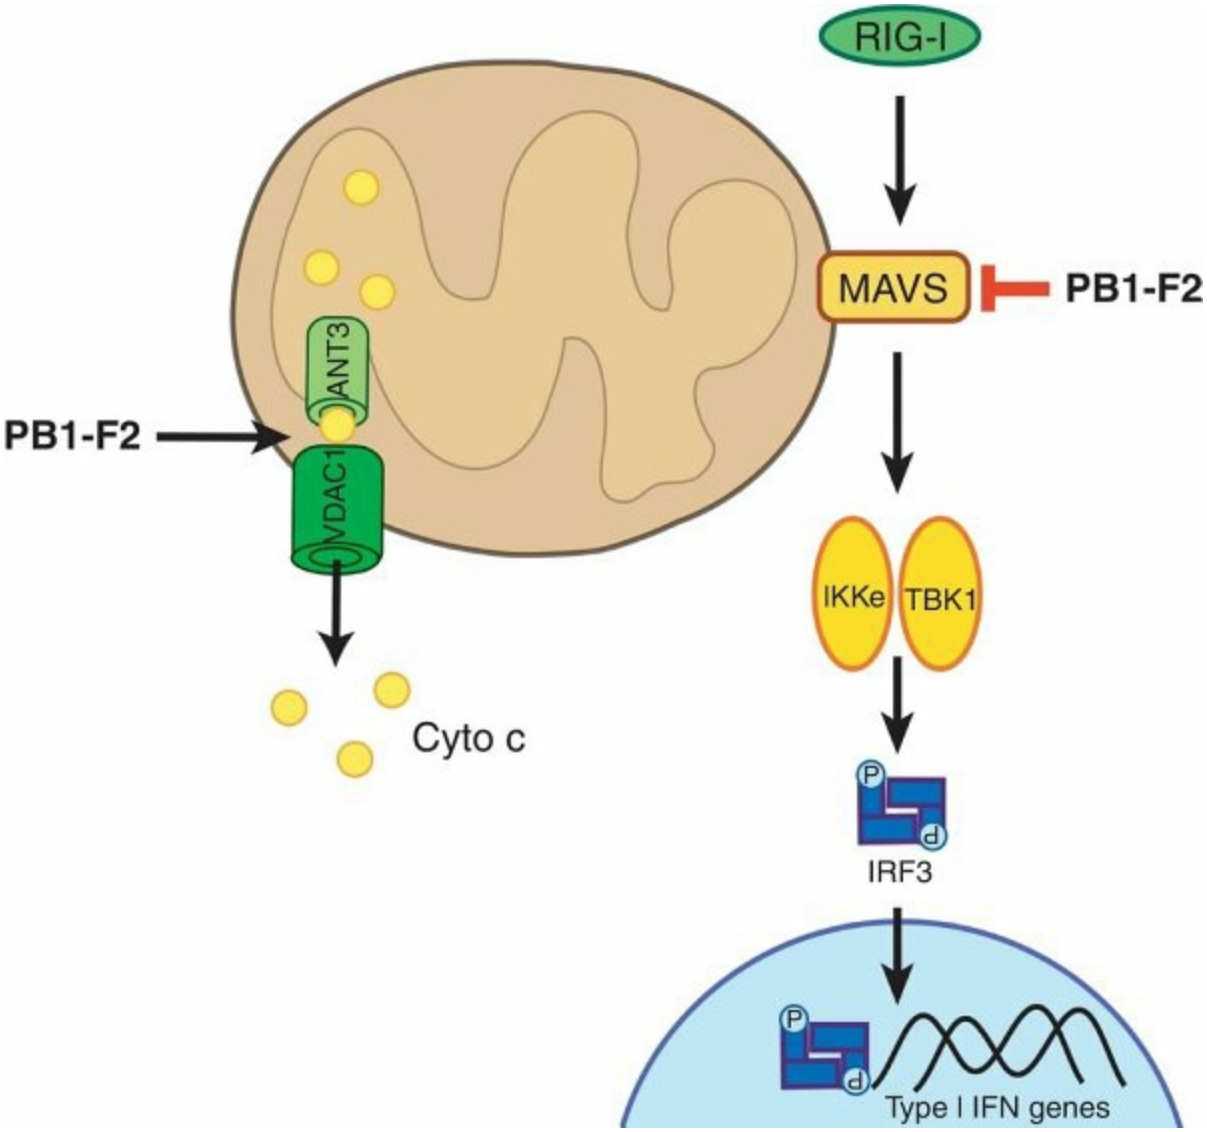

FIGURE 14.27 The proapoptotic and anti-interferon activities of the influenza A virus protein PB1-F2. The protein promotes

apoptosis by interacting with the mitochondrial VDAC1 and ANT3 proteins and interferes with the induction of interferon at the level of the MAVS adaptor protein. Cyto c, cytochrome c. (Courtesy of Zsuzsanna T. Varga.)

In addition to its proapoptotic activity, PB1-F2 was reported to have proinflammatory properties. Specifically, it was observed that PB1-F2–expressing viruses increase the levels of several cytokines and chemokines, enhance cell infiltration, and exacerbate lung injury in infected mice.[163,164,585,586] Notably, it was found that a serine (S) at position 66 in the PB1-F2 protein dramatically increases immunopathology and mortality caused by the 1918 pandemic strain and by highly pathogenic H5N1 viruses.[164] Transcriptional profiling of mice infected with a PB1-F2 N66S-expressing virus revealed an early suppression of interferon-stimulated genes (ISGs),[163] and *in vitro* studies demonstrated an anti-interferon activity of PB1-F2 at the level of the MAVS adaptor protein (Fig. 14.27).[909] Interestingly, PB1-F2 N66S, which is associated with increased pathogenicity, inhibited the induction of IFN more efficiently than a WT PB1-F2 protein.[909] It is hypothesized that there may be a possible link between the proapoptotic and anti-interferon functions of PB1-F2 through the MAVS protein.[908]

The Actions of the PA-X Protein

Recently, a novel protein translated from the PA segment has been discovered and named PA-X.[433] This protein consists of the N-terminal 191 amino acids of PA plus additional amino acids that are added from an alternative reading frame. At the codon for amino acid 191, a +1 ribosomal frameshift occurs resulting in attachment of 41 or 61 novel amino acids to the N-terminus of PA.[246,810] The N-terminus of PA, which is retained in PA-X, hosts the endonuclease domain of the protein.[188] It has been shown that PA-X has cap-snatching activity, which induces degradation of host mRNA and leads to shutoff of the host protein expression.[188] The first 15 amino acids of the C-terminus of PA-X are also actively involved in this activity.[361,675] It is assumed that the main activity of PA-X takes place in the nucleus, but

mRNA degradation in the cytoplasm by this protein has also been demonstrated.[361,668,676] Importantly, the shutoff of host mRNA translation leads to suppression of the antiviral response and disables antiviral stress-induced arrest.[362,461] NS1 also has mRNA translation shutoff activity and it was recently reported that there is an interplay between NS1 and PA-X that modulates pathogenesis and suppression of the innate immune response.[114,668] While NS1 shutoff activity seems to be more targeted toward antiviral gene expression, the PA-X activity has been described as relatively unspecific but with a preference for RNA polymerase II–transcribed mRNA in the nucleus.[114,462] Strong activity of both proteins can decrease viral fitness and pathogenesis suggesting that the effect of PA-X activity on virulence might be strain specific and dependent on NS1.[668]

The Role of Other Accessory Proteins

Several additional accessory proteins or putative ORFs have been described for influenza A viruses including PB2-S1, PB1-N40, PA-N155, PA-N182, M42, NS3, and ORF NEG8.[912] A hallmark of accessory proteins is that they are not required for virus replication and might not be expressed by all strains. PB2-S1 is a splice variant that includes the 462 N-terminal of PB2 plus 46 additional amino acids from a +1 ORF. It is found in pandemic H1N1 viruses but not seasonal H3N2 or prepandemic seasonal H1N1 viruses, and its biological function is unclear.[998] PB1-N40 is a truncated version of PB1 that lacks the N-terminal 39 amino acids and starts at PB1 methionine 40.[970] The lack of the N-terminus ablates its ability to interact with PA and its proposed role is in regulation of PB1 and PB1-F2 expression.[876] PA-N155 and PA-N182 are proteins expressed from the PA segment, lack the N-terminal endonuclease domain of PA, and start at methionines 155 and 182 of PA, respectively.[876] Their deletion has been shown to have a slightly negative impact on virus replication and pathogenicity, but no specific function has been assigned to them.[629] In addition to the M segment splice variant that forms the M2 mRNA, two more splice variants, M mRNA3 and M mRNA4, have been detected.[814,971] M mRNA3 does not encode a protein, but mRNA4 has been predicted to encode a protein named M4.[814] A variant of this predicted protein, M42, was indeed found in a mutated virus lacking M2 (through deletion of the M mRNA2 splice donor site) and functionally

replaced M2. This is not surprising since M42 is basically M2 with a variant ectodomain.[971] Similarly, a splice variant of the NS segment has been detected that translates into the NS3 protein, which is a NS1 protein isoform with a large deletion in its effector domain.[796] Again, the function of this protein is unknown and it is only encoded by a very small number of natural viral isolates. Finally, the enigmatic NEG8 ORF is a highly conserved antisense direction ORF of the NS segment. The putative approximately 25-kDa protein it might encode was termed NSP and is predicted to have a signal peptide, two TMDs, and an N-linked glycosylation motif.[778] However, despite significant efforts, this protein has never been detected in infected cells except for a T-cell response.[30,381,912] It remains unclear if influenza viruses express additional accessory proteins with significant functionality. Especially for influenza B, C, and D viruses, this area is not well explored.

REVERSE GENETICS

Because the *Orthomyxoviridae* are negative-strand RNA viruses, introduction of the genomic RNAs into cells does not result in the formation of infectious virus (as it does in the case of positive-strand RNA viruses). Initial experiments eventually leading to the genetic engineering of influenza viruses involved the reconstitution of functional RNP complexes *in vitro*[392,700] and transfection of functional RNPs into cells. In these experiments, cDNA-derived RNA for a specific segment was mixed with purified virion NP and polymerase proteins and transfected into cells before or after infection with a helper influenza virus in order to provide the remaining vRNP segments.[560] Initially, rescue of infectious virus containing the cDNA-derived RNA required selection of the novel virus against the helper virus.[233] Instead of using cDNA-derived RNA, cells can be transfected with a plasmid construct containing the gene of interest flanked by an RNA polymerase I promoter and terminator sequences. Cellular RNA polymerase I normally transcribes rRNA (which lacks a 5′ cap and 3′ poly[A] tail), and therefore the RNA synthesized from the plasmid construct is an exact replica of the vRNA. The viral polymerase proteins were supplied by transfection with polymerase II–driven expression plasmids, and the remaining genomic segments were provided by infection with a helper influenza virus.[654,719] A disadvantage of these early systems was the need for helper virus, which

must be selected against in order to isolate the rescued virus.

In 1999, a decade after the initial influenza reverse genetics system had been described, Fodor et al.[251] and Neumann et al.[653] reported the generation of influenza viruses entirely from cloned cDNAs. In the system reported by Fodor et al., cDNA from each of the eight genome segments was cloned in negative orientation between a truncated human RNA polymerase I promoter and the hepatitis delta virus ribozyme.[251] Transfection of the eight vRNA-encoding plasmids into Vero cells along with four polymerase II–driven plasmids expressing NP and the polymerase complex (PB1, PB2, PA) resulted in recovery of infectious virus (Fig. 14.28). As helper virus is not required for the generation of recombinant virus, the cumbersome selection process was unnecessary. Improvements to this system now include the transfection of cocultured 293T cells (necessary due to the human RNA polymerase I promoter) and Madin-Darby Canine Kidney (MDCK) cells, which support high levels of virus replication.[652]

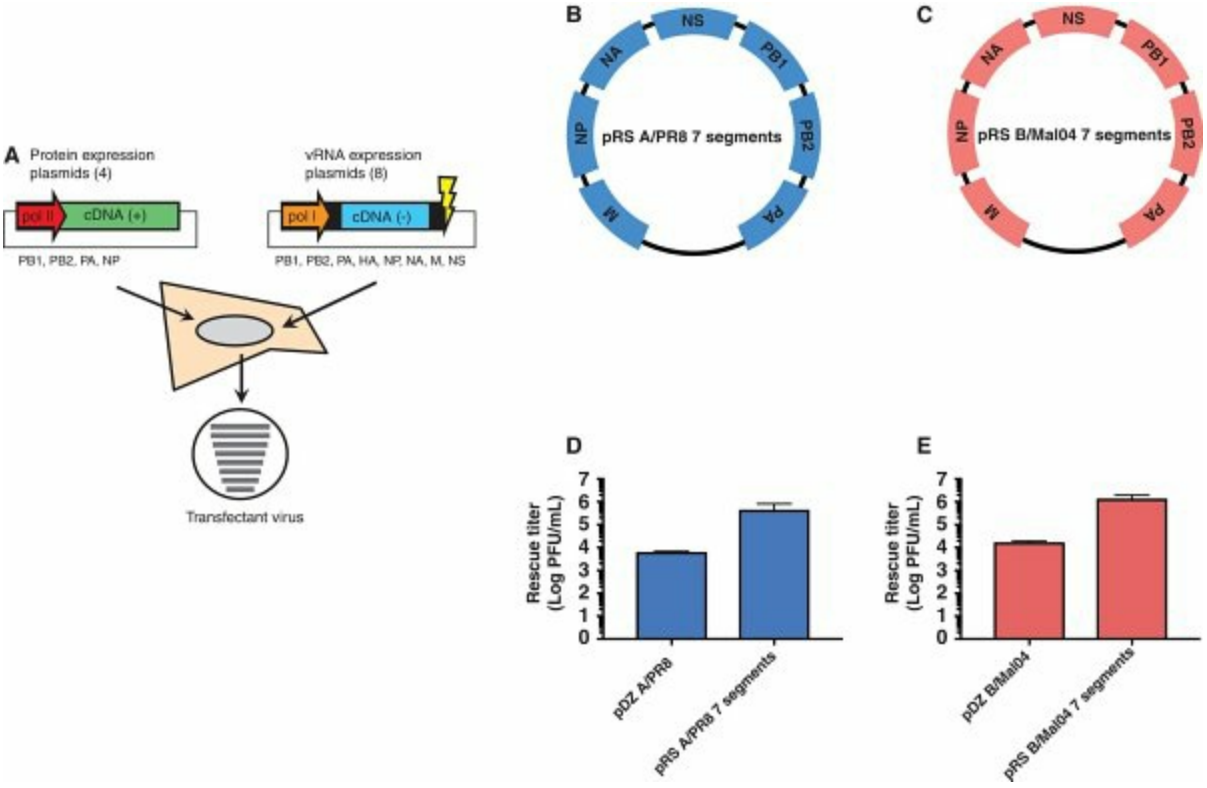

FIGURE 14.28 A: Schematic representation of the plasmid-based rescue system for influenza A virus. The negative-sense

complementary DNA (cDNA) for each viral segment is cloned between a polymerase I promoter and the hepatitis delta virus ribozyme or polymerase I terminator. These eight plasmids are transfected into mammalian cells along with four expression plasmids for the polymerase proteins and nucleoprotein (NP). The resulting transfectant virus is then passaged on fresh cells. For details, see Ref.[251] (Courtesy of Adolfo García-Sastre.) The plasmid-based rescue system can be optimized by combining bidirectional (including Pol I and Pol II promoters) transcription cassettes for multiple genomic segments onto one plasmid. Examples include pRS A/PR8 7 for influenza A virus **(B)** and pRS B/Mal04 for influenza B virus **(C)**, which contain seven genomic segments (PB2, PB1, PA, NP, NA, M, NS) and can be combined with a second plasmid encoding the HA of choice. These optimized rescue systems result in increased rescue efficiency as compared to the eight-plasmid pDZ system (**D and E**, respectively).[272] Segments are not to scale but show their order within the plasmid backbone. (Courtesy of Weina Sun.)

Further improvements to these systems were reported in which only eight plasmids were required.[389,390] The plasmids contained cDNAs of genomic segments cloned in negative orientation with a human RNA polymerase I promoter at the 5′ end and the mouse RNA polymerase I terminator at the 3′ end. The cellular RNA polymerase I was responsible for copying the cDNA into vRNA. Downstream of the RNA polymerase I terminator was a CMV immediate-early promoter. A polyadenylation sequence was inserted at the other end, giving rise to a polymerase II–driven mRNA transcript from the opposite DNA strand. Expressed viral proteins and vRNAs then assembled in the transfected cells and resulted in the formation of infectious virus derived entirely from only eight plasmids. A single plasmid containing the cDNAs of all eight RNAs resulted in the generation of infectious virus when transfected into human cells.[650] Most likely, transcription of mRNA-like molecules occurred from this plasmid, which then gave rise to the formation of the

complementing viral polymerase proteins. These proteins, together with the full-length vRNA segments (also transcribed from the plasmid), allowed rescue of fully infectious virus. Another one-plasmid system was developed for the rescue of influenza A viruses in chicken cells.[1025] Other modifications of the rescue system involve the use of uncloned PCR-amplified products, which obviates possible problems in cloning toxic sequences,[200,1042,1043] and the use of adenovirus as a vector to deliver the required plasmid constructs.[683] In past studies, others have demonstrated that reducing the number of required plasmids for rescue could greatly increase virus recovery.[650,1025] Therefore, two plasmids, termed pRS A/PR8 7 segment and pRS B/Mal04 7 segment, were generated for the A/PR8 (H1N1) and B/Mal04 (Vic/87) viruses, respectively (Fig. 14.28B, C). The plasmids contain all of the segments of the influenza viral genome except HA. Viral rescue with this system requires only two plasmids: the pRS 7 segment plasmid and an additional plasmid encoding the HA segment. Transfection of the pRS rescue system results in an approximately 2-log increase in rescue titer over the conventional methodology (Fig. 14.28D, E).[272] De Wit et al.[185] designed a rescue system built on transcription by the T7 polymerase, which allows the rescue of influenza viruses in practically all cells independent of the species origin.

Influenza viruses expressing foreign genes have also been generated, demonstrating the use of influenza virus as a vector to deliver foreign antigens to the immune system. Numerous approaches have been successful for the expression of foreign antigens by influenza viruses. These include (a) replacement of the antigenic domains of either the influenza HA or NA glycoproteins with epitopes from foreign proteins[536,538] and (b) modification of existing viral genomic segments to express influenza viral proteins fused to other foreign proteins. These polyproteins can then be subsequently cleaved into two separate proteins. Also reported was the rescue of an influenza virus that expresses an uncleaved chimeric HA with a 140–amino acid insertion of the receptor-binding domain of the *Bacillus anthracis*–protective antigen (PA),[534] (c) replacement of ectodomains of surface glycoproteins with those of foreign glycoproteins,[247] and (d) preparation of viruses with foreign antigens encoded by a ninth RNA segment.[296,351,652,705]

Advantages of influenza viruses over other viruses for the expression of foreign proteins include the fact that influenza viruses are extremely safe as a

nonintegrating and nononcogenic virus. Infection with influenza viruses also elicit a strong and long-lasting immune response, and thus recombinant influenza viruses may be useful as vaccine vectors in the future. The limitations related to the use of influenza viruses for the expression of foreign antigens include the limited (but not yet well-defined) capacity of influenza viruses to express foreign sequences and the requirement for packaging signals on both the 5′ and 3′ ends of the vRNA, which may interfere with the expression of foreign genes.

The advances in reverse genetics technology have been of great benefit to the study of structure/function of different influenza virus genes and their proteins. In many cases, the definitive role of a gene or of a domain (or even of a single amino acid) can only be explored by introducing appropriate mutations into the genome of the virus and then analyzing the phenotype of the rescued virus. As discussed, rescue systems have been described for influenza A viruses[296,524,578] and B viruses.[388,429,431] Also, rescue systems have now been developed for influenza C viruses.[171,626,627,685] Influenza viruses have been generated that express chimeric (type A/B) HAs and NAs. For example, such viruses may express, in a type A genetic background, the extracellular portion (ectodomain) of an influenza B HA and/or NA.[247,397,399] These findings show that the HA and NA of an influenza A virus can be functionally replaced with the corresponding protein from an influenza B virus. In turn, viruses have been made in the influenza B virus background expressing proteins derived from influenza A viruses.[337] By taking advantage of the knowledge about packaging sequences, influenza A viruses have been made to contain nine segments expressing an H1 and an H3 HA[290] or only seven segments.[288] In the latter virus, the HA and the NA have been replaced by the HEF protein of an influenza C virus. Whole-organ imaging and analysis of infected cells are now facilitated by chimeric influenza viruses that express a green fluorescent protein (GFP) molecule for visualization of influenza virus–infected cells.[175,271,367,452,453,566,694,896,897] Reverse genetics has also been successfully used to rescue an influenza virus expressing all eight genes of the “extinct” 1918 pandemic virus, which has allowed its extraordinary virulence to be studied.[695,901]

Reverse genetics has also helped in designing improved influenza virus vaccines.[666] The live attenuated pH1N1 2009 vaccine was made from a plasmid-generated strain, into which HA gene mutations were introduced to

give high yields without changing the antigenicity of the strain.[129] Also, killed and live pandemic H5N1 virus vaccines were prepared using reverse genetics, allowing the removal of the basic peptide from the HA cleavage site, to make the strains used for manufacturing less virulent.[398]

Thogoto virus, which has six negative-strand RNA segments, has also been rescued by a reverse genetics system.[472,927] The vRNAs were transcribed from the plasmids under the control of a polymerase I promoter, and the structural proteins were expressed from six plasmids driven by a T7 polymerase promoter in the presence of a T7 vaccinia recombinant.

INHIBITORS OF INFLUENZA VIRUSES

Because influenza viruses remain a constant health threat, major efforts have been directed at discovering effective antivirals over the past several decades. Presently, there are seven drugs available for use in humans: amantadine, rimantadine, oseltamivir, zanamivir, peramivir, laninamivir (in Japan), and baloxavir marboxil (Fig. 14.29). Past and current approaches to antiviral therapy are briefly discussed here (according to the steps in the viral replication cycle targeted by each drug). Extensive reviews cover the vast literature on this subject.[38,50,64,157,190,302,363,430,481,754,805]

Inhibition of Attachment and Uncoating

While vaccination, in essence, targets the HA so that specific antibodies are generated that block attachment of the virus to the receptor, drugs that interfere with the HA–sialic acid interaction have not been successfully developed.[1023] This is perhaps surprising because the x-ray crystallographic structures of the HA and of HA–ligand complexes have now been known for decades. In principle, such an approach could work,[140,308] but this strategy, using sialic acid analogs (or polymers bearing sialic acids), has not led to an FDA-approved drug. Whether removal of receptor molecules from the respiratory tract by administration of exogenous sialidase/neuraminidase is a viable antiviral approach remains to be seen. A sialidase fusion protein, DAS181, has been shown to be an effective antiviral strategy in tissue culture and animal models.[48,510] Ongoing clinical trials with this drug will demonstrate if it is effective in humans.[1024]

Quinone derivatives that prevent the first stage of the conformational change of the HA and thus inhibit infection were discovered in 1993,[62] and other compounds with a similar mechanism showed inhibition for some strains but not for others.[177,839] Additional examples include Arbidol (umifenovir) and S20.[59,446,960] Compounds have also been identified that appear to push the HA into an inactive state[386] or that associate with the N-terminal heptad-repeat trimer, thus interfering with the *trimer of hairpin* (helix bundle) formation.[147] This latter approach would be similar to that successfully applied for human immunodeficiency virus (HIV) using the fusion inhibitor T-20.[464] In addition, several other approaches aimed at preventing virus attachment have been reported.[283,331,525,617,779,827,838]

Nitazoxanide (a thiazolide) is thought to prevent terminal glycosylation of HA and thereby impair HA maturation and trafficking to the cell surface.[481,767] Of these approaches, Arbidol is currently used in humans in Russia and China and nitazoxanide is in late-stage clinical trials.

Monoclonal antibodies that broadly bind to the HA and block attachment to sialic acid receptors or fusion between viral and endosomal membranes and/or work via effector functions have recently been discovered and might also serve as therapeutics. A number of these antibodies are currently in clinical development.[634,985] Insights from these monoclonal antibodies have also been used to design and engineer small proteins that block attachment or fusion.[248,475,852,964] In addition, multidomain camelid antibody constructs capable of blocking both fusion and attachment have been developed as well.[511] Polyclonal antibodies in the form of influenza-specific human intravenous immunoglobulin (IVIG) are currently tested in clinical trials as well.[760]

Another approach concerns the inhibition of the posttranslational cleavage of the HA, which results in a molecule unable to undergo the conformational change required for fusion/uncoating. Several exogenous protease inhibitors have been investigated,[47,71,518,1040,1041] of which aprotinin has been found to be effective in humans.[1038] Drugs belonging to this general class have been successful against HIV but have not been further developed for widespread therapeutic or prophylactic use against influenza virus in humans.

Amantadine, which has been known for many decades to inhibit most influenza A viruses, has been found to target the M2 ion channel (for details, see M2 Protein and Fig. 14.28A). During uptake, virus enters endosomes where the acid pH activates the ion channel, resulting in the transport of protons into the viral interior. This process, which is required for the dissociation of the RNP complex from the M1 protein and subsequent release of the RNP into the cytoplasm, is blocked by amantadine and its derivatives (including rimantadine; Fig. 14.28B).[718,958] In addition, amantadine can affect the pH regulation of vesicles involved in the transport of viral glycoproteins to the cell surface during assembly.[841] Thus, there are two possible steps at which amantadine can exert an antiviral effect: uncoating and HA stability (in some strains) during transport in vesicles. Unfortunately,

resistance to amantadine and to its 10-fold more active derivative, rimantadine, develops with increased use in humans and animals.[613] In fact, according to Centers for Disease Control and Prevention (CDC) guidelines, adamantanes are not recommended for clinical use as of 2018/2019.

Inhibitors of the Viral Replication Complex

The vRNA-dependent RNA polymerase is a good antiviral target as it possesses unique features not found in the cell. In recent years, rapid progress has been made in the development of inhibitors of the influenza virus polymerase complex. Increases in structural and functional knowledge of the influenza virus polymerases are expected to even further catalyze the development of drugs interfering with this molecular machine.[555,712,743,930]

Already in the 1990s, Tomassini et al.[888,889] reported that 2,4-dioxobutanoic acid and 2,6-diketopiperazine derivatives selectively inhibit the endonuclease activity (PA) of the influenza virus polymerase. Since then, rapid progress has been made with the first inhibitor against this activity of both the influenza A and B PA, baloxavir marboxil (S-033188), which is already in the market in the United States (Fig. 14.28G, H).[364,999] Of note, resistant mutants have already been detected during clinical trials and at low frequency within the population.[364] Additional endonuclease inhibitors including AL-974 are also in development.[1011]

Capped- and uncapped-RNA fragments that can interfere with cap binding, capped-RNA primed transcription, or panhandle formation have been reported,[556] but these compounds would have pharmacologic limitations because of difficulties in getting charged molecules into cells. A small molecule inhibitor of the cap-snatching activity of PB2, pimodivir, is currently being tested in late-stage clinical trials.[245] Other compounds with similar activity are in earlier stages of development.[149,562,702,711]

Ribavirin (which is approved for treatment of hepatitis C) and several other nucleotide analogs are known to inhibit influenza virus replication in humans, but toxicity remains a problem.[443,529,556] For RNA viruses, most of the antiviral effects of ribavirin are likely due to its incorporation as a purine analog during viral replication, resulting in lethal mutations. Favipiravir (T-705) inhibits influenza virus RNA polymerase activity also by acting as a purine analog and has been shown to be effective against several RNA

viruses.[186,276,277,467] Favipiravir is approved for use in Japan as treatment for influenza virus infections in a pandemic setting. Screens of small molecules have also uncovered novel inhibitors of influenza virus replication that target the NP and PB1 proteins.[406,408,449,854,959]

Neuraminidase Inhibitors

The study of temperature-sensitive influenza virus mutants with defects in the NA has shown that the function of this enzyme is to release the newly formed virus from the cell surface.[693] Additional studies showed that neuraminic acid analogs inhibit influenza virus replication in tissue culture and that aggregates of virus are formed at the cell surface in the presence of these drugs (Fig. 14.22).[688,692] von Itzstein et al.[921] designed a derivative of neuraminic acid that had a guanidino group at C atom 4 instead of the OH group of the previously studied neuraminidase inhibitor, 2,3-didehydro-2-deoxy-*N*-acetylneuraminic acid (DANA).[593] This compound, zanamivir (Fig. 14.29), is not orally bioavailable and is FDA approved for administration by inhalation or by nasal spray. Most recently, intravenous administration has been investigated.[742] In numerous studies, this compound has been shown to be a potent anti-influenza drug, both prophylactically and therapeutically.[155,298,430,590,658] Peramivir is another approved neuraminidase inhibitor that can be administered intravenously.[476,641] A long-acting neuraminidase inhibitor (laninamivir) that requires only a single administration for the entire course of treatment was recently developed and is currently approved for use in Japan.[993] The search for compounds with oral bioavailability led to the development of oseltamivir.[533] Its prodrug is an ethyl ester of a compound that has the three OH groups of C atoms 7, 8, and 9 of sialic acid replaced by a hydrophobic side chain, which allows the drug to pass through the gut and into the bloodstream (Fig. 14.29). Oseltamivir has been shown to be highly effective against both influenza A and B viruses, including strains containing the NA gene of the 1918 pandemic virus.[423,430,590,658,902] Although neuraminidase inhibitor–resistant variants had been described with escape mutations in the HA as well as the NA,[31,156,324,428,466] it was still unexpected that such widespread resistance would be seen among the seasonal H1N1 viruses by the 2009 season.[412,679] Prior to 2007, the presence of the NA H274Y (H275Y in N1 numbering)

mutation was associated with a cost to viral fitness.[378,425] By 2008/2009, this mutation had a fitness advantage even in the absence of oseltamivir, and these resistant viruses were shown to be highly transmissible in a guinea pig model.[76] It has been proposed that compensating mutations in the NA resulted in a more stable molecule with enhanced expression at the cell surface than was observed for a mutant with only the H274Y mutation.[61] Interestingly, for the H3N2 viruses, oseltamivir resistance is associated with a loss of fitness and is detrimental to transmissibility of these viruses.[75,1007] Resistant H3N2 viruses have been isolated particularly from immunocompromised patients undergoing therapy.[598,677] Similarly, oseltamivir-resistant isolates of the 2009 pandemic virus have been observed in these patient populations but not in the community.[318,599] Based on experiments in animal models, it is predicted that an H274Y change in the NA of the 2009 pandemic virus would not be associated with any substantial loss in fitness or transmissibility.[206,597,795] With this virus already being resistant to the adamantanes, acquisition of oseltamivir resistance would make it a multi–drug-resistant virus and a significant threat. Oseltamivir-resistant influenza B viruses have also been detected, although at a relatively low frequency.[102,428,701] Of note, avian and zoonotic influenza viruses can also carry resistance mutations.[210,316,339,404] For H7N9, it has been shown that these mutations do not impact on viral fitness.[339] Fortunately, mutations associated with oseltamivir resistance do not generally confer zanamivir resistance, and reports of zanamivir resistance in patients are rare.[325] Structures of oseltamivir-resistant NAs that remain sensitive to zanamivir show that this is due to an altered hydrophobic pocket in the active site that affects oseltamivir but not zanamivir binding.[153] As an alternative to small molecule inhibitors, broadly protective monoclonal antibodies that inhibit the NA have recently been isolated. Like antibodies to HA, they are being considered for development into future therapeutics.[130,975]

Inhibition of Cellular Factors

The identification of host factors that are required for optimal influenza virus replication (see section Cellular Functions Required for Influenza Virus Replication) provides additional targets that can be explored for potential antiviral development.[211,368,553,742,804,807,1010] There are distinct advantages

and disadvantages to this approach. The obvious disadvantage is that inhibition of a cellular activity that is essential for cell survival or growth may be detrimental to the host, so such proteins may not be suitable as antiviral targets. However, particularly with acute infections like influenza, the short duration of therapy may allow for temporary loss or down-regulation of a cellular function without harming the host. The major advantage of targeting a host factor over a viral factor is that resistance is much less likely to develop. There is also greater opportunity for host-directed compounds to have broad-spectrum activity as many viruses may rely on the same host function. For example, HSP90 inhibitors have been shown to inhibit influenza virus[118] and other viruses including hepatitis C virus and Ebola virus.[640,831] Several inhibitors of enzymes in the *de novo* pyrimidine synthesis pathway have been shown to inhibit the replication of a wide range of viruses, including influenza virus,[65,387,933] presumably because viral replication is particularly dependent on large pyrimidine pools. Inhibitors of receptor tyrosine kinases have also been shown to inhibit influenza virus replication as well as other viruses.[493,494] Identification of the target of a novel compound can be difficult, but a cellular target is strongly suggested if the compound can inhibit viruses belonging to different families and/or shows species-specific activity. This is the case with a compound shown to block replication of both influenza viruses and several paramyxoviruses,[491] and future identification of the target may reveal an important virus–host interaction. Likewise, known inhibitors of host factors or signaling pathways identified as critical for influenza virus replication could be repurposed as antivirals or at least chemical probes for investigating the function of specific virus–host interactions. Inhibitors of the following cellular factors have all been shown to inhibit influenza virus growth: MEK, CAMK2B, vATPase, and CLK1.[204,451,478,720] Rather than inhibiting the activity of a required host protein, it is also feasible for an antiviral compound to function by activating a cellular factor with antiviral activity, as shown by chemical activation of REDD1 expression, which decreases growth of both influenza and vesicular stomatitis viruses.[580]

PERSPECTIVES

Human influenza viruses were first isolated in 1933, and since that time, they

have been studied extensively. Extraordinary progress has been made in elucidating the components of the virus and in understanding the medical consequences of an influenza virus infection. Many of these discoveries have had implications far beyond the influenza virus field and have sparked new developments in disciplines such as immunology and protein structure as well as furthering our basic understanding of viruses in general. For example, the ability of virus to agglutinate red blood cells (hemagglutination) was first recognized as a property associated with influenza virus, hence the name of its major surface glycoprotein. With the discovery that this phenomenon extends to other viruses (e.g., measles virus, rubella virus), this property became the basis for viral diagnostic tests, allowing for easy detection of virus or of protective antibody (hemagglutination inhibition) in patient sera. The influenza virus neuraminidase was also the first enzyme found to be associated with an animal virus, even before it was recognized that viruses encode their own polymerases, including those with reverse transcriptase activity. The discovery of interferon by Isaacs and Lindenmann in 1957 was the result of studying infection with heat-inactivated influenza virus (the anti-interferon activity of the NS1 protein was inhibited by the heat inactivation of the virus).

Structural analyses of the HA and NA proteins helped to lay the foundation for the exploration of structure/function relationships of large, biologically active proteins. Today, the intensity of influenza research has not diminished, and a PubMed search yields more than 100,000 entries at the time this chapter was revised.

Many approaches that served us well in the past have now been superseded by newer techniques, but the contribution of these earlier techniques to our current knowledge should not be overlooked. The superb collections of temperature-sensitive mutants obtained and characterized by Akira Sugiura in Japan and by Christoph Scholtissek and Rudolf Rott in Germany made it possible to study the genetics of the virus on a gene-by-gene level and allowed the field to take giant steps forward. The early sequencing of the influenza virus proteins and RNAs was an effort of months, if not years. Now, this can be done in a matter of hours, and since the last edition of this book, there has been an enormous increase in the number of influenza virus sequences submitted to GenBank and GISAID. We also have exciting new molecular technologies (including reverse genetics) that have

allowed us to obtain an excellent understanding of the virus on a molecular level and to learn how it has changed over the years. Using this technology, we have even been able to resurrect the 1918 pandemic influenza virus from sequenced RNA fragments and to study its pathogenicity in animal models. Reverse genetics is also a technique that allows us to develop influenza virus constructs, which can induce long-lasting and broadly protective antibody responses in humans and animals bringing us closer to a universal influenza virus vaccine.

What are the challenges for the future? With the threat of yet another pandemic influenza virus emerging, a detailed molecular understanding of virus–host interactions is needed in order to know how best to disable the virus. Perhaps, one of the most pressing questions is, what makes an influenza virus transmissible from human to human and from animal to animal? This aspect has been notoriously difficult to study and will require the use of complex animal models. On a molecular level, it will be important to learn more about the cell's signaling pathways and how they are modulated during influenza virus replication. What makes the virus a pathogen in one species and not in another? How does the virus affect the host immune response, and—in turn—how is the virus globally affected by the immune system in humans and animals? What role does the age of a person (child, adult, elderly), the sex of a person,[616] and conditions/diseases (pregnancy, obesity, diabetes) play in influenza virus replication? What are the complicating factors (coinfection with other viral/bacterial agents, environmental changes) in an influenza virus infection? And last but not least, we need to address the question of host genetics in influenza virus infection and in virus infections in general. Which genetic makeup (polymorphisms and gene expression profiles) determines susceptibility to (and recovery from) influenza virus infection in humans and animals?

These efforts will need to be accompanied by the development of reliable rapid diagnostic tests and safe, broadly effective antivirals. As we begin to obtain a better understanding of the host factors involved in influenza virus replication, we have the opportunity to start using these host factors as new antiviral drug targets. Potentially, this approach can lead to the development of broad-spectrum antivirals that can be used to treat influenza and other viral diseases. Since the isolation and characterization of broadly protective monoclonal antibodies directed against conserved portions of the HA, it is

now possible to design novel immunogens that may serve as vaccine constructs. Such universal influenza vaccines may eliminate the need for annual revaccinations against influenza and provide protection against intrasubtype variants (antigenic drift) and against strains belonging to different subtypes (antigenic shift). In a new pandemic outbreak, the availability of such tools will be imperative. We might even consider eradicating influenza B with an effective universal influenza B virus vaccine since humans are the only reservoir for the virus. It is likely that answers to these challenges will come from a vigorous basic science enterprise, which has brought us a long way in the past several decades of influenza virus research.

Acknowledgments

We want to apologize to all our colleagues whose work we could not reference due to space limitations. We would also like to acknowledge the work of Megan Shaw, Ph.D., coauthor of this chapter in the fifth and sixth editions of *Fields Virology*. Finally, we want to thank Jordan Bragg and Molly Deroy for their help with editing as well as Fatima Amanat, Guha Asthagiri-Arunkumar, Mark Bailey, James Duehr, Alec Freyn, Ericka Kirkpatrick, Andrea Parsons, Daniel Stadlbauer, Gayathri Vijayakumar, and Allen Zheng for their help proofreading this chapter.

Perspectives

INTRODUCTION

Influenza viruses (family *Orthomyxoviridae*) cause highly contagious respiratory disease with potentially fatal outcomes. Symptoms include fever, headache, cough, sore throat, nasal congestion, sneezing, and body aches. Influenza viruses also cause local epidemics or pandemics (worldwide outbreaks) with significant infection rates. Although the economic burden of influenza is most prominent during pandemics, the combined annual costs of seasonal epidemics due to sick days, emergency room visits, and medications are significant. With the realization that avian influenza viruses can be directly transmitted to humans (Fig. 15.1), influenza viruses are now considered a major, global health threat.

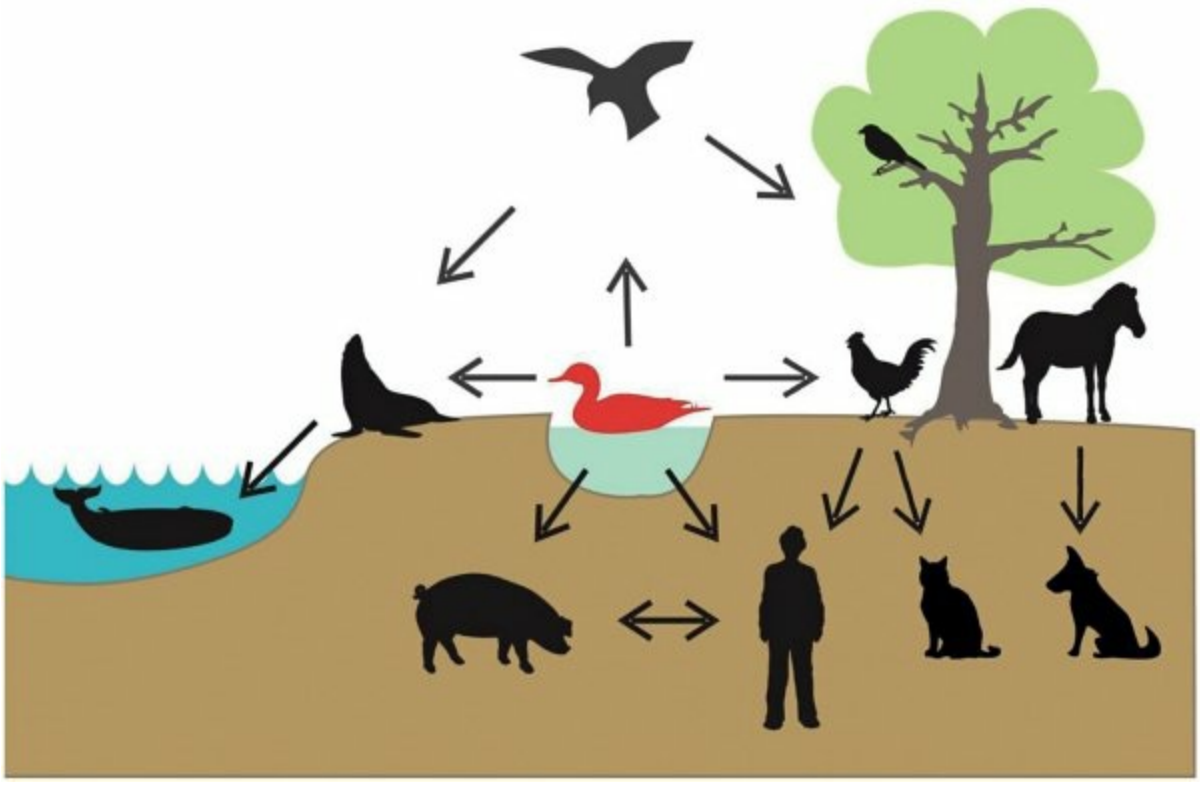

FIGURE 15.1 Influenza A virus reservoir. Wild aquatic birds are the main reservoir of influenza A viruses. Virus transmission has been reported from wild waterfowl to poultry, sea mammals, pigs, horses, and humans. Viruses are also transmitted between pigs and humans and from poultry to humans. Equine influenza viruses have been transmitted to dogs. Cats can be infected by avian, human, or canine viruses.

Technologies such as reverse genetics[103] have allowed the routine manipulation of influenza viral genomes. In addition, a number of other technologies and approaches—including large-scale sequencing of viral genomes (through conventional Sanger sequencing and next-generation sequencing); improved computational tools for sequence analysis; small interfering RNA (siRNA)–mediated screens; transcriptomics, proteomics, metabolomics, and lipidomics studies; gene knockout technologies including CRISPR/Cas9–mediated gene knockout; and much-improved approaches for the production of human monoclonal antibodies—are being used to study the viral and cellular factors that control influenza virus replication, interspecies transmission, pathogenesis, and host immune responses to viral infections. Despite recent advances, much still needs to be learned about the molecular determinants of these events.

NOMENCLATURE

Influenza viruses belong to the *Orthomyxoviridae* family. This family comprises seven genera: *Alphainfluenzavirus* with the species *Influenza A virus*; *Betainfluenzavirus* with the species *Influenza B virus*; *Deltainfluenzavirus* with the species *Influenza D virus*; *Gammainfluenzavirus* with the species *Influenza C virus*; *Isavirus* with the species *Salmon isavirus*; *Quaranjavirus* with the species *Johnston Atoll quaranjavirus* and *Quaranfil quaranjavirus*; and *Thogotovirus* with the species *Dhori thogotovirus* and *Thogoto thogotovirus* (see the International Committee on Taxonomy of Viruses Web site: http://www.ictvonline.org). *Deltainfluenzavirus*, *Isavirus*, *Quaranjavirus*, and *Thogotovirus* do not circulate in humans and will not be discussed in this chapter. Influenza A viruses are further classified into subtypes based on the antigenicity of their hemagglutinin (HA) and neuraminidase (NA) proteins; currently, 18 HA subtypes (H1–H18) and 11 NA subtypes (N1–N11) are known. The present nomenclature system includes type of virus, host of origin (except for humans), geographic site of isolation, strain number, and year of isolation, followed by the antigenic description of the HA and NA subtypes in parenthesis: for viruses isolated before 2000, the year should be given as two digits; for viruses isolated in 2000 or later, the year should be given as four digits. For example, A/swine/Iowa/15/30 (H1N1) describes an influenza A virus isolated from a

pig in Iowa in 1930 with a strain number of 15 and an H1N1 subtype. Antigenic subtypes have not been identified for influenza B and C viruses. Orthomyxoviruses of different genera do not cross-react antigenically.

Seroarcheology

Retrospective seroepidemiologic analysis, or seroarcheology, has provided information about influenza virus outbreaks that preceded the virologic techniques currently used to unequivocally identify infectious agents. Early studies suggested that the pandemic of 1889 to 1891 was caused by a virus of the H2N2 subtype, whereas that of 1900 had been attributed to an H3N8 strain. More recent reevaluation of the data indicates that the 1889 to 1891 pandemic was caused by an H3-like virus and there is no compelling evidence that links the H2 subtype to a pandemic other than that of 1957 (see The Pandemic of 1957— Asian Influenza section). The latter conclusion is substantiated by the lack of protection among those who were at least 80 years old during the 1957 pandemic. Seroarcheology has also linked the 1918/1919 pandemic to an H1 virus, a finding that has been confirmed by sequence determination of influenza viral RNA (vRNA) from the lung tissues of victims[117] (see also The Pandemic of 1918/1919—Spanish Influenza [H1N1] section). Studies using antibodies to the NA protein suggest that in the late 1800s, viruses of the N8 subtype were circulating and were later replaced by N1 and N2 subtype viruses. Thus, during the 1900s, only a limited number of virus subtypes (H1N1, H2N2, H3N2, H3N8) were established in humans. Reassortant H1N2 viruses emerged in humans in 2001 and circulated in 2002 and 2003 but have not been isolated from humans since early 2004.

Virus Isolation

In 1930, the first swine influenza virus, A/swine/Iowa/30, was isolated, but it was not until 1933 that the first human virus was isolated by Wilson Smith, Sir Christopher Andrewes, and Sir Patrick Laidlaw of the National Institute for Medical Research in London, England. These investigators inoculated ferrets intranasally with human nasopharyngeal washes from an influenza patient. The animals exhibited an influenza-like disease, and the virus was transmitted to cage mates. One of their junior colleagues (later Sir Charles Stuart-Harris) became infected by these experimentally infected animals, and

the virus was subsequently isolated from him. Because it was the first human influenza virus, it was named influenza A virus. In 1940, an antigenically distinct virus was isolated and named type B virus (B/Lee/40). The first influenza C virus was isolated in 1947. “Fowl plague” was first described in 1878 as a disease that affected chickens in Italy. The causative agent was isolated in 1902 (A/chicken/Brescia/1902 [H7N7]); however, it was not until 1955 that Schafer recognized fowl plague virus as an influenza virus.

Virus Propagation

Influenza viruses were first propagated in embryonated hens’ eggs, which continue to be the most widely used system for vaccine production, although cell culture systems are now also in use (see later discussion). Avian and equine strains of influenza A viruses can be isolated from the allantoic cavity of 10- to 11-day-old embryonated eggs after 2 to 3 days of incubation at 33°C to 37°C. Human influenza A and B viruses have also been isolated from clinical samples inoculated into the allantoic or amniotic cavity of eggs and incubation at 33°C to 34°C. However, recent human influenza viruses of the H3N2 subtype are difficult to isolate from embryonated eggs because of mutations in HA that alter the receptor-binding specificity. Influenza virus growth in embryonated eggs leads to the selection of antigenic variants that are characterized by mutations in the HA protein[9] (see also Host Cell–Mediated Selection of Antigenic Variants section). Influenza C viruses amplify in the amniotic, but not allantoic, cavity of eggs and are usually grown for 5 days in 7- to 8-day-old embryonated eggs.

Influenza viruses can also be propagated in cell culture. Madin-Darby canine kidney (MDCK) cells support the efficient replication of many influenza A and B viruses and are used to isolate viruses from human samples. Recent human H3N2 viruses do not efficiently grow in MDCK cells and are often amplified in modified MDCK cells overexpressing Siaα2,6Gal (i.e., human-type receptors; see Receptor Specificity of Influenza Viruses section). Although many influenza viruses can grow in African green monkey kidney (Vero) cells, they do so less efficiently than in MDCK cells. Cell culture systems based on MDCK, Vero, and PER.C6 (human primary embryonic retinoblast) cells have been developed for influenza virus vaccine production, and MDCK and Vero cell–based vaccines are approved in Europe for use in humans; MDCK cell–based vaccines are now also

approved in the United States. Influenza viruses also replicate in a number of primary cell cultures, including monkey, calf, hamster, and chicken kidney cells, as well as in chicken embryo fibroblasts and primary human epithelial cells. With the exception of primary human airway epithelium and kidney cells, most cell culture systems require the addition of trypsin to cleave the HA protein of human viruses (except highly pathogenic H5 and H7 viruses), a prerequisite for efficient replication (see HA Cleavage section).

Replication of influenza viruses in eggs or cell culture is measured by using conventional plaque assays, hemagglutination assays that measure the viruses' ability to agglutinate erythrocytes (note that recent human H3N2 viruses have lost the ability to agglutinate commonly used erythrocyte species), or molecular biology techniques, such as reverse transcriptase (RT)–polymerase chain reaction (PCR).

EVOLUTION OF INFLUENZA VIRUSES

Influenza viruses evolve via a complex process that involves the accumulation of mutations over time and the rearrangement of vRNA segments in cells infected with two (or more) different viruses (known as "reassortment"). In wild aquatic birds, avian influenza viruses evolve slowly; while mutations occur, most are not sustained in viral populations because they do not provide an evolutionary advantage. The exceptions are avian viruses in terrestrial poultry, including highly pathogenic H5 viruses, which evolve rapidly (see Infections of Humans with H5 Viruses of the A/goose/Guangdong/1/1996 Lineage section). In contrast to most avian influenza viruses, human influenza viruses show detectable net evolution over time.

Evolutionary Rates of Influenza A Viruses

The mutation rate (i.e., the rate at which mutations occur during viral replication) is higher for RNA viruses than for DNA viruses. For influenza viruses, the reported mutation rates range from approximately 10^{-6} to approximately 10^{-4} substitutions per nucleotide site per cell infection (s/n/c). Not all mutations occur at the same frequency: for example, transitions are detected more frequently than transversions, and G-to-A mutations occur

more frequently than other transitions. These differences in mutation rates affect the probability with which particular amino acid changes can be expected. In contrast to the mutation rate, the evolutionary rate describes the rate at which mutations are fixed in a population. The evolutionary rate is affected by multiple factors including the mutation rate; the fitness effect of mutations (mutations can be deleterious, neutral, or beneficial); clonal interference (i.e., the competition among different lineages with beneficial mutations); epistatic effects (in which the effect of one mutation is dependent on another mutation); and population and within-host dynamics (including population sizes and host immune selective pressure). For influenza viruses, the reported evolutionary rates range from approximately 5×10^{-4} to approximately 8×10^{-3} substitutions per nucleotide site per year (s/n/y).[155]

At the amino acid level, viruses from wild aquatic birds evolve slower than those from terrestrial poultry, swine, or humans.[155] The fact that in wild aquatic birds, most avian influenza A viruses seem to evolve slowly suggests that they are well adapted to their hosts. Thus, although mutations may occur with similar frequency to that in other hosts, they do not result in many amino acid changes. Among avian influenza A viruses, the evolutionary rates are highest for the HA, NA, and NS1 proteins, possibly reflecting their immunogenic or immunomodulatory functions.

Proteins of mammalian and terrestrial poultry viruses continuously accumulate amino acid substitutions. For human influenza A viruses, the evolutionary rates differ among the proteins, likely reflecting differences in the selective pressure of the host. For example, the HA protein has a higher evolutionary rate than the other viral proteins, reflecting host immune pressure acting on HA. This is further supported by the finding that the HA head region (in which the antigenic epitopes are located) has a higher evolutionary rate than that of the HA stalk region; moreover, the antigenic epitopes exhibit a higher rate of nonsynonymous nucleotide changes than do other regions of HA. The human M1 and M2 proteins, encoded by overlapping reading frames, are under different selective pressures: for the M1 protein, a higher percentage of changes is silent than for the M2 protein. The M1 protein thus appears to be well adapted to its mammalian hosts, whereas the M2 protein is under stronger selective pressure. The biologic reason for the selective pressure on the M2 protein is unknown. The two proteins encoded by the NS vRNA segment also differ in their evolutionary

rates, with NS1 showing more variation between alleles than NS2. High evolutionary rates have been reported during the establishment of new virus lineages, for example, the introduction of avian H1N1 influenza viruses into European pigs in 1977, the emergence of highly pathogenic avian H5N2 influenza viruses in poultry in Mexico in 1993/1994, and the emergence of highly pathogenic avian H5N1 influenza viruses in Hong Kong in 1997, which may reflect preferential selection of mutants that provide an advantage in a new host.

Host-Specific Lineages, and Geographic Segregation of Influenza A Viruses

Extensive phylogenetic analyses have revealed host-specific virus lineages for several viral genes.[155] The phylogenetic trees of the PB2, PA, NP, M1/M2, and NS1/NS2 genes (which encode the viral polymerase subunits PB2 and PA, the nucleoprotein NP, the matrix protein M1, the ion channel protein M2, the interferon-antagonist protein NS1, and the nuclear export protein NS2 or NEP; see Chapter 14 for more information) are similar in that they can be divided into two major branches consisting of avian and avian-like swine, or classic swine and human influenza viruses, respectively.

The phylogenetic tree of the PB1 gene (which encodes one of the viral polymerase subunits) differs from those of other influenza virus genes. The PB1 genes of human H1N1 viruses cluster with classic swine viruses, whereas the PB1 genes of human H2N2 and H3N2 viruses form a different sublineage that reflects the introduction in 1957 and 1968 of avian virus PB1 genes into human influenza viruses.[67,123] The genes other than the HA and NA of equine H7N7 viruses do not cluster with avian, human, or swine influenza viruses, suggesting their early separation into a separate lineage.

The phylogenetic tree of the NS1 gene is divided into two alleles: A and B. All mammalian virus NS1 genes belong to allele A, whereas avian influenza virus NS1 genes can belong to allele A or B.

The H1 HA genes can be separated into a branch consisting of avian and avian-like swine influenza viruses versus a branch consisting of human and classic swine viruses. The phylogenetic tree of the H3 HA gene consists of two major branches: one branch splits into two major sub-branches that represent equine/canine and North American avian virus isolates. The second

branch can be separated into Eurasian avian viruses and human and swine H3 HAs that separated from the avian viruses in the 1960s. The human H3 gene has evolved in a single lineage since its introduction into the human population in 1968.

The phylogenetic tree of N1 NA genes shows two major branches that separate into human and classic swine, or Eurasian swine and avian N1 NA genes, respectively. The phylogenetic tree of the N2 NA gene can be divided into a North American avian clade, and a second clade that evolved into Eurasian avian and human virus genes at the beginning of the last century.

The bat influenza virus PB2, PB1, PA, NP, M1/M2, and NS1/NS2 genes are ancestral to those of other influenza A viruses.[141,142] The bat influenza virus HA genes are more closely related to Group 1 HAs (i.e., H1, H2, H5, H6, H8, H9, H11, H12, H13, and H16 HAs) than to Group 2 HAs (i.e., H3, H4, H7, H10, H14, and H15 HAs).[141,142] The bat influenza virus NA genes are ancestral to the known influenza A and B virus NAs.[141,142]

These analyses also reveal that influenza virus genes can be separated by their geographic origin, with a North American and a Eurasian gene pool. These gene pools appear to evolve largely independently, although reassortment between North American and Eurasian viruses has been reported.

Host-Specific Amino Acids

Recent large-scale sequencing efforts have generated thousands of full-genome influenza viral sequences (https://www.ncbi.nlm.nih.gov/genomes/FLU/Database/nph-select.cgi?go=database; www.fludb.org; www.gisaid.org). The comparison of viral proteins derived from different host species and virus lineages has revealed signature amino acids at specific positions that distinguish viruses of different host origins and/or from different lineages. In particular, comparative studies have identified a number of mammalian-adapting signature amino acids in highly pathogenic avian H5 influenza viruses, H7N9 influenza viruses of low or high pathogenicity, the pandemic 1918 virus, and A(H1N1)pdm09 viruses that may play a role in adaptation to humans. For some of these signature amino acids, a role in pathogenicity has been demonstrated (see Molecular Determinants of Host-Range Restriction and Pathogenesis section).

Computational analyses of viral sequences have also identified differences in mutation patterns and codon usage between human and avian influenza viruses. Such approaches may improve our understanding of influenza virus evolution.

Quasispecies

The high error rate of the replication complex of RNA viruses results in the generation of different genetic variants within a host organism, referred to as quasispecies. In the event of host or environmental pressure (including innate and adaptive immune responses and selective pressure resulting from a host change or antiviral pressure), a quasispecies may become the dominant virus population. In the past, the detection of quasispecies was cumbersome due to the detection limits of conventional sequencing techniques. However, with robust deep-sequencing platforms, minor sequence variants can now be detected more easily. These techniques are used to assess the levels of minor variants encoding mammalian-adapting amino acid changes, mutations that confer resistance to antivirals, antigenic escape variants, and so forth. The increasing number of datasets on viral quasispecies may facilitate our understanding of mutational patterns, selective pressures, and evolutionary trends.

Evolution in Influenza B and C Viruses

Significant differences in evolutionary rates exist for influenza A, B, and C viruses. Type B viruses, and especially type C viruses, evolve more slowly than do influenza A viruses. Type B and C viruses seem to be near or at an evolutionary equilibrium in humans; in contrast, the genes of type A human viruses were introduced from birds and have not reached an equilibrium in humans. Influenza A viruses in humans evolve along single lineages, which suggests evolution by clonal selection and limited cocirculation of sublineages. Cocirculation of sublineages has been shown over only limited periods. In contrast, the evolution of influenza B and C viruses is characterized by the cocirculation of antigenically and genetically distinct lineages over extended periods of time. For influenza B viruses, two lineages —B/Victoria (represented by B/Victoria/2/87) and B/Yamagata (represented by B/Yamagata/16/88)—have been cocirculating for about 25 years with changing patterns of prevalence and geographic distribution.

INFLUENZA VIRUS GENETICS

Reassortment

Reassortment is the rearrangement of vRNA segments in cells infected with two (or more) different influenza viruses (Fig. 15.2). Reassortment between 2 viruses can theoretically result in 256 (2^8) different vRNA constellations (i.e., the 2 parental genotypes and 254 new vRNA combinations). Reassortment occurs for influenza A, B, and C viruses but has not been observed among the different types of influenza viruses.

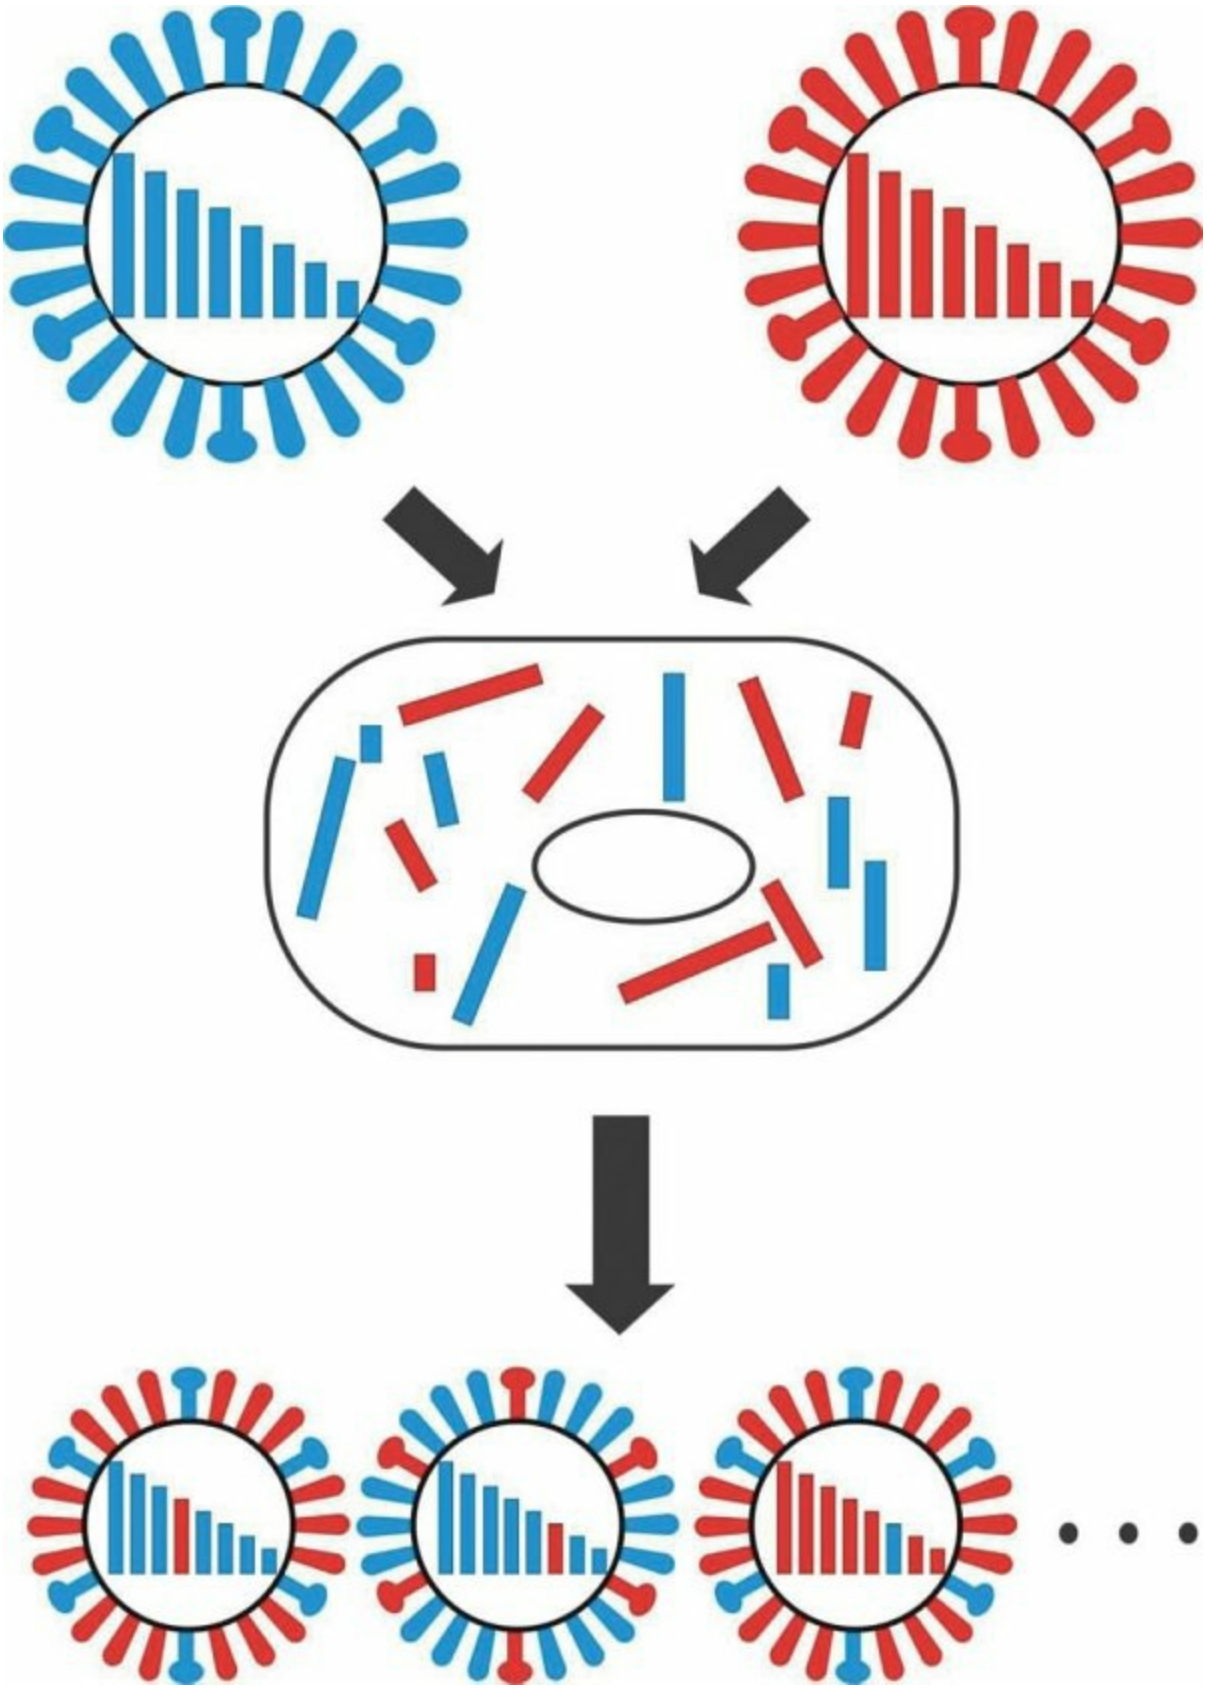

FIGURE 15.2 Reassortment. Coinfection of cells with 2 different influenza A viruses can theoretically result in 256 different genotypes (2^8, i.e., the two parental genotypes and 254 new genotypes). Reassortment is a major mechanism for the generation of pandemic influenza viruses, as demonstrated in 1957, 1968, and 2009.

The importance of reassortment to the generation of new influenza virus strains is highlighted by the last three pandemics, which resulted from reassortment[39,67,105,123,130] (see The Pandemic of 1957—Asian Influenza [H2N2]; The Pandemic of 1968—Hong Kong Influenza [H3N2]; and The H1N1 Pandemic in 2009 sections). In addition, the highly pathogenic H5 viruses currently circulating in Southeast Asia and other parts of the world arose from multiple reassortment events among avian influenza viruses[12,46,78,82]; these viruses continue to undergo reassortment, including reassortment between the HA and NA vRNA segments of different subtypes (see Infections of Humans with H5 Viruses of the A/goose/Guangdong/1/1996 Lineage section). Similarly, the H7N9 viruses that emerged in China in 2013 resulted from reassortment among avian influenza viruses[37] and have undergone additional reassortment since their emergence (see Infections of Humans with Low and Highly Pathogenic H7N9 Viruses section).

In addition to reassortment events that create new pandemics, reassortment has also resulted in multiple novel influenza virus lineages in pigs and poultry. For human influenza viruses, intrasubtypic reassortment may be more important than previously thought and may have led to the epidemics observed with reassorted H1N1 viruses in 1947 and 1951, reassorted H2N2 viruses in 1967, and reassorted H3N2 viruses in 1997 and 2003.

In experimental settings, multiple reassortants can be generated between highly pathogenic avian H5N1 and human H3N2 or A(H1N1)pdm09 viruses; between A(H1N1)pdm09 and seasonal H1N1 or avian H9N2 viruses; between human H3N2 and genetically distant equine H7N7 viruses; and between avian H7N3 and A(H1N1)pdm09 viruses. However, not all vRNA

segment combinations can be generated experimentally, and others may not be compatible in nature. Experimentally generated reassortant viruses have also been used to assess the virulence determinants of the 1918 pandemic virus and to study the determinants of influenza H5, H7, and H9 virus transmissibility in mammals.

Recombination

For negative-sense RNA viruses, homologous recombination is uncommon; however, recombination by "template switching" can occur and lead to increased biologic fitness of the virus. For example, the insertion of 54 nucleotides of 28S ribosomal RNA into the A/turkey/Oregon/71 HA gene increased HA cleavability.[68] Similarly, an A/seal/Massachusetts/1/80 variant contained a 60-nucleotide insertion (derived from the NP gene) in its HA gene, which also enhanced HA cleavability. Avian influenza viruses of low pathogenicity have converted to high pathogenicity following the insertion of 21 nucleotides of the M segment or 30 nucleotides of the NP segment into the HA segment. Serial egg passages of an A/WSN/33 virus containing a 24-amino-acid deletion in the NA stalk led to variants that replicated efficiently in eggs. The NA stalk of these variants contained sequences that originated from the PB1, PB2, and NP genes. In another example, a virus contained an NP gene that likely resulted from intracistronic recombination between two NP segments. In this case, it is unclear whether the recombination event provided a selective advantage to the virus.

Defective Interfering (DI) Viral RNAs and Particles

DI vRNAs possess large internal deletions in a viral genome segment, while the terminal regions of the vRNAs (which contain the viral promoters for replication and transcription) remain intact. The internal deletions result from replication errors in which the viral polymerase complex falls off the template and reinitiates replication at a downstream site. DI vRNAs have been reported for all influenza vRNAs but occur most frequently for the three largest vRNAs that encode the polymerase proteins. Due to their reduced length, DI vRNAs are replicated faster than the parent vRNA, resulting in "interference" with the replication of the parent vRNA. DI vRNAs can be packaged into virus particles; these DI particles are "defective" because they lack a full viral genome and cannot initiate a new round of replication and

progeny virus generation. DI vRNAs are frequently detected under experimental conditions but are also found in clinical samples. Their role in the viral life cycle is not understood, although they may stimulate innate immune responses.

Reverse Genetics

Highly efficient systems are now in place for the artificial generation of influenza A,[29,103] B, and C viruses and of *Thogotovirus*. These systems rely on the intracellular synthesis of influenza vRNAs by a cellular enzyme, RNA polymerase I, that transcribes ribosomal RNA in the nucleus of eukaryotic cells. The influenza viral segments are encoded by cDNAs flanked by the RNA polymerase I promoter and the RNA polymerase I terminator or a ribozyme sequence. RNA polymerase I transcription in transfected cells results in the efficient synthesis of RNA transcripts with defined 5′ ends, whereas the integrity of the 3′ ends is achieved by using the nucleotide-specific RNA polymerase I terminator or a self-cleaving ribozyme. To generate influenza viruses, cells are transfected with RNA polymerase I plasmids to provide all eight vRNAs, as well as with up to four plasmids for the expression of the polymerase and NP proteins that are required to initiate viral replication. These systems have revolutionized influenza virus research in that they allow researchers to study the functions of viral proteins in the viral life cycle, as well as their roles in pathogenesis and hostrange restriction. Moreover, these systems are now used to generate recombinant influenza viruses expressing fluorescent proteins that can be used to monitor the infection process in live animals, thus providing novel insights into influenza target cells and the dynamics of virus spread.

Most importantly, reverse genetics systems are now invaluable tools for the generation of influenza virus vaccines and vaccine vectors. In fact, reverse genetics has permitted the generation of inactivated and live vaccine strains for H5 and H7 viruses that could not have been produced by conventional approaches because highly pathogenic viruses kill chicken embryo, resulting in low vaccine yield; this hurdle was overcome with genetically modified vaccine strains of low pathogenicity in eggs. In addition, reverse genetics systems have opened the door for conceptually novel vaccine candidates including vaccines with chimeric or headless HAs or single-cycle replication viruses (see Vaccines section).

INFLUENZA IN HUMANS—PAST PANDEMICS

Pandemics are outbreaks that impact large geographic areas and large portions of the population in a short period of time. Pandemics are the most dramatic manifestation of influenza, attacking 20% to 40% of the world population and causing significant mortality. Influenza pandemics have occurred in 10- to 40-year intervals, although reliable records only date back to the 1918/1919 pandemic (Fig. 15.3). The cumulative death toll of epidemics in interpandemic periods, although less dramatic, parallels those of pandemics.

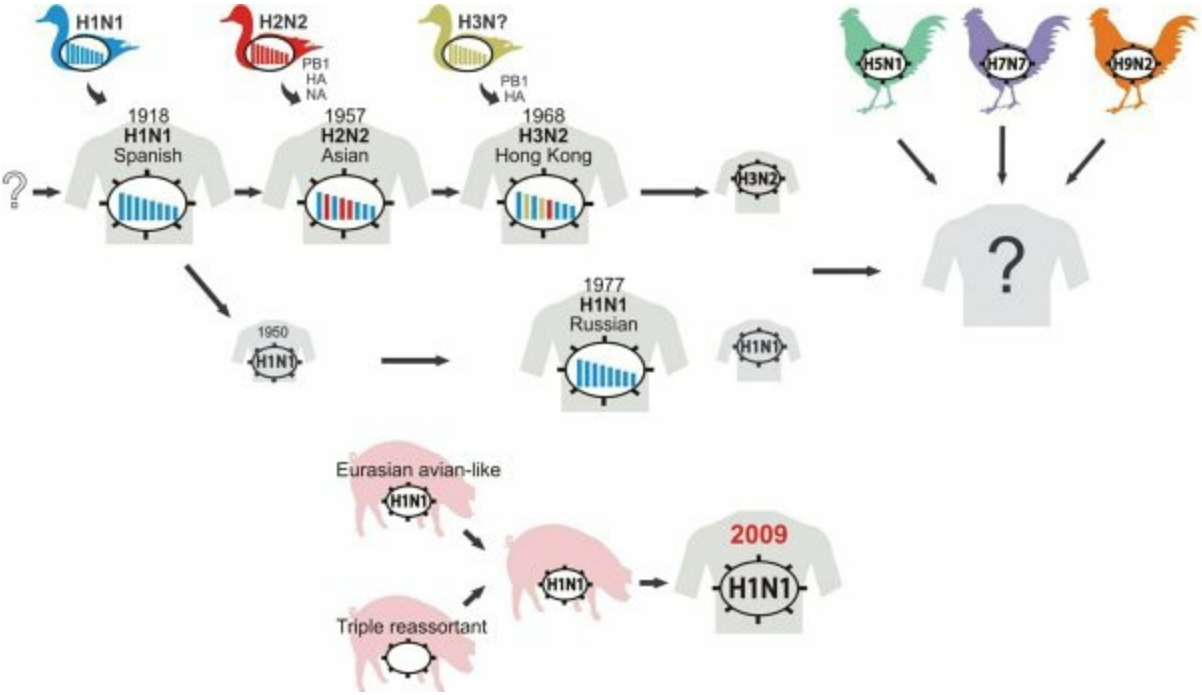

FIGURE 15.3 Evolution of influenza A viruses circulating in humans. An avian H1N1 virus caused the Spanish influenza in 1918. Its descendants circulated until the mid-1950s and reemerged in 1977, causing the Russian influenza. Viruses of this lineage continued to circulate in human populations until 2009. The 1957 pandemic was caused by an H2N2 virus that acquired its HA, NA,

and PB1 vRNA segments from an avian H2N2 virus. A similar reassortment event in 1968 resulted in the introduction of avian virus HA and PB1 vRNA segments into the human population, causing the 1968 pandemic. H3N2 viruses circulate in humans to this day. In 2009, reassortment of triple reassortant swine viruses and Eurasian avian–like swine viruses (which donated the NA and M vRNA segments) resulted in the A(H1N1)pdm09 virus, which replaced the then-circulating H1N1 viruses. Sporadically, humans are infected by avian influenza viruses of the H5, H7, or H9N2 subtypes.

The Pandemic of 1918/1919—Spanish Influenza (H1N1)

The pandemic of 1918/1919 remains unprecedented in its severity. It killed more people than World War I and reduced life expectancy in the United States by 10 years. AIDS has killed 25 million people in its first 25 years—the Spanish influenza killed an equal number in 25 weeks (from September 1918–March 1919). This pandemic occurred in three waves. In the spring of 1918, a mild respiratory disease started at Fort Funston, Kansas (now Fort Riley), attributed to a soldier who had been cleaning pig pens. There is no mention of the presence of poultry in the camp at that time. The disease spread among soldiers from Fort Funston along the rail lines to other military bases and cities in the United States and on troopships to Europe. This first wave was highly contagious but caused few deaths and received limited attention in most parts of the world. In Spain, a neutral country without news censorship, the outbreak was covered extensively by news media and was soon referred to as the “Spanish influenza.” In late August, a second wave with a higher mortality rate started, probably in Western France, from where it spread around the world; this wave peaked between September and November. During that time, death tolls reached more than 10,000 people per week in some US cities. About one-third of the US population became sick, and the mortality rate was estimated to be over 2.5%, compared to less than 0.1% in typical influenza outbreaks. These figures reflect the impact of the

pandemic on the developed world; death rates are believed to have been significantly higher in African and Asian countries. In some isolated populations, the mortality rate reached 70%, likely because of the lack of previous exposure to influenza virus. A third wave of similar impact to that of the second wave struck in late 1918/early 1919.

Typically, the onset of symptoms was sudden, with high fever, severe headache and myalgia, cough, pharyngitis, and coryza. Pathologic findings were mostly restricted to the respiratory tract; death was often due to secondary bacterial pneumonia and respiratory failure. There was no evidence of systemic viral infection. Most patients died of secondary bacterial pneumonia, but some showed massive acute pulmonary hemorrhage or pulmonary edema, indicating the extreme virulence of the virus. The high rate of bacterial complications may be attributed to the lack of antibiotics at that time.

Age-specific morbidity was similar to that of other pandemics, with children younger than 15 years experiencing the highest infection rates. The mortality pattern, however, differed significantly from that of other influenza virus outbreaks. In typical influenza outbreaks, the highest death rates are observed in very young children and in the elderly. In 1918 and 1919, many deaths occurred among young, otherwise healthy adults. The death rate for the 15- to 35-year-old age group was 20 times higher in 1918 than in previous years, and persons younger than 65 years accounted for more than 99% of excess deaths. In particular, people born in 1889, the year of the outbreak of the then most recent pandemic (which, based on seroarcheological studies, was caused by an H3 virus), suffered from a high mortality rate. These findings suggested that prior exposures to influenza viruses shaped the immune response to infection with the 1918 pandemic virus.

The origin of the 1918/1919 virus remains an enigma. In 1927, E. Jordan published a comprehensive review of the origin of the pandemic. He found no evidence that the disease had originated in China. He also evaluated two reports that described local outbreaks of respiratory infections associated with high mortality and heliotrope cyanosis, which was observed during the 1918/1919 outbreak, in army camps in Étaples in Northern France in the winter of 1916 and in Aldershot barracks in March 1917. He dismissed both reports because the disease did not spread but disappeared after short

episodes. The most likely origin of the pandemic was Haskell County, Kansas, where Dr. L. Miner noticed an outbreak of influenza in early February 1918 that differed from other influenza outbreaks in that it attacked young, healthy adults, who developed pneumonia that often led to sudden death. Dr. Miner's observations were published in *Public Health Reports* (now *Morbidity and Mortality Weekly Report*) and appear to be the first reference to the 1918/1919 pandemic. Men from Haskell County reported to Fort Funston for military training between February 26 and March 2, 1918. On March 4, the first soldier at the camp was reported ill; within a 3-week period, more than 1,100 soldiers at the camp required hospitalization.

Seroarcheology suggested that the causative agent was an H1N1 virus. This was confirmed by Taubenberger et al., who recovered vRNA from formalin-fixed, paraffin-embedded tissues from two soldiers who died in 1918 and from an Inuit female of unknown age whose body was exhumed from a mass grave in the permafrost of Alaska.[117,139] RT-PCR amplification of the vRNAs provided viral gene sequences. Phylogenetic analyses revealed that 1918 Spanish influenza virus proteins contain both "avian-like" and "human-like" signature amino acids (see Host-Specific Amino Acids section). Further analysis suggested that the 1918 virus genes were not directly transmitted from an avian species but likely circulated in a mammalian host for several years before causing the pandemic outbreak in 1918. Another study suggested that reassortment between human and avian influenza viruses created the 1918 pandemic virus.

Reconstitution of the 1918 Spanish influenza virus by use of reverse genetics demonstrated its high pathogenicity in mice, ferrets, and nonhuman primates.[72,143,144] In nonhuman primates, the virus caused severe respiratory disease with extensive edema and hemorrhagic exudates, similar to reports of human infections. Rapid recruitment of macrophages and neutrophils was observed in the lungs of infected mice, in line with findings of altered immune responses in infected mice and nonhuman primates. In both animal models, infection with 1918 virus resulted in dysregulated host responses to viral infection. In contrast to its high virulence in humans, mice, ferrets, and nonhuman primates, the 1918 virus is of low pathogenicity in pigs, guinea pigs, chickens, and mallard ducks. In one study, vRNA segments of naturally occurring viruses were identified that differed by a small number of mutations from those of the 1918 pandemic virus. A virus composed of these

naturally occurring, “1918-like” avian vRNA segments was more pathogenic in mice and ferrets than a low pathogenic avian influenza virus. Consecutive passages in ferrets yielded an “1918-like” avian virus with seven amino acid mutations in HA and the polymerase complex that together conferred respiratory droplet transmissibility in ferrets. This study demonstrated that viruses with “1918-like” genes still circulate in nature.

Studies with reassortant and mutant 1918 viruses indicated a role in virulence for several viral proteins (see later discussion and Molecular Determinants of Host-Range Restriction and Pathogenesis section), in particular, HA and the polymerase proteins. Both HA and PB2 are critical for 1918 virus transmissibility in ferrets.[147] Reassortants possessing the 1918 HA, or HA and NA, vRNA segments are highly pathogenic in mice. Moreover, reassortant viruses containing the 1918 HA gene induce high levels of macrophage-derived cytokines and chemokines, which stimulate inflammatory cell infiltration and hemorrhage—hallmarks of Spanish influenza infection.

The amino acids at HA positions 190 and 225 determine the receptor-binding specificity of H1 HA proteins (see Receptor Specificity of Influenza Viruses section). The reconstituted A/South Carolina/1/1918 (SC18) virus encodes aspartic acid (i.e., “human-type”) amino acids at both positions, conferring binding to Siaα2,6Gal and respiratory droplet transmission in ferrets. The reconstituted A/New York/1/1918 virus possesses HA-190D, but HA-225G (i.e., the “avian-type” residue), resulting in dual binding to Siaα2,6Gal and Siaα2,3Gal and less efficient respiratory droplet transmission in ferrets compared with the SC18 isolate. An artificially generated mutant 1918 virus encoding the “avian-type” residues (HA-190E and HA-225G) no longer bound to human-type receptors and did not transmit among ferrets, although the mutant virus maintained its lethal phenotype in infected animals.[144] Autopsy samples of people who succumbed to the 1918 pandemic revealed that samples from the spring of 1918 predominately encoded HA-225G (i.e., the “avian-type” amino acid), whereas most samples from the fall of 1918 encoded HA-225D (i.e., the “human-type” amino acid); however, the distribution of viral antigen in respiratory tissues was not significantly different between autopsy samples harboring the HA-225G or HA-225D variants. The HA variants may reflect adaptation to humans, or they may reflect adaptation to specific cell types, as shown with the A(H1N1)pdm09

HA-225G variants found in human lungs.

The NS1 protein is an interferon antagonist and, as such, is considered a determinant of pathogenicity. The 1918 virus NS1 gene blocks the expression of interferon (IFN)-regulated genes more efficiently than does the parental A/WSN/33, and the PDZ ligand domain motif of the 1918 NS1 protein (formed by the four C-terminal amino acids of this protein; see The NS1 Protein section) increased the virulence in the background of A/WSN/33 virus. In addition, the PB1-F2 protein (see The PB1-F2 Protein section) of the 1918 virus contributes to virulence. Further studies using recombinant viruses found no significant contributions of the 1918 M and NP vRNA segments to viral pathogenicity.

The Pandemic of 1957—Asian Influenza (H2N2)

This pandemic originated in the Southern Chinese province of Guizhou in February 1957 and spread to Hunan Province and to Singapore and Hong Kong in March and April, respectively. In May 1957, the causative agent of the outbreak, an influenza A virus of the H2N2 subtype, was isolated in Japan. A first wave struck the United States and United Kingdom in October 1957 and was followed by a second wave in January 1958. The infection rate was highest in 5- to 19-year-olds, in whom it exceeded 50%. Both waves were characterized by heightened mortality, with about 70,000 deaths in the United States and more than 1 million deaths worldwide.

Genetic and biochemical analyses indicated that the 1957 pandemic virus originated from reassortment between human and avian viruses (Fig. 15.3). It contained H2 HA and N2 NA genes of avian virus origin.[123] Because the pandemic virus did not appear to be extraordinarily pathogenic, the increased mortality is attributed to the lack of preexisting immunity among humans to the new surface glycoproteins of this virus. In addition to avian virus HA and NA genes, the 1957 pandemic virus also possessed a PB1 gene of avian virus origin.[67] The contribution of this gene segment to the pathogenicity of the 1957 pandemic virus is unknown.

Influenza viruses of the H2 subtype continue to be isolated from avian species and were isolated from pigs in 2006. A risk assessment of greater than 20 avian H2N2 viruses collected over 6 decades demonstrated binding to avian-type receptors (see Receptor Specificity of Influenza Viruses section), a

lack of markers of adaptation to mammals, and antigenic properties similar to those of the prototype pandemic H2N2 virus. However, several viruses replicated in mice and/or ferrets, and three were transmitted to ferret cage mates. Since vaccination against H2N2 viruses was discontinued in the late 1960s, only individuals 50 years of age or older have protective antibodies against this subtype, suggesting that a new pandemic by an H2 virus would cause appreciable excess morbidity and mortality in a large section of the population. However, avian H2N2 viruses have evolved slowly, so the pandemic H2N2 vaccine from 1957 still protects mice against recently circulating avian or swine H2 strains; this vaccine may therefore provide a first line of defense in the event of an H2N2 pandemic.

The Pandemic of 1968—Hong Kong Influenza (H3N2)

Eleven years after their emergence, viruses of the H2N2 subtype were completely replaced by those of the H3N2 subtype (Fig. 15.3). The first signs of a new pandemic emerged in Southern Asia in the summer of 1968. A virus of the H3N2 subtype was isolated in Hong Kong in July 1968, which soon spread around the world. The attack rates reached 40% and were highest in 10- to 14-year-olds. The excess mortality was estimated to be 33,800 in the United States.

The 1968 pandemic virus contained an avian virus HA protein of the H3 subtype[123] that shared less than 30% sequence homology with its predecessor. However, preexisting antibodies to the N2 protein in human populations likely accounted for the moderate severity of the outbreak. In addition to an avian H3 gene, the 1968 pandemic strain also acquired an avian virus PB1 gene,[67] as did the 1957 pandemic strain. It is unknown whether the introduction of an avian virus PB1 gene into the human population contributed to the pathogenicity of the 1968 pandemic virus. The HA and PB1 genes originated from viruses of the Eurasian avian lineage, consistent with epidemiologic findings that Asia was the likely origin of the pandemic. Since the pandemic in 1968, H3N2 viruses have continued to circulate in humans and are now referred to as “seasonal” or “human” H3N2 influenza viruses.

The Reemergence of H1N1 Viruses in 1977—Russian Influenza

The first signs of a new influenza virus outbreak were noted in Tianjin, China, in May 1977. From November 1977 through the end of 1978, young adults around the world suffered from an influenza virus outbreak in the Union of Soviet Socialist Republics and in China. The United States experienced a similar outbreak in mid-January 1978, and outbreaks in other countries occurred during the following winter. Among school-age children, the attack rates were more than 50%. Morbidity was almost exclusively limited to persons younger than 25 years, suggesting that older individuals were protected by preexisting immunity. This assumption was proven when the causative agent was identified as an influenza H1N1 virus (A/USSR/77) closely related to strains that had circulated in the early 1950s (Fig. 15.3). This close relationship and the lack of mutations that are typically acquired during replication argued against maintenance of the virus in a nonhuman species. It is now believed that accidental release of this virus or a vaccine trial with an insufficiently attenuated live virus started the pandemic. In contrast to 1968, when the newly emerging H3N2 viruses replaced the circulating H2N2 viruses, replacement of H3N2 viruses did not occur in 1977 with the reemergence of H1N1 viruses. Instead, both H1N1 and H3N2 viruses continue to circulate to this day.

The H1N1 Pandemic in 2009 [A(H1N1)pdm09]

The first reports of an influenza-like outbreak in a small Mexican town can be traced back to mid-February 2009. In mid-April, genetically similar swine-origin H1N1 influenza A viruses were detected in several specimens collected in Southern California and Mexico.[39,105] The novel virus spread rapidly among humans across different continents, prompting the World Health Organization (WHO) to declare Phase 6 (pandemic phase, which is characterized by community-level outbreaks with human-to-human spread in at least two countries in more than one WHO region) on June 12, 2009. The WHO suggested the name A(H1N1)pdm09 for the new virus. This outbreak marked the first pandemic in more than four decades. Viruses of the H1N1 subtype have circulated in humans since 1977; hence, pandemics are not limited to viruses with novel HA subtypes (i.e., those not recently circulating

in humans) but can be caused by viruses possessing HA subtypes that are circulating in human populations, as long as the novel HA is antigenically distantly enough from its predecessor to escape human immune responses.

The pandemic virus spread rapidly and replaced the H1N1 viruses previously circulating in humans. The Southern Hemisphere (where the influenza season lasts from May–September) experienced significant pandemic influenza activity from May to mid-July of 2009; the United States experienced a first wave in May and June and a second wave that started in late August and peaked during the 2nd week of October. The Centers for Disease Control and Prevention (CDC) estimated that between 151,700 and 575,400 people died worldwide from A(H1N1)pdm09 infections during its 1st year of circulation (https://www.cdc.gov/flu/pandemic-resources/basics/past-pandemics.html). Morbidity and mortality rates differed significantly between age groups.[26] In contrast to seasonal influenza epidemics, the elderly experienced a low infection but high case fatality rate. The low infection rate among the elderly can be explained by serum cross-reactivity between A(H1N1)pdm09 viruses and close descendants of the pandemic 1918 virus,[39,58] which is a consequence of shared antigenic epitopes between the HA proteins of these two viruses. Those aged 5 to 59 years accounted for the highest absolute numbers of deaths and cases of pneumonia, in contrast to seasonal outbreaks. Epidemiologic data identified several factors associated with an increased risk of severe disease, including pregnancy (particularly in the last trimester), underlying chronic conditions, and obesity.

Human infections with A(H1N1)pdm09 viruses typically caused mild upper respiratory tract illnesses with fever, cough, sore throat, shortness of breath, headache, and rhinorrhea.[26,105,109] In addition, gastrointestinal symptoms (which are unusual with seasonal influenza infections) were reported in some cases. In some patients, respiratory and multiorgan failure occurred, leading to death. These severe infections caused diffuse alveolar damage, hemorrhagic interstitial pneumonitis, and peribronchiolar and perivascular lymphocytic infiltrates (Fig. 15.4), similar to human infections with avian H5N1 viruses (see Infections of Humans with H5 Viruses of the A/goose/Guangdong/1/1996 Lineage section). These findings are in line with animal infection studies that demonstrated more severe lung lesions and higher lung virus titers in mice, ferrets, and nonhuman primates infected with

A(H1N1)pdm09 virus compared with seasonal influenza virus infections.[58,88,101] In nonhuman primates, viral antigen was detected in type 1 and 2 pneumocytes, as has been reported for some human cases of A(H1N1)pdm09 infection and for nonhuman primates infected with avian H5N1 influenza virus. Efficient replication in type 1 and 2 pneumocytes in the infected lung (which likely contributes to the observed alveolar damage) may thus be a hallmark of severe influenza virus infections. In many human A(H1N1)pdm09 cases, bacterial coinfections were detected (Fig. 15.4), a finding that has rekindled interest in the contribution of bacterial infections to influenza-related morbidity and mortality.

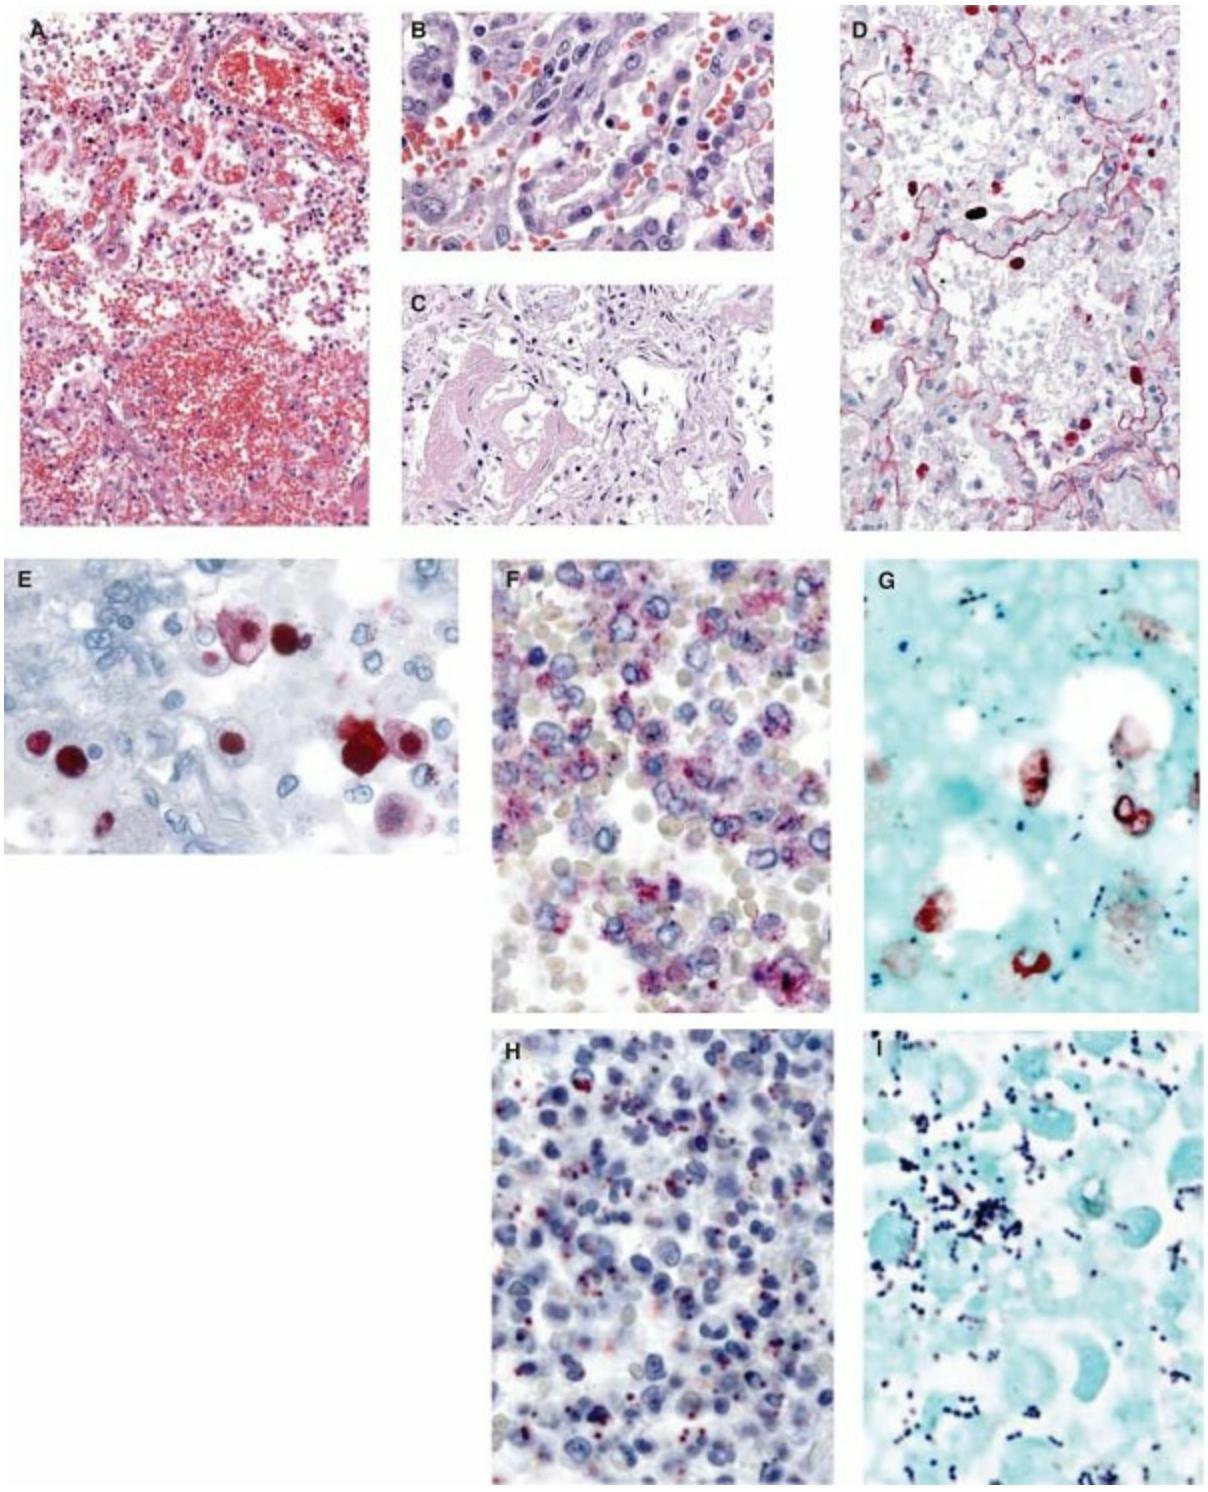

FIGURE 15.4 Histopathology of fatal human infections with A(H1N1)pdm09 virus. Histopathologic studies of infected lung tissue demonstrate intra-alveolar hemorrhage **(A)** with type 2 pneumocyte hyperplasia **(B)** and organizing fibrosis **(C)**. Viral

antigens are primarily observed in type 1 and type 2 pneumocytes **(D,E)**. Histopathology studies also revealed bacterial coinfections, as shown for *Streptococcus pneumoniae* antigens **(F)** and gram-positive cocci **(G)** in the same serial section and for group A *Streptococcus* antigens **(H)** and gram-positive cocci **(I)** in the same serial section. (From Shieh WJ, Blau DM, Denison AM, et al. 2009 pandemic influenza A (H1N1): pathology and pathogenesis of 100 fatal cases in the United States. *Am J Pathol* 2010;177:166–175, with permission.)

Sequence and phylogenetic analyses revealed that the A(H1N1)pdm09 virus possesses PB2 and PA vRNA segments of North American avian virus origin; a PB1 vRNA segment of human H3N2 virus origin; HA (H1), NP, and NS vRNA segments of classic swine virus origin; and NA (N1) and M vRNA segments of Eurasian avian virus origin[39,105,130] (Fig. 15.3). In line with its presumed porcine origin, the virus replicates efficiently, but without symptoms, in experimentally infected miniature pigs and transmits efficiently among pigs. Other studies have demonstrated efficient transmission of A(H1N1)pdm09 viruses in ferrets. In nature, A(H1N1)pdm09 viruses have also infected turkeys, cats, dogs, and ferrets. The widespread circulation of A(H1N1)pdm09 viruses may lead to reassortment with other human, swine, or avian influenza viruses. In fact, the pandemic virus has infected pigs, and reassortment with swine influenza viruses has been reported. Experimental studies demonstrated ready reassortment of A(H1N1)pdm09 viruses with avian H5N1, avian H9N2, or contemporary human influenza viruses; some of these reassortants showed increased replicative ability compared with the A(H1N1)pdm09 parental viruses.

In the United States and Europe, the first vaccines to the novel virus were approved in September 2009 (after the first and second waves of the pandemic had already swept through many communities). A(H1N1)pdm09 viruses have now become seasonal influenza viruses and are part of annual trivalent and quadrivalent influenza vaccines (see also Vaccines section).

INFLUENZA IN HUMANS—EPIDEMIOLOGY

Since 1977, seasonal H1N1 and H3N2 viruses have been circulating together with influenza B viruses; in 2009, the seasonal H1N1 viruses were largely replaced by A(H1N1)pdm09 viruses. The prevalence of these groups of viruses varies geographically and temporally, making influenza virus epidemiology complex.

Several studies have assessed the global circulation patterns of influenza viruses; some analyses indicate that human H3N2 and H1N1 epidemic strains originate from Southeast Asia, from where they are seeded into temperate regions. Temporally overlapping epidemics in Southeast Asia result in continuous virus circulation. Even though influenza viruses circulate in tropical regions throughout the year, seasonality has been observed in these areas, although it is less pronounced than in temperate climates. In the temperate regions of North America and Europe, multiple variants may circulate during the early epidemic period, which are replaced by a dominant variant at the peak of an epidemic.

The epidemiology of human influenza viruses is defined by their constant antigenic variation to escape the host immune response. Unlike most other respiratory viruses, influenza viruses possess two different mechanisms that allow them to reinfect humans and cause disease—antigenic drift and antigenic shift.

Antigenic Drift

Antigenic drift describes gradual antigenic changes in the HA and/or NA proteins as a result of the accumulation of point mutations in the antigenic epitopes. In humans, antigenic drift variants result from the positive selection of mutants by neutralizing antibodies circulating in the infected individual. These variants can no longer be neutralized by antibodies to the “parental” strains. Antigenic drift variants cause epidemics and require the update of the vaccine strain; they typically prevail for 1 to 5 years before being replaced by a different variant. Antigenic drift has also been observed among influenza viruses in terrestrial poultry, pigs, and horses, although to a lesser extent than

in humans.

Antigenic Drift of the HA Protein

The HA protein is the major antigenic component of the virus. Its function and structure are described in more detail in Chapter 14. The rate of antigenic drift of human H3 virus HAs has been faster than that of human H1 virus HAs, necessitating the update of the H3 vaccine component 19 times since 1968, whereas the H1 component has been replaced only nine times. The HA of A(H1N1)pdm09 viruses has undergone limited antigenic drift since its emergence, with one vaccine strain update in 2017.

Three major categories of HA epitopes have been identified as the following: (a) epitopes in the HA head with high sequence variability, which are immunodominant and primarily responsible for antigenic drift; (b) highly conserved epitopes in the HA stalk region, which do not play a role in antigenic drift but, instead, are attractive targets for the development of "universal" vaccines that elicit broadly protective antibodies that interact with HAs of various subtypes (see Vaccines section); and (c) conserved epitopes in the HA head, which are targeted by antibodies that confer various levels of cross protection (although not necessarily heterosubtypic cross protection).

For H3 HA, five immunodominant antigenic domains with high sequence variability have been identified[71,154,157,158] (Fig. 15.5A): site A is formed by a protruding loop (amino acids 140–146); site B is formed by another loop (amino acids 155–160) and an α-helix (amino acids 188–198) and is situated at the membrane distal end of HA; site C is located at the base of the globular domain in the antiparallel sheet of HA1; site D is situated near the trimeric interface of the globular head domains; and site E lies near the bottom of the globular distal domain between sites C and A. Based on limited experimental and computational modeling data, the immunodominant antigenic epitopes of H7 HAs are likely similar to those of H3 HAs, reflecting the phylogenetic relationship between these two subtypes.

A: Crystallographic structure of the trimeric complex of influenza A virus H3 HA protein (Protein Data Bank #1HGD) showing the locations of the five antigenic epitopes: antigenic site A (amino acids 122, 124, 126, 130–133, 135, 137, 138, 140, 142–146, 150, 152, 168), *red*; antigenic site B (amino acids 128, 129, 155–160, 163–165, 186–190, 196–198), *green*; antigenic site C (amino acids 44–48, 50, 51, 53, 54, 273, 275, 276, 278–280, 294, 297, 299, 300, 304, 305, 307–312), *blue*; antigenic site D (amino acids 96, 102, 103, 117, 121, 167, 170–177, 179, 182, 201, 203, 207–209, 212–219, 226–230, 238, 240, 242, 244,

246–248), *yellow*; and antigenic site E (amino acids 57, 59, 62, 63, 67, 75, 78, 80–83, 91, 92, 94, 109, 260–262, 265), *purple*. **B:** Crystallographic structure of the HA protein of A(H1N1)pdm09 virus. Shown is the trimeric complex with the antigenic sites Ca (amino acids 140–145, 169–173, 206–208, 224, 225, 238–240), *orange*; Cb (amino acids 79–84), *dark blue*; Sa (amino acids 128, 129, 156–160, 162–167), *red*; and Sb (amino acids 187–198), *light blue*. (**B:** Reproduced from Xu R, Ekiert DC, Krause JC, et al. Structural basis of preexisting immunity to the 2009 H1N1 pandemic influenza virus. *Science* 2010;328:357–360, with permission.)

For H1 viruses, the immunodominant antigenic sites are designated Ca1, Ca2, Cb, Sa, and Sb[40] (Fig. 15.5B). Some overlap exists among these sites. For H5 HAs, several x-ray crystallographic structures, some with monoclonal antibodies bound, have been resolved. Depending on the virus and antibodies used for the analysis, three to five immunodominant antigenic sites that confer neutralization have been identified, some of which overlap with antigenic sites in H3 or H1 HA proteins.

Numerous studies have analyzed antigenic drift in nature. In the laboratory, antigenic drift has historically been mimicked by virus propagation in the presence of monoclonal antibodies to a single site, with a low frequency of variant selection. Over the past decade, novel molecular virology methods have been established in which reverse genetics-generated mutants have been tested for their antigenic properties. In other approaches, virus libraries comprising millions of mutant viruses with arbitrary or specific mutations at random or preselected amino acid positions have been generated and incubated with ferret sera and/or human sera to select potential antigenic escape variants. The selected variants are then tested for their antigenic properties by using hemagglutination-inhibition (HI) and/or focus reduction assays (FRA). The visualization and analysis of the resulting data can be achieved through antigenic cartography, a computational method based on HI or FRA data that provides an interpretation of antigenic clusters and their relationships, as well as the extent and directionality of the antigenic drift[129]

(Fig. 15.6). Antigenic cartography is now routinely used by the WHO for the selection of vaccine strains.

FIGURE 15.6 Antigenic cartography. The map shows seasonal H3N2 viruses from 1968 to 2003. Each *open circle* represents an antiserum used for analysis. Each *colored circle* represents an H3N2 strain tested by using the hemagglutination-inhibition assay against the selected antisera. The distances between strains and antisera are relative to their antigenic distances (in HI units). The spacing between the grid lines is equivalent to a twofold dilution of antiserum in the HI assay. Typically, fourfold changes in HI titers (i.e., two gridlines in the map) require an update of the vaccine. The different colors represent the antigenic clusters to which the strains belong (HK68, Hong Kong 1968; EN72, England 1972; VI75, Victoria 1975; TX77, Texas 1977; BK79, Bangkok 1979; SI87, Sichuan 1987; BE89, Beijing 1989; BE92, Beijing 1992; WU95, Wuhan 1995; SY97, Sydney 1997; FU02, Fujian 2002). (From Smith DJ, Lapedes AS, de Jong JC, et al. Mapping the antigenic and genetic evolution of influenza virus. *Science* 2004;305:371–376, with permission.)

The characterization of antigenic escape mutants has established that antigenic drift of human H3N2 viruses occurs in clusters: while nucleotide changes occur continually, clusters of antigenically similar variants exist for several years until they are replaced by a new cluster, founded by an antigenic variant that necessitates an update of the vaccine strain.[129] Hence, the genetic evolution of H3 HA genes is continuing, whereas their antigenic evolution is punctuated. Moreover, the major antigenic changes of human H3N2 viruses can be mapped to seven amino acid positions (in the known antigenic epitopes) located around the receptor-binding pocket.[74] Antigenic cluster changes that necessitate a replacement of the vaccine strain often result from single amino acid changes. Due to existing immunity in human populations, human H3 HAs evolve “away” from currently and previously circulating viruses. Thus, overall, human H3 HAs evolve in a single direction. A similar pattern of antigenic cluster transitions likely also exists for human H1 viruses.

H5 HA proteins of the lineage that emerged in Hong Kong in 1996 have also diversified into multiple antigenically and genetically distinguishable clades and subclades (see Infections of Humans with H5 Viruses of the A/goose/Guangdong/1/1996 Lineage section). Amino acid changes responsible for antigenic differences appear to be located around the receptor-binding site, similar to the antigenic cluster transitions described for human H3 HAs. Antigenic changes have also occurred among the H7N9 viruses that emerged in China in 2013 (see Infection of Humans with Low and Highly Pathogenic H7N9 Viruses). Based on limited data, the amino acids responsible for these changes appear to be located in the vicinity of the receptor-binding site.

Antigenic Drift of the NA Protein

The function and structure of this protein are discussed in detail in Chapter 14. In addition to HA, antigenic drift has also been reported for NA and correlated with amino acid differences in the molecule.[17,121] Studies with monoclonal antibodies and amino acid sequence analyses have revealed several antigenic sites. The NA of most influenza A virus subtypes and of influenza B viruses has been crystallized, and several structures are available for NA/antibody complexes. Two major antigenic sites of NA are located on the upper surface of the molecule, where they flank the sialic acid–binding site. A possible third antigenic site resides on the side of the head; some antibodies binding to this site provide protection via antibody-dependent cellular cytotoxicity (ADCC). A more detailed structural analysis of the Fab fragment of a monoclonal antibody to N9 NA showed that five peptide loops, located at the rim of the enzyme active site, constitute the epitope. The second epitope, characterized with monoclonal antibodies to N8 NA, is located at the interface of two adjacent monomers in the tetrameric NA protein and involves peptide loops on both monomers. Antibodies with this epitope bind only to NA tetramers. Another antibody makes contacts with two monomers of the A(H1N1)pdm09 N1 NA. Overall, our understanding of NA antigenic sites and epitopes remains limited.

The antigenic drift rates of human influenza virus NA proteins are lower than those of human influenza virus HA proteins. Antigenic changes can be conferred by single amino acid changes in NA, as has been reported for HA (see Antigenic Drift of the HA Protein section). Antigenic changes in HA and

NA appear to occur independently from one another.

Antigenic Shift

Antigenic shift involves major antigenic changes in which an HA and/or NA that is antigenically distinct from the circulating variant is introduced into the human population. Infections with such viruses result in high infection rates in immunologically naïve populations, leading to pandemics. Typically, antigenic shift is caused by an HA of a new subtype, that is, one that did not circulate in humans prior to the pandemic; in addition, an NA of a novel subtype may be introduced into human populations. The H1N1 pandemic in 2009 was a notable exception because it was caused by a virus of the H1N1 subtype, even though viruses of this subtype had been circulating in humans since 1977.

Since the beginning of the last century, five antigenic shifts have occurred: in 1918, with the appearance of the H1N1 viruses that caused the Spanish influenza; in 1957, when the H1N1 subtype was replaced with H2N2 viruses, causing the Asian influenza; in 1968, when H3N2 viruses replaced the H2N2 subtype, leading to the 1968 pandemic; in 1977, when H1N1 viruses similar to those circulating in humans in the 1950s reappeared and caused the Russian influenza; and in 2009, when a novel, antigenically distinct H1N1 virus caused a pandemic that largely replaced seasonal H1N1 viruses (see The H1N1 Pandemic in 2009 section). These new subtypes emerged suddenly and at irregular and unpredictable intervals.

Transmission Among Humans

Influenza viruses are transmitted from person-to-person via the respiratory tract, which could include small particle aerosols (<10 μm mass diameter) suspended in the air, larger particles or droplets, and indirect transmission via contaminated surfaces and fomites. The relative contributions of each of these routes have not been completely determined and could vary depending on the specific virus and levels of immunity in both the host and the recipient.

Small particle aerosols are generated by infected humans, and influenza genome can be detected in these small particles by PCR techniques. A significant portion of fine particle aerosols contain infectious virus,[160] and experimental studies in humans have shown that varying small amounts (~5

infectious particles) may be sufficient to infect humans by the aerosol route. Aerosol transmission has also been demonstrated in animal models in which infected and exposed ferrets or guinea pigs are separated by several meters, with transmission occurring in the direction of airflow.

Airborne transmission has also been implicated in outbreaks where an airborne route of transmission appears to be the most plausible explanation for the characteristics of the outbreak. The most often cited such outbreak occurred in a commercial airliner that was delayed for approximately 4½ hours with a poorly functioning ventilation system. The risk of transmission of influenza A from the index case to other passengers was related to the amount of time passengers spent on the aircraft, and not on their seating proximity to the index case. Since most of the passengers did not have direct contact with the index case, airborne transmission appears to be likely.[100] In hospital outbreaks, UV light and air handling procedures have been associated with decreased risks of transmission. In addition, in a study of zanamivir prophylaxis of influenza in families,[64] subjects who received short-term prophylaxis with inhaled zanamivir were protected compared to placebo recipients, but recipients of zanamivir administered by nasal spray were not.

In most of these scenarios, there were alternative explanations for the observations that could at least partially explain the epidemic behavior without requiring aerosol transmission, and the real role of aerosol transmission remains controversial. Several studies have attempted to evaluate the role of face masks in infection prevention in hospitals. In one large, randomized trial, nursing staff who were randomly assigned to wear N-95 respirators had the same rate of influenza as staff assigned to wear simple surgical masks while caring for patients with influenza.[83] This study suggests that airborne transmission does not play a major role at least in nosocomial influenza, although it has been pointed out that cases in the N-95 group could have been acquired outside the hospital and that compliance with these masks is frequently poor. In contrast, hand hygiene and simple surgical masks were reported to be modestly effective in the prevention of influenza transmission in households suggesting that in this setting, droplet spread was the predominant modality.

Seasonality

Influenza epidemiology is characterized by marked seasonality. In the Northern Hemisphere, epidemics generally peak between January and April but may flare up as early as December or as late as May, while in the Southern Hemisphere, seasonal epidemics typically occur between May and September. Seasonal periodicity is also observed in tropical climates, with increased activity during periods of low absolute humidity, although influenza can occur throughout the year and seasonal fluctuations are not as marked. The reasons for these seasonal changes are not entirely clear but might be the result of more favorable environmental conditions for virus survival. Using a statistical model called convergent cross mapping, temperature and absolute humidity were shown to be important drivers of seasonal epidemicity.[23] Studies in animal models have also supported a role for conditions of cold temperature and dry humidity in facilitating transmission.

Seasonality may also be associated with behavioral changes that may increase transmission, such as indoor crowding or school attendance. Possibly for this reason, the effects of weather variability may be greater in young children. Modeling studies based on medical claims data have suggested that winter holidays delay seasonal epidemic peaks and shift disease visits toward adults.

In contrast to seasonal influenza, novel influenza viruses can emerge at any time of the year. The occurrence of pandemics outside of the usual window of seasonality may be related to inherently greater transmissibility, allowing them to spread even under conditions that would not be favorable for transmission of seasonal influenza viruses.

Influenza Disease Burden

The impact of seasonal influenza on public health is generally measured in terms of excess deaths, hospitalizations, and illness associated with detectable influenza activity in the community, as compared to an expected seasonal baseline during periods of time when influenza is not present. As rapid and accurate diagnostic has become more widely available, these assessments have become more specifically based on testing results. It is important to recognize that in addition to these, influenza also causes prolonged negative impact on activities of daily living, absences from work or school, and significant resulting economic impact.

Mortality

The increase in mortality during pandemics and epidemics is a hallmark of influenza virus infection. Levels of excess mortality vary considerably from season to season depending on the extent of influenza activity and the specific types and subtypes of viruses circulating. In general, years with predominant H3N2 activity tend to be associated with the highest levels of excess mortality, partly because this subtype tends to be especially impactful in older populations. Years with predominant H1N1 or influenza B circulation are also associated with excess mortality but at substantially lower levels. Recent estimates of excess mortality associated with seasonal influenza in the United States are shown in Figure 15.7. As many as 51,000 deaths annually in the United States can be attributed to influenza.[140] It is recognized that because not all influenza deaths are necessarily noted on death certificates as pneumonia or influenza related, these are generally underestimates of the overall impact. After correcting for under-reporting by assessing the fraction of cases with diagnostic testing, it has been estimated that there were between 155,000 and 624,000 hospitalizations, 18,000 and 95,000 ICU admissions, and 5,000 to 27,000 deaths per year in the United States attributable to influenza.[115]

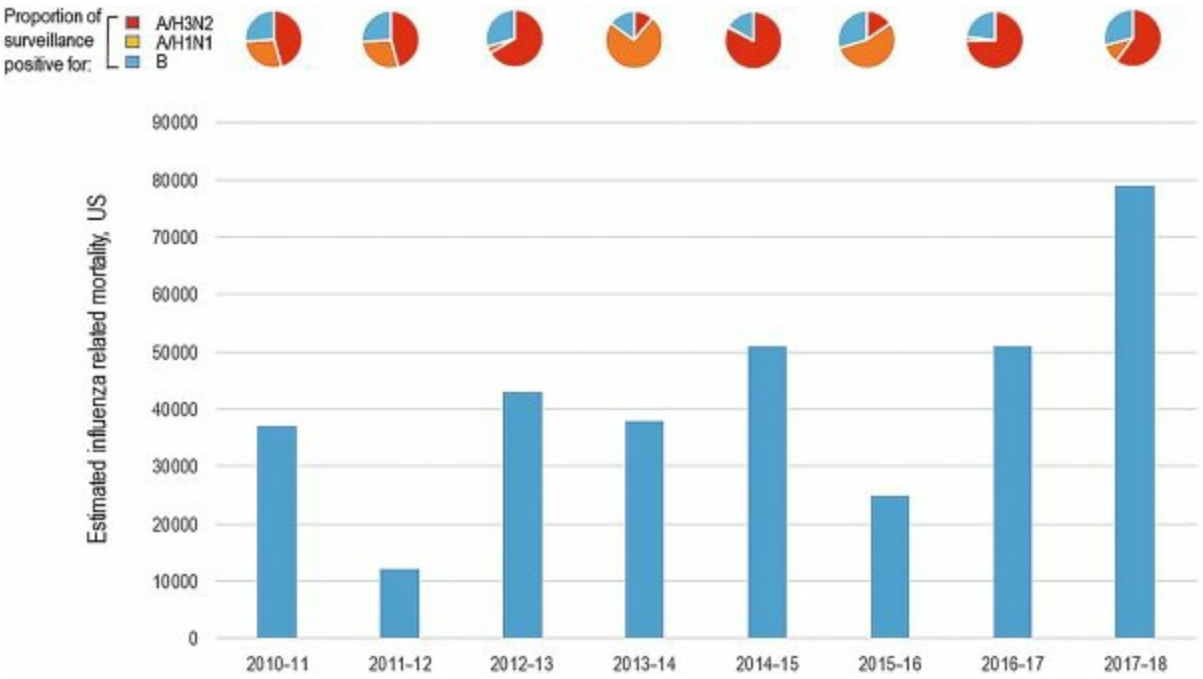

FIGURE 15.7 Influenza-related mortality is higher in years with predominant H3N2 viruses. Estimates of influenza-related mortality assessed using a mathematical model[115] as reported on the Centers for Disease Control and Prevention Web site (https://www.cdc.gov/flu/about/burden/past-seasons.html). The pie charts show the relative proportion of detected H3, H1, and B viruses in national surveillance conducted during that influenza season (https://www.cdc.gov/flu/weekly/fluviewinteractive.htm).

Years in which pandemic influenza viruses emerge are usually associated with levels of excess mortality above those seen in seasonal influenza, because of general lack of immunity to these viruses. For example, excess mortality was estimated to be between 20 and 50 million deaths for the 1918 H1N1 pandemic worldwide, 70,000 excess deaths associated with the H2N2 pandemic of 1957, and 33,800 deaths associated with the H3N2 pandemic of 1968. In contrast, the recent emergence of the pandemic H1N1 virus in 2009 is estimated to have been associated with 12,470 deaths in the United States. However, a large proportion of deaths in the 2009 pandemic occurred in younger individuals, so that when evaluated in terms of years of life lost, this pandemic had significant impact. Although individual pandemics are associated with the largest numbers of excess deaths, the repetitive nature of seasonal epidemics results in a greater total overall mortality burden.

During seasonal epidemics, excess mortality tends to be highest in those older than 65 years, who account for approximately 90% of such excess mortalities, largely due to the presence of age-related concurrent medical conditions that increase the risk of influenza deaths. However, very different patterns of mortality may be seen during pandemics, where older age groups may be partially protected because of earlier exposures to antigenically related viruses, a phenomenon termed "antigenic recycling.[90]" For example, the highest mortality during the 1918 pandemic occurred in young adults, while older adults appeared to have been partially protected by exposure to previous H1N1 viruses circulating 50 years earlier. Similarly, older adults were relatively spared from the A(H1N1)pdm09 outbreak because of exposure to antigenically related viruses that circulated in the 1930s.

Morbidity

Mortality is only the most severe manifestation of influenza impact, and similar techniques can be used to estimate excess morbidity due to influenza epidemics. Influenza virus is estimated to cause about 50 million illnesses annually in the United States. Much of the impact of influenza is related to the malaise and consequent disability that it produces, even in young, healthy individuals. It has been estimated that a typical case of influenza, on average, is associated with 5 to 6 days of restricted activity, 3 to 4 days of bed disability, and about 3 days lost from work or school. Direct medical costs of illness account for only about 20% or the total expenses of a case of influenza, with a major proportion of the economic impact due to loss of productivity. Direct costs include hospitalizations, medical fees, drugs, and testing and were estimated in 1986 to be about $1 billion annually, while indirect costs such as loss of productivity reached $2 to $4 billion annually.

The impact of seasonal influenza is generally highest in identified high-risk groups such as young children and elders. Children younger than 2 years of age and the elderly have the highest hospitalization rates, reaching 1 per 270 for those older than 65 years, compared to 1 per 2,900 for the 1- to 44-year-old age group. Among children, 14% to 16% of those seeking medical care for acute respiratory illness or fever are infected with influenza virus.[113]

Surveillance

Surveillance efforts in humans are coordinated by the WHO through the Global Influenza Surveillance and Response System (GISRS). The system currently includes 6 Collaborating Centres (in Atlanta, Memphis, Beijing, London, Melbourne, and Tokyo), greater than 100 National Influenza Centres in greater than 100 countries, and several H5 Reference Laboratories and Essential Regulatory Laboratories. The National Influenza Centres collect samples each year from patients with influenza-like illness and submit representative samples per year to the Collaborating Centres for antigenic and genetic characterization. These data are used to monitor antigenic drift and resistance to antiviral compounds. Based on surveillance, antigenic, and genetic data, vaccine viruses are recommended by the WHO each February and September for the Northern and Southern Hemispheres, respectively.

Ongoing summaries of influenza activity in the United States, including

the percent of influenza-like illness visits among all medical visits, proportions of positive diagnostic tests, genetic and antigenic characterization of selected viruses, and frequency of antiviral resistance, are maintained by the CDC and similar data worldwide by the WHO. In addition, these organizations collaborate to conduct intensive surveillance of zoonotic influenza viruses that could represent pandemic threats.

TRANSMISSION OF AVIAN AND SWINE INFLUENZA VIRUSES TO HUMANS

Infections of Humans with H5 Viruses of the A/goose/Guangdong/1/1996 Lineage

Outbreaks of highly pathogenic avian influenza (HPAI) occurred mainly in poultry until the emergence of HPAI H5 viruses of the A/goose/Guangdong/1/1996 lineage (H5/Gs/Gd) in 1996. Viruses of this lineage have infected many wild bird species, numerous mammalian species, and more than 860 people with a case fatality rate of approximately 53%.

H5 Virus Outbreaks of the A/goose/Guangdong/1/1996 Lineage Between 1996 and 2008

H5/Gs/Gd viruses were isolated from sick domestic geese in 1996 in Guangdong Province, followed by outbreaks in poultry in Hong Kong in 1997. The causative agent was identified as an H5N1 reassortant virus with an HA vRNA segment from an A/goose/Guangdong/1/96–like virus, an NA vRNA segment from another avian N1 virus, and the remaining six vRNA segments (i.e., PB2, PB1, PA, NP, M, and NS) from other avian viruses. The outbreaks in poultry were accompanied by the first transmissions of wholly avian influenza viruses to humans with fatal outcomes: in May 1997 in Hong Kong, a 3-year-old boy was infected with an H5N1 virus of the H5/Gs/Gd lineage and succumbed to the infection.[15,16,136] In November and December 1997, 17 additional cases were reported, 5 of which had fatal outcomes. The

slaughter of poultry in Hong Kong in late December 1997/early January 1998 eliminated H5/Gs/Gd viruses from the Hong Kong poultry markets at the time, but these viruses reappeared in poultry in Hong Kong in 2001. Waterfowl is usually resistant to HPAI viruses; however, in late 2002, waterfowl in Hong Kong succumbed to H5/Gs/Gd influenza virus infections. In February 2003, two Hong Kong residents were infected with H5/Gs/Gd virus, one of whom died.

In April/May 2005, more than 6,000 wild birds died from H5/Gs/Gd virus infection at the Qinghai Lake Nature Reserve in Gangcha County, Qinghai Province, China.[12,82] Although viruses of several genotypes were detected during the outbreak, one genotype was dominant. H5/Gs/Gd viruses closely related to the Qinghai Lake isolates have since spread through Russia, into Europe, the Middle East, and several African countries, most likely through migratory birds.

H5 Virus Outbreaks of the A/goose/Guangdong/1/1996 Lineage Since 2008

Since their reemergence in 2003, the H5/Gs/Gd viruses have undergone substantial evolution in their HA. A classification and nomenclature scheme based on the H5 HA nucleotide sequence has been established to describe the phylogenetic relationships of the H5/Gs/Gd viruses: currently 10 different clades (clades 0–9) are recognized, many of which have second-, third-, or fourth-tier subclades. Until 2008, frequent reassortment resulted in multiple genotypes that differed in the constellation of the internal vRNA segments; however, the HA/NA constellation was stable. This changed when H5N1/Gs/Gd viruses reassorted with different avian influenza viruses, resulting in viruses of the H5N2, H5N5, and H5N8 subtypes in 2008 to 2011 and the emergence of H5N6 viruses in 2013. These novel reassortant viruses possessed an HA of clade 2.3.4.4, which has since become dominant in several parts of the world; by 2012/2013, these viruses had further diversified into four genetically distinct groups (A–D).

The group A viruses caused an H5N8 virus outbreak in South Korea in 2014, and descendants of these viruses were detected in North America in late 2014, marking the first isolation of H5/Gs/Gd viruses on the American continent. These viruses underwent reassortment with North American avian

viruses, resulting in novel H5/Gs/Gd viruses with NAs of different subtypes. Newly emerged North American H5N2 viruses of the H5/Gs/Gd lineage caused multiple outbreaks in commercial poultry operations in North America in the spring and summer of 2015 and were eradicated through rigorous control measures and the culling of approximately 48 million birds. No human infections were reported. Sister subgroups of the viruses that were introduced into North America caused outbreaks in South Korea during the following years and were introduced into Europe where they were primarily isolated from wild birds in 2014 to 2015. Group B viruses of the H5N8 subtype emerged in China in 2013 and caused outbreaks in the Republic of Korea. Descendants of these viruses moved westward and were isolated in Siberia, Europe, the Middle East, and Africa in the winter of 2016 to 2017. These novel H5N8 viruses caused multiple outbreaks in poultry farms in Europe, and more than 1,200 infected wild birds were reported in Germany alone. Group C viruses of the H5N6 subtype have been detected in China since 2013 and have spread to other Asian countries, but not to other continents. The H5N6 group C viruses have now replaced H5N1 as the most dominant subtype of H5/Gs/Gd viruses in Southern China. In contrast to H5N2 and H5N8 viruses, the H5N6 viruses have caused human infections[161]; to date, 28 confirmed cases (with most, but not all, viruses belonging to group C) with several fatalities have been reported. In addition, group C viruses have been isolated from pigs and cats. The infection of mammals with H5N6 group C viruses may be explained by the ability of the viruses to bind to human-type receptors, in addition to avian-type receptors. Consistent with this finding, these viruses bind to and replicate in *ex vivo* human organoids and transmit to cohoused ferrets (see Infections of Humans with H5 Viruses of the A/goose/Guangdong/1/1996 Lineage section). Group D viruses (mostly of the H5N6 subtype) were detected in China and Vietnam in 2013 to 2014.

As of September 2018, the majority of circulating H5/Gs/Gd viruses belonged to clade 2.3.4.4 with H5N8 viruses dominating in Europe and H5N6 viruses dominating in Southern China. In addition, viruses of clade 2.3.2.1a were circulating in parts of Asia, and viruses of clade 2.3.2.1c were circulating in parts of both Asia (including Indonesia) and Africa. In total, more than 70 countries have reported H5/Gs/Gd outbreaks to date.

Host Range of H5 Viruses of the

A/goose/Guangdong/1/1996 Lineage

Since their emergence, H5/Gs/Gd viruses have become enzootic in poultry populations in different parts of the world. While HPAI outbreaks are typically limited to terrestrial poultry, the H5/Gs/Gd viruses have been isolated from a number of different wild birds including water birds (order Anseriformes) such as ducks, geese, and swans; shorebirds (order Charadriiformes) such as gulls and waders; small songbirds (order Passeriformes) such as sparrows and crows; large wading birds (order Ciconiiformes) such as herons, storks, and egrets; several *Ratites* species including ostriches, emu, and rhea; and species of several other bird orders. In addition, these viruses have been isolated from carnivores including dogs, cats, tigers, leopards, a stone marten, Owston civets, and raccoon dogs. Moreover, H5N1 and H5N6 viruses have been isolated from pigs on several occasions. No HPAI H5 infections have yet been reported in horses.

Virulence and Transmissibility of H5 Viruses of the A/goose/Guangdong/1/1996 Lineage

H5/Gs/Gd viruses have been extensively studied in primary human cells and in several animal models including mice, ferrets, guinea pigs, and nonhuman primates. In alveolar epithelial cells and macrophages, as well as in the lungs of infected mice, ferrets, and nonhuman primates, H5/Gs/Gd viruses typically elicit higher levels of proinflammatory cytokines than are observed upon infection with contemporary human viruses. In these animal models, the H5/Gs/Gd viruses are highly pathogenic and cause diffuse alveolar damage with massive infiltration of immune cells and infection of pneumocytes. In nonhuman primates, H5/Gs/Gd viruses cause severe pneumonia although the infections are usually not lethal. Two European H5N8 group B viruses were highly virulent in ducks and in mice but caused mild, nonlethal disease in ferrets.

The infection of more than 860 people with H5N1 and H5N6 viruses (no human infections have been reported with H5N2 and H5N8 viruses) has raised concern over a potential H5 pandemic. However, there are no reports of sustained human-to-human transmission of H5/Gs/Gd viruses. A number of studies have tested the transmissibility of H5/Gs/Gd viruses in ferrets, the most widely accepted mammalian model for influenza virus transmission

studies. To date, no natural H5/Gs/Gd virus has been found to transmit among ferrets via respiratory droplets; however, several studies reported transmission of H5N6 viruses to cohoused ferrets (contact transmission). Several groups also tested the respiratory droplet transmissibility in ferrets of human/avian reassortant viruses bearing an H5 HA or of H5 viruses with mutations in HA known to increase the affinity for human-type receptors; no respiratory droplet transmission was detected in these studies. However, four studies[10,52,55,164] in 2012/2013 established that H5/Gs/Gd viruses can acquire respiratory droplet transmissibility in ferrets or guinea pigs. Although these studies used different H5/Gs/Gd viruses and different approaches (including reassortment, site-directed mutagenesis to introduce mammalian-adapting amino acid changes, and/or sequential passages in ferrets to acquire mutations that facilitate replication in mammals), common properties emerged that appear to be essential for respiratory droplet transmissibility in ferrets: HA binding to human-type receptors (see Receptor Specificity of Influenza Viruses); lack of a glycosylation site in HA, resulting in increased binding to human-type receptors; HA thermostability and fusogenicity at a relatively low pH; and highly efficient replication in mammalian cells, typically conferred by mutations in the PB2 polymerase protein (see The Replication Complex section).

Human Infections with H5 Viruses of the A/goose/Guangdong/1/1996 Lineage

As of January 21, 2019, 860 confirmed human infections have been reported since 2003 with H5N1/Gs/Gd viruses, resulting in 454 fatalities (https://www.who.int/influenza/human_animal_interface/2019_01_21_tableHua=1). The largest numbers of human infections with H5N1 viruses have occurred in Indonesia, Vietnam, Egypt, and China. In Egypt in 2015, 136 people were infected with H5N1/Gs/Gd viruses; of those, 39 succumbed to their infections. The reasons for the large number of human H5N1 infections in Egypt in 2015 are not known. Since 2016, only a few human H5N1 infections have occurred, and they were limited to Egypt and Indonesia. Highly pathogenic H5N6/Gs/Gd viruses emerged in 2013 in China and have since infected 28 individuals, including several fatal cases. As stated earlier, there are no reports of sustained human-to-human transmissions of H5N1 or H5N6 viruses of the Gs/Gd lineage.

Although H5/Gs/Gd viruses have not acquired the ability to spread efficiently among humans, isolated cases of human-to-human transmission may have occurred. However, most of these clusters involved family members living in the same household, and infection may have occurred through exposure to a common source (such as sick or dead poultry), rather than human-to-human transmission. Overall, transmission of H5/Gs/Gd viruses to humans appears to be rare and primarily associated with contact with sick or dead poultry, although other modes of infection (e.g., through virus-contaminated feces or water) have also been considered.

During the 1997 and 2003 H5N1 outbreaks in Hong Kong, there was no evidence of systemic viral infection in infected individuals. However, after 2003, human infections with H5N1 viruses appear to be systemic[21]: virus has been recovered from not only respiratory organs but also stool and cerebrospinal fluid (CSF), while viral sequences and/or antigens have been detected in brain neurons; in epithelial cells of the intestinal tract; in the heart, spleen, kidney, and liver; and in the placenta and fetus of a pregnant women infected with an H5N1 virus. The detection of viral sequences and antigen in the intestinal tract is consistent with the expression of avian-like virus receptors in the human gut, the *ex vivo* infection of gut tissue with an H5N1 virus, and reports of gastrointestinal symptoms. In H5N1 virus–infected patients, acute respiratory distress syndrome (ARDS) with diffuse alveolar damage is common.[3] Virus and/or antigen binding has been detected to nonciliated epithelial cells in the bronchioles and type 2 pneumocytes and macrophages in the alveoli.[127,148] Type 2 pneumocytes differentiate to type 1 pneumocytes, which are critical for gas exchange in the alveoli; the infection of type 2 pneumocytes may therefore result in more severe lung damage. The levels of proinflammatory cytokines are higher in individuals infected with H5N1 viruses than in those infected with seasonal influenza virus and higher in fatal than in nonfatal cases of H5N1 infection.[21] The pathology in humans is in line with cell culture studies that demonstrate increased levels of proinflammatory cytokines upon H5N1 infection, animal infection studies that show increased pathology, viral targeting of type 2 pneumocytes,[148] and stronger innate immune responses upon H5N1 virus infection compared to infection with control viruses. Collectively, the available data suggest that the high mortality in humans results from a combination of high virus loads and the induction of high levels of proinflammatory pathways, which may

culminate in extensive alveolar damage. Based on a small number of human H5N6 cases that have been studied in detail, H5N6 virus infection is comparable to H5N1 infections.

Some of the currently circulating H5N1 and H5N6 viruses are resistant to the antiviral drugs amantadine and rimantadine. Most H5N1 and H5N6 viruses are sensitive to the NA inhibitors (NAIs) oseltamivir and zanamivir; however, oseltamivir-resistant viruses have been isolated from H5N1 and H5N6 virus–infected patients treated with this drug. These viruses contain an amino acid substitution at position 274 or 294 (N2 NA numbering) of the NA protein.

Infections of Humans with Low and Highly Pathogenic H7N9 Viruses

On March 31, 2013, Chinese authorities announced three fatal human infections with novel H7N9 influenza viruses.[37] This marked the beginning of the first outbreak of novel H7N9 viruses in the spring of 2013, which was followed by a second outbreak in the winter of 2013/2014. In the following years, waves of human H7N9 virus infections occurred every winter until 2016/2017, with the fifth wave in 2016/2017 causing more human infections than the previous four waves combined. In the winter of 2017/2018, only three human cases were reported, presumably due to the use of an H5/H7N9 bivalent vaccine in poultry (see below). The first wave of human H7N9 infections in 2013/2014 was limited to provinces in the southeastern part of China, but the geographic range of human H7N9 infections expanded in the following years to southern, central, and western provinces of China.

To date, 1567 confirmed human infections with H7N9 viruses have occurred with a case fatality rate of 39%. Individuals with confirmed H7N9 virus infection typically develop a respiratory tract infection with fever and coughing, which may progress to severe pneumonia and ARDS, potentially with fatal outcome. In addition to the confirmed cases, a 10- to 100-fold higher number of asymptomatic or mild cases may have occurred. The case fatality rate of human H7N9 infections may therefore be lower than currently reported; however, appreciable numbers of unrecognized human H7N9 infections pose considerable challenges to the control of this virus.

Epidemiologic studies established an association between human H7N9

infections and exposure to poultry, typically in live-bird markets. Demographic studies revealed that the average age of H7N9-infected individuals is higher than that of people infected with H5/Gs/Gd viruses and that males have accounted for two-thirds of the human H7N9 cases, in contrast to a more balanced sex ratio among H5-infected people. One possible explanation is that elderly males spend more time in live-bird markets than females or younger people of both sexes. Several studies reported antibodies to H7N9 viruses in up to approximately 15% of the sera collected from workers in live-bird markets, and H7N9 viruses have been isolated repeatedly in live-bird markets in different provinces of China since 2013. Closures of live-bird markets or mandatory rest and cleaning days in various cities reduced the influenza virus load in these live-bird markets but did not eliminate the novel H7N9 viruses from Chinese poultry populations. In 2017, a poultry vaccination campaign with a recombinant bivalent inactivated vaccine against H5N1 (A/chicken/Guizhou/4/2013, clade 2.3.4.4) and H7N9 (A/pigeon/Shanghai/S1069/2013) viruses was implemented and reduced the seropositivity rate to the targeted virus in poultry by greater than 90%.[163] Importantly, only three human H7N9 cases have been reported since the implementation of the poultry vaccination campaign.[163] However, most poultry vaccines do not induce sterilizing immunity in the field, so the viruses targeted by the vaccine continued to circulate and evolve. It remains to be seen whether the inactivated H5N1/H7N9 vaccine recently used in China will eradicate the targeted viruses from Chinese poultry populations.

Soon after the first reports of fatal human H7N9 virus infections in China in 2013, the viral genomic sequences were determined and immediately made publicly available through GISAID, the Global Initiative on Sharing All Influenza Data (www.gisaid.org). Phylogenetic analyses suggested that the H7 HA segment originated from an H7N3 duck influenza virus, the N9 NA segment originated from an H7N9 virus from wild waterfowl, and the six remaining segments originated from H9N2 viruses circulating in poultry.[37,63,81] Since the emergence of the novel H7N9 viruses, reassortment has resulted in a number of constellations of the internal segments. Moreover, the HA genes of the H7N9 viruses have now evolved into two lineages, referred to as the “Yangtze River Delta” and “Pearl River Delta” lineages.

The HA of the H7N9 viruses circulating in 2013 to 2016 does not encode a multibasic sequence at the HA cleavage site (see HA Cleavage section), a

hallmark of highly pathogenic influenza viruses. Based on the currently used Office International des Epizooties (OIE) criteria for the classification of influenza viruses, the H7N9 viruses that circulated between 2013 and 2016 are therefore low pathogenic avian influenza viruses (despite their appreciable mortality rate in humans). This is consistent with the lack of severe disease in H7N9-infected chickens and ducks. Prolonged circulation of low pathogenic H5 and H7 viruses in poultry can result in the emergence of highly pathogenic variants with multiple basic amino acids at the HA cleavage site (see HA Cleavage section). In fact, highly pathogenic H7N9 viruses emerged at the end of December 2016, and 32 human infections with highly pathogenic H7N9 viruses had been reported by September 2017. These viruses belong to the Yangtze River Delta lineage of H7N9 viruses and are characterized by an amino acid insertion of KRTA, resulting in the KRKRTAR/G or KGKRTAR/G sequence at the HA cleavage site (the backslash denotes the cleavage site between HA1 and HA2).

The H7N9 viruses replicate efficiently in cultured mammalian cells. In mice and ferrets, they replicate in the respiratory tract of infected animals but typically do not cause severe disease or death.[5,118,153] H7N9 viruses transmit to contact ferrets and, more importantly, to exposed ferrets via respiratory droplets; however, the transmission kinetics are delayed compared with seasonal human influenza viruses.[5,118,153] In contrast to H5/Gs/Gd viruses, H7N9 viruses therefore possess the intrinsic ability to transmit among mammals via respiratory droplets. A comparison of H7N9 viruses of low and high pathogenicity demonstrated that the highly pathogenic H7N9 virus was more pathogenic in mice and ferrets than the low pathogenic H7N9 isolate, killing some of the infected and exposed ferrets.

The replicative ability and transmissibility of H7N9 viruses in mammals likely result from several mammalian-adapting features of these viruses. H7N9 viruses bind to both human-type and avian-type receptors (see Receptor Specificity of Influenza Viruses), a property likely conferred by the HA-226L (H3 HA numbering) and HA-186V residues known to increase the affinity for human-type receptors, which are encoded by most H7N9 viruses. Interestingly, almost all highly pathogenic H7N9 viruses isolated to date encode HA-186V but possess the avian-type HA-226Q residue. In addition, the novel H7N9 viruses lack the glycosylation site at positions 158 to 160 of HA, which is important for the transmissibility of H5 viruses (see

Glycosylation section). Moreover, most human (but not avian) H7N9 viruses encode PB2-627K or PB2-D701N, which facilitate the efficient replication of avian influenza viruses in mammals (see The Replication Complex section). During the fifth wave, the PB2-A588V mutation, which enhances the pathogenicity of avian influenza viruses in mice, was detected in most human H7N9 virus isolates.

The novel H7N9 viruses encode the M2-S31N mutation, which confers resistance to adamantanes. However, the circulating H7N9 viruses are sensitive to NA inhibitors, and early initiation of treatment with NA inhibitors has been shown to be beneficial. Treatment of H7N9-infected patients with NA inhibitors may result in the emergence of mutants that are resistant to the drug used for treatment. In fact, treatment of an H7N9-infected patient with oseltamivir resulted in the emergence of a virus resistant to both oseltamivir and zanamivir.

Infections of Humans with Other Avian Influenza Viruses

Prior to 1997, the direct transmission of avian influenza viruses to humans was not considered a serious human health threat. This assumption was based on findings that avian viruses do not replicate efficiently in experimentally infected humans and that no severe cases of human infections had been reported during any outbreaks of HPAI. The differences in receptor-binding specificities between human and avian viruses (for details, see Molecular Determinants of Host-Range Restriction and Pathogenesis section) were believed to provide a host-range barrier that limited the transmission of avian viruses to humans. Until 1997, only four cases of direct avian-to-human transmission of influenza viruses had been described: (a) an HPAI virus of the H7N7 subtype isolated from a patient with hepatitis in 1959; (b) an H7N7 HPAI virus isolated from a laboratory worker who developed conjunctivitis; (c) an H7N7 virus of low pathogenicity isolated from a woman who developed conjunctivitis and was likely infected from ducks she kept; and (d) an H7N7 virus isolated from a person in contact with a harbor seal experimentally infected with an H7N7 virus. With the emergence of the A/goose/Guangdong/1/1996-like H5 viruses in 1996 (see Infections of Humans with H5 Viruses of the A/goose/Guangdong/1/1996 Lineage section) and the novel H7N9 viruses in 2013 (see Infections of Human with Low and

Highly Pathogenic H7N9 Viruses), the number of human infections with avian infections has increased considerably.

The vast majority of human infections with avian influenza viruses have been caused by viruses of the H5 and H7 subtypes. Human infections with H5/Gs/Gd viruses are described in the Infections of Humans with H5 Viruses of the A/goose/Guangdong/1/1996 Lineage section. Likewise, human infections with the novel H7N9 viruses are described in the Infections of Human with Low and Highly Pathogenic H7N9 Viruses section. In addition, during an outbreak of HPAI H7N7 viruses in poultry in the Netherlands in February/March 2003, 89 people were infected, 83 of whom developed conjunctivitis.[32,75] Most cases were mild and self-limiting, although a veterinarian developed acute respiratory distress and an ultimately fatal pneumonia. In three cases, human-to-human transmission was documented, and antibodies were detected in 59% of those who had contact with infected poultry workers. In November 2003, an H7N2 virus was isolated from an adult in New York who was hospitalized for upper and lower respiratory tract illness but eventually recovered. In 2004, two people developed conjunctivitis and mild respiratory symptoms after an outbreak of an HPAI H7N3 virus in poultry in Canada. Additional cases of human infection with avian influenza viruses were detected in the United Kingdom in 2006 and 2007, when H7N3 and H7N2 viruses caused conjunctivitis in one and four individuals, respectively, and in Mexico in 2013, when two poultry workers became infected with HPAI H7N3 viruses. In the winter of 2016/2017, a veterinarian who treated sick cats infected with novel H7N2 influenza viruses (see Influenza in Cats section) developed respiratory symptoms, and the novel feline H7N2 virus was isolated from the veterinarian. A low pathogenic avian H7N4 virus (A/Jiangsu/1/2018) was recently isolated from a person in China who was exposed to live poultry prior to the onset of symptoms. This individual was hospitalized with symptoms of severe pneumonia but recovered from the infection.

In addition to H5 and H7 viruses, avian H9N2 viruses have caused human infections (see Low Pathogenic H9N2 Avian Influenza Viruses section). In 1998 and 1999, H9N2 viruses transmitted from birds to pigs and humans. Five human infections were reported in Southern China, and, in March 1999, two children were infected in Hong Kong. Both presented with symptoms of typical influenza and recovered. The isolates were genetically

similar to those from quail (A/quail/Hong Kong/G1/97 [H9N2]). In 2003, a young child in Hong Kong was infected with an H9N2 virus but recovered uneventfully. In Hong Kong in 2008 and 2009, genetically different H9N2 viruses were isolated from two immunocompromised patients. Additional human infections with H9N2 viruses have been reported in recent years, but the overall rate of reported human H9N2 viruses has not increased, perhaps because many of these infections are mild and not recognized as H9N2 virus infections.

In 2004, two cases of human infection with H10N7 virus were reported in Egypt (http://www.paho.org/english/ad/dpc/cd/eid-eer-07-may-2004.htm). In 2012, two Australian abattoir workers experienced conjunctivitis and mild respiratory systems after they processed chickens from a farm with an H10H7 poultry outbreak. Both workers tested positive for H10N7 virus. Influenza viruses of the H10N8 subtype caused three human infections in China in the winter of 2013/2014, two with fatal outcomes; the internal vRNA segments of these viruses originated from H9N2 influenza viruses (see Low Pathogenic H9N2 Avian Influenza Viruses section). A human H10N8 virus bound to avian- and human-type receptors, perhaps in part explaining its ability to replicate in humans. Moreover, an H10N8 virus isolated from an environmental sample replicated in mice without the need for prior adaptation and became lethal for mice after two passages. An avian H10N8 virus has also been isolated from dogs in live-bird markets in China. Collectively, these data indicate that H10N8 viruses are able to infect mammals.

In Taiwan in 2013, the first known human infection with an H6N1 virus occurred. Collectively, the number of reported human infections with avian influenza viruses has increased, most likely as a consequence of increased public awareness, increased surveillance, and frequent exposure of humans to animals at the human–animal interface.

Infections of Humans with Swine Influenza Viruses

In general, human infections with swine influenza viruses cause mild illness; however, several fatal cases have been reported. The most prominent example of swine influenza virus transmission to humans is the H1N1 pandemic of 2009[39,105] (see The H1N1 Pandemic in 2009 section) (Figs. 15.1 and 15.8). However, several other instances of human infection with swine influenza viruses have been reported. Human infections with H1N1 swine

influenza viruses of different lineages occurred in North America, Europe, and Asia. Also, Eurasian reassortant human–like H3N2 swine viruses were transmitted to two children in The Netherlands in 1992/93 and to a child in Hong Kong in 1999. In North America in 2007, a number of people became infected with H1N1 viruses possessing an HA vRNA segment related to clade 1B.2 (see Influenza in Swine section) and internal vRNA segments derived from triple reassortant viruses (see The H1N1 Pandemic in 2009 section). North American H3N2 swine viruses (clade 3.1990.4; see Influenza in Swine section) with the M vRNA segment of H1N1pdm09 caused more than 300 human infections in 2011 to 2013, which were linked to exposure to swine at agricultural fairs. Most of the infected individuals were small children, most likely because they lacked protective antibodies to the HA, which originated from human viruses circulating in the late 1990s. In subsequent years, the number of human infections with H3N2 swine viruses remained small but has increased again since 2016; these post-2016 viruses differ in their HA gene from those that caused human infections in 2011 to 2013.

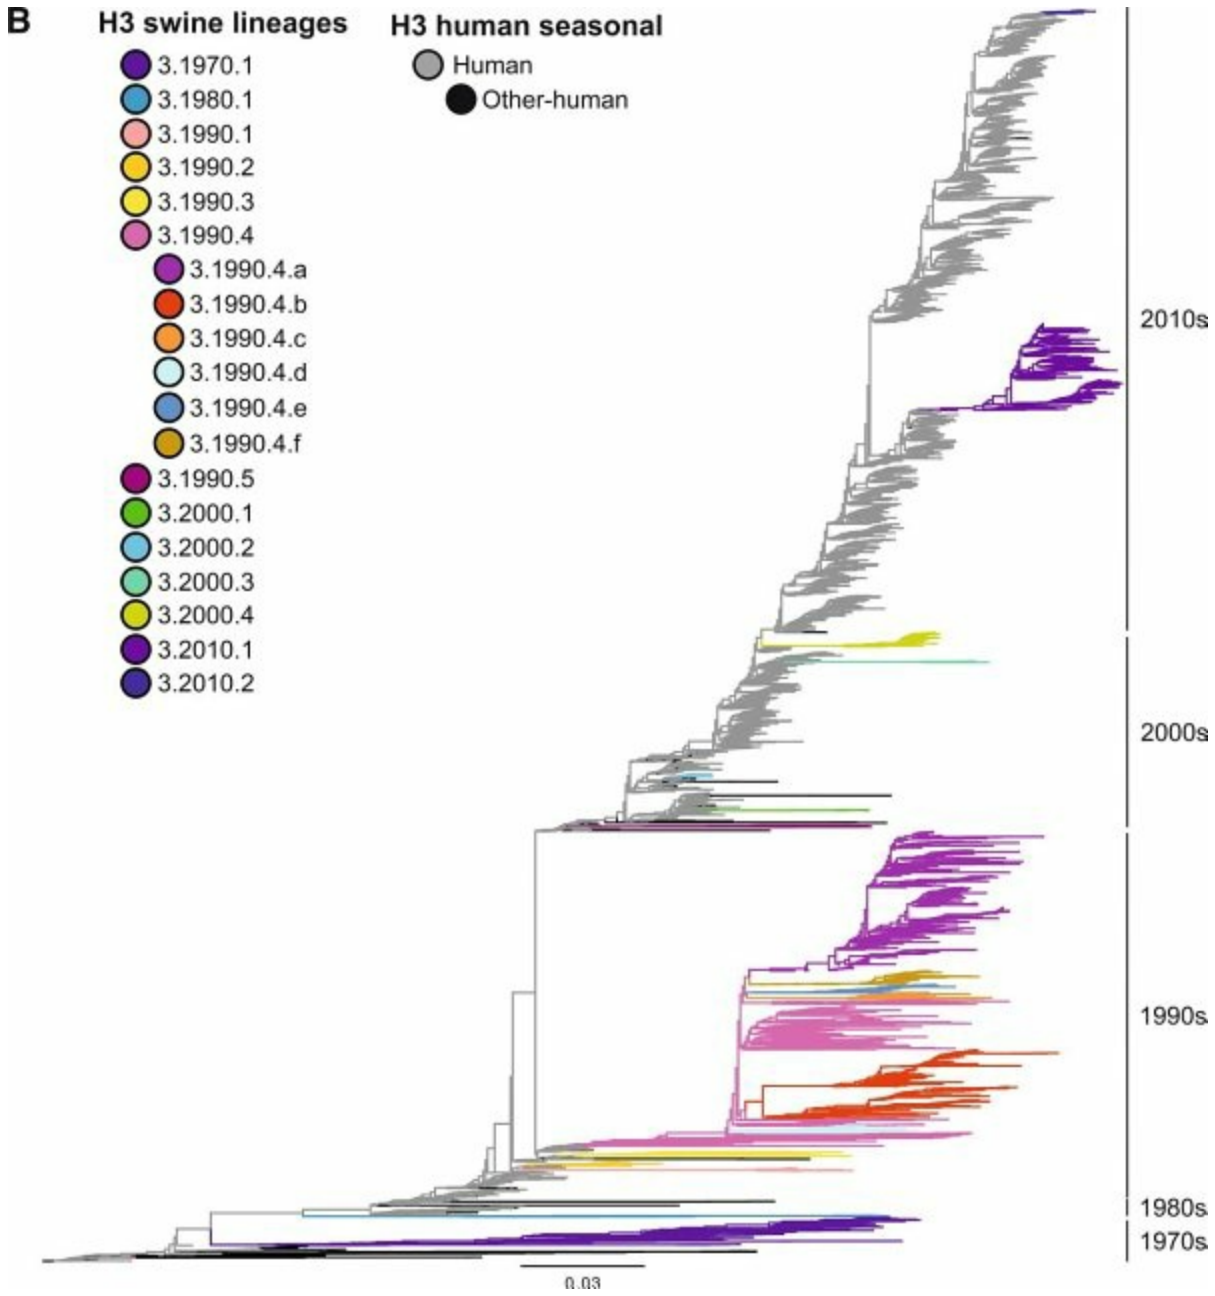

FIGURE 15.8 Phylogeny of swine H1 and H3 HA gene sequences. A: For swine H1 HA gene sequences, the phylogenetic tree was inferred by using maximum likelihood methods for 6296 H1 swine and 775 randomly sampled human and avian HA gene sequences demonstrating the three major lineages: 1A classical swine lineage, 1B human seasonal lineage, and 1C Eurasian avian lineage.

B: For swine H3 HA gene sequences, 3507 swine HA gene sequences were combined with 5548 randomly sampled human seasonal HA gene sequences collected from 1968 to present. “Other-human” indicates seasonal H3 HA gene sequences detected in swine without evidence of sustained transmission. Branch color represents clade designations of currently circulating swine viruses. Each tree is midpoint rooted for clarity; all branch lengths are drawn to scale, and the scale bar indicates the number of nucleotide substitutions per site. Phylogenetic trees were generated by Tavis Anderson and Amy Vincent, U.S. Department of Agriculture (USDA). (**A** was adapted from Anderson TK, Macken CA, Lewis NS, et al. A phylogeny-based global nomenclature system and automated annotation tool for H1 hemagglutinin genes from swine influenza A viruses. *mSphere* 2016;1(6), pii: e00275-16; covered under an open access license.)

EPIZOOLOGY AND PATHOGENESIS IN ANIMALS

Influenza A viruses infect a variety of animals, including humans, birds, swine, horses, and dogs (Fig. 15.1). Occasionally, influenza viruses have been isolated from cats, tigers and leopards, stone martens and Owston civets, whales, seals, mink, and camels. Serologic evidence also suggests exposure of bats, several ruminant, reptile, and amphibian species to immunogens related to influenza viruses.

Viruses of all known HA and NA subtypes are maintained in aquatic birds (with the exception of H17N10 and H18N11 viruses; see Influenza in Bats section),[155] generally without causing disease; therefore, aquatic birds are considered the natural reservoir of influenza A viruses. Nonpathogenic viruses of the H5 and H7 subtypes can evolve into highly pathogenic avian strains and cause significant losses to the poultry industry. Viruses of the H5, H7, and H9 subtypes have established lineages in terrestrial birds. Although human pandemics have been associated with viruses of the H1 to H3 subtypes, the ability of avian viruses of the H5, H7, and H9 subtypes to infect humans has flagged viruses of these subtypes as potential candidates for future influenza pandemics. Influenza B viruses typically replicate in humans

but have been isolated from seals. Influenza C virus infects humans, swine, and dogs.

Influenza in Birds

The natural reservoir of influenza A viruses are the orders Anseriformes (ducks, geese, swans) and Charadriiformes (gulls, terns, shorebirds), although influenza A viruses have been isolated from at least 105 different avian species from 26 different families. Almost all HA and NA subtypes have been detected in dabbling ducks (*Anas* spp.), suggesting that these species are the major reservoir of influenza A viruses. In mallard ducks (*Anas platyrhynchos*), viruses of the H5, H3, H4, and H6 subtypes are isolated most frequently; the most prevalent subtypes are H5N1, H4N6, and H3N8. In addition, viruses of several HA subtypes (including H1, H2, H5, H7, and H9–H12), in combination with several NA subtypes, have been detected in waders of the Charadriidae family, suggesting a role for these species in the perpetuation of influenza A viruses. Viruses of the H13 and H16 subtypes appear to circulate only in Laridae (gull and tern) species. For the NA gene, N3, N4, N6, and N8 subtypes predominate in ducks, whereas N2 and N9 are most frequently detected in chickens. Poultry play a critical role in the perpetuation of influenza A viruses; in fact, most HA and NA subtypes can be isolated from poultry in live-bird markets.

Surveillance studies have demonstrated seasonal patterns in prevalence; the infection rate of mallard ducks reaches 60% before the autumn migration and declines to less than 10% in spring and summer. This pattern may represent the influx of immunologically naïve juveniles every summer and/or the high population density in marshalling areas before the migration. In contrast, in North American shorebirds, the infection rate is highest in late spring and early summer. Since the prevalence of infection declines along the migration route and is relatively low at the wintering grounds of mallard ducks, geographic patterns in prevalence can be observed (i.e., infection rates are higher at the marshalling areas in the north than at the wintering grounds in the south). Moreover, the prevalence of virus subtypes in the same species changes from year to year. In particular, cyclic patterns exist in which high rates of prevalence for one subtype in a certain population may be followed by low detection rates in this population in subsequent seasons, perhaps due to herd immunity to viruses of the respective subtype.

Reassortment plays a critical role in the evolution of avian influenza viruses with significant contributions of both intrasubtypic reassortment (i.e., reassortment between viruses of the same subtype) and intersubtypic reassortment (i.e., reassortment between viruses of different subtypes), as well as of reassortment between the North American and Eurasian gene pools, which evolve largely independently, as described earlier.

Based on their pathogenicity in chickens, avian influenza viruses are classified as HPAI or low pathogenicity avian influenza (LPAI) viruses. LPAI viruses cause mild respiratory disease, depression, and/or a decrease in egg production. For outbreak control purposes, the OIE classifies an avian influenza virus as HPAI if it is "lethal for six, seven, or eight of eight 4- to 8-week-old susceptible chickens within 10 days following intravenous inoculation with 0.2 mL of a 1/10 dilution of a bacteria-free, infective allantoic fluid" (OIE Manual of Diagnostic Tests and Vaccines for Terrestrial Animals 2010; accessible at: http://www.oie.int/en/international-standard-setting/terrestrial-manual/access-online/), or if it has an intravenous pathogenicity index (IVPI) greater than 1.2 (the IVPI is the mean clinical score of ten 6-week-old chickens intravenously infected).

The infection of aquatic birds with LPAI is typically asymptomatic, although even LPAI viruses can cause mild disease in mallards and swans. In ducks, avian viruses replicate in the epithelial cells in the intestinal tract and, to a substantially lesser extent, in cells of the respiratory tract. These viruses are resistant to the low pH environment they encounter during their passage through the digestive tract. Avian species shed influenza viruses in high concentrations in feces. The viruses are relatively stable in water and have been isolated from water samples of lakes where wild birds have nested or congregated before migration. Contaminated water and feces may, therefore, serve as major routes of transmission of LPAI among wild birds. By contrast, HPAI H5 viruses replicate efficiently in the upper respiratory tract of infected birds.

Typically, outbreaks of HPAI occur in poultry; historically, the resulting disease was called "fowl plague." Viruses that are highly pathogenic for chickens often cause high mortality in turkeys and Japanese quail but are usually nonpathogenic for ducks, geese, and other wild birds, with the exception of some of the recently circulating H5/Gs/Gd viruses (see Infections of Humans with H5 Viruses of the A/goose/Guangdong/1/1996

Lineage section). Infection of ducks with some H5/Gs/Gd viruses results in systemic infections with high virus titers in the respiratory organs; neurologic symptoms may also be observed. However, infected birds may die without clinical symptoms. In experimental infections of several bird species, H5/Gs/Gd viruses were not uniformly lethal, and infected animals shed appreciable amounts of viruses, which could facilitate virus spread. A characteristic feature of H5/Gs/Gd infection in ducks is that virus titers in oropharyngeal swabs are higher than those in cloacal swabs.[135] In chickens, influenza virus infections with HPAI viruses can result in mortality rates of up to 100%. Historically, outbreaks of HPAI were controlled by depopulation and vaccination. While these and other control measures continue to be implemented, H5/Gs/Gd viruses have become enzootic in poultry populations in different parts of the world.

Most HPAI viruses have a series of basic amino acids at the HA cleavage site (see HA Cleavage section); however, exceptions exist in which viruses with multiple basic amino acids at this site are not highly pathogenic in chickens, or highly pathogenic viruses do not possess a conventional HA cleavage site. All HPAI viruses known to date belong to the H5 or H7 subtype; however, only a small proportion of all H5 and H7 viruses are highly pathogenic.

Occasionally, avian influenza viruses infect mammalian species (see Transmission of Avian and Swine Influenza Viruses to Humans section). Most of these infections are self-limiting, and stable lineages have emerged rarely, such as in pigs in 1979 with the introduction of an avian H1N1 virus. In mammals, LPAI viruses cause bronchitis, bronchiolitis, and pneumonia. A major exception is the H7N9 virus that emerged in China in 2013 (see Infections of Human with Low and Highly Pathogenic H7N9 Viruses section). Although most H7N9 viruses are of the low pathogenic type, they have infected 1567 people with a case fatality rate of 39%.

In the last 5 years, more than 7,100 outbreaks of HPAI viruses in domestic birds in 68 countries have been reported to the OIE (http://empres-i.fao.org/eipws3g/); most were caused by H5 viruses.

Non–Gs/Gd Lineage HPAI H5N2 Virus Outbreaks

Pennsylvania outbreak

In April 1983, a low virulent H5N2 virus (A/chicken/Pennsylvania/1/83) emerged in chickens in Pennsylvania. By October, this virus had mutated into a highly pathogenic variant (A/chicken/Pennsylvania/1370/83) causing a mortality rate of more than 80% in chickens. The virus was eventually eradicated by the slaughter of more than 17 million birds. The avirulent predecessor was unusual in that it had multiple basic amino acids at the HA cleavage site. The virulent strain differed from its predecessor by only a few nucleotides including one that caused the loss of an HA glycosylation site, thereby exposing the multiple basic HA cleavage site to the ubiquitous cellular proteases furin and PC6.

Mexican outbreak

In May 1994, a mildly pathogenic H5N2 virus was isolated from Mexican chickens (A/chicken/Mexico/26654-1374/94). This virus was not eradicated by mass slaughter because it had already spread widely. Stepwise accumulation of mutations over several months yielded moderately (A/chicken/Puebla/8624-602/94) and highly (A/chicken/Queretaro/14588-19/95) pathogenic strains with a series of basic residues at the HA cleavage site. Vaccination was implemented in 1995 and by 2001, more than 1 billion doses of inactivated vaccine had been used. Between 1998 and 2001, 459 million doses of recombinant fowlpox-vector vaccine were also administered. Low pathogenic H5N2 strains continue to circulate, as do genetically related viruses in the neighboring countries of Guatemala and El Salvador. In 2005, an H5N2 virus with low pathogenicity emerged in chickens in Japan. This virus is a descendant of the virus responsible for the Mexican outbreak and is closely related to a virus isolated from Guatemala. The origin of the Japanese strain remains unknown.

H7N1 Outbreaks

In March 1999, an LPAI virus of the H7N1 subtype was isolated from a poultry farm in Italy. The virus was not eradicated and the infection spread, resulting, in December, in the emergence of a highly pathogenic isolate. More than 13 million birds were destroyed to control the outbreak. The reemergence of this LPAI in August 2000 was controlled by additional

depopulation followed by a vaccination campaign from November 2000 to May 2002. The vaccine was based on an inactivated H7N3 virus to allow *d*ifferentiation of *i*nfected and *v*accinated *a*nimals (DIVA). Vaccination in combination with intensive monitoring led to the eradication of this H7N1 virus. Outbreaks of HPAI viruses of the H7N1 subtypes also occurred in ostriches in South Africa in 2012 and among wild water birds in Algeria in 2016. Both outbreaks were relatively small.

H7N2 Outbreak

Highly pathogenic H7N2 viruses killed more than 18,000 domestic chickens in a free-ranging and cage bird layer flock in Australia in 2013.

H7N3 Outbreaks

Several outbreaks of HPAI H7N3 viruses have occurred in poultry in Asia and in North and South America. During an outbreak in Canada in 2004, two workers developed symptoms of influenza virus infection. H7N3 viruses isolated from these individuals had increased affinity for human-type receptors (see Receptor Specificity of Influenza Viruses section). Both the Chilean and 2004 Canadian isolates arose from LPAI viruses through recombination events that inserted 10 amino acids from the NP protein (Chilean virus) or 7 amino acids from the M1 protein (Canadian virus) into the HA cleavage site.

In June 2012, an outbreak of HPAI H7N3 viruses (represented by A/chicken/Jalisco/CPA1/2012) started in commercial poultry farms in the Mexican state of Jalisco (a major egg production area), resulting in the death through disease or culling of more than 22 million poultry. During a second wave in the first half of 2013, the HPAI viruses spread to industrial and backyard poultry in neighboring states. Another large outbreak occurred in 2016 that led to greater than 250,000 poultry being culled.

Genetic and phylogenetic analysis revealed close similarity of the HPAI H7N3 Mexican viruses with North American avian viruses of different subtypes, suggesting that reassortment played a role in the generation of the Mexican H7H3 viruses. The HA gene of the Mexican HPAI H7N3 viruses possesses a 24-nucleotide insertion at the cleavage site, which was most likely derived from chicken 28S rRNA through nonhomologous

recombination; this insertion encodes several basic amino acids. Interestingly, nonhomologous recombination of HA and 28S rRNA sequences had been reported previously, when sequential passages of A/turkey/Oregon/71 (H7N3) virus in embryonated chicken eggs resulted in the insertion of 54 nucleotides of 28S rRNA near the HA cleavage site.[68] The virus with the 28S rRNA insertion no longer required exogenous trypsin for HA cleavage (see HA Cleavage section) and was more pathogenic in chickens than the parent virus. Two human infections with the Mexican HPAI H7N3 viruses occurred among poultry workers; both developed conjunctivitis. The virus isolated from one of the infected people (A/Mexico/InDRE7218/2012) was lethal in mice. In ferrets infected with this virus, clinical signs of illness were observed; the virus replicated efficiently in the upper and lower respiratory tract and transmitted to naïve contact animals in the same cage.

H7N7 Outbreaks

In 2003, an HPAI of the H7N7 subtype caused outbreaks in layer farms in The Netherlands, resulting in the death or culling of more than 30 million birds. Experimental infection of chickens confirmed the highly pathogenic phenotype of the virus. The outbreak spread to Belgium and Germany but was brought under control by mass slaughtering. In The Netherlands, the outbreak was associated with one fatal human case, a veterinarian who contracted the disease, and with conjunctivitis in 78 individuals who either directly handled affected poultry or had family members who did.[32,75] These data suggest human-to-human transmission, and experimental infection of cats demonstrated that the virus isolated from the fatal case caused alveolar damage with infection of type 2 pneumocytes and nonciliated bronchial cells, comparable to infection with an H5/Gs/Gd virus. The virus isolated from the fatal case differed by 14 amino acids from a virus isolated from another individual with conjunctivitis; the acquisition of PB2-627K (a known determinant of pathogenicity in mammals; see The Replication Complex section[48,137]) was pivotal for increased pathogenicity and tissue tropism. Depopulation of infected poultry and the treatment of at-risk individuals with NAIs likely prevented further spread of this virus.

In 2005, an outbreak of H7N7 HPAI occurred in chickens in the Democratic People's Republic of Korea. More than 200,000 chickens died

from influenza virus infection or were destroyed. Further outbreaks of H7N7 HPAI occurred in several European countries including Spain, the United Kingdom, Italy, and Germany between 2008 and 2016, resulting in small to moderate numbers of poultry that succumbed to infection or were culled.

Non–Chinese Lineage H7N9 Outbreak

The H7N9 viruses that emerged in China in 2013 and caused human infections are discussed in the Infections of Humans with Low and Highly Pathogenic H7N9 Viruses section. In March of 2017, an outbreak of HPAI H7N9 viruses occurred in poultry farms in Tennessee. At the same time, LPAI H7N9 viruses were isolated in a neighboring county and later also in the neighboring states of Alabama, Kentucky, and Georgia. More than 100,000 animals were culled to stop the further spread of the viruses. The sequences of the LPAI and HPAI viruses were very similar, except for an 8-amino-acid insertion at the HPAI HA cleavage site that matched the sequence of chicken 28S rRNA. Interestingly, this insertion was almost identical to that detected in the 2012 Mexican HPAI H7N3 viruses. The American LPAI and HPAI H7N9 viruses were closely related to an American teal virus (A/blue-winged teal/Wyoming/AH0099021/2016; H7N9) but differed from the H7N9 viruses that emerged in China in 2013.

Low Pathogenic H9N2 Avian Influenza Viruses

Since the mid-1990s, LPAI viruses of the H9N2 subtype have become enzootic in poultry populations in many countries in Asia, the Middle East, and North Africa. H9N2 influenza viruses are currently the most prevalent LPAI in poultry in the world. Chickens infected with H9N2 viruses often experience respiratory distress with reduced egg production. In the field, mortality rates as high as 40% have been observed, which may be the consequence of coinfections with other pathogens. In contrast, H9N2 infections of specific pathogen-free chickens in laboratory settings are typically nonlethal with mild influenza-like symptoms. H9N2 influenza viruses are rarely detected in wild birds.

H9N2 influenza viruses can be separated into North American and Eurasian lineages. In Eurasia, several lineages are circulating, often referred to as the Y280-like lineage (named after A/duck/Hong Kong/Y280/97), the

G1-like lineage (named after A/quail/Hong Kong/G1/97), the Korean or Y439-like lineage (named after A/duck/Hong Kong/Y439/97), the BJ/94–like lineage (named after A/chicken/Beijing/1/1994), and the F/98–like lineage (named after A/chicken/Shanghai/F/1998). Frequent reassortment has resulted in a large number of different genotypes within these lineages.

Since their introduction into poultry, the host range and virulence of H9N2 viruses have increased. Overall, early H9N2 virus isolates replicated less efficiently in poultry and were shed for shorter periods of time than more recent isolates. Since the early 2000s, many H9N2 viruses of the Y280 and G1 lineages have acquired an HA-Q226L (H3 numbering) mutation, which increases binding to human-type receptors (see Receptor Specificity of Influenza Viruses). The ability to efficiently bind to human-type receptors may explain the expanded host range of these H9N2 viruses, which have infected humans and other mammalian species including pigs, dogs, cats, weasels, and mink. In humans, H9N2 infections are typically mild, and serosurveillance studies suggest many unreported cases. All human H9N2 virus infections have been caused by viruses of the Y280 and G1 lineages, most of which encoded the mammalian-adapting HA-Q226L change. Since the late 1990s, H9N2 viruses have been isolated repeatedly from pigs; serosurveillance studies detected seroconversion rates of, for example, 16% in pigs in Southern China in 2010 to 2012. However, experimental infection of pigs with H9N2 viruses demonstrated that these viruses do not readily spread among pigs. H9N2 viruses replicate in mice and ferrets without the need for prior adaptation, and their virulence in mice differs, ranging from respiratory to systemic infection (with fatal outcome). In ferrets, H9N2 viruses replicate in the respiratory tract and transmit to cage mates. Importantly, six of nine H9N2 viruses isolated from chickens in China in 2010 to 2013 transmitted via respiratory droplets to exposed ferrets,[79] demonstrating that these viruses possess the ability to transmit among mammals via the airborne route.

Reassortment of H9N2 viruses with other avian influenza viruses has resulted in a number of viruses with all or some of their internal vRNA segments from H9N2 viruses, including viruses that have infected humans such as H5N1, H5N6, H7N9, and H10N8 viruses (see Transmission of Avian and Swine Influenza Viruses to Humans). The prevalence of H9N2 viruses in poultry and the donation of H9N2 internal vRNA segments to various

subtypes that have caused human infections identify H9N2 influenza viruses as an important component of the influenza virus ecology.

Vaccines for Avian Influenza Viruses

The increasing number of outbreaks caused by H5 and H7 viruses, the fact that H5, H7, and H9 viruses are now enzootic in poultry populations in parts of the world, and the increasing number of human infections with these viruses have spurred the development of avian vaccines and the vaccination of poultry flocks. Most approved vaccines for H5, H7, and H9 viruses are based on inactivated whole-virus preparations, although some live recombinant vaccines based on Newcastle disease, fowl pox, and turkey herpesvirus are now available.

Official vaccination programs against H5 viruses have been carried out in several Asian and African countries but have failed to eradicate H5 viruses in most of these countries. Possible reasons include limited adoption of vaccination campaigns, failure to induce sterilizing immunity that may result in undetected virus spread and evolution, and limited cross-reactivity with viruses of different clades. In September of 2017, China implemented a vaccination campaign with a recombinant bivalent vaccine directed against H5 and H7 viruses. As a result, the isolation rate of H7N9 viruses from poultry dropped by greater than 90%, and only three human H7N9 virus infections were reported between October 1, 2017, and September 30, 2018.

Influenza in Swine

The first isolation of an influenza A virus from pigs dates to 1930 (A/swine/Iowa/15/30 [H1N1]). Swine influenza viruses are enzootic in swine populations around the world and cause a respiratory disease with high morbidity but low mortality in these animals. Signs of infection include inactivity, nasal discharge, coughing, fever, labored breathing, weight loss, and conjunctivitis. Infections are limited to the respiratory tract with tracheobronchial lesions. Avian and human viruses of several subtypes (or reassortants thereof) have caused local outbreaks or become enzootic in pigs. A novel H1N1 virus, which most likely originated from reassortment of different influenza viruses in pigs,[39,105,130] caused the 2009 H1N1 pandemic.

Collectively, the prominent role for pigs in the emergence of novel

influenza viruses is supported by several findings: (a) pigs are sporadically infected with certain human seasonal influenza viruses and to a lesser extent avian influenza viruses, and swine influenza viruses have transmitted to humans; (b) epithelial cells in pig trachea contain both human- and avian-type receptors (i.e., Siaα2,6Gal and Siaα2,3Gal, respectively); and (c) frequent reassortment (both intra- and intersubtypic) occurs among swine influenza viruses, and reassortment has also been detected between swine and human influenza viruses and infrequently occurs between swine and avian viruses. These observations support the "mixing vessel" hypothesis that simultaneous infections of pigs with swine, avian, and human influenza viruses may result in the generation of reassortants capable of causing pandemics.

Over the last century, several major lineages of influenza A viruses of the H1 and H3 subtypes have circulated in swine populations in several continents (Fig. 15.8).

Swine H1 Viruses

Based on the phylogenetic relationships of swine influenza virus HA nucleotide sequences, a nomenclature system has been implemented that groups H1 swine influenza viruses into three major lineages, termed 1A, 1B, and 1C (Table 15.1). The 1A viruses were formerly known as "classical swine lineage"; they are descendants of the 1918 H1N1 pandemic virus and have been isolated in swine populations in North America, Europe, and parts of Asia.

TABLE 15.1 Overview of major H1 swine virus lineages

Major Lineage	Clade	Geographic Distribution[a]	Comments
1A (formerly known as classical swine lineage)	1A.1	Americas, Europe, Asia	Descendants of 1918 pandemic virus; formerly called α-H1 viruses; 3 subclades (1A.1.1–1.3)
	1A.2	North America, (Asia)	Descendants of North American triple reassortant viruses; formerly called β-H1 viruses
	1A.3	Worldwide	Descendants of North American triple reassortant viruses; 3 subclades (1A.3.1–3.3); 1A.3.3 is further divided into 3 subclades: 1A.3.3.2 H1N1pdm09 viruses with worldwide distribution, and the numerically dominant 1A.3.3.3, formerly called γ-H1 viruses
1B (formerly known as human seasonal lineage)	1B.1	Europe	Descendants of human seasonal H1 viruses introduced into European pig populations in the 1990s; 2 subclades (1B.1.1–1.2); 1B.1.2 is further divided into 3 subclades
	1B.2	Americas	Descendants of human seasonal H1 viruses that were introduced into North American pig populations in the 2000s; 2 subclades (1B.2.1–2.2); 1B.2.1 and 1B.2.2 were formerly known as δ2- and δ1-H1 viruses, respectively; 1B.2.2 is further divided into 2 subclades
1C (formerly known as Eurasian avian lineage)	1C.1	Europe	Descendants of avian influenza viruses introduced into European pig populations in 1979
	1C.2	Europe, Asia, (North America)	Descendants of avian influenza viruses introduced into European pig populations in the late 1990s; 3 subclades (1C.2.1–2.3); subclade 1C.2.3 viruses originated in Europe but are now mostly detected in Hong Kong and mainland China

[a]Parenthesis indicates that only small proportions of viruses of the respective clade were detected in the indicated geographic location.

In 1997 and 1998, H3N2 double human/swine reassortant and triple human/avian/swine reassortant viruses emerged in North America.[165] The double reassortant virus possessed human-like HA, NA, and PB1 genes, whereas the remaining genes were of classical swine virus origin, but this virus did not establish a stable lineage. The human/avian/swine triple reassortant viruses that contained HA, NA, and PB1 polymerase genes of human virus origin; PB2 and PA polymerase genes of avian virus origin; and NP, matrix (M), and nonstructural (NS) genes of classical H1N1 swine virus origin quickly became established throughout the North American swine population.[165] These viruses reassorted with enzootic classical H1N1 swine viruses, resulting in the diversification of H1 genes into the 1A.1, 1A.2, and 1A.3 subclades that have cocirculated in the United States and in parts of Asia. While reassortment has resulted in different HA/NA gene constellations, the constellation of the internal genes (i.e., PB2, PB1, PA, NP, M, and NS) was relatively stable for several years and became known as the TRIG (*t*riple *r*eassortant *i*nternal gene) cassette. The combination of the NA and M segments of a European avian–like swine virus with the remaining six segments from a triple reassortant virus resulted in the emergence of the H1N1pdm09 virus (subclade 1A3.3.2) in 2009.[39,105,130] This virus caused a pandemic and has now established a stable lineage in humans. Multiple

“reverse zoonosis” (anthroponosis) events have repeatedly reintroduced the H1N1pdm09 virus from humans to pigs, where it has since reassorted with enzootic swine viruses.

The 1B lineage (formerly known as “human seasonal lineage”) resulted from the introduction of human influenza viruses into pigs. Clade 1B.1 includes European human–like reassortant H1N2 viruses with an HA of human virus origin and the remaining genes from Eurasian reassortant human–like swine H3N2 viruses. The clade 1B.1 viruses have been limited to European swine populations. Clade 1B.2 viruses were detected globally in the early 2000s, with two separate introductions of human influenza viruses into pig populations in North America forming subclades 1B.2.1 and 1B.2.2.

The 1C lineage viruses were colloquially known as “Eurasian avian lineage” swine viruses. The 1C.1 H1N1 clade was founded by transmission of avian H1 influenza viruses into pigs in Europe in the late 1970s. Viruses of this clade caused multiple outbreaks throughout European pig populations, diverged, and formed a new clade 1C.2 in the late 1990s. Most 1C.2 viruses have been isolated in Europe, but viruses of the 1C.2.3 clade (which emerged in France in 1999) spread to Hong Kong and mainland China.

Swine H3 Viruses

Human H3N2 viruses have been transmitted to pigs multiple times in different locations and have founded several swine virus lineages. A new nomenclature for swine H3 similar to that developed for H1 viruses was proposed by the OIE and FAO influenza network (OFFLU) swine working group and is currently in development (T.K. Anderson, personal communication); it separates the currently circulating swine virus lineages based on the decade of their introduction into swine populations. For example, the human H3N2 viruses that were introduced into the European pig population in the early 1970s similar to A/Port Chalmers/1/73 are referred to as lineage 3.1970.1 (Table 15.2). In 1984, severe disease among Italian and French pigs was traced to a novel reassortant H3N2 strain that possessed human virus–like HA and NA genes from the 1970s introduction, but its internal genes were derived from Eurasian avian–like H1N1 swine viruses. This virus (referred to as Eurasian reassortant human–like swine H3N2 virus) soon became enzootic and replaced the human-like swine H3N2 viruses.

TABLE 15.2 Overview of major, currently circulating H3 swine virus lineages

Major Lineage	Clade	Geographic Distribution[a]	Comments
1970s human-to-swine transmissions	3.1970.1	Europe, Asia	Formerly called A/Port Chalmers/1/73–like swine H3N2 viruses
1980s human-to-swine transmissions	3.1980.1	Taiwan	
1990s human-to-swine transmissions	3.1990.1	North America	Descendants of triple reassortant H3N2 viruses
	3.1990.2	Korea, United States, Mexico	Descendants of triple reassortant H3N2 viruses (formerly called cluster I)
	3.1990.3	Asia	
	3.1990.4	North America, (Korea, Vietnam)	Descendants of triple reassortant H3N2 viruses (formerly called cluster IV); 6 subclades (3.1990.4.a–f; formerly called clusters IV-A through IV-F)
	3.1990.5	Brazil	
2000s human-to-swine transmissions	3.2000.1	Argentina	
	3.2000.2	Asia	
	3.2000.3	Europe	
	3.2000.4	China, Hong Kong, Vietnam	
2010s human-to-swine transmissions	3.2010.1	North America	Formerly called US 2010 human-like
	3.2010.2	North America	

[a]Parenthesis indicates that only small proportions of viruses of the respective clade were detected in the indicated geographic location.

Viruses of the H3 subtype did not circulate widely in North American swine populations until the late 1990s, although low rates of seropositive samples were reported. As discussed with the swine H1 viruses, this changed in 1997/1998 with the introduction of double and triple reassortant H3N2 influenza viruses into North American pig populations. The triple reassortant H3N2 viruses evolved into five HA clades and the major HA clade (3.1990.4) has further diversified into several subclades. Viruses from clade 3.1990.4 have also infected humans (see Infections of Humans with Swine Influenza Viruses section). In the 2000s and 2010s, several independent introductions of human H3N2 viruses into pigs, followed by reassortment with enzootic swine viruses, resulted in new swine virus lineages in different continents. An introduction from the 2010/2011 influenza season led to a new stable lineage in the United States, 3.2010.1, that is now the dominant swine H3 lineage detected in this country and has caused a number of human infections.[114,162]

Genetic Diversity of Swine Influenza Viruses

In the 20th century, a limited number of swine influenza virus genotypes were known, some of which (such as the classical H1N1 viruses) circulated for several decades. Over the last few decades, changes in the epizoology of swine influenza viruses (such as increased swine movement), and increased surveillance in pigs, have resulted in the detection of multiple novel genotypes. As described above, multiple clades and subclades of H1 and H3 viruses are now (co)circulating in several parts of the world. In addition, NAs of several major genetic lineages are (co)circulating in swine populations worldwide. The remaining viral segments typically originate from classical H1-1A, the TRIG cassette, H1-1C Eurasian avian, or H1N1pdm09 viruses.

Establishment of avian viruses in swine has been infrequent, although there is serologic and virologic evidence demonstrating that transmission events occur. In 1998, avian H9N2 viruses were first detected in swine in Hong Kong but did not establish a stable lineage. Based on their HA sequences, some of the swine H9N2 viruses may bind to human-type receptors. HPAI H5N1 viruses have been isolated from pigs in Asia on several occasions, although the prevalence of HPAI H5N1 viruses in pigs appears to be low. Moreover, H9N2 viruses with HPAI H5N1–like sequences have been described, suggesting reassortment between H5N1 and H9N2 viruses. To date, no H7N9 influenza viruses (see Infections of Humans with Low and Highly Pathogenic H7N9 Viruses) have been isolated from pigs. Viruses of other subtypes including H2N3, H3N1, H3N3, H3N8, H4N6, H4N8, H5N2, H6N6, H7N2, and H11N6 have been isolated from pigs, but these viruses have not established stable lines in swine populations.

Influenza in Horses

Two different subtypes of influenza A viruses are recognized in horses: H7N7, historically referred to as equine-1, and H3N8, referred to as equine-2. Equine influenza is typically associated with fever, nasal discharge, dry hacking cough, loss of appetite, muscular soreness, and tracheobronchitis. The disease is usually more severe with equine-2 (i.e., H3N8) viruses and can include inflammation of the heart muscle. Secondary bacterial infections can be fatal. Equine H3N8 influenza virus was the parent of the canine H3N8 influenza virus that emerged in 2004. Prior to the 20th century, equine and human or avian “influenza” epidemics were often temporally associated. Serum antibodies to influenza D virus have been detected in horses although

as yet no virus isolation or clinical disease has been reported. Equine influenza viruses cause disease in experimentally infected mice and ferrets.

The first equine influenza virus (A/equine/Prague/56 [H7N7]) was isolated in 1956 during a widespread enzootic of respiratory disease among horses in Eastern Europe. The last confirmed outbreak of this subtype occurred in 1979. It is believed to be extinct; however anecdotal reports of equine H7N7 outbreaks in Egypt and India, and the sporadic detection of H7-specific antibodies in reportedly unvaccinated horses, suggest the possibility that the viruses still circulate in small geographic pockets or in a subclinical form since their last isolation. In 1963, an equine influenza virus of the H3N8 subtype (A/equine/Miami/63 [H3N8]) was isolated in the United States and caused a major epidemic. It was later found to have been introduced into North American horses via the importation of horses from Argentina. Several studies suggested reassortment between the equine H7N7 and H3N8 viruses while they were cocirculating. Another enzootic with an H3N8 virus occurred in China in 1989. This virus caused morbidity rates of up to 80% and mortality rates of up to 20%. Based on sequence analysis, the virus was of avian origin and unrelated to the H3N8 virus already established in horse populations. It remained confined to the Chinese horse population and was not isolated after the mid-1990s.

Phylogenetic separation of Eurasian and American lineages has been observed in the equine H3 HA proteins since 1987; within the American lineage, three sublineages (South American/Argentinian, Kentucky, and Florida) are recognized. The Florida sublineage has evolved into two clades (Florida clade 1 and Florida clade 2); viruses of these two clades have caused the major recent equine influenza virus outbreaks in horses around the world since 2003. For the other viral gene segments, phylogenetic lineages have been described corresponding to the Florida clade 1 and clade 2 lineages in HA.

Inactivated vaccines of the H3N8 subtype have been widely used. Studies suggest that the immunity conferred by inactivated vaccines is short-lived (<6 months in young horses); therefore, outbreaks of equine influenza can affect vaccinated horses as well. Outbreaks of equine H3N8 continue to occur throughout the world, probably supported by the international transportation of vaccinated horses, in which virus replicates in a subclinical form. For example, international transportation of vaccinated horses likely led to the

introduction of equine influenza into Australia in 2007. Several equine influenza vaccines are now commercially available including inactivated vaccines (some of which are adjuvanted with immune-stimulating complexes); cold-adapted, temperature-sensitive, modified live equine influenza virus vaccine; and recombinant canarypox-vectored vaccine. Some of these vaccines do not provide sterilizing immunity, so the vaccinated horses continue to shed virus.

Influenza in Dogs

In 2004, outbreaks of respiratory disease occurred in racing greyhounds in Florida. The causative agent was an influenza A virus (A/canine/Florida/43/2004 [H3N8]) closely related to contemporary H3N8 equine viruses, suggesting interspecies transmission. The virus spread among the greyhound populations, indicating that the equine influenza viruses replicated in and transmitted among these dogs. This virus soon spread to other dog breeds but was largely maintained in large animal shelters in the United States, where the turnover of dogs and introduction of new susceptibles allowed the virus to be maintained for several years, although since 2016 the virus has only been detected at low levels and may have died out. The H3N8 viruses that circulated in horses and dogs in North America became genetically distinguishable and no additional interspecies transmission from horses to dogs or back to horses has been reported. Infection of individual dogs with an equine H3N8 virus was also reported in Australia in 2007, and a retrospective study showed that an outbreak of respiratory disease in English foxhounds in the United Kingdom in 2002 was also caused by an equine H3N8 virus. In experimental studies, horses infected with the canine virus seroconverted but showed little signs of disease. The infection of dogs with equine influenza viruses may be facilitated by the presence on canine respiratory epithelial cells of Siaα2,3Gal receptors, which are preferentially bound by equine influenza viruses.

In 2006, an avian H3N2 influenza–derived virus was isolated in Korea from domestic dogs with respiratory symptoms. Experimental testing showed that this virus caused tracheobronchitis and bronchiolitis in dogs and was transmitted to contact animals. While it is not clear where this virus first emerged, it was widespread in China and also isolated from an outbreak in Thailand. The virus may be maintained in farmed dogs, but seroprevalence

studies have also detected it in household dogs. In 2015, the canine H3N2 virus was introduced into the United States from Korea, and in 2017 and 2018, there were multiple epidemics that spread through many US states; these epidemics mostly stemmed from the new introductions of viruses from Asia, although there was some long-term transmission.

Seroprevalence studies detected antibodies to human H1 and H3 viruses in dogs in China. Moreover, reassortants between canine H3N2 and human influenza viruses have been isolated from dogs. Several cases of canine infections with highly pathogenic H5 viruses have also been reported although without significant transmission, and experimental studies have confirmed the susceptibility of dogs to H5N1 viruses. Under experimental conditions, dogs are also susceptible to H9N2 influenza viruses. Collectively, these data demonstrate the susceptibility of dogs to human and avian influenza viruses. Inactivated vaccines are available against the canine H3N2 and H3N8 viruses.

Influenza in Cats

Cats are susceptible to both human and avian influenza viruses. In Italy in 2009, an outbreak of A(H1N1)pdm09 viruses occurred in a colony of approximately 90 cats; half of the animals exhibited disease symptoms and 25 cats died. Serum samples were collected from 38 animals; more than half were seropositive. Infections of cats with A(H1N1)pdm09 viruses have also been reported in the United States and Canada.

In 2016, approximately 500 cats in large shelters in New York City became infected with an H7N2 low pathogenic influenza virus similar to viruses circulating in live-bird markets in the New York area in the late 1990s to the early 2000s. A veterinarian who treated sick cats became infected with the virus and experienced respiratory symptoms. A retrospective serosurvey demonstrated that 1 of 121 shelter workers tested was seropositive for H7N2 influenza virus. The novel feline virus and the virus isolated from the infected veterinarian replicated in the respiratory organs of mice and ferrets but did not cause severe disease. The feline H7N2 virus transmitted via respiratory droplets to exposed ferrets; in an independent experiment carried out by a different research group, the H7N2 virus isolated from the veterinarian did not transmit to cohoused ferrets.

In addition to the outbreaks described above, transmission of canine H3N2 viruses (see Influenza in Dogs section) to cats resulted in an outbreak in an animal shelter in Seoul, South Korea, with 100% morbidity and 40% mortality. Infections of cats with highly pathogenic H5 viruses have been reported in China and South Korea; and zoo tigers died after eating poultry infected with highly pathogenic H5N1 viruses, with probable virus transmission among the tigers. The experimental infection of cats with two low pathogenic North American avian viruses resulted in virus replication in the respiratory tract of cats; no signs of disease were observed. Seroprevalence studies in various cat populations in North America showed low rates of exposure to highly pathogenic H5 viruses but appreciable rates of seropositivity to human influenza viruses. The susceptibility of cats to human and avian influenza viruses may, in part, be explained by the expression of both Siaα2,6Gal and Siaα2,3Gal in the respiratory tract of these animals.

Influenza in Seals and Whales

A significant epizootic in seals occurred in 1979 and 1980, when approximately 20% of the harbor seal (*Phoca vitulina*) population of the northeast coast of the United States died of a severe respiratory infection with consolidation of the lungs typical of primary viral pneumonia. Antigenic and genetic analyses revealed that the influenza virus isolated from the lungs and brains of dead animals (A/seal/Massachusetts/1/80 [H7N7]) was of avian origin. This virus replicated to high titers in ferrets, cats, and pigs and caused conjunctivitis in humans. From June 1982 to March 1983, harbor seals along the New England coastline again died of viral pneumonia, which was caused by an avian H4N5 virus that replicated in the intestinal tracts of ducks. Harbor seals along the New England coast experienced another outbreak of pneumonia in September through December of 2011, when more than 160 animals died. The causative agent was an avian H3N8 virus that possessed mammalian-adapting features, such as the ability to transmit among ferrets via respiratory droplets and the PB1-D701N mutation, which facilitates the replication of avian influenza viruses in mammals (see The Replication Complex section). In the second half of 2014, thousands of seals died along the coast of Sweden, Denmark, Germany, and The Netherlands due to infection with an H10N7 influenza virus (closely related to avian H10N7

viruses from wild birds) and secondary bacterial infections. Ferrets infected with the seal H10N7 virus displayed mild disease signs. Serology studies and direct virus isolation have also revealed infection of several seal species with different influenza A and B viruses.

Influenza viruses of the H13N2 and H13N9 subtypes were isolated from the lungs and hilar nodes of a stranded pilot whale. It is not known whether the influenza virus infection caused or contributed to the stranding of this whale. In addition, H1N3 viruses have been isolated from lung and liver samples of whales from the South Pacific.

Influenza in Mink

Mink are naturally susceptible to infection with human and avian influenza viruses. Avian influenza viruses of the H10N4 subtype killed mink in Sweden and spread to contact animals. In 2006, respiratory problems were noticed among mink in mink farms in Canada; subsequently, an influenza A virus was isolated from one animal with clinical signs. Further analysis identified the virus as a swine triple reassortant H3N2 virus. Another outbreak in a mink farm in the United States in 2010 was caused by a reassortant H1N2 virus. Moreover, HPAI H5N1 viruses have been isolated from dead mink in China; these viruses were also pathogenic in experimentally infected mice. Seroprevalence studies indicate high levels of exposure to avian H9N2 influenza viruses in Chinese mink populations. Two different H9N2 influenza viruses isolated from a Chinese mink farm in 2014 were tested in mice: one virus caused weight loss and 20% mortality in experimentally infected mice, whereas the other virus did not cause disease in infected mice. The virulent H9N2 virus encoded PB2-701N, a mammalian-adapted marker (see The Replication Complex section). Seroprevalence studies also indicate exposure of free-ranging mink in Spain to influenza viruses. Influenza viruses of human, swine, avian, and equine origin replicate in experimentally infected mink, and transmission to cage mates has been observed for some of these viruses.

Influenza in Bats

In 2012 and 2013, two new influenza virus genomic sequences were identified in yellow-shouldered bats in Guatemala and in flat-faced fruit bats

in Peru, respectively.[141,142] Based on sequence and phylogenetic analyses, the viral sequences were provisionally designated as H17N10 and H18N11 subtypes, respectively. Serologic studies demonstrated antibodies to H17N10 and H18N11 viruses in bat populations; however, to date, no H17N10 or H18N11 live virus has been isolated from bats.

Initial attempts to generate live bat influenza viruses by employing reverse genetics failed. However, the *in vitro* characterization of bat influenza virus proteins and the characterization of reassortant viruses possessing one or several bat influenza virus genomic segments combined with the remaining genomic segments of conventional influenza viruses revealed that the polymerase complex of bat influenza viruses can catalyze the replication of vRNAs of conventional influenza A virus and that the bat influenza NS1 protein possesses RNA-binding and interferon-inhibiting activity similar to that of conventional influenza A viruses. The studies with reassortant viruses also revealed an incompatibility between conventional influenza A and bat influenza viruses at the level of vRNA packaging into new virions. The N10 and N11 NA proteins bear structural similarity with the NA proteins of conventional influenza A viruses, but the putative active site is wider than that of conventional NA proteins and lacks sialidase activity. Currently, the role of the bat influenza NA–like protein in the viral life cycle is not known. The H17 and H18 HA proteins are structurally similar to H1 to H16 HA proteins but lack the amino acids known to determine the receptor-binding specificity of conventional influenza A viruses. In fact, microarrays with hundreds of different glycans did not identify sialylglycopolymers that bind to the H17 and H18 HAs. The cellular receptor of bat influenza viruses may therefore differ from the sialic acids to which conventional influenza A viruses bind. In line with these findings, H17 and H18 HAs do not bind efficiently to MDCK cells, which are routinely used for the propagation of conventional influenza A viruses. However, the H17 and H18 HAs bind efficiently to MDCKII cells, which are derived from MDCK cells but differ from them in their passage history. With the identification of a cell line that supported H17 and H18 HA binding, both viruses were generated by reverse genetics. Further studies revealed that the bat influenza viruses infected MDCKII cells via the basolateral site, whereas conventional influenza A viruses infect polarized cells from the apical site. Recently, the MHC-II HLA-DR complex has been identified as the cellular receptor of bat influenza viruses; this finding will open the door for additional studies on the host

range of bat influenza viruses.

Experimental Infections

Mice

Although mice are not naturally infected, they can be experimentally infected with influenza A or B viruses. Most human influenza viruses cause indiscernible infection of the upper and lower respiratory tract and do not cause lethal disease without adaptation, although A(H1N1)pdm09 viruses are more pathogenic than other human viruses.[58,88] Recent human H3N2 and influenza B viruses do not replicate efficiently in mice. Most avian influenza viruses will replicate in respiratory organs (but not cause lethal infections) without prior adaptation, most likely because of the presence of Siaα2,3Gal receptors in murine respiratory tissues. Notable exceptions include the highly pathogenic H5 and H7N9 viruses, which can cause lethal infections without prior adaptation. Most laboratory mouse strains are susceptible to infection with influenza A viruses and have been used widely to study the pathogenesis of and the immune response to influenza viruses. However, most laboratory strains lack the Mx gene, which plays a role in the innate host defense (see Mx Proteins section), and data obtained from laboratory strains may not therefore be strictly comparable to natural virus infections. Knockout mice are useful tools for deciphering the molecular basis of virus–host interactions. In addition, two genetically diverse groups of mice are now available to correlate phenotypes with genotypes. Based on eight genetically diverse founder strains, several carefully designed rounds of breeding between founder strains, and between their offspring, were carried out to increase the genetic diversity among these mice. Genetically diverse mice are available as Diversity Outbred (DO) or inbred (Collaborative Cross, CC) mice. These resources are now used to study the susceptibility of mice to various pathogens and the contribution of host genetics to the outcome of infection.

Guinea Pigs

Influenza virus propagation in guinea pigs was first reported in 1938 and then in the 1970s. Recently, guinea pigs have been established as a transmission model for influenza viruses. Human, swine, and avian influenza viruses can

be isolated from the lungs and nasal turbinates of infected animals, suggesting efficient virus replication; however, signs of disease such as weight loss and increased temperature are largely lacking, and no mortality was observed upon infection with H5/Gs/Gd or pandemic 1918 virus. The nasal tract and trachea of guinea pigs possess both avian-type (Siaα2,3Gal) and human-type (Siaα2,6Gal; see Receptor Specificity of Influenza Viruses section) receptors, whereas the lungs contain predominately avian-type receptors.

Syrian Hamsters

Syrian hamsters are susceptible to infection with human influenza A and B viruses. Importantly, recent human H3N2 viruses, which are restricted in their growth in mice, replicate in Syrian hamsters without prior adaptation. Human H3N2 viruses replicated in the respiratory tract of animals and caused pathologic effects, although no clinical signs of influenza virus infection were observed. Human influenza H3N2, A(H1N1)pdm09, and influenza B viruses are transmitted to exposed hamsters via respiratory droplets. Lectin binding studies have shown that the distribution in the respiratory organs of Siaα2,6Gal (i.e., human-type receptors, see Receptor Specificity of Influenza Viruses section) and Siaα2,3Gal (i.e., avian-type receptors) is identical to that of humans; that is, abundant human- and avian-type receptors were detected in the upper respiratory tract. In the lungs, human-type receptors were expressed on type 1 pneumocytes, whereas avian-type receptors were detected on type 2 pneumocytes.

Ferrets

Ferrets infected with influenza A or B viruses develop a febrile rhinitis. Upon infection with human influenza viruses, the lesions are usually confined to the nasal mucosa, but infection of the lower respiratory tract has been demonstrated. The pathologic changes of bronchitis and pneumonia resemble those seen in humans, which makes ferrets a valuable animal model to study various aspects of influenza virus infection. Unlike mice, ferrets can also be used to study the transmissibility of influenza viruses. The high susceptibility of ferrets to human influenza viruses may be due to the predominance of Siaα2,6Gal receptors in their upper respiratory tract. The genome of domestic ferrets has now been sequenced, which may aid in the characterization of the

host responses to influenza virus infection.

Nonhuman Primates

Nonhuman primates can experience natural infections with influenza viruses. The rates of seropositive animals can be substantial among captive primates, most likely resulting from exposure to infected humans. Experimental infections with influenza viruses have been conducted with various old-world (e.g., rhesus and cynomolgus macaques, African green, chimpanzees, baboons, gibbons) and new-world (e.g., squirrel monkeys, tamarins, marmosets, capuchins) primates; rhesus and cynomolgus macaques are the most frequently used nonhuman primate species for influenza virus infection studies. Nonhuman primates have been infected with various human influenza A and B viruses, pandemic 1918 virus (or reassortants thereof), several avian influenza viruses including highly pathogenic H5N1 and H7N7 viruses, and the H7N9 viruses that emerged in China in 2013. These studies assessed the pathogenicity of influenza viruses in nonhuman primates, the effect of antivirals, the protective efficacy of approved or experimental vaccines, and the host responses to infection. In addition, immunosuppression models have been established to mimic the effect of immunosuppression on influenza virus infections. In general, influenza virus replication is confined to the respiratory tract. Infections with seasonal human influenza viruses typically cause few, mild signs of disease, whereas infection with A(H1N1)pdm09 viruses can result in high fever. Infection with pandemic 1918 virus resulted in severe disease that required euthanasia. Primates infected with highly pathogenic H5N1 viruses typically develop fever and visible signs of disease, and subsets of animal succumb to the infection. The severity of H7N9 virus infection ranges between that of infection with H5N1 and seasonal human influenza viruses.

MOLECULAR DETERMINANTS OF HOST-RANGE RESTRICTION AND PATHOGENESIS

Four influenza virus proteins—HA, PB2, NS1, and PB1-F2—are known

determinants of host-range restriction and pathogenicity. Other viral proteins also participate in these events.

The HA Protein

The HA protein is responsible for virus attachment and the subsequent fusion of viral and cellular membranes. It is synthesized as a single polypeptide chain (HA0) that undergoes post-translational cleavage by cellular proteases. This cleavage is essential for infectivity because it exposes the hydrophobic N-terminus of HA2, which mediates fusion between the viral envelope and the endosomal membrane.[70]

HA Cleavage

HA is a critical determinant of the pathogenicity of avian influenza viruses, with a clear link between HA cleavability and virulence.[54] The HA proteins of highly pathogenic H5 and H7 viruses contain multiple basic amino acids at the cleavage site, which are recognized by ubiquitous proteases such as furin, PC6, mosaic serine protease large (MSPL), and transmembrane protease serine 13 (TMPRSS13). For this reason, these viruses can cause systemic infections in poultry. In cell culture, the HAs of these viruses do not need exogenous proteases to form plaques. In contrast, the HA proteins of low pathogenic avian and nonavian influenza A viruses, with the exception of H7N7 equine influenza viruses, contain a single arginine residue at the HA cleavage site and are cleaved in only a few organs. These viruses, therefore, produce localized infection of the respiratory and/or intestinal tract that is usually asymptomatic or mild. The tissue tropism of viruses is thus partly determined by the availability of host proteases to recognize and cleave the two types of amino acid sequences found at the HA cleavage site. The significance of HA cleavability for pathogenicity of avian influenza viruses is underscored by the finding that the acquisition of an amino acid sequence with multiple basic amino acids can convert low pathogenic strains to highly pathogenic strains, as occurred in Mexico in 1994 (H5N2), in Italy in 1999 (H7N1), in Chile in 2002 (H7N3), in Canada in 2004 (H7N3), in Mexico in 2012 (H7N3), and in China in 2016 (H7N9). Highly pathogenic viruses can also emerge if avirulent viruses with a multibasic cleavage site lose a nearby glycosylation site, so that the cleavage site becomes accessible to proteases; this scenario resulted in the emergence of HPAI H5N2 viruses in

Pennsylvania in 1983.

Two groups of proteases are responsible for HA cleavage. The first group recognizes a single arginine and cleaves all HAs. Members of this group include plasmin; blood-clotting factor X–like proteases; tryptase Clara; mast-cell tryptase; ectopic anionic trypsin I; tryptase TC30; miniplasmin; HAT (human airway trypsin–like protease); TMPRSS2 and TMPRSS4 (transmembrane protease serine S1 members 2 and 4, respectively); matriptase (a type II transmembrane serine protease); kallikrein-related peptidases 1, 5, and 12 (KLK1, 5, and 12, respectively; which are secreted serine proteases); and bacterial proteases. *In ovo*, a protease similar to the blood-clotting factor Xa that is present in allantoic fluid cleaves HA, which explains why influenza viruses grow efficiently in eggs. Tryptase Clara is secreted from specialized respiratory epithelial cells in rats and mice; mast-cell tryptase is found in mast cells, whereas ectopic anionic trypsin I is present is stromal cells in the peribronchiolar region. Tryptase TC30 has been isolated from mammalian airways. Similarly, the type II transmembrane serine proteases HAT, TMPRSS2, TMPRSS4, and matriptase localize to human airways and support influenza virus replication *in vitro* and/or *in vivo*. In TMPRSS2 knockout mice, H1 virus replication is substantially reduced, whereas smaller effects were observed for H3 viruses. Knockout of TMPRSS4 did not affect the body weight loss or survival of mice infected with an H3N2 virus. However, H3N2 virus titers and symptoms of disease were substantially reduced in double knockout mice lacking TMPRSS2 and TMPRSS4. The kallikrein-related peptidases 1, 5, and 12 are expressed in the human respiratory tract. These three peptidases differ in their preferred cleavage sequence: KLK1 cleaves H1, H2, and H3 HAs; KLK5 preferentially cleaves H1 and H3 HAs, whereas KLK12 cleaves H1 and H2 HAs most efficiently. Miniplasmin is a trypsin-type serine protease in the epithelial cells of the bronchia that cleaves HA downstream of the consensus motif Gln(Glu)-X-Arg. Cleavage of HA by plasmin can be augmented by the ability of the A/WSN/33 (H1N1) NA protein to sequester its protease precursor, plasminogen. Bacterial proteases can also activate HA, either directly or indirectly by activating plasminogen, a property that may explain the development of pneumonia after mixed infections with viruses and bacteria.

The second group of proteases that cleaves HA proteins comprises the

ubiquitous intracellular subtilisin-related endoprotease furin and PC6. These enzymes are calcium-dependent, have an acidic pH optimum, and are located in the Golgi and/or *trans*-Golgi network. Two other ubiquitous type II membrane serine proteases (mosaic serine protease large [MSPL] form and transmembrane protease serine 13 [TMPRSS13]) have been identified that do not require calcium for enzymatic activity and support the replication of an H5/Gs/Gd virus in cell culture. The cleavage efficiency of these ubiquitous proteases is determined by the sequence at the cleavage site and absence or presence of a nearby carbohydrate chain on the HA molecule. The sequence required for the cleavage of HPAI HA is Q-R/K-X-R/K-R (X, nonbasic amino acid) in the absence of a nearby carbohydrate chain. The presence of a nearby carbohydrate chain requires insertion of two additional residues, Q-X-X-R-X-R/K-R, or alteration of the conserved glutamine at position 5 or the proline at position 6, B(X)-X(B)-R/K-X-R/K-R (B, basic residue).

Introduction of multibasic HA cleavage sites into low pathogenic avian H6N1 or H9N2 viruses creates highly pathogenic variants. However, this finding is not universally applicable, as the introduction of multibasic HA cleavage sites into low pathogenic H5N1 or H3N8 viruses or into a human H3N2 virus did not create highly pathogenic viruses. Thus, a multibasic HA cleavage site seems to be necessary, but not always sufficient, for high pathogenicity.

Sialic Acid Receptors

Influenza viruses bind to sialic acids, that is, negatively charged 9-carbon sugars that typically occupy the terminal positions of glycoproteins or glycolipids. *N*-Acetylneuraminic acid (NeuAc) and *N*-glycolylneuraminic acid (NeuGc) are prevalent in many animal species, but notably humans and ferrets lack the latter. Influenza viruses differ in their recognition of these two sialic acid species. Most sialic acids are linked to galactose (Gal) or *N*-acetylgalactosamine (GalNAc) by *α*2,3- or *α*2,6-linkages (Sia*α*2,3/6Gal, Sia*α*2,3/6GalNAc) or to *N*-acetylglucosamine (GlcNAc) by *α*2,6-linkages (Sia*α*2,6GlcNAc).

Sialic acid receptors in humans

Early studies demonstrated that epithelial cells in the human trachea contain

Siaα2,6Gal sialyloligosaccharides on their cell surface but lack those with α2,3-linkages.[20] Consequently, viruses with Siaα2,6Gal specificity (i.e., human viruses, which preferentially bind to Siaα2,6Gal), but not those with Siaα2,3Gal specificity (i.e., avian viruses, which preferentially bind to Siaα2,3Gal), bind to the epithelial cells lining the human trachea.[20] Data obtained with *in vitro* differentiated human epithelial cells from tracheal/bronchial tissues, as well as data obtained with "natural shotgun glycomics" (in which the glycans released from glycoproteins and glycolipids are separated by multidimensional HPLC to assess the natural sialylglycopolymers of the respective tissue), revealed a more detailed influenza virus receptor environment: Siaα2,6Gal oligosaccharides are dominant on epithelial cells in nasal mucosa, paranasal sinuses, pharynx, trachea, and bronchi. Siaα2,3Gal oligosaccharides (in addition to Siaα2,6Gal) are found on nonciliated cuboidal bronchiolar cells at the junction between the respiratory bronchiole and alveolus and on type 2 pneumocytes lining the alveolar wall (Fig. 15.9).[127,148] Nonciliated epithelial cells express more Siaα2,6Gal oligosaccharides than do ciliated cells, which contain predominantly Siaα2,3Gal.[91] Collectively, these findings offer an explanation for the severe pneumonia observed after infection of humans with some avian influenza viruses and suggest that the limited human-to-human transmission of H5/Gs/Gd viruses likely reflects the restrictive replicative efficiency of these viruses in the upper portion of the respiratory tract, where transmission could occur via droplets generated by coughing and sneezing. Moreover, avian influenza viruses may be trapped by mucins secreted by goblet cells in the nasal passage, which are rich in glycans containing Siaα2,3Gal. Conversion to preferential recognition of the human-type receptor is required for efficient human-to-human transmission, an assumption supported by the finding that the earliest isolates of pandemic viruses preferentially recognized Siaα2,6Gal, rather than Siaα2,3Gal, sialyloligosaccharides.[92] One study found higher amounts of Siaα2,3Gal in the respiratory tract of children compared with adults, a finding that may suggest higher susceptibility of children to infection with avian influenza viruses. Another study reported predominant expression of Siaα2,3Gal in epithelial cells of the human eye, which may explain the conjunctivitis associated with H7 influenza virus infections.

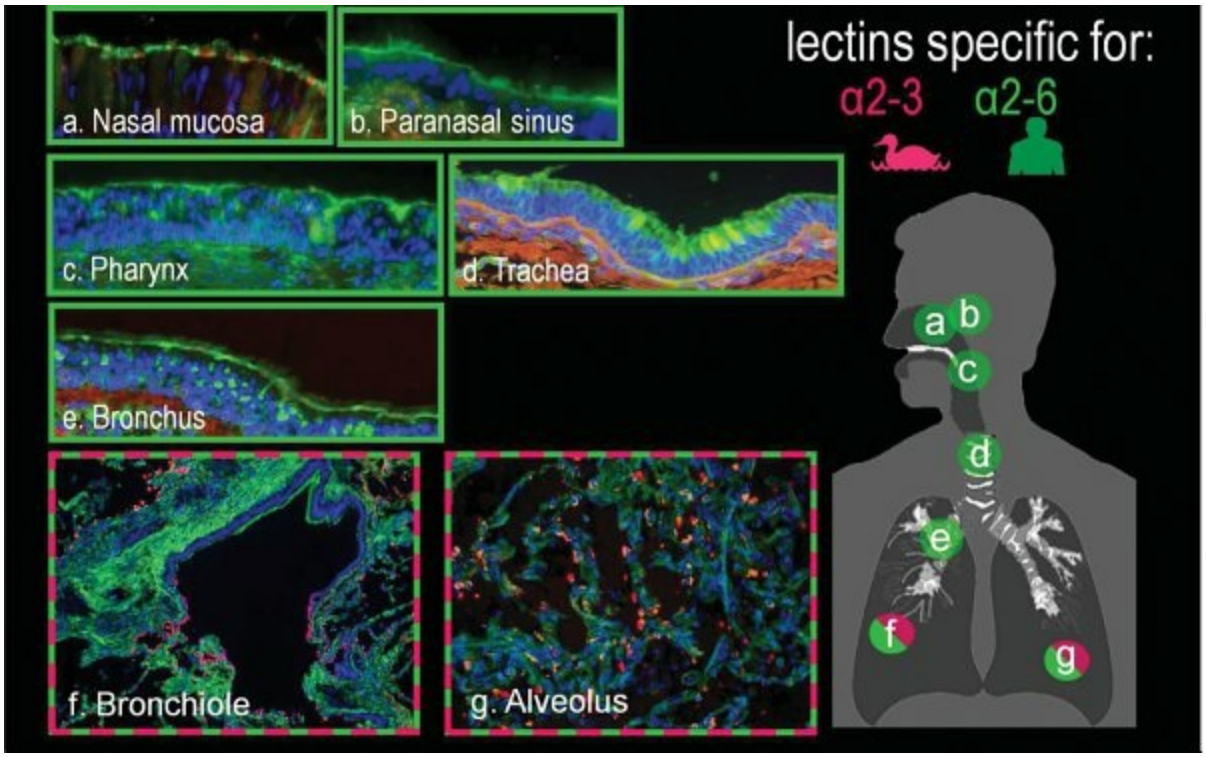

FIGURE 15.9 Expression of human virus (Sia*α*2,6Gal) and avian virus (Sia*α*2,3Gal) receptors in human respiratory tissue. The indicated tissues were tested with *Sambucus nigra* lectin (*green*), indicating the presence of sialic acid linked to galactose by an *α*2,6-linkage (Sia*α*2,6Gal), or with *Maackia amurensis* lectin (*red*), indicating the presence of Sia*α*2,3Gal. Cells were counterstained with DAPI (4,6-diamidino-2-phenylindole; *blue*). In the nasal mucosa, paranasal sinuses, pharynx, trachea, and bronchus, Sia*α*2,6Gal dominated. In the bronchiole and alveolus, both Sia*α*2,6Gal and Sia*α*2,3Gal were detected. The letters a-g refer to the respective area of the human respiratory tract. (From Shinya K, Ebina M, Yamada S, et al. Avian flu: influenza virus receptors in the human airway. *Nature* 2006;440:435–436, with permission.)

Sialic acid receptors in other mammals

Epithelial cells in pig trachea contain both Sia*α*2,3Gal and Sia*α*2,6Gal (with the latter predominating), which may explain why this species can be infected by both avian and human influenza viruses. Moreover, NeuGc is found in pigs (but not in humans). For mice, one study reported the expression of both types of receptors in the trachea, lung, and other organs, whereas another study did not detect human-type receptors in these animals. Ferrets express predominantly Sia*α*2,6Gal on cells of the upper respiratory tract. In the alveoli, both Sia*α*2,3Gal and Sia*α*2,6Gal were detected. In Syrian hamsters, the distribution of Sia*α*2,3Gal and Sia*α*2,6Gal is similar to that in humans with, for example, Sia*α*2,3Gal being expressed on type 2 pneumocytes in the lungs. The nasal tract and trachea of guinea pigs possess avian-type (Sia*α*2,3Gal) and human-type (Sia*α*2,6Gal) receptors, whereas the lungs contain predominately avian-type receptors. Equine viruses preferentially bind to Sia*α*2,3Gal sialyloligosaccharides, which predominate in horse trachea. These studies also demonstrated that epithelial cells in horse trachea express NeuGc in addition to NeuAc and that influenza viruses isolated from horses bind to oligosaccharides possessing NeuGc. Sia*α*2,3Gal is also found on epithelial cells in the respiratory tract of dogs and in the lungs of seals and whales.

Sialic acid receptors in avian species

The epithelial cells of duck intestine (where avian influenza viruses replicate) express predominantly Sia*α*2,3Gal,[57] although Sia*α*2,6Gal has also been detected. Likewise, both Sia*α*2,3Gal and Sia*α*2,6Gal have been detected in the respiratory tract of ducks, although Sia*α*2,3Gal predominates. The duck intestinal tract also possesses NeuGc, which appears to be absent in chickens. In the respiratory and intestinal tract of chickens, Sia*α*2,6Gal and Sia*α*2,3Gal are expressed. Similarly, both Sia*α*2,3Gal and Sia*α*2,6Gal are expressed on tracheal and intestinal cells of quail, turkey, pheasant, and guinea fowl, that is, species that may play a role in the adaptation of avian influenza viruses to mammalian species (see Role of Terrestrial Poultry in the Emergence of New Influenza Viruses section). However, differences exist among poultry species in the relative abundances of influenza virus receptors in the different organs and cell types tested. Substantial amounts of Sia*α*2,6Gal were detected in the respiratory tract of pigeons, which are not known to play a significant role in influenza virus ecology.

Receptor Specificity of Influenza Viruses

The specificity of HA for the different sialyloligosaccharides is responsible for the host-range restriction of influenza virus. Human and classical H1N1 swine influenza viruses bind preferentially to Siaα2,6Gal, whereas most avian and equine viruses have higher affinity for Siaα2,3Gal.[19,35,92,120]

Receptor specificity is determined by the amino acids that surround the receptor-binding site. For H2 and H3 HAs, glutamine at position 226 and glycine at position 228 (H3 numbering; found in avian viruses) determine the specificity for Siaα2,3Gal oligosaccharides, whereas leucine and serine at these positions (found in human viruses) confer Siaα2,6Gal specificity[19,92,120,144] (Fig. 15.10). For H1 viruses, aspartate at positions 190 and 225 (H3 numbering; found in human viruses) confers binding to Siaα2,6Gal, whereas aspartate and glycine at these positions (found in swine viruses) allow binding to both α2,6 and α2,3 linkages; glutamate and glycine at positions 190 and 225 (found in avian viruses) are responsible for the interaction with α2,3-linked sialic acids.[36,73,92,134] In addition to these key residues, the amino acids at several other positions also affect receptor-binding properties. X-ray crystallographic structures of HA proteins in complex with receptor analogs are available for human H1 to H3 HAs, avian H1 to H3 and H5 HAs, swine H1 and H9 HAs, H7 HA, and an avian H10 HA isolated from a person infected with an H10N8 virus; these structures provide detailed insights into the role of individual HA amino acids in receptor binding.

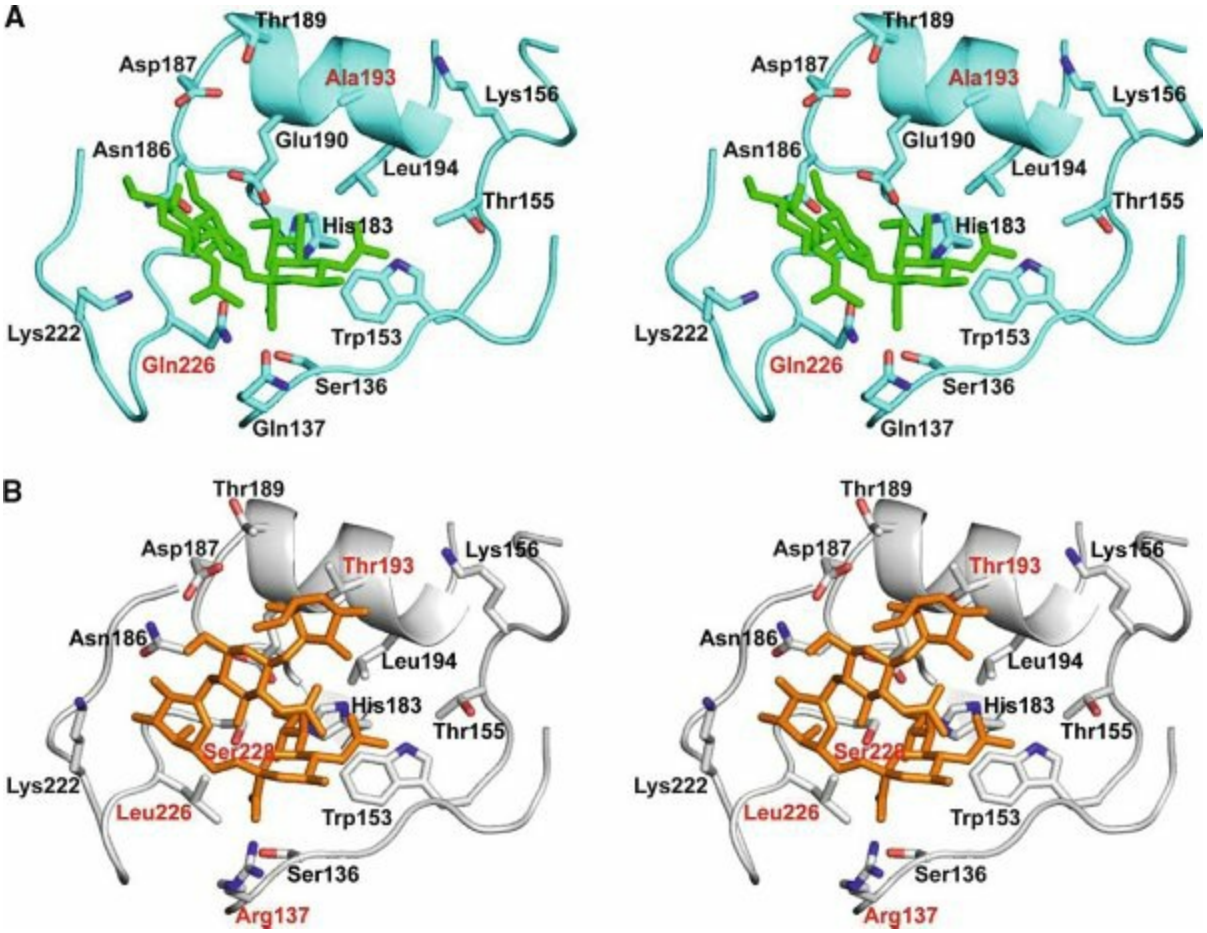

FIGURE 15.10 Structural models of HA–glycan receptor complexes. A: Interaction of avian H2 HA receptor–binding site (*magenta*) with avian-type receptor (*green*). **B:** Interaction of human H2 HA receptor–binding site (*gray*) with human-type receptor (*orange*). (From Viswanathan K, Koh X, Chandrasekaran A, et al. Determinants of glycan receptor specificity of H2N2 influenza A virus hemagglutinin. *PLoS One* 2010;5:e13768, with permission.)

With the use of synthetic sialylglycopolymers and glycan arrays that allow the simultaneous testing of hundreds of carbohydrates and glycoproteins, a more complex picture of influenza viral receptor specificities has emerged. These studies have been complemented by approaches to catalogue the sialylglycopolymers in the lungs and/or respiratory organs of

pigs and humans, including surface plasmon resonance, mass spectrometry, and natural shotgun glycomics. Collectively, these studies revealed that binding of influenza viruses to their receptors is not only determined by the linkage between the sialic acid and the penultimate sugar residue (*α*2,3 vs. *α*2,6) but also by the nature of the penultimate sugar (Gal, GalNAc, or GlcNAc), the length of the carbohydrate chain, and the inner core of the carbohydrate (such as the linkage between the second and third sugar residue, modifications such as sulfation, or other sugar residues such as fucose). Noteworthy differences exist between human and avian influenza viruses and among avian viruses. For example, viruses isolated from ducks, chickens, and gulls differ in their preference for the inner core structure of the receptor. Avian influenza viruses favor NeuAc*α*2,3 attached to shorter carbohydrate chains over the same sialic acid attached to a longer chain; by contrast, human-adapted H1 and H3 influenza viruses bind to *α*2,6 linkages preferentially in the context of long oligosaccharides. Avian virus HAs bind to their receptors in a narrow cone-like topology, whereas human virus HAs bind in a more flexible umbrella-like topology. Moreover, bi- and multiantennary glycans are bound by some viruses, most likely by two HA molecules within the trimer, which could increase the binding avidity. As a consequence of the steric differences between Sia*α*2,3Gal and Sia*α*2,6Gal linkages, biantennary binding is only possible with Sia*α*2,6Gal, and not with Sia*α*2,3Gal.[62] It has been speculated that biantennary binding could offset the reduced avidity of recent H3N2 viruses to Sia*α*2,6, resulting from antigenic drift mutations near the receptor-binding site, which have weakened the interaction between the virus and the cellular receptor.

Receptor specificity of avian influenza viruses

H5/Gs/Gd viruses bind efficiently to Sia*α*2,3Gal. Experimentally introduced mutations at position 190 or 225 (H3 numbering) that change the receptor-binding specificity of H1 HAs do not confer H5N1 virus binding to Sia*α*2,6Gal; however, the introduction of human-type amino acids at positions 226 and 228 (H3 numbering) increase binding to Sia*α*2,6Gal while retaining substantial binding to Sia*α*2,3Gal.[133] The combination of the HA-Q226L and HA-G228S mutations with mutations detected in wild-type H5N1 viruses (such as HA-N186K or HA-S227N) results in even stronger binding to human-type receptors.

H5/Gs/Gd viruses isolated from infected individuals typically retain specificity for Siaα2,3Gal. However, several H5/Gs/Gd viruses have been isolated that recognize Siaα2,6Gal and Siaα2,3Gal. This change in binding properties can be linked to several specific amino acid changes in HA.

All three ferret-transmissible H5 viruses described to date possess amino acid changes in HA that confer binding to Siaα2,6Gal. The experimentally introduced or *in vitro* selected sets of mutations differed (HA-N224K/HA-Q226L[55]; HA-Q226L/HA-G228S[52]; HA-Q196R/HA-Q226L/HA-G228S[10]; all H3 numbering) but shared the HA-Q226L mutation, which increases Siaα2,6Gal binding for the HAs of other subtypes. Collectively, these findings indicate that the amino acid at position 226 of HA plays an important role in HA receptor–binding specificity.

Most of the H7N9 influenza viruses that emerged in China in 2013 encode the HA-Q226L (H3 numbering) mutation that increases binding to Siaα2,6Gal; however, these viruses retained their ability to interact with Siaα2,3Gal. One of the human H7N9 virus isolates, A/Anhui/1/2013, was extensively tested for its receptor-binding specificity and found to bind to biantennary sialic acids (see above). Typically, the H7N9 viruses that emerged in China in 2013 bind to cells in the upper and lower respiratory tract of humans and to type 1 and 2 pneumocytes. Three mutations in an H7N9 virus–derived HA (HA-V186K/G, HA-K193T, and HA-G228S; all H3 numbering) switched the receptor-binding specificity from Siaα2,3Gal to Siaα2,6Gal, resulting in a receptor-binding profile very similar to that of the prototype H1N1pdm09 virus, A/California/04/2009.

Poultry H9N2 viruses isolated in China in 1999 possessed mutations at positions 190 and 226 (H3 numbering) that conferred binding to Siaα2,6Gal. Several low pathogenic H7 viruses isolated from avian species and humans in the United States in 2002 to 2003 and in Canada in 2004 showed increased binding to Siaα2,6Gal, although they retained their ability to bind to avian-type receptors. In contrast, two highly pathogenic H7N7 viruses isolated from humans during the poultry outbreak in The Netherlands in 2003 bound to Siaα2,3Gal.

Receptor specificity of human influenza viruses

The HA proteins of the pandemic 1918, 1957, and 1968 viruses originated

from avian influenza viruses; nonetheless, the earliest available human isolates of these pandemic viruses already possessed Siaα2,6Gal receptor–binding specificity,[19,41,92] indicative of strong selective pressure. However, early pandemic H3N2 viruses differ from more recent isolates in their amino acid sequence and their binding affinity for nonciliated cells.

For the pandemic 1918 virus, two variants have been identified that differ at amino acids 190 and 225 (H3 numbering): A/South Carolina/1/18 (possessing aspartate at positions 190 and 225, as is typically found in human influenza viruses) binds to Siaα2,6Gal and transmits efficiently among ferrets, whereas A/New York/1/18 (possessing aspartate at position 190 but glycine at position 225) binds to both Siaα2,6Gal and Siaα2,3Gal and transmits with reduced efficiency compared with A/South Carolina/1/18.[41,144] Replacement of aspartate at positions 190 and 225 with the avian-like amino acids at these position—that is, glutamate and glycine—abolishes binding to Siaα2,6Gal and transmission in ferrets.[144] The x-ray crystallographic structure of a 1918 HA protein in complex with receptor analogs demonstrates how this overall avian-like protein interacts with human-type receptors.[36]

The A(H1N1)pdm09 viruses possess aspartate at positions 190 and 225 (H3 numbering) and bind efficiently to Siaα2,6Gal,[88] although one study reported dual recognition of both Siaα2,6Gal and Siaα2,3Gal. Molecular dynamic simulations of the H1 proteins of the 1918 pandemic virus, a swine virus from 1930, a seasonal human H1N1 virus from 2005, and the A(H1N1)pdm09 virus showed that lysine at position 145 and glutamate at position 227 (H3 numbering; found in the A(H1N1)pdm09 virus) increased the binding affinity for a human-type receptor and that aspartate 225 increased the number of hydrogen-bonding interactions compared with glycine at this position. An aspartate-to-glycine change at position 225 (H3 numbering) has been found in some A(H1N1)pdm09 viruses and appears to correlate with more severe disease outcomes in humans.[69] Few transmission events have been reported for this variant, suggesting that it does not transmit efficiently among humans. The aspartate-to-glycine change at position 225 arises during passage in eggs or adaptation to mice and increases virulence in mice. Experimental infection of pigs with a mixed population of viruses encoding glycine or glutamate at position 225 resulted in the selection of glutamate in viruses isolated from nasal secretions but glycine in viruses

isolated from the lower respiratory tract.

As stated above, the receptor-binding specificity of human H2N2 and H3N2 viruses is determined by the amino acid residues at positions HA-226 and HA-228, with HA-226Q/HA-228G conferring avian-type binding specificity, and HA-226L/HA-228S conferring human-type binding specificity (all H3 numbering). Glycan arrays in combination with x-ray crystallographic structures of 1957 pandemic H2 HA highlighted the significance of position 226 for H2 HA receptor–binding specificity. This was further supported by the finding that A/El Salvador/2/57, which possesses glutamine and glycine at positions 226 and 228, respectively, preferentially binds avian-type receptors and transmits poorly among ferrets, whereas A/Albany/6/58, which possesses leucine and serine at position 226 and 228, respectively, recognizes human- and avian-type receptors and transmits efficiently in ferrets. Moreover, a mutational study demonstrated a critical role for the amino acids at positions 226 and 228 in converting an avian H2N2 virus into one that binds human-type receptors. The amino acids at positions 137 and 193 also contributed to receptor-binding specificity.

Human H3N2 viruses encode HA-226L/HA-228S, which confer binding to Siaα2,6Gal. Viruses isolated in the 2000s have reduced affinity for both human- and avian-type receptors, which may be a consequence of an HA-L226V mutation, followed a few years later by the HA-V226I mutation. Thus, the currently circulating human H3N2 viruses encode an isoleucine at position HA-226. In addition, mutations have occurred at the surrounding residues (i.e., positions 222, 225, and 193), and crystal structures demonstrated that these amino acid changes affect the interaction between HA and the receptor. The changes in receptor-binding affinity are paralleled by altered binding patterns to red blood cells: essentially, human H3N2 viruses first lost their ability to agglutinate chicken red blood cells, followed by a loss of agglutination of turkey red blood cells. Recent human H3N2 viruses do not efficiently agglutinate any of the red blood cell species routinely used for hemagglutination assays, greatly affecting the characterization of these viruses. Concomitantly, human H3N2 viruses lost their ability to replicate efficiently in embryonated chicken eggs, followed by a loss of efficient replication in commonly used MDCK cells. Recent human H3N2 viruses are now typically propagated in MDCK cells that have been modified to overexpress human-type receptors (see Virus Propagation

section).

Glycosylation

Influenza virulence and host range are also affected by the number and location of oligosaccharide side chains, which are not conserved among strains or subtypes. HAs typically contain 5 to 11 glycosylation sites that affect receptor-binding affinity and/or specificity, antigenicity, innate immune responses, replication, fusion activity, virulence, and host range. For H1N1 and H3N2 viruses, the numbers of N-glycosylation sites have increased since they were introduced into human populations, most likely to shield the HA from antibodies. Also, H5 and H7 viruses isolated from terrestrial birds have more HA glycosylation sites than viruses isolated from wild birds. Two of the H5 viruses that acquired respiratory droplet transmissibility in ferrets lost the glycosylation site at HA-158 to HA-160 (H3 numbering) during passages in ferrets[52,55]; the third ferret-transmissible H5 virus naturally lacks this glycosylation site. The lack of HA-158 to HA-160 glycosylation affected the receptor-binding specificity and was critical for respiratory transmissibility in ferrets. The H7N9 viruses that emerged in China in 2013 naturally lack the glycosylation site at HA-158 to HA-160. HA glycosylation may also hamper the development of broadly protective influenza vaccines that elicit antibodies to conserved regions in the HA stalk. Several broadly reactive antibodies react with influenza viruses of group A, but not with viruses of group B, perhaps because of N-linked glycosylation at HA-38N in Group 2 HAs.

The NA protein is also glycosylated, but the number of glycosylation sites on human N1 and N2 NAs has remained relatively stable. For efficient virus replication, a functional balance between HA and NA is critical.

Role of Terrestrial Poultry in the Emergence of New Influenza Viruses

Terrestrial poultry, such as chickens and quail, are susceptible to infection with influenza viruses. Most influenza viruses circulating in wild birds are asymptomatic in poultry, but their continued circulation among terrestrial poultry can lead to viruses with increased virulence in these birds.

Adaptation of waterfowl viruses in terrestrial poultry may lead to the

emergence of viruses that are better able to replicate in humans or pigs than their original counterparts due to altered receptor specificity. Support for this hypothesis comes from the finding that viruses isolated from terrestrial poultry resemble human viruses in their low affinity for Siaα2,3Gal relative to viruses isolated from wild birds. In addition, many of the H9N2 and H7N9 viruses isolated from terrestrial poultry bind to human-type receptors to some extent. The H5N1 viruses isolated from terrestrial poultry may possess an additional glycosylation site in HA that reduces the affinity for the receptor and a deletion in the NA stalk that reduces NA functionality and balances the functions of the HA and NA proteins. The presence of additional glycosylation sites and a deletion in the NA stalk are typical for human viruses and have also been found in different virus subtypes isolated from terrestrial poultry. Collectively, these data suggest that waterfowl viruses acquire certain mutations in terrestrial poultry, such as NA stalk deletions and additional HA glycosylation sites that may facilitate their transmission to humans or other mammals such as pigs.

Host Cell–Mediated Selection of Antigenic Variants

Historically, human influenza viruses have been isolated by virus amplification in the allantoic cavity of embryonated chicken eggs or by inoculation of samples into the amniotic cavity, followed by amplification in the allantoic cavity. In 1942, Burnet and Clarke first described “O” (original) and “D” (derived) variants that differed in their ability to agglutinate human or guinea pig erythrocytes after passage in eggs. The mutations acquired during egg passages typically cluster around the receptor-binding pocket of HA, resulting in reduced binding to Siaα2,6 and increased binding to Siaα2,3. This change in receptor-binding specificity likely reflects adaptation to the selective pressure in eggs with allantoic cells expressing Siaα2,3.

Subsequent studies established that the egg-adapting mutations in HA may also affect the antigenicity of viruses.[122] In fact, the low vaccine effectiveness of some H3N2 influenza vaccines has been linked to egg-adapting changes in HA. This is supported by findings that some vaccine recipients possess higher antibody titers to egg-adapted vaccine strains than to the circulating wild-type virus. Most influenza vaccine viruses are currently propagated in embryonated chicken eggs, requiring close monitoring of the potential antigenic effects of egg-adapting mutations in

HA. Cell culture–based influenza vaccines are now available in several countries. Influenza virus amplification in these cell lines does not result in HA mutations that alter antigenicity; influenza vaccine production in cell culture may, therefore, be preferable to virus amplification in embryonated chicken eggs.

The NS1 Protein

The NS1 protein functions as an IFN antagonist that allows efficient virus replication in IFN-competent hosts,[38] in addition to having roles in the splicing and nuclear export of viral mRNAs and the enhancement of viral mRNA translation. NS1 interferes with type I IFN (IFN-α, IFN-β) synthesis and with the activation of IFN-induced antiviral factors. These functions are described in the Innate Immune Responses section.

The Replication Complex

The influenza viral replication complex comprises the three polymerase proteins—PB2, PB1, and PA—and the nucleoprotein NP (for a more detailed description of the functions of these proteins, see Chapter 14). The PB2 protein recognizes and binds to type I cap structures of cellular mRNAs. It has emerged as an important determinant of virulence and host-range restriction. Early studies suggested that the PB2 segment, in particular the amino acid at position 627, was involved in host-range restriction.[137] The significance of this finding in the context of interspecies transmission was not recognized, however, until 2001, when a substitution at position 627 of PB2 from glutamic acid (found in most avian isolates) to lysine (found in most human isolates with the exception of the A(H1N1)pdm09 viruses; see below) was shown to enhance the pathogenicity of an H5/Gs/Gd virus in mice.[48]

Multiple lines of evidence now suggest that PB2-627K is a major determinant of pathogenicity in mammals: (a) PB2-627K leads to increased virulence of H5/Gs/Gd viruses[48]; (b) PB2-627K is critical for the respiratory droplet transmissibility of recombinant H5/Gs/Gd viruses in ferrets[52,80]; (c) PB2-627K is selected during the replication of avian H5/Gs/Gd, avian H7N9, and avian H7N7 viruses in humans; (d) H5/Gs/Gd viruses with PB2-627K have been isolated from mammalian species including tigers and cats; (e) viruses possessing PB2-627K were isolated after the adaptation of avian

influenza viruses to mice, including HPAI H5, H7N7, and H9N2 viruses, and after virus replication in pigs; (f) PB2-627K has been found in viruses isolated from chickens and quail, suggesting that PB2-627K selection can occur in some avian species, which may facilitate the adaptation of avian influenza viruses to mammals (see Role of Terrestrial Poultry in the Emergence of New Influenza Viruses section); and (g) PB2-627K increases replicative ability in mammalian cells, particularly at the lower temperatures of the upper respiratory tract. Collectively, these findings suggest that PB2-627K provides a replicative advantage in mammals and is hence selected in these species. In particular, PB2-627K may facilitate PB2 adaptation to the mammalian form of ANP32A (acidic nuclear phosphoprotein 32 kDa); the differences between mammalian and avian ANP32A proteins were recently identified as a major host restriction factor of influenza viruses.[85] However, PB2-627K also emerged in H5/Gs/Gd viruses isolated from wild waterfowl at Qinghai Lake in 2005[12,82] (see Infections of Humans with H5 Viruses of the A/goose/Guangdong/1/1996 Lineage) and is maintained in descendants of the Qinghai Lake viruses to this day.

Considering the significance of PB2-627K for influenza virus replication in humans, the finding of PB2-627E (i.e., the avian-type amino acid) in A(H1N1)pdm09 viruses was unexpected; however, the lack of PB2-627K is compensated for by a basic amino acid at position 591.[96] In fact, PB2-627K does not provide a replicative advantage in the background of A(H1N1)pdm09 viruses. Structural analyses demonstrated that positions 591 and 627 are in close proximity and that a basic amino acid at position 591 alters both the shape and charges on the surface of the protein, which may affect the interaction of PB2 with other host and/or viral factors.

A second amino acid in PB2—at position 701—was first identified as a virulence factor of H5/Gs/Gd viruses in mice[77] and is now known to facilitate viral adaptation to mammalian species. Replacement of aspartic acid (found in most avian influenza viruses) with asparagine at residue 701 enhances the binding of PB2 to the cellular nuclear import factor importin α and facilitates PB2 nuclear import and replicative ability in mammalian cells.[34] This amino acid change was found upon adaptation of an avian H7N7 virus to mice; it also proved to be critical for virus transmission in guinea pigs. Like PB2-627K, PB2-701N is selected during the replication of H5/Gs/Gd and H7N9 viruses in humans but does not provide a replicative advantage to

A(H1N1)pdm09 viruses.

Replacement of the avian-type threonine residue at position 271 of PB2 with alanine (i.e., the residue typically found in human influenza viruses) increases virus replication in mammalian cells and mice. The PB2 protein of the A(H1N1)pdm09 virus (which is of avian virus origin) encodes alanine at position 271, suggestive of mammalian adaptation. Another study found that the combination of three amino acid changes in PB2 (I147T/K339T/A588T) increased the replicative ability of a H5/Gs/Gd virus in mammalian cells and its virulence in mice to a level comparable to that of H5/Gs/Gd viruses encoding 627K. The percentage of H5/Gs/Gd viruses encoding the 147T/339T/588T residues in PB2 increased substantially between 2009 and 2012, and many of the circulating H5/Gs/Gd viruses now encode these residues. The residue at position 588 of PB2 has also been implicated in the mammalian adaptation of H7N9, H9N2, and H10N8 viruses.

The PB1 protein possesses conserved motifs found in all RNA-dependent RNA polymerases and is considered critical for the polymerase enzymatic function. In a minireplicon system, reporter gene expression was more efficient with avian than with human virus PB1 protein. Avian virus PB1 protein may therefore provide a replicative advantage over its human counterpart, an attractive hypothesis since both the 1957 and 1968 pandemic strains contained avian PB1 vRNA segments (in combination with avian HA or HA and NA genes). Moreover, in reassortment studies between H5/Gs/Gd and human H3N2 viruses, one of the most pathogenic reassortants possessed the avian PB1 vRNA segment. Reassortment studies also demonstrated a critical role for the pandemic 1918 PB1 vRNA segment in virulence in animal models. Studies with a recombinant H5N1 virus that acquired respiratory droplet transmissibility in ferrets (see Virulence and Transmissibility of H5 Viruses of the A/goose/Guangdong/1/1996 Lineage section) identified an H99Y mutation in PB1, which emerged during virus passages in ferrets; this mutation increased the viral polymerase activity and was essential for respiratory droplet transmissibility in ferrets.

The PA protein is an integral part of the influenza viral replication complex with a role in the cap-snatching process. Recent studies now also suggest a role for PA in the host adaptation of avian influenza viruses in mammals. For example, replacement of an avian virus PA vRNA segment with a human virus PA vRNA segment increased viral polymerase activity

and mouse pathogenicity; a single mutation of T552S in PA was responsible for this effect. In another example, the PA vRNA segment of a A(H1N1)pdm09 virus conferred respiratory droplet transmissibility in guinea pigs to an H5N1 virus that otherwise lacked this ability.

In addition to the polymerase genes, the NP gene plays a role in host-range restriction[22] (see Mx Proteins section).

A large body of information has thus demonstrated that the composition of the replication complex affects viral pathogenicity. As a general trend, more efficient replication in minireplicon assays translates into increased pathogenicity in animal models.

The PB1-F2 Protein

PB1-F2 is a short protein of 87 to 90 amino acids that was discovered in 2001.[11] It is expressed from the +1 reading frame of the PB1 gene of most avian and human influenza viruses; however, human H1N1 viruses isolated after 1950 encode a truncated version of 57 amino acids. Most swine virus isolates (particularly classical H1N1 swine influenza viruses) do not encode a functional PB1-F2 peptide, due to several in-frame stop codons. These stop codons are also found in the reading frames of A(H1N1)pdm09 virus PB1-F2s, which likely originated from pigs; therefore, A(H1N1)pdm09 viruses do not encode a functional PB1-F2 protein. Reconstitution of full-length PB1-F2 expression in the background of A(H1N1)pdm09 viruses had only minor effects on replicative ability and virulence in mice and ferrets, suggesting that PB1-F2 is not critical for the pathogenicity of A(H1N1)pdm09 viruses. The role of PB1-F2 in viral pathogenicity is discussed in more detail in the Innate Immune Responses section.

The NA Protein

As stated earlier, the structure and function of NA are discussed in more detail in Chapter 15. The sialidase activity of the NA protein removes sialic acid from sialyloligosaccharides, thereby serving two functions: (1) the removal of sialic acid from HA, NA, and the cell surface, facilitating virus release, and (2) the removal of sialic acid from the mucin layer, which likely allows the virus to reach the surface of the epithelial cells. The NA protein also has a role in host-range restriction and pathogenicity. Multiple studies

now indicate that the length of the NA stalk affects pathogenicity; in particular, deletions in the NA stalk have been observed after virus replication in eggs and in poultry.

Notably, the NA activity of some avian viruses is more resistant to the low pH of the upper digestive tract than that of human- or swine-derived NA, a feature that may contribute to host-range restriction. Interestingly, low pH stability has also been reported for the NA protein of the pandemic 1918 virus. The NA protein of A/WSN/33 (H1N1) virus is critical for plaque formation in Madin-Darby bovine kidney cells and for neurovirulence; these two phenotypes are linked to the loss of a carbohydrate chain on NA and the presence of a C-terminal lysine residue. The lack of the carbohydrate chain at position 146 of NA (N2 numbering) allows the NA protein to bind to and sequester plasminogen, a plasmin precursor. This function facilitates HA cleavage and, thereby, virus pathogenicity in mice.

Like HA, the NA protein shows preference for certain types of sialyloligosaccharides according to the host species. Avian virus NAs cleave α2,3-linked, but not α2,6-linked, sialic acids. After their introduction into the human population, N2 NAs acquired the ability to cleave α2,6-linked sialic acids in addition to α2,3-linked sialic acids; however, the enzymatic activity for α2,6-linked sialic acids is significantly lower than that for α2,3-linked sialic acids. This acquired ability likely represents adaptation to the respective recognition pattern of the HA protein. NA substrate specificity is determined by the amino acid at position 275. Some NA proteins also have receptor-binding properties, a function encoded by amino acids outside the enzymatic site.

Although not directly related to host-range restriction and pathogenesis, the NA protein has recently (re)gained increased attention as a viral antigen. When administered as purified protein, NA is as immunogenic as HA. However, upon natural infection, antibody responses to NA are typically weaker than those elicited by HA, most likely because of the larger amount of HA protein compared with NA protein on the virion surface. Current vaccine preparations do not possess standardized amounts of NA and elicit low levels of antibodies to NA; current live attenuated vaccines in particular do not elicit substantial amounts of antibodies to NA. However, the addition of recombinant NA protein to vaccine preparations increased the antibody titers to NA. Higher titers of NA-inhibiting antibodies correlate with higher

vaccine effectiveness and reduced disease severity. In addition, NA antibodies can confer intrasubtypic protection. It is now generally accepted that HA- and NA-specific antibodies are independent correlates of protection against influenza.

CLINICAL FEATURES AND PATHOGENESIS IN HUMANS

Pattern of Virus Shedding

Human influenza viruses replicate almost exclusively in superficial cells of the respiratory tract and are released from the apical surface of the cell, facilitating respiratory transmission. Alveolar macrophages and dendritic cells can also be infected and serve as antigen presenting cells for recognition by the adaptive immune system. Influenza virus replicates throughout the respiratory tract, with virus being recoverable from the upper and lower tracts of people naturally or experimentally infected with virus. As discussed earlier, the site of optimal growth in the respiratory tract for influenza viruses is in part determined by the distribution of the Siaα2,3Gal or Siaα2,6Gal sialic acid receptors.

A representative example of the pattern of virus shedding and cytokine responses of healthy adults experimentally infected by intranasal inoculation with influenza virus is shown in Figure 15.11.[50] The patterns of virus shedding in naturally infected individuals have not been measured as precisely but follow the same general pattern. Virus is first detected just before the onset of illness (within 24 hours), rapidly rises to a peak of 3.0 to 7.0 $\log_{10}$ tissue culture infectious doses 50 ($TCID_{50}$)/mL of nasal wash, remains elevated for 24 to 48 hours, and then rapidly decreases to low titers. Usually, virus is no longer detectable after 5 to 10 days of virus shedding. However, because of the relative lack of immunity in the young, more prolonged shedding of higher titers of virus is seen in children. Children also appear to exhibit heterogeneous shedding, with the top 20% of shedders estimated to represent 90% of infectiousness. In children, virus can be found for up to 13 days after the onset of symptoms. The higher titers and more prolonged shedding in children contribute to the important role of this

population in the spread of influenza. While virus is typically confined to the respiratory tract, genome can be detected by PCR in peripheral blood in immunocompromised patients and may be a marker for more severe outcomes.

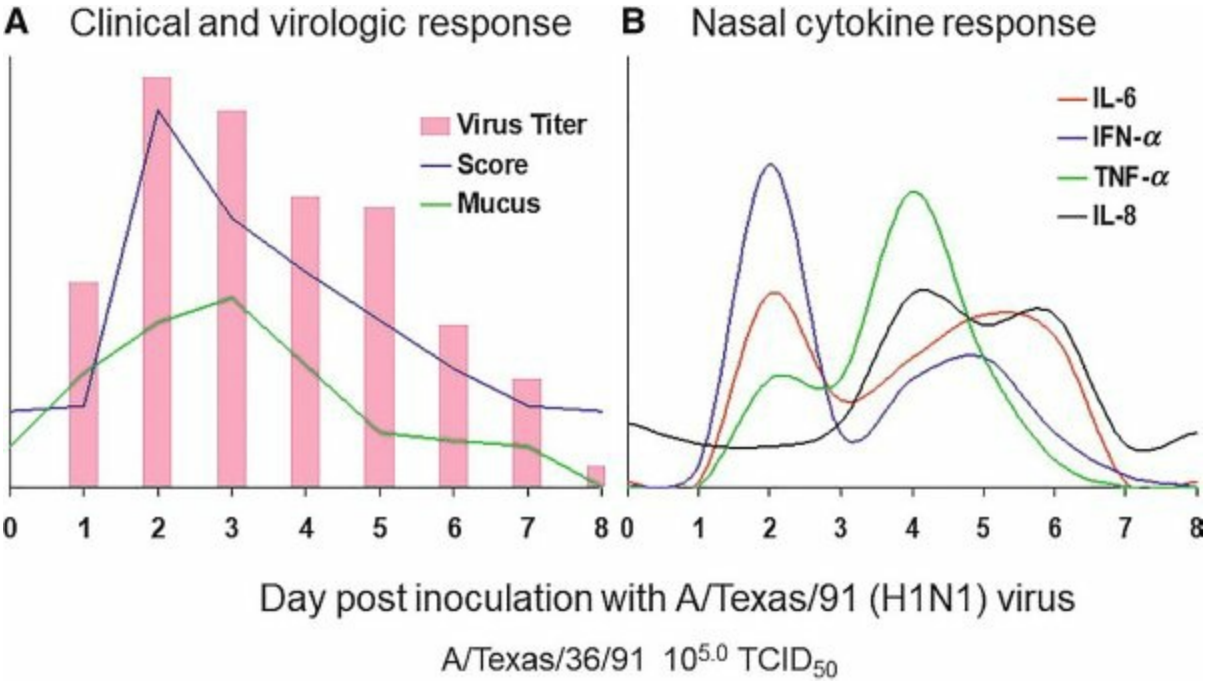

FIGURE 15.11 Time course of virus shedding, symptoms, and cytokine responses of healthy seronegative adults after experimental nasal inoculation with wild-type A/Texas/36/91 virus. A: Level of virus recovered from nasal wash, clinical symptom scores, and nasal mucus weights. **B:** Nasal cytokine levels measured by enzyme-linked immunosorbent assay (ELISA). In both graphs, multiple measurements have been combined for illustration, so that the y-axes are relative values only. (Data from Hayden FG, Fritz R, Lobo MC, et al. Local and systemic cytokine responses during experimental human influenza A virus infection. Relation to symptom formation and host defense. *J Clin Invest* 1998;101:643–649, with permission.)

Pathology and Pathophysiology

Influenza A virus induces changes throughout the respiratory tract, but the most clinically important pathology develops in the lower respiratory tract. Bronchoscopy of individuals with typical, uncomplicated acute influenza has revealed diffuse inflammation of the larynx, trachea, and bronchi, with mucosal injection and edema. Biopsy in these cases has revealed a range of histologic findings, from vacuolization of columnar cells with cell loss to extensive desquamation of the ciliated columnar epithelium down to the basal layer of cells. Individual cells show shrinkage, pyknotic nuclei, and a loss of cilia. Viral antigen can be demonstrated in epithelial cells. Generally, the tissue response becomes more prominent as one moves distally in the airway. Epithelial damage is accompanied by cellular infiltrates primarily composed of lymphocytes and histiocytes. In more severe primary viral pneumonia, there is an interstitial pneumonitis with marked hyperemia and broadening of the alveolar walls, with a predominantly mononuclear leukocyte infiltration and capillary dilation and thrombosis. Influenza virus–specific antigen is present in type 1 and 2 alveolar epithelial cells, as well as in intra-alveolar macrophages[126] (Fig. 15.4).

Influenza infection causes the release of potent cytokines, such as type I interferons, tumor necrosis factor, and interleukins (ILs), by infected cells and responding lymphocytes. In fact, it has been suggested that an overly vigorous cytokine response to infection may contribute to the high fatality rate seen with H5N1 influenza[21] (see Human Infections with H5 Viruses of the A/goose/Guangdong/1/1996 Lineage section), sometimes referred to as a cytokine storm. On the other hand, defects in the cytokine response may increase the risk of severe influenza. Single nucleotide polymorphisms (SNPs) in the gene for interferon-inducible transmembrane 3 (IFITM3) have been associated with cytokine dysfunction and increased severity of seasonal influenza (see Effect of Host Genetics on Susceptibility to Infection and Disease Outcome section). Similar SNPs have also been identified as associated with increased severity of human H7N9. Carriers of the risk allele were shown to have decreased levels of CD8+ T cells in their airways during influenza infection, suggesting a critical function of this protein may be to promote immune cell persistence at mucosal sites.[1] Interferon deficiency related to mutations in IRF7 has also been contributory to severe influenza in a human child. Mutations in TLR3 and CD55 have also been associated with

influenza hospitalizations or death.

Therapies designed to reduce the cytokine response have been beneficial in severe influenza in animal models, although this has not been tested rigorously in humans. However, a recent meta-analysis suggests that steroid therapy of severe influenza in humans is associated with increased mortality.[119] Commonly used statins also have anti-inflammatory properties, and an observational study has suggested that use prior or during hospitalization may be associated with decreased mortality. Because these drugs are very common, it has been suggested they may be useful in a pandemic response.

Clinical Features

Typical uncomplicated influenza often begins with an abrupt onset of symptoms after an incubation period of 1 to 2 days. The typical uncomplicated influenza syndrome is a tracheobronchitis with some involvement of small airways. The incubation period ranges from 1 to 5 days. The onset of illness is usually abrupt, with headache, chills, and dry cough, which are rapidly followed by high fever, myalgias, malaise, and anorexia, and many patients can pinpoint the hour of onset. The predominance of systemic symptoms is a major feature distinguishing influenza from other viral upper respiratory infections. Substernal tightness and soreness can accompany the cough. Fever is the most important physical finding. The temperature usually rises rapidly, concurrent with the development of systemic symptoms. Fever is usually continuous but may be intermittent. Typically, the duration of fever is 3 days, but it may last 4 to 8 days.

Physical findings in influenza are focused on the respiratory tract. Nasal obstruction, rhinorrhea, sneezing, and pharyngeal inflammation without exudate are common. Conjunctival inflammation and excessive tearing may occur. Small cervical nodes can be felt in a minority of cases. Chest radiograph and auscultatory findings are usually normal, although occasionally patchy rales and rhonchi are heard.

At the extremes of age, there are prominent differences in clinical presentation of influenza. Maximal temperatures tend to be higher among children, and cervical adenopathy is more frequent among children than among adults. Croup associated with influenza virus infection occurs only

among children. Otitis media, croup, pneumonia, and myositis are also more frequent in children than in adults. Among older adults, fever remains a very frequent finding, although the height of the febrile response may be lower than among children and young adults. Pulmonary complications are far more frequent in older adults than in any other age group.

Lower Respiratory Tract Complications

Abnormalities of pulmonary function are frequently demonstrated in otherwise healthy, nonasthmatic young adults with uncomplicated (nonpneumonic) acute influenza. Demonstrated defects include diminished forced flow rates, increased total pulmonary resistance, and decreased density-dependent forced flow rates consistent with generalized increased resistance in airways less than 2 mm in diameter, as well as increased responses to bronchoprovocation. In addition, abnormalities of carbon monoxide diffusing capacity and increases in the alveolar–arterial oxygen gradient have been seen. Of note, pulmonary function defects can persist for weeks after clinical recovery. Individuals with acute influenza may be more susceptible to bronchoconstriction from air pollutants such as nitrates.

Primary Viral Pneumonia

The syndrome of primary influenza viral pneumonia was first well documented in the H2N2 pandemic of 1957 to 1958. However, many of the deaths of young healthy adults in the 1918 to 1919 outbreak may have been were the result of this syndrome. In outbreaks since 1918, primary influenza viral pneumonia has occurred predominantly among persons with cardiovascular disease, especially rheumatic heart disease with mitral stenosis,[86] and to a lesser extent in others with chronic cardiovascular and pulmonary disorders and in pregnancy. The illness begins with a typical onset of influenza, followed by a rapid progression of fever, cough, dyspnea, and cyanosis. Physical examination and chest radiographs reveal bilateral findings consistent with the adult respiratory disease syndrome but no consolidation. Blood gas studies show marked hypoxia, gram stain of the sputum fails to reveal significant bacteria, and bacterial culture yields sparse growth of normal flora, whereas viral cultures yield high titers of influenza A virus. Such patients do not respond to antibiotics and mortality is high. At autopsy, findings consist of tracheitis, bronchitis, diffuse hemorrhagic

pneumonia, hyaline membranes lining alveolar ducts and alveoli, and a paucity of inflammatory cells within the alveoli.

The trachea and bronchi contain bloody fluid, and the mucosa is hyperemic.[86] Tracheitis, bronchitis, and bronchiolitis are seen, with loss of normal ciliated epithelial cells. Submucosal hyperemia, focal hemorrhage, edema, and cellular infiltrate are present. The alveolar spaces contain varying numbers of neutrophils and mononuclear cells admixed with fibrin and edema fluid. The alveolar capillaries may be markedly hyperemic with intra-alveolar hemorrhage. Acellular hyaline membranes line many of the alveolar ducts and alveoli.

Secondary Bacterial Pneumonia

Secondary bacterial pneumonia is classically described as occurring as the patient is recovering from influenza. After a period of improvement lasting usually 4 to 14 days, fever recurs associated with symptoms and signs of bacterial pneumonia such as cough, sputum production, and lung consolidation. Secondary bacterial pneumonia was described following the 1957 H2N2[86] and 1968 H3N2 pandemics,[124] and available data suggests bacterial superinfections played a significant role in the mortality associated with the 1918 H1N1 pandemic. Bacterial superinfections were also frequently observed with A(H1N1)pdm09 infections, in particular with fatal cases[126] (Fig. 15.4).

The two pathogens that are currently most commonly associated with influenza are *Streptococcus pneumoniae* and *Staphylococcus aureus*, which is otherwise an uncommon cause of community-acquired pneumonia. Community-acquired, methicillin-resistant *S. aureus* has been seen in children following influenza, and recent study suggests that addition of a second active antibiotic may be important in children with MRSA complicating infection. *Haemophilus influenzae* and group A streptococci have also been associated with influenza.

Combined Viral–Bacterial Pneumonia

Clinically, this syndrome may be indistinguishable from primary viral pneumonia, except that the symptoms of pneumonia appear somewhat after the influenza symptoms and chest radiographs are more likely to show

pleural effusions. Virus has been recovered from the lungs and pleural fluid. The case fatality rate for combined viral–bacterial pneumonia is 10% to 12%. Coinfection with influenza and *S. aureus* can have a fatality rate of up to 42%.

During an outbreak of influenza, many patients do not clearly fit into either of the aforementioned categories. The disease is not relentlessly progressive, and yet the fever pattern may not be biphasic. These patients may have primary viral, secondary bacterial, or mixed viral and bacterial infection of the lung. In addition, milder forms of influenza viral pneumonia involving only one lobe or segment have been described that do not invariably lead to death and that are more likely to be confused with pneumonia caused by *Mycoplasma pneumoniae* than to pneumonia produced by bacterial infection. Some studies have suggested that elevated levels of procalcitonin or C-reactive protein, as well as specific transcriptional profiles, can be helpful in distinguishing secondary bacterial from primary viral pneumonia.

The pathophysiology of bacterial superinfection has been studied intensively,[65] and a number of factors have been identified that could play a role. Uncomplicated influenza is associated with significant abnormalities in ciliary clearance mechanisms, resulting in reduced clearance of bacteria from epithelial surfaces. Alterations in polymorphonuclear neutrophils (PMNs) and mononuclear cells may also contribute to enhanced bacterial infection. In mouse models, the inflammatory response to influenza, particularly the type I interferon response, also contributes to the down-regulation of host antibacterial defense mechanisms. The cytokine IL-10 plays an important role in this regard. Influenza infection also reduces clearance by alveolar macrophages and weakens NK responses. In humans with H1N1 influenza, the development of pneumonia was associated with an early increase in regulatory T cells (Treg) in peripheral blood. All of these observations are consistent with the concept that the inflammatory response to influenza infection leads to disruption in the normal host defense against bacterial pathogens, although direct demonstration of this in humans is lacking.

Some bacterial infections could also increase the pathogenicity of influenza virus. There are strains of *S. aureus* that secrete proteases capable of activating the infectivity of influenza virus by proteolytic cleavage of the HA. These strains play a synergistic role in experimental pneumonia in mice.

Such protease-secreting bacterial strains could be an added pathogenic factor in combined viral–staphylococcal pneumonias in humans. An apparent increase in combined viral–bacterial pneumonias was being noted with the 2003 to 2004 influenza A H3N2 epidemic, perhaps coincident with the rapidly increasing impact of staphylococcal disease and emergence of methicillin-resistant *S. aureus*.[61]

Other Pulmonary Complications

In addition to pneumonia, other pulmonary complications of influenza have been recognized. Bronchiolitis may also occur as a result of influenza A or B virus infection, but respiratory syncytial virus and parainfluenza virus type C are more important causes of bronchiolitis. Significant numbers of cases of croup occur in influenza A and B outbreaks. Croup associated with influenza A virus appears to be more severe but less frequent than that associated with parainfluenza virus types A or C or respiratory syncytial virus infections. Acute exacerbation of chronic bronchitis is a common complication of influenza and may result in a permanent loss of pulmonary function. Exacerbations of asthma and worsening pulmonary function in children with cystic fibrosis may also occur.

Extrapulmonary Manifestations

Myositis

Myositis and myoglobinuria with tender leg muscles and elevated serum creatine phosphokinase (CPK) levels have been reported, mostly in children, but they can occur in adults as well. Symptoms may be sufficiently severe to interfere with walking. Although influenza virus has been recovered from muscle, the relation between the virus and myositis remains unclear. Onset of myositis occurs as respiratory illness wanes. The course is usually benign and reversible, and light microscopic changes of muscle necrosis and inflammatory cell infiltrates are seen.

Cardiac Involvement

Both myocarditis and pericarditis have been rarely associated with influenza A or B virus infection, although not observed at autopsy among those who

died of primary influenza viral pneumonia. Myocardial infarction may also be triggered by influenza infection, possibly as an effect on platelet aggregation. Recent studies have showed a substantially increased risk of myocardial infarction in the 7 days following hospitalization for influenza.[76]

Reye Syndrome

Reye syndrome is a rapidly progressive noninflammatory encephalopathy and fatty infiltration of the viscera, especially the liver, which results in severe hepatic dysfunction with elevated serum transaminase and ammonia levels. This syndrome is seen following respiratory, varicella, and gastrointestinal viral infections. The onset of the central nervous system (CNS) and hepatic symptoms usually begins as respiratory tract symptoms wane. The etiology and pathogenesis of this syndrome are unknown; however salicylate administration is a critical cofactor. There has been a dramatic decrease in Reye syndrome cases in the United States associated with reduced use of salicylates, which are now widely recognized to be contraindicated in influenza virus infection. Children who require continuous aspirin therapy are an important target group for influenza vaccination to reduce the risks of Reye syndrome.

Central Nervous System Involvement

A wide spectrum of CNS disease has been observed during influenza A and B virus infections in humans, ranging from irritability, drowsiness, boisterousness, and confusion to serious manifestations such as psychosis, delirium, and coma. Febrile convulsions leading to hospitalization occur in children with and without underlying CNS abnormalities. The pathogenesis of these CNS symptoms is unclear. Nonspecific metabolic effects such as hypoxia resulting from severe pulmonary infection may contribute to the CNS signs and symptoms.

Encephalopathy can occur during influenza, typically at the height of illness and may be fatal. A subset of influenza encephalopathy has been described extensively in Japan and seen in other countries as an acute necrotizing encephalopathy with bilateral thalamic and cerebellar involvement.[106,156] The syndrome of encephalitis lethargica followed by postinfluenzal encephalitic Parkinson disease was associated with the

influenza epidemics of 1918 and the epidemics that followed. Experiments in animals suggest that avian H5N1 viruses can cause pathology similar to Parkinson disease.

Guillain-Barré syndrome has been reported to occur after influenza A infection, as it has after numerous other infections. In addition, cases of transverse myelitis and encephalitis have occurred rarely. Most cases occur in children, but associated morbidity is higher in adults.[106]

Toxic Shock Syndrome

Toxic shock has occurred in previously healthy children and adults during outbreaks of influenza A or B, presumably because viral infection changed colonization and replication characteristics of the toxin-producing staphylococcus.

Infection During Pregnancy

The increased risk of influenza during pregnancy was dramatically demonstrated during the 2009 pandemic. Previous studies had identified an increased risk of hospitalization associated with influenza epidemics during pregnancy, especially in the second and third trimester and in the immediate postpartum period. During the pandemic, women in each stage of pregnancy, or in the immediate postpartum period, were significantly over represented among those admitted to hospitals and ICUs. A recent meta-analysis has suggested that the overall risk of influenza related hospitalization was more than twice as great during pregnancy. The mechanism(s) by which pregnancy enhances the risk of influenza is not clear but might include the increased cardiovascular demands of pregnancy as well as hormonally mediated changes to the innate and adaptive immune response. Influenza virus itself has not been implicated as a cause of congenital defects and no consistent association between specific defects or malignancies and influenza epidemics has emerged.

Infection in Immunosuppressed Patients

Influenza has been noted to cause severe disease with an increased incidence of pneumonia in immunosuppressed children with cancer, particularly in bone marrow transplant recipients and leukemic patients. Relatively more

immunosuppressed individuals early after transplantation appear to be at greater risk. Influenza virus shedding can be quite prolonged in immunosuppressed children, particularly those with HIV and low CD4+ counts. In general, T-cell defects appear to have a greater negative effect on recovery than do B-cell defects. Because of the prolonged, unchecked replication of influenza viruses in immunosuppressed individuals, resistance to antiviral drugs eventually occurs in many treated patients[56] (see Resistance to Neuraminidase Inhibitors section).

Influenza B and C Virus Infections

Influenza B virus causes the same spectrum of disease as influenza A, but the frequency of serious influenza B virus infections requiring hospitalization is about fourfold less than that of influenza A virus. Generally, years with predominant influenza B circulation are associated with lower rates of pneumonia- and influenza-associated hospitalizations and deaths. However, in children, myositis, Reye syndrome, and gastrointestinal symptoms appear to occur more commonly with influenza B than A virus infection.

Influenza C virus causes sporadic upper respiratory tract illness and is rarely associated with severe lower respiratory tract disease. By early adulthood, most individuals have antibody to influenza C virus, and most cases occur in children younger than 6 years of age. Although very young children may experience complications of bronchitis, bronchiolitis, and bronchopneumonia, overall influenza C virus is not a major cause of lower respiratory tract infection in children.

Innate Immune Responses

In vertebrates, innate immune responses are a vital first line of defense against microbes. Innate immune responses can broadly be divided into three steps: (1) microbe recognition by a pathogen recognition receptor (PRR), resulting in the production of type I IFN, chemokines, and cytokines; (2) activation of IFN-signaling pathways leading to the up-regulation of IFN-stimulated genes (ISGs), many of which have antimicrobial functions; and (3) the actions of cellular proteins with antimicrobial functions. Recent data also demonstrate high induction of IFN-λ upon influenza virus infection, suggesting a role for type III IFN in innate immune responses to influenza

virus infections.

Microbes are recognized by PRRs, including toll-like receptors (TLRs), RIG-I–like receptors, and NOD-like receptors (NLRs). Recognition of pathogen-associated molecular patterns by PRRs results in the activation of signaling pathways that ultimately converge on the expression of antimicrobial genes. Influenza virus infection is sensed by TLR3 and TLR7, up-regulating their expression. RIG-I is activated by 5′-triphosphate groups on influenza vRNAs, resulting in the stimulation of IRF3, IRF7, and NF-κB activity. The inflammasome, a complex of a NLR and the ASC adaptor protein, is also activated by influenza virus infection. Inflammasome activation leads to the cleavage and activation of procaspase-1, which in turn cleaves and activates certain cytokines, particularly IL-18 and IL-1β.

Role of NS1 in the Modulation of Host Immune Responses to Viral Infection

Influenza viruses have evolved mechanisms to counteract the induction of antiviral responses, primarily through their NS1 protein.[38] NS1 interferes with antiviral responses through several mechanisms, including the following:

1. NS1 suppresses RIG-I activation[93,107,111,116] by interacting with it directly, by interacting with the RIG-I ligands TRIM25 and Riplet, and by sequestering double-stranded RNA.
2. NS1 expression prevents the activation of several transcription factors including IRF3, AP-1, and NF-κB, thus blocking IFN expression.
3. NS1 also controls IFN levels by blocking the splicing and polyadenylation of cellular premRNAs (including IFN-β mRNA). This function requires the interaction of NS1 with the 30-kDa subunit of the cleavage and polyadenylation specificity factor (CPSF). Two amino acids in NS1, at positions 103 and 106, are critical for CPSF30 binding and affect virulence.
4. NS1 directly binds to and blocks the antiviral factor protein kinase R (PKR), thereby preventing the phosphorylation of the translation initiation factor eIF2α, which is required for the translation of host proteins.

5. NS1 also binds to 2′–5′-oligoadenylate synthetase (OAS) and thus interferes with RNA degradation mediated by the OAS/RNase L complex.
6. NS1 interaction with NLRP3 prevents the activation of the inflammasome, hence preventing the activation of proinflammatory responses.
7. NS1 activates the PI3K/Akt pathway, which plays a role in the transcriptional regulation of ISGs and in the regulation of TLR-mediated cytokine production. The PI3K/Akt pathway is activated by the NS1 proteins of influenza A, but not by those of influenza B viruses.
8. The four C-terminal amino acids of some (but not all) NS1 proteins form a PDZ ligand domain motif, which is recognized by PDZ domain proteins. The amino acid sequence of the PDZ ligand domain motif can affect the virulence of influenza viruses, possibly because the proapoptotic function of some PDZ domain proteins is modulated by NS1 binding.
9. NS1 binds to several host proteins involved in the nuclear export of mRNA (including NXF1 and P15), a function that may contribute to the shutoff of host protein synthesis.
10. The amino acid at position 92 of NS1 affects the pathogenicity of H5 viruses in pigs (with aspartic acid conferring low pathogenicity and glutamic acid conferring high pathogenicity); the underlying mechanism and the potential involvement of innate immune responses are currently unknown.
11. Since 2000, most H5/Gs/Gd viruses possess a deletion of amino acids 80 to 84 in their NS1 proteins, which enhances virulence. Interestingly, H5/Gs/Gd viruses isolated in 2004 and 2005 in Thailand possessed both the 5-amino-acid deletion at positions 80 to 84 and the D92E mutation. In virus-infected cells, the 5-amino-acid deletion and the D92E mutation affect responses to TNF-α and the induction of IFN, respectively.

The PB1-F2 Protein

Depending on the virus strain and the length of the PB1-F2 protein, PB1-F2

increases viral pathogenicity, inflammation, and the frequency and severity of bacterial coinfections in mice.[11,93] These phenotypic differences likely result from the currently known functions of PB1-F2 in the modulation of host immune responses and the induction of apoptosis.

PB1-F2 modulates host immune responses by interacting with MAVS and other components of the RIG-I/MAVS signaling pathway, resulting in the inhibition of IRF3 and type I IFN induction. The PB1-F2/MAVS interaction may be regulated by CALCOCO2 (calcium-binding and coiled-coil domain-containing protein 2), which was recently identified as a binding partner of PB1-F2. In addition, PB1-F2 interferes with the activation of NF-κB–dependent signaling pathways.

PB1-F2 translocates into mitochondria via the Tom40 channel, the import channel of the mitochondrial outer membrane. PB1-F2 oligomers can form amyloid-like structures that disrupt membranes. Moreover, PB1-F2 interaction with the ANT3 (adenine nucleotide translocator 3) and VDAC1 (voltage-dependent anion channel 1) proteins induces the formation of membrane pores in mitochondrial membranes and subsequently changes mitochondrial permeability. The resulting induction of apoptosis, which is primarily observed in immune cells, may contribute to the increased virulence upon PB1-F2 expression. However, the induction of apoptosis may be strain specific and not the major function of PB1-F2.

PB1-F2 enhances inflammatory responses, as demonstrated by an increased influx of inflammatory cells into the lungs of mice infected with an influenza virus expressing the PB1-F2 protein derived from the 1918 pandemic influenza virus.[18] This PB1-F2 protein encodes serine at position 66, instead of the asparagine residue commonly found among human influenza viruses at this position. Serine at position 66 of PB1-F2 increases virus titers and pathogenicity, immunopathology, cytokine levels, and the severity of secondary bacterial pneumonia in mice, resulting in higher mortality. The virulence-enhancing effect of serine at this position has also been demonstrated for other influenza viruses, including H5/Gs/Gd viruses.

The PA-X Protein

The PA-X protein was discovered in 2012.[59] It is encoded by the PA vRNA segment and shares its first 191 amino acids with the PA protein before a

ribosomal frameshift shifts the open reading frame into the +1 frame relative to PA. Consequently, PA-X has a unique C-terminus of 61 amino acids (the majority of PA-X proteins) or 41 amino acids (~25% of the PA-X proteins including those of the A(H1N1)pdm09 viruses). Only approximately 2% of PA mRNA transcripts undergo the ribosomal frameshift, resulting in low amounts of PA-X in influenza virus–infected cells.

The main function of PA-X is the degradation of host mRNAs, causing a shutoff of host protein expression. PA and PA-X share the endonuclease domain encoded in the N-terminal portion of PA (see The Replication Complex section); the endonucleolytic cleavage of host mRNAs contributes to the shutoff of host protein expression. However, the unique PA-X C-terminus in itself plays a major role in host RNA degradation, and several studies have implicated the first 15 and the last 20 amino acids of the unique PA-X C-terminus in this function.

PA-X acts as a modulator of innate immune responses. Loss of PA-X expression typically leads to increased viral replicative ability and apoptosis in cultured cells, increased induction of proinflammatory cytokines *in vitro* and *in vivo*, and increased virulence in animal models, although exceptions have been noted.

Host Defense Mechanisms

In addition to the host defense mechanisms that are counteracted by NS1 (see previous section), several other host defense mechanisms against influenza virus infections exist.

ISG15

Interferon-stimulated gene 15 (ISG15) conjugation to its target proteins is believed to alter the normal (enzymatic) function of those proteins. $ISG15^{-/-}$ mice are more susceptible to infection with influenza A and B viruses than are control mice. Mechanistically, conjugation of ISG15 to NS1 appears to impair the dimerization of the NS1 RNA–binding domain; disrupt NS1 binding to dsRNA, U6 snRNA, and PKR; interfere with NS1-mediated disruption of antiviral gene expression; and inhibit NS1 association with importin α. In contrast to the influenza A virus NS1 protein, the influenza B virus NS1 protein blocks the antiviral activity of ISG15 by interfering with

the E1 ligase for ISG15.

Mx proteins

Mx proteins are IFN-induced GTPases of the dynamin superfamily. They have been identified in several mammalian and avian species; most, but not all, inhibit influenza viruses (e.g., the Mx proteins of chickens and ducks lack antiviral activity against influenza viruses) (reviewed in Reference[47]). Mx proteins confer resistance to influenza virus infections by interfering with viral replication. Murine Mx1 localizes to the nucleus and interferes with viral mRNA elongation, whereas the human Mx1 protein resides in the cytoplasm and blocks influenza virus replication through a mechanism that is not yet fully understood. Influenza viruses differ in their sensitivity to Mx proteins: in general, avian influenza viruses are more sensitive to inhibition by Mx proteins than are human influenza viruses. Mx1 binds to the influenza viral NP, and human influenza viruses have acquired mutations in NP that confer partial resistance to Mx1,[22] which explains the lower sensitivity of human influenza viruses to Mx1 inhibition. Most conventional laboratory mice lack a functional Mx gene. This fact should be taken into account when interpreting data obtained with such mice.

IFITM

The host interferon–inducible transmembrane (IFITM) proteins 1 to 3 localize to the plasma membranes and the membranes of lysosomes and endocytic vesicles. They block the cell entry step of a variety of enveloped viruses (including influenza viruses) by inhibiting the fusion of the viral and cellular membranes; the underlying mechanism is not fully understood.

MicroRNAs

MicroRNAs (miRNAs) are short, noncoding RNAs that modulate gene expression in eukaryotes by binding to their target mRNAs and destabilizing them and/or blocking their translation. Several studies have now been conducted to catalogue the miRNAs that are differentially regulated upon influenza virus infection and whose levels may correlate with the severity of disease. miRNAs can affect pathogen infections by modulating innate immune responses and/or by targeting pathogen mRNAs directly.

Several miRNAs bind to the influenza virus PB1 mRNA and regulate PB1 expression. Another miRNA targets the viral M1 mRNA. The expression levels of viral proteins can also be affected through indirect mechanisms: for example, one miRNA has been shown to affect the levels of two viral proteins by targeting the mRNA of a host protein (ARCN1) that plays a role in influenza virus entry and assembly.

A number of miRNAs modulate influenza virus-induced innate immune responses by regulating the activation of RIG-I, NF-κB, IFN-α/β, MAPK3, and IRF3/IRF7, among others. For example, infection with influenza viruses results in the up-regulation of several miRNAs that bind to the 3′-untranslated region of RIG-I, thus suppressing the activation of type I and II IFN and of ISGs. Currently, the mechanisms by which influenza virus infection modulates the levels of miRNAs are not understood.

Mitogen-activated protein kinase (MAPK) signaling pathways

Stimulation of PRRs activates the mitogen-activated protein kinase (MAPK) signaling cascades, which activate the expression of multiple genes, including factors involved in inflammatory responses. Several MAPK pathways have been extensively studied for their role in innate immunity, including the extracellular signal-regulated kinases 1/2 (ERK1/ERK2), the c-jun N-terminal kinase (JNK), and p38 pathways. These pathways are activated upon influenza virus infection and modulate viral infections through their roles in the expression of cytokines and chemokines. These effects differ depending on the influenza virus tested.

Effect of host genetics on susceptibility to infection and disease outcome

Genome-wide association studies (GWAS) based on the genomic data of groups of people have allowed the identification of single nucleotide polymorphisms (SNPs) that are associated with susceptibility to infection or the severity of disease. Alternatively, the genome of a single patient of interest (e.g., a person experiencing a severe infection) can be analyzed to identify rare mutations that may be correlated with the disease phenotype. These approaches have identified SNPs in IFITM3, IRF7 (IFN regulatory

factor 7), and SFTPA/SFTPB (surfactant, pulmonary-associated proteins A and B) that are associated with the severity of influenza virus infections. SNPs in the carnitine palmitoyltransferase II (CPTII) gene are linked to influenza-associated encephalopathy.

Adaptive Immune Responses

Humoral Immunity

Infection with influenza virus results in the development of antibody to the influenza virus envelope glycoproteins HA and NA, as well as to the structural M and NP proteins. Some individuals may develop antibody to the M2 protein as well. As measured by enzyme-linked immunosorbent assay (ELISA), serum IgM, IgA, and IgG antibody to the HA appear simultaneously within 2 weeks of inoculation of virus. The antibody response is more rapid after reinfection. The development of anti-NA antibodies parallels that of hemagglutinin-inhibiting (HI) antibodies. Peak antibody responses are seen at 4 to 7 weeks after infection and decline slowly thereafter; titers can still be detected years after infection even without reexposure.[2]

Antibody to the HA can prevent attachment of the virus to the cell and neutralizes virus infectivity. A surrogate measurement of the neutralizing activity of serum is the hemagglutination-inhibition (HI) assay, in which sera is tested for the ability to prevent agglutination of red blood cells by a virus preparation. An increased risk of laboratory-documented influenza among those with the lowest titers of preexposure HI or neutralizing antibody is a consistent finding of most but not all studies. However, there is considerable uncertainty about the actual level of HA antibody that is the best predictor of protection, with estimates ranging from HI titers of 1:8 to 1:160 or higher.[8] Given the substantial variation from laboratory to laboratory in the estimation of the HI titer on the same set of samples, the inability to use an absolute value for protection is not unexpected. In addition, the amounts of antibody needed to mediate protection could vary by population, degree of exposure, age, and specific influenza type or subtype, although this has not been analyzed comprehensively. Most neutralizing antibodies are believed to bind conformational epitopes.

Studies evaluating the B-cell response of patients infected with novel influenza viruses, such as H5N1 or primary infections with pandemic H1N1, have identified B cells directed against epitopes on the stalk of the HA molecule.[66] The monoclonal antibodies produced by these B cells are typically highly cross-reactive among HA molecules within the same group, for example, group 1 specific antibodies reacting with H1, H2, and H5 viruses and group 2 specific antibodies reacting with H3 and H7 viruses. Some levels of stalk-specific antibody are present in the sera of most adults, and the role of these antibodies in protection in humans has not been defined. However, there is considerable interest in exploiting this observation in the development of broadly cross protective influenza vaccines.

Antibody to the NA can be measured by NA inhibition or ELISA. In contrast to anti-HA antibody, anti-NA antibody does not neutralize virus infectivity but instead reduces efficient release of virus from infected cells, resulting in decreased plaque size in *in vitro* assays and in reductions in the magnitude of virus shedding in infected animals. Observations on the relative protection of those with anti-N2 antibody during the 1968 pandemic,[97] as well as experimental challenge studies in humans, have shown that anti-NA antibody can be protective against disease and results in decreased virus shedding and severity of illness but that it is infection permissive.

Antibody to other influenza viral proteins has also been evaluated for potential protection. Antibody to M2 reduces plaque size *in vitro*, and passive transfer studies in mice have also suggested that antibody to the M2 protein of influenza A viruses may be partially protective if present in large enough amounts. The mechanism of protection *in vivo* is related to mediation of ADCC.[60] Antibody to internal viral proteins such as M or NP is also elicited by infection, but they are non-neutralizing. Studies in mice have suggested that such non-neutralizing but cross-reactive antibody may mediate protection under some circumstances. The mechanism by which antibody to viral proteins that are not exposed on the surface can mediate protection is unclear.

Infection with influenza virus is somewhat unique in that humans are repeatedly exposed throughout their lifetimes with influenza viruses that share many immunologic epitopes but differ in others. There is increasing evidence that the result of this repeated exposure is that the antibody response tends to be dominated by epitopes that are shared with the individuals' original exposure to influenza virus. This phenomenon of imprinting by prior

exposure continues throughout life and impacts the susceptibility to infection and the response to vaccination.[99] For example, it has been suggested that the differential age-related impact of H7N9 and H5N1 may be related to prior exposures to group A (H1N1 and H5N1) or group B (H3N2 and H7N9) viruses, such that older individuals with childhood exposure to H1 are relatively more susceptible to H7 than H5, with the opposite effect is seen in individuals whose first exposures may have been to H3 viruses.[43]

Cellular Immunity

The induction of cellular immune response to influenza virus infection has been studied intensively in murine models, and such studies suggest that B-cell, CD4+ T-cell, and CD8+ T-cell responses all can play a role in protection against disease and recovery from infection. A large number of HLA class I restricted (CD8+ T-cell) and HLA class II restricted (CD4+ T-cell) epitopes have been described, and in situations where those epitopes are relatively well conserved on proteins such as the polymerase, NP, and M proteins, the cellular responses are cross-reactive between subtypes, although not between types A and B.

Cellular immune responses to influenza vaccination and infection have not been studied as extensively in humans, but B-cell (memory B-cell and antibody secreting cell), CD4+ T-cell, and CD8+ T-cell responses in peripheral blood have been described after infection or vaccination. It can be difficult to capture the peak of the response as detectable increases in antigen-specific cells may only be seen in peripheral blood on a few days after exposure. Generally, the peak cellular response occurs somewhere between 5 and 14 days depending on the status of the subject and the nature of the response. As seen in murine models, a major component of the cellular response is directed at conserved peptides to which the subject has already been exposed during previous infections or vaccinations.

An important role of the cellular immune response in recovery from influenza infection in humans is strongly supported by the observation of prolonged illness and viral shedding in individuals who are lymphopenic as a result of disease or chemotherapy. However, it has been difficult to develop specific markers of T-cell immunity as correlates of protective immunity. Activated T cells, in the form of granzyme B–positive T cells, have been

associated with protection in older subjects.[94] In the human challenge model, early studies identified virus-specific cytotoxic T cells as correlated with reductions in the duration and level of virus replication in adults.[95] In a subsequent study done many years later by the same group, prechallenge CD4+ T cells, but not CD8+ T cells, correlated with relatively lower levels of viral shedding and symptoms following experimental infection.[159]

In community surveillance of healthy adults during the pandemic of 2009, and in a setting of low baseline antibody to the pandemic virus, CD8+ T cells were strongly correlated with protection against severe illness.[132] Under similar circumstances, the presence of NP-specific, predominantly CD8+ T cells was correlated with less symptomatic influenza.[51] In addition, an early CD8+ T-cell response is associated with successful recovery from severe H7N9 illness in humans.[152] The development of more sophisticated markers that can specifically identify reactive cells in peripheral blood will help to define the role of cellular immunity in protection, but the field remains limited by the lack of convenient access to compartments other than the peripheral blood in humans.

Mucosal Antibody Response

The majority of studies of mucosal responses to influenza in humans have concentrated on measurement of HA responses by ELISA or by neutralization tests, because nonspecific inhibitors of hemagglutination present in nasal mucus interfere with the standard HI test. These studies have demonstrated significant mucosal responses to infection with wild-type virus or live attenuated influenza vaccines. Both IgA and IgG are found in nasal secretions. Nasal HA-specific IgG is predominantly IgG_1, and its levels correlate well with serum levels of HA-specific IgG_1, suggesting that nasal IgG originates by passive diffusion from the systemic compartment. Nasal HA-specific IgA is predominantly polymeric and IgA_1, suggesting local synthesis. Local IgA antibody stimulated by natural infection is detectable for 3 to 5 months after infection, and there is local IgA memory for influenza antigen. After secondary infection, local antibody is also primarily of the IgA isotype, those with a local IgA response also have a serum IgA response, and the magnitude of the serum IgA HA antibody response correlates with that of the local response.

Studies in mice and ferrets have emphasized the importance of local IgA antibody in resistance to **infection**, particularly in protection of the upper respiratory tract. Polymeric IgA was shown to be specifically transported into the nasal secretions of mice and to protect against nasal challenge. Protection could be abrogated by intranasal administration of antiserum against IgA but not IgM or IgG. Local antibody has also been shown to play a role in protection against antigenic variants in mice. Studies in humans have also suggested that the resistance to reinfection induced by virus infection is mediated predominantly by local HA-specific IgA, whereas that induced by parenteral immunization with inactivated virus depends also on systemic IgG. Importantly, either mucosal or systemic antibody alone can be protective if present in high enough concentrations, and optimal protection occurs when both serum and nasal antibodies are present.

DIAGNOSIS

Clinical Diagnosis

Most cases of influenza are diagnosed based on compatible clinical symptoms and seasonal epidemiology. That is, when the presence of influenza virus is confirmed in a region or community, healthy adults with acute influenza–like illness most commonly have influenza. In fact, several studies have shown that the accuracy of a clinical diagnosis in healthy adults in the setting of an influenza outbreak is as high as 80% to 90%. In an analysis of symptoms in young adults being assessed for entry into studies of influenza virus treatment, the best multivariate predictors of laboratory-confirmed influenza virus infection were cough and fever,[98] with an increasing predictive value with increasing levels of fever. However, the predictive value of such a symptom complex may be less in older adults and in children.

Virus Isolation

Isolation of influenza virus in cell culture has traditionally been the definitive laboratory test to diagnose influenza infection. Virus can be isolated readily from nasal swab specimens, throat swab specimens, nasal washes, or

combined nose and throat swab specimens or sputum samples. Over 90% of positive cultures can be detected within 3 days of inoculation and the remainder by 5 to 7 days. However, virus isolation requires specialized expertise and equipment and does not provide diagnosis within the timeframe of clinical decision-making. Thus, a wide variety of more rapid diagnostic approaches have been developed. Available diagnostic testing is updated frequently by the Centers for Disease Control and Prevention (CDC) on the Web site http://www.cdc.gov/flu/professionals/diagnosis/table-testing-methods.htm.

Rapid Influenza Diagnostic Tests (RIDT)

The most widely used rapid diagnostic tests are based on immunologic detection of viral antigen in respiratory secretions. In this approach, the sample is treated with a mucolytic agent and then tested with specific antibody that results in a color change or similar endpoint that is read visually. All of these rapid tests are relatively simple to perform and can provide results within 30 minutes, and many tests are eligible for Clinical Laboratory Improvement Amendments (CLIA) waiver and can be performed at the point of care (POC). The reported sensitivities of each test in comparison to cell culture have ranged between 40% and 80%, and they are somewhat dependent on the nature of the samples tested and the patients from whom they were derived. In general, sensitivities in adults and older adult patients tend to be lower than those reported in young children, who shed much larger quantities of virus in nasal secretions and therefore have much higher concentrations of antigen in their samples. Similarly, sensitivity is likely to be higher early in the course of illness, when viral shedding is maximal. Although all types of respiratory samples can be used in such tests, the sensitivity appears to be better with nasopharyngeal swabs and aspirates than with throat swabs or gargles. In some tests, the use of a digital readout can improve sensitivity compared to visual inspection. However, because of the relatively low sensitivities of these tests, their utility in clinical decision-making may be limited.

Polymerase Chain Reaction–Based Tests

PCR-based tests have the advantage of being potentially more sensitive than cell culture and allow detection in samples in which the virions have lost

viability. In addition, it is possible to devise multiplex techniques so that a single test can detect a number of different agents, and many PCR methods allow rapid subtyping of the virus as well. For these reasons, real-time reverse transcriptase PCR (rtRT-PCR) has become the gold standard of influenza diagnostic testing and is generally available at clinical laboratories. Diagnostic sensitivities of the tests depend on the level of virus present in various specimens; generally, samples obtained by nasopharyngeal swabs have slightly higher sensitivity, similar to the findings with antigen detection tests. In some patients with lower respiratory tract disease, sputum samples or tracheal aspirates have been positive when nasal swabs were not. Swabs with wooden handles should be avoided for PCR diagnostic testing, as these can interfere with the chemistry of the assay.

Clinical laboratory–based PCR diagnostics will typically require transport of the specimen from the POC to the laboratory and typically take 3 to 4 hours to complete. Although highly accurate, this may not be useful for patient management, particularly in an outpatient setting. Therefore, there has been considerable effort to develop simple, rapid nucleic acid–based detection methods that could be utilized at the POC.

Rapid Nucleic Acid Amplification Tests (NAAT)

An alternative method of nucleic acid detection is isothermal amplification, which does not require a thermal cycler. A variety of isothermal amplification techniques have been developed, with the most frequently used approach being loop-mediated isothermal amplification (LAMP). These assays are highly accurate, on a par with PCR-based tests, and are rapid, giving results in less than 30 minutes.[4] Because they are simple to operate, they can be approved for use at the POC, therefore greatly improving their potential utility. However, these assays are currently expensive and not generally designed to identify other respiratory viruses.

Role of Viral Diagnosis in Clinical Decision-Making

Most cases of influenza, occurring in otherwise healthy individuals with typical symptoms during the course of a recognized influenza epidemic, do not need specific viral confirmation. However, diagnostic testing should be used if the results of the test will influence subsequent clinical management.

This would include decisions regarding the use of antiviral agents, the need for antibacterial drugs, and considerations for infection control (reviewed in Reference145).

ANTIVIRALS

Several antiviral compounds—the M2 ion channel inhibitors amantadine and rimantadine; the NA inhibitors oseltamivir, zanamivir, peramivir, and laninamivir; and the viral polymerase inhibitors baloxavir marboxil and favipiravir—are currently approved in one or several countries for use in humans (for restrictions on favipiravir use, see below). Most influenza A and B viruses currently circulating in humans are sensitive to the NA and polymerase inhibitors. The currently circulating human influenza A viruses are resistant to the ion channel inhibitors, which are also not effective against influenza B viruses. Accordingly, ion channel inhibitors are no longer recommended for use in humans.

M2 Ion Channel Inhibitors

Amantadine hydrochloride and rimantadine, an analog of amantadine, were licensed for prophylactic and therapeutic use against influenza A virus in humans in the United States in the 1960s. These compounds are active against all subtypes of influenza A virus, but not against influenza B or C viruses. Amantadine and rimantadine are adamantane derivatives. They inhibit virus replication by blocking the acid-activated ion channel formed by the virion-associated M2 protein.[49] These compounds also inhibit the replication of viruses that have multiple basic amino acids at their HA cleavage site by inhibiting M2 ion channel activity in the *trans*-Golgi network, which prevents the premature low pH-induced conformational change of HAs cleaved by furin.

Until 2004, amantadine and rimantadine were used for prophylaxis and to treat infections caused by seasonal influenza A viruses. Before 2004, the rates of drug resistance among seasonal influenza viruses were low, although adamantane-resistant variants had been isolated from infected individuals. However, from 2003 to 2005, the rate of adamantane-resistant seasonal H3N2 viruses increased to more than 90%, typically conferred by a Ser-to-

Asn mutation at position 31 of M2. At that time, many seasonal H1N1 viruses remained sensitive to ion channel inhibitors. In 2009, the seasonal H1N1 viruses were largely replaced by the novel A(H1N1)pdm09 viruses, which are resistant to adamantanes. Hence, the H1N1 and H3N2 viruses circulating in humans since 2009 are resistant to adamantanes, and the use of these compounds is no longer recommended.

Resistance to adamantanes is conferred by mutations at position 26, 27, 30, 31, 34, or 38 of M2, with mutations at position 27, 30, or 31 found most frequently. Structural studies of the M2 ion channel in the absence and presence of amantadine show that the channel is relatively narrow at position Val27 but opens into a wider cavity that is lined by Ala30 and Ser31 (among other amino acids), providing structural information on the effect of mutations at these key positions.

For H5/Gs/Gd viruses, the rate of adamantine resistance varies greatly depending on their geographic origin. With few exceptions, the H7N9 viruses that emerged in China in 2013 encode asparagine at position 31 of M2, resulting in resistance to adamantanes. Many European swine viruses of several lineages are resistant to adamantanes, likely because their M genes belong to the same phylogenetic lineage. The pandemic 1918 virus is sensitive to ion channel inhibitors.

Neuraminidase Inhibitors

The first NAIs included DANA (2-deoxy-2,3-dihydro-*N*-acetylneuraminic acid; Neu5Ac2en) and its *N*-trifluoroacetyl analog FANA, which were effective *in vitro* but did not inhibit replication of influenza viruses in animals. After resolution of the NA structure, DANA served as the lead compound in the rational design of drugs targeting the NA protein. All four currently approved NAIs bind to the catalytic site of NA and block its function. The compounds differ in their side chains, which affects their bioavailability, their binding kinetics to NA, and the rate with which resistant NA variants emerge.

Indications and Dosages

The NAI oseltamivir phosphate (US trade name Tamiflu®) was approved in the United States in 1999 and is also available in many other countries. It is

effective against influenza A and B viruses and is currently approved in the United States for the “treatment of acute, uncomplicated influenza A and B in patients 2 weeks of age and older who have been symptomatic for no more than 48 hours” and for the “prophylaxis of influenza A and B in patients 1 year and older.” It is available as capsules and for oral suspension. Tamiflu® is a prodrug that is converted in the liver into the active form, oseltamivir carboxylate. For therapeutic treatment, 5-day courses are recommended with 75 mg of Tamiflu® twice a day for patients 13 years and older; lower doses are recommended for pediatric patients. For prophylaxis, the therapeutic doses are recommended for at least 10 days; community outbreaks may require treatment for up to 6 weeks. Treatment with Tamiflu® may cause nausea and discomfort, and rare cases of serious skin reactions and neuropsychiatric events have occurred.

Zanamivir (US trade name Relenza®) was also approved in the United States in 1999 and is available in other countries as well. In the United States, it is indicated for the “treatment of acute, uncomplicated influenza type A and B infections in patients 7 years and older who have been symptomatic for no more than 2 days.” The prophylactic indication is for patients 5 years and older. Relenza® is provided as a powder and administered by inhalation. For patients of all age groups, two daily inhalations (10 mg each) are recommended for the treatment of infections, whereas one daily inhalation of 10 mg for up to 28 days is recommended for prophylaxis. Because Relenza® is administered by oral inhalation, it is not recommended for patients with underlying airway diseases. In rare cases, Relenza® may cause bronchospasm, allergic reaction, or neuropsychiatric episodes.

Peramivir (US trade name Rapivab®) received emergency use authorization by the U.S. Food and Drug Administration from October 23, 2009, to June 23, 2010, during the 2009 H1N1 pandemic. It was permanently approved in the United States in 2014 and is currently indicated for the “treatment of acute uncomplicated influenza in patients 2 years of age and older who have been symptomatic for no more than 2 days.” Peramivir is also available in Japan, South Korea, and China. It is administered intravenously as a single dose of 600 mg for patients 13 years of age or older or 12 mg/kg (up to 600 mg) for pediatric patients 2 to 12 years of age. Patients treated with peramivir may experience diarrhea; in rare instances, serious skin reactions and neuropsychiatric events can occur.

Laninamivir octanoate (Japanese trade name Inavir®) was approved in Japan in 2010 for the treatment of patients over 10 years of age. In 2013, it was also approved for prophylactic use in Japan. It has completed phase III clinical trials in the United States. Patients 10 years of age or older receive a single inhaled dose of 40 mg, whereas younger patients are treated with 20 mg. For prophylaxis, a single inhalation of 20 mg is recommended for 2 days. Since Inavir® is effective in humans for several days, a single inhaled dose is sufficient to treat influenza virus infections. The prodrug laninamivir octanoate is converted to the active compound, laninamivir, in the respiratory tract. Gastrointestinal side effects, including vomiting and diarrhea, may occur.

Efficacy of Neuraminidase Inhibitors

The efficacy of NAIs in the treatment and prevention of influenza A and B virus infections has been assessed in a number of studies. In general, the initiation of treatment within 48 hours of the onset of symptoms is critical; however, treatment later in infection may still provide some benefit. For uncomplicated infections with human influenza viruses, these drugs reduce the duration of illness by about 1 day (if treatment is started early). In addition, the amount of virus shed appears to be reduced. Several studies suggest that treatment with NAIs also reduces the risk of severe complications.

The currently available NAIs are also effective against H7N9 and H5/Gs/Gd viruses. Clinical data from infected individuals suggest that treatment with NAI improves survival rates; early treatment was again noted as a critical factor. Based on these findings, NAIs are recommended by the WHO for the treatment for human H7N9 and H5/Gs/Gd virus infections. While treatment with NAIs improves the outcome of H7N9 or H5/Gs/Gd infections in humans, a significant percentage of individuals still succumb to the infection. One reason might be that treatment is not always started within 48 hours after the onset of symptoms. Higher doses and prolonged treatment with NAIs have shown additional benefits in animal studies and in infected individuals.

Treatment with NAIs does not appear to prevent the development of humoral antibodies, which is critical to protect against reinfection with antigenically similar viruses. Ferret studies have demonstrated protection

against reinfection, and seroconversion has also been noted in individuals.

Resistance to Neuraminidase Inhibitors

Variants with reduced sensitivity to NAIs can be selected experimentally and have been isolated from patients treated with NAIs. Mutations that confer resistance to NAIs typically map to catalytic sites in NA (R118, D151, R152, R224, E276, R292, R371, and Y406; N2 numbering here and below) or to framework sites (E119, R156, W178, S179, D/N198, I222, E227, H274, E277, N294, and E425) that stabilize the active site.[149] NAI-resistant viruses have often been isolated from immunocompromised patients treated with a NA inhibitor. In this group of patients, delayed virus clearance results in prolonged virus replication and thus a higher risk for the emergence of drug-resistant mutants.

Among human H1N1 and H5N1 viruses, the most frequently detected resistance mutation is H274Y, which is primarily detected after treatment with oseltamivir. This mutation confers high resistance to oseltamivir and peramivir; however, zanamivir and laninamivir remain effective against H274Y mutants. Other oseltamivir-resistance mutations map to amino acid position 222; while these variants are sensitive to the other NAIs, double mutants possessing I222V/H274Y are moderately or highly resistant to all four NAIs. For human H3N2 viruses, frequently detected oseltamivir-resistant variants include those with R292K or E119A/V mutations. The R292K mutation confers resistance to oseltamivir, zanamivir, and peramivir, but not to laninamivir. The E119A mutation renders mutants resistant to oseltamivir and zanamivir, while the sensitivity to the other two NAI has not been tested. Variants encoding E119V are resistant to oseltamivir but can be controlled with the other three NAIs. Treatment with zanamivir or oseltamivir, respectively, resulted in the isolation of influenza B viruses with R152K and D198N mutations in NA; these mutants are resistant to oseltamivir, zanamivir, and peramivir.

Overall, resistance to oseltamivir is more frequently detected in treated patients than is resistance to zanamivir. This may be a consequence of the structural differences between zanamivir and oseltamivir, or it may result from the more frequent use of oseltamivir compared with zanamivir. However, several viruses have been isolated that are resistant to both oseltamivir and zanamivir.

The rate of resistance to oseltamivir among human influenza viruses remained relatively low until the influenza season of 2007/2008, when resistance was observed more often with H1N1 viruses than with H3N2 or influenza B viruses. During the 2007/2008 season, an increase in the number of oseltamivir-resistant H1N1 viruses was noted, and by March 2009, 1291 of 1362 seasonal H1N1 viruses analyzed had acquired resistance. Clinical data indicated that oseltamivir-resistant H1N1 viruses were comparable in their severity to oseltamivir-sensitive viruses, a finding that is consistent with studies in ferrets. In 2009, the oseltamivir-resistant H1N1 viruses were largely replaced by A(H1N1)pdm09 viruses. Among currently circulating H1N1, H3N2, and B viruses, approximately 1% are resistant to oseltamivir. Typically, these viruses are not transmitted efficiently, although small community clusters of oseltamivir-resistant viruses have been reported. Currently, most H7N9 and H5/Gs/Gd viruses are sensitive to NAIs, although several resistant variants have been isolated.

Early studies indicated that viruses resistant to oseltamivir are attenuated in animal models, so viruses resistant to NAIs were not expected to outcompete the viruses circulating at the time. Therefore, the rapid spread of oseltamivir-resistant seasonal H1N1 viruses in 2007/2008 was unexpected. However, these viruses possessed additional mutations in NA (V234M and R222Q) that compensated for the loss of viral fitness due to the H274Y mutation. Several pairs of NAI-resistant or NAI-sensitive viruses have now been compared in animal models: while most NAI-resistant viruses are attenuated, some are comparable in their pathogenicity and transmissibility to the respective NAI-sensitive variant.

Polymerase Inhibitors

Baloxavir Marboxil

Baloxavir marboxil (trade name Xofluza®) was approved in the United States and in Japan in 2018. It is indicated for the “treatment of acute uncomplicated influenza in patients 12 years of age and older who have been symptomatic for no more than 48 hours.” It is available in tablet form and is administered at a single dose of 40 or 80 mg (for patients with a body weight of less than, or at least, 80 kg, respectively). The most common adverse reaction is diarrhea.

Baloxavir marboxil is a rationally designed prodrug that is metabolized to baloxavir acid, the active compound. It interacts with the PA subunit of the viral polymerase complex and blocks its endonuclease activity, which is critical to generate short, capped oligomers that serve as primers for influenza virus transcription[104] (see Chapter 14). In clinical trials, almost one-quarter of the drug recipients developed resistance to baloxavir acid, conferred by amino acid changes at position 38 of PA. Drug-resistant influenza A viruses were attenuated in their replicative ability compared to the drug-sensitive viruses, whereas drug-resistant influenza B viruses replicated to titers similar to those obtained with the drug-sensitive viruses.

Favipiravir

Favipiravir (T-705) is an antiviral compound that has completed a phase III clinical trial in the United States. In Japan, its use is highly restricted and limited to the treatment of "novel or reemerging influenza virus infections to which NAI or other antiviral agents could be ineffective." It has favorable pharmacokinetics and is recognized by RNA-dependent RNA polymerases as a purine analog. Consequently, it is effective against influenza viruses and a number of other RNA viruses. In contrast to ribavirin, favipiravir does not affect cellular DNA or RNA polymerases.

Combination Therapy

Several studies have assessed the potential benefits of combination therapies compared with monotherapies. In particular, the combination of inhibitors that target different steps in the viral life cycle could lead to synergistic beneficial effects and reduce the rate of emergence of resistant variants. Accordingly, combinations of NAIs and ion channel inhibitors have been tested for use against viruses that are sensitive to the latter category of compounds, such as H5/Gs/Gd viruses. The combination of amantadine and oseltamivir was well tolerated in volunteers and superior to monotherapy in terms of efficacy in mice. Similarly, the combination of rimantadine with oseltamivir, zanamivir, or peramivir provided additive effects in cell culture and mice. A triple combination regimen consisting of amantadine, oseltamivir, and ribavirin was superior to monotherapy or dual therapies in mice. Synergistic effects relative to monotherapy were also detected for several combinations of a polymerase inhibitor and a NA inhibitor including

favipiravir/oseltamivir, favipiravir/peramivir, and baloxavir marboxil/oseltamivir.

Experimental Antivirals Against Influenza

Several compounds are in different stages of development as inhibitors of influenza viruses. Among them is FluDase (DAS181), a recombinant fusion protein of a bacterial sialidase with an anchor domain that mimics the sialidase activity of NA. In a phase II clinical trial, treatment with FluDase reduced virus load and shedding. Nitazoxanide (NT-300) is an approved antiparasitic agent that blocks HA maturation; it is currently being tested in a phase III clinical trial for its efficacy and safety in the treatment of uncomplicated influenza. JNJ63623872 (VX-787) inhibits the polymerase complex of influenza A viruses (but not that of influenza B viruses) by binding to the influenza A virus PB2 subunit. Phase II clinical trials demonstrated a reduction in virus shedding and a shorter duration of influenza symptoms relative to controls. Celecoxib, an approved COX-2 inhibitor, is undergoing phase III clinical trials in combination with oseltamivir for the treatment of patients with severe influenza virus infection. Monoclonal antibodies targeting the highly conserved stalk region of HA have gained attention because of their broadly protective potential; several candidates are now being evaluated in clinical trials. For two monoclonal antibodies, data from phase II clinical trials indicated a reduction in virus shedding following treatment.

VACCINES

Currently Available Vaccines

Multiple forms of influenza vaccine are currently available both in the United States and elsewhere, including virion- or protein-based inactivated influenza vaccines (IIV) administered intramuscularly and live attenuated influenza vaccines (LAIV) administered intranasally. Both types of vaccines are thought to work primarily by inducing antibody against the viral HA, although other mechanisms probably also play a role.

As described earlier, influenza viruses undergo continual antigenic

evolution to escape from prior immunity. As a result, the match between the viruses chosen as components of the vaccine and the viruses that circulate during the season is an important determinant of the efficacy of that season's vaccine. Successfully matching the vaccine to epidemic requires a considerable effort devoted to worldwide surveillance and subsequent antigenic characterization of emerging new variants. A final decision regarding strain selection for next year's vaccine generally must be made at least 6 months before expected vaccination, for example, in February for the Northern Hemisphere and September for the Southern Hemisphere. The need to constantly update vaccine formulations, and readminister vaccine on a yearly basis, represents some of the biggest challenges in effectively controlling the impact of influenza.

The composition of the vaccine has changed over time to reflect changes in the epidemiology of influenza viruses. Since 1977, influenza vaccines have contained three strains representing the most up-to-date antigenic variants of A/H3N2, A/H1N1, and B viruses. Since approximately 2004, two antigenically distinct lineages of influenza B viruses, the Victoria lineage and the Yamagata lineage, have cocirculated. Therefore, quadrivalent formulations of vaccine containing both lineages were licensed beginning in the 2013 to 2014 influenza season. The nomenclature of influenza vaccines has changed to reflect this difference, with trivalent preparations now termed inactivated influenza vaccine-3 (IIV-3) and quadrivalent IIV-4.

Protein-Based or Inactivated Vaccines

The original influenza vaccine, which consisted of formalin-inactivated whole virions grown in embryonated chicken eggs, was demonstrated to have a protective efficacy of 70% in healthy adults[33] and licensed in 1945. Since then, although there have been several important advances in the techniques for producing vaccine, the basic vaccine strategy has remained the same. The development of the zonal gradient centrifuge allowed more efficient production and more highly purified vaccines from which reactogenic contaminants had been removed. Treatment of the whole virus with solvents to create "split" vaccines, or with detergents to create "subunit" vaccines, resulted in a vaccine with fewer adverse reactions, particularly fever, than the whole-cell vaccine. The efficiency of vaccine production was also improved through the development of techniques to create reassortant viruses adapted

to provide high yield from hens' eggs. Since the late 1970s, egg-grown vaccines have been standardized to contain at least 15 μg of each HA antigen as assessed by single radial immunodiffusion (SRID) using antibody reagents prepared against the components of the vaccine. Embryonated hen's eggs are an extremely efficient substrate for the growth of most influenza viruses, and consequently egg production remains the primary mode of production for current influenza vaccines. However, while eggs are an efficient substrate for vaccine production, the process of adapting to growth in an avian substrate can result in mutations in the HA protein that result in significant antigenic differences from the original starting material and adversely affect vaccine performance in unpredictable ways[166] (see Host Cell–Mediated Selection of Antigenic Variants section).

One strategy to avoid the problems associated with egg-adaptation would be to produce the vaccine by propagating the viruses in mammalian cell culture. Currently, a vaccine produced in a qualified line of MDCK cells is licensed for use in individuals age 4 years and above in the United States. Other cell lines such as Vero cells and PerC.6 cells have also been explored for influenza vaccine production. Another alternative is to express the HA using an appropriate expression system. The expression of proteins in insect cells using recombinant baculovirus expression vectors can be achieved rapidly and results in proteins with mammalian-like glycosylation. A recombinantly expressed HA vaccine is currently licensed in the United States for ages 18 and above. This vaccine uses a higher dose of HA antigen per component (45 μg), although the reagents used for release criteria are different than those used for egg-derived vaccine.

Several attempts have been made to improve the performance of IIV in risk population such as older adults. A vaccine that uses four times the usual dose (60 μg per component) has been developed and shown to induce higher levels of antibody and improved protection against H3N2 viruses in older adults. The vaccine is produced in eggs and contains a single B virus lineage and is licensed for use in adults 65 and above. Another approach to improving vaccine performance is the use of adjuvants or immune stimulators designed to improve the response to a coadministered antigen. The squalene-based oil-in-water adjuvant MF59 has been shown to increase the immunogenicity of egg-derived influenza vaccine in older adults and has been licensed in the United States and elsewhere in this age group. MF59

adjuvanted vaccine is also currently being evaluated for potential improved efficacy in children.

Live Attenuated Influenza Vaccines

Live attenuated vaccines (LAIV) have a long track record of success against a wide variety of viral diseases, such as smallpox, measles, polio, and others, in part because they generate a diverse immune response that mimics the immune response to the pathogen. Developing live vaccines for influenza represents a special challenge because of the frequent antigenic changes in the virus. Creation of reproducibly attenuated antigenically variant LAIVs takes advantage of the principle of reassortment to generate attenuated vaccines for new antigenic variants using a vaccine master donor virus. The master donor viruses used in the LAIV currently licensed in the United States are the cold-adapted influenza A/Ann Arbor/6/60 (H2N2) and B/Ann Arbor/1/66 viruses. A quadrivalent formulation of these viruses (LAIV-4) is currently licensed in the United States and other countries for use in individuals ages 2 to 49. A second type of LAIV, based on the cold-adapted A/Leningrad/60 and B/Leningrad/66 master donor viruses, is also licensed in some countries.

Safety

Intramuscular Protein Vaccines

Hundreds of millions of doses of IIV are administered to adults, elders, and children each year, and the safety of these vaccines has been repeatedly confirmed. For example, no increase in clinically important medically attended events has been noted among over 251,000 children less than 18 years of age who were enrolled in 1 of 5 health maintenance organizations within the Vaccine Safety Datalink, the largest published postlicensure population–based study of vaccine safety. The most common adverse events reported following immunization with IIV are tenderness and/or pain at the injection site. Most injection site reactions are mild and rarely interfere with daily activities. Systemic reactions following immunization of adults with inactivated vaccine are uncommon. In placebo-controlled clinical trials in younger and elderly adults, rates of systemic reactions were similar among

groups given inactivated vaccine or placebo.

Immediate hypersensitivity reactions (hives, wheezing, angioedema, or anaphylactic shock) following inactivated vaccine can also occur, and vaccine is considered contraindicated for persons who experienced a previous anaphylactic reaction following vaccine. However, recent studies support the safety of egg-derived IIV among persons who experience mild allergic reactions to eggs such as hives.[14] Current recommendations for persons with other forms of egg allergy such as history of angioedema or respiratory distress are that any inactivated vaccine may be used but that vaccine should be administered in a medical setting where emergent severe allergic reactions can be treated.

The Guillain-Barré syndrome (GBS), an acute inflammatory demyelinating polyneuropathy, was associated with the 1976 swine influenza vaccination campaign, with an increased risk of approximately 1 per 100,000 vaccinees. Subsequent studies have suggested a statistically significant but very slight increased relative risk of GBS within 7 weeks of influenza vaccination. A recent meta-analysis of 39 observational studies conducted from 1981 to 2014 confirmed a slightly increased risk of GBS following influenza vaccination.[89]

Pregnancy is recognized as a risk factor for more severe influenza, and pregnant women are an important target group for immunization. Most studies of pregnancy outcomes have found no association between vaccination and adverse pregnancy outcomes, although relatively less information is available regarding first trimester vaccination. Influenza vaccine is currently considered safe in all trimesters.

During the response to the 2009 pandemic, monovalent H1N1 inactivated vaccines were administered in several countries adjuvanted with the squalene-based adjuvant AS03. The use of the AS03 with A(H1N1)pdm09 vaccine was associated with an increased risk of narcolepsy during vaccine campaigns in Europe. Initially noted in Finland, this association has been established in multiple other locations where AS03-adjuvanted A(H1N1)pdm09 vaccines were used routinely in young children. The pathogenesis of this disorder involves presumably immune destruction of neurons in the hypothalamus responsible for synthesis of the neurotransmitter hypocretin. The mechanism that might link the use of influenza vaccine to the development of narcolepsy is unclear. An increased incidence of narcolepsy

was also reported following H1N1 infection in China, suggesting that narcolepsy may be linked in some way to the specific antigen in the vaccine. Narcolepsy cases exhibited higher T-cell reactivity to a specific A(H1N1)pdm HA peptide and single-cell T-cell receptor sequencing has suggested that in some cases, narcolepsy may have been associated with molecular mimicry between H1 and the hypocretin protein.[87]

Live Attenuated Influenza Vaccines

LAIV based on the cold-adapted A/Ann Arbor and B/Ann Arbor viruses display three characteristic phenotypes: effective replication at low temperatures (25°C), reduced replication at high temperature (38°C–39°C), and attenuation in a variety of animal models. Multiple mutations in the internal gene segments contribute to these phenotypes. Studies using single-gene reassortants demonstrated that at least three of these gene segments (PB1, PB2, and PA) independently participate in attenuation in both animals and human subjects. For the influenza B/Ann Arbor virus, the PA, PB2, NP, and M gene segments contribute to the cold-adapted and attenuation phenotypes. The attenuated A/Leningrad/134/17/57 virus was developed through 17 sequential passages in embryonated chicken eggs at 25°C. It differs by eight amino acids from the parental virus, which map to the PB2, M1, M2, and NS2 proteins (one amino acid change each) and the PB1 and PA proteins (two amino acid changes each). The ts phenotype is conferred by mutations in the polymerase proteins. The ts phenotype of the attenuated B/USSR/60/69 virus is defined by mutations in the PB2 and PA genes. Because both donor viruses are attenuated at multiple sites, it would be predicted that the vaccines should be phenotypically stable even after prolonged replication in seronegative children, and this has been shown in clinical studies.

Cold-adapted LAIV based on the Ann Arbor master donor viruses have been well tolerated in adults and children, with mild nasal symptoms and sore throat occurring at rates slightly in excess of those in placebo recipients. However, wheezing has been consistently identified as a vaccine-associated side effect in young children, although occurring at low rates. In the largest trial, medically significant wheezing within 42 days of vaccination was reported in 3.8% of children less than 2 years old after receipt of LAIV compared to 2.1% in those who received IIV.[6] Wheezing generally occurs in

the youngest, previously unvaccinated children following the first dose of vaccine. Because of this observation, LAIV is currently approved for use in the United States for children ≥2 years old who do not have a history of asthma.

Safety of LAIV has also been demonstrated in some high-risk patient groups. No significant vaccine-related adverse events were seen in studies of children with cystic fibrosis or asthma, and vaccinated children with asthma did not experience significant changes in FEV_1, use of beta-adrenergic rescue medications or asthma symptom scores compared with placebo recipients. LAIV has also been well tolerated in adults with chronic obstructive airway disease and older adults although the vaccine is not recommended for use in these populations.

Transmission of LAIV to susceptible contacts does not appear to happen frequently. LAIV can be recovered from nasal secretions of about half of adult recipients, although generally shedding of LAIV by adults is of low titer and short duration. Transmission of LAIV from vaccine recipients to susceptible contacts has been rarely detected in studies of young children involved in day care–like settings. In the largest study, 197 children between 8 and 36 months of age in a day care setting were randomized to receive LAIV or placebo, and LAIV was detected in one placebo recipient. The estimate of transmissibility in this age group was 0.6% to 2.0%.[150] However, because of the possibility of transmission, LAIV is not recommended for close contacts of individuals who have levels of immunocompromised that require a protected environment.

Immune Responses to Vaccination

Intramuscular Protein Vaccines

Increases in serum HI antibody are seen in about 90% of healthy adult recipients of vaccine. Only a single dose of vaccine is required in individuals who were previously vaccinated or who experienced prior infection with a related subtype, but a two-dose schedule is required in unprimed individuals. Primed individuals also generally respond with antibody that recognizes a broader range of antigenic variants than do unprimed individuals. Serum antibodies peak between 2 and 4 weeks after vaccination but fall quickly,

reaching near baseline before the next influenza season. Despite evidence that NA-specific antibody responses contribute to protection, neither the NA content nor the enzymatic activity of the vaccine is standardized, and NA-specific antibody responses are not routinely assessed.

Mucosal HA-specific antibody responses are generally not a major component of the response to parenterally administered inactivated vaccine. However, dose-related increases in mucosal HA-specific antibody responses have been observed following intramuscular immunization with increasing doses of a monovalent influenza A/H1N1 vaccine.

Cellular responses, including CD4+ T-cell responses are also noted after IIV, and there is a strong correlation between the CD4 T-cell response and the antibody response.[102] Baseline frequencies of influenza-specific, interferon *γ*–producing memory CD4+ T cells are higher in children who received more previous vaccinations. An increase in HA-specific CD8+ T cells on day 7 after vaccination has also been detected by tetramer staining in adults receiving IIV. While the induction of HI antibody is generally accepted as a correlate of vaccine protection, in some populations such as the elderly, it has been suggested that induction of cellular responses may also correlate with protection.[94]

Unimmunized young children generally require two doses of IIV given at least 4 weeks apart to generate substantial serum antibody responses. Once a child has been primed with two doses of vaccine, a single dose of vaccine is recommended in subsequent seasons regardless of age. While most children 6 months of age or older respond to vaccine after receiving the recommended number of doses, antibody responses in infants are reduced compared to older children. Reduced responses among very young children may be related to a combination of immaturity of the immune system and a lower degree of priming.

When compared with younger adults, the proportions of elderly subjects who achieve a putative protective HI antibody titer are lower. Both age and underlying conditions may contribute to these lowered responses. Unlike children, the administration of a second dose of vaccine in elders is not associated with improved responses. In some studies, the history of multiple prior vaccinations was better correlated to reduce vaccine responses than was age.[53] While the dose-response curve for seasonal influenza vaccine is rather

flat, the administration of a fourfold higher dose (60 μg/HA) is associated with an improved serum HI response in elders and higher levels of antibody to the NA. The high-dose vaccine is licensed in the United States for use in adults over 65.

The MF59 adjuvant is also associated with improved antibody responses in older adults. While there is relatively little effect on the immune response to seasonal vaccines in healthy young adults, the oil-in-water emulsion results in an approximately 50% increase in antibody titers in older adults, and MF59 adjuvanted seasonal inactivated vaccines have been licensed for use in elders in Italy for several years. Recently, MF59 adjuvanted standard-dose inactivated vaccine was licensed for elders in the United States based on studies showing noninferiority of the immune response to that of standard-dose inactivated vaccine.

Individuals on immunosuppressive therapy, those with renal disease, and transplant recipients have impaired responses to vaccination. To be maximally effective, immunizations should be given before transplantation, should avoid the nadir of white counts, and should include vaccination of close contacts. Factors impacting the response in stem cell transplant recipients include the type of transplant, the time since transplantation, the use of myeloablative therapy as opposed to reduced intensity, the presence of graft versus host disease, and the specific immunosuppressive chemotherapy being used. In both allogeneic HSCT recipients and SOT types of transplant recipients, there is concern regarding whether the immune stimulus of vaccination, with or without an adjuvant, might nonspecifically stimulate increased severity of graft versus host disease or organ rejection. However, the weight of evidence does not support a significant association between vaccination and the development of autoimmune adverse events.

Live Attenuated Influenza Vaccines

Studies of the immunogenicity of cold-adapted reassortant vaccines have been carried out in children, adults, and older adults. The results of these studies are consistent with the hypothesis that the replication of cold-adapted vaccines in the upper respiratory tract, and hence their immunogenicity, is influenced by the susceptibility of the host at the time of vaccination. The frequency and magnitude of immune responses to vaccination are therefore highest in young children, intermediate in adults, and lowest in older adult

subjects who have been repeatedly infected with influenza viruses throughout their lifetime. In addition, the mucosally administered LAIV is generally more effective than parenterally administered IIV at inducing nasal HA-specific IgA, whereas inactivated vaccine usually induces higher serum titers of HI and HA-specific IgG antibody.

Most susceptible children demonstrate measurable serum and mucosal HA-specific antibody responses. Mucosal responses have been demonstrated in up to 85% of young children after LAIV. In contrast, adults generally have a low rate of serum antibody response after LAIV and relatively lower rates of mucosal responses. Even in those prescreened to have low prevaccination vaccine–specific influenza antibody, the rates of serum antibody responses to intranasal LAIV in adults and older adults are low. Influenza-specific IgA and IgG antibody–secreting cells (ASC) peak on days 7 to 12 after either LAIV or IIV in both adults and older children and may be a more sensitive indicator of vaccine take after LAIV than antibody response. Influenza-specific interferon-gamma (IFNγ) producing CD4+ and CD8+ lymphocytes have also been detected following both LAIV or IIV.

The mechanism of protection induced by cold-adapted vaccine has mostly been evaluated in experimental infection studies. Cold-adapted vaccine is protective in these experiments in the absence of significant serum HI responses, suggesting that the main protective effect is induction of mucosal antibodies. Finally, an analysis of data collected during a large field trial evaluation of LAIV concluded that the postvaccination numbers of influenza virus–specific IFNγ producing T cells was the best correlate of vaccine-induced protection.[31] However, no definitive correlate of immune protection afforded by LAIV has been identified.

Efficacy (Results of Randomized Prospective Studies)

The ability of influenza vaccines to prevent influenza has been assessed in numerous clinical studies which vary greatly in design, populations, and endpoints. These studies have included prospective, randomized controlled studies, in which case they are referred to as efficacy studies, as well as a wide variety of nonrandomized cohort and retrospective study designs which assess vaccine effectiveness. Endpoints evaluated in these studies have

included both laboratory confirmed influenza and nonlaboratory confirmed respiratory illnesses. In this regard, it has been recognized that studies that utilize a serologic definition of influenza infection may overestimate the efficacy of influenza vaccine, since it will be harder to demonstrate postvaccination to postseason antibody increases in the vaccinated group.[110]

Intramuscular Protein Vaccines

Randomized studies of inactivated vaccine efficacy against laboratory confirmed influenza have mostly been conducted in healthy adults. These studies have shown a wide range of efficacy, from approximately 40% to 80%, with lower levels of efficacy typically seen in years with apparent antigenic mismatch. For example, the efficacy of IIV for preventing culture-proven influenza A illness in adults was 76% (95% confidence interval [CI], 58%–87%) for H1N1 and 74% (95% CI, 52%–86%) for H3N2 in a controlled trial comparing live and inactivated vaccines.[27] Vaccination of adults is also associated with decreased absenteeism from work or school and is significantly cost-effective, but these benefits may not be seen in years when there is not a good match between vaccine and circulating viruses.

A recent meta-analysis of eight randomized, controlled trials in healthy adults during 2004 to 2008 estimated the pooled efficacy of trivalent inactivated vaccine (TIV) against culture-confirmed influenza to be 59% (95% CI, 51%–67%) among those aged 18 through 64 years.[108] The role of antigenic mismatch in the efficacy observed in these trials is unclear, and some studies in young adults have demonstrated high levels of efficacy despite a degree of antigenic mismatch. Recent studies using virus culture and/or PCR endpoints have demonstrated similar levels of efficacy for both egg-grown 78% and cell culture–grown TIVs (84%). The protective efficacy of the recombinant HA vaccine in healthy adults was approximately 47% in healthy adults in a study done in a single season with significant antigenic mismatch.

Although annual vaccination of elders and other high-risk persons has been recommended for many years, there are few randomized trials demonstrating absolute efficacy in these groups, in part because the existing vaccine recommendations make it difficult to do studies using a placebo group. In the most commonly referenced study, TIV was 52% (95% CI,

29%–67%) efficacious in preventing serologically documented influenza illness in a population of adults 60 years of age and older.[44] When the groups were further stratified by age, efficacy estimates against serologically documented influenza illness were 57% (95% CI, 33%–72%) in those 60 through 69 years and 23% (95% CI, 51%–61%) in those ≥70 years old. However, interpretation of this study is complicated by the use of postvaccination to postseason serologic response as definition of infection.

Using higher doses of vaccine induces a stronger antibody response in older subjects, and in a large randomized study, the relative efficacy of high-dose vaccine was 24% compared to standard-dose vaccine,[24] with reductions in small numbers of more severe endpoints as well. As described earlier, recombinant HA vaccine is also administered at a higher HA dose than standard-dose egg-vaccine and was also shown to have approximately 30% improved efficacy compared to standard-dose egg vaccine during a season with substantial H3N2 vaccine mismatch.[25] Standard-dose inactivated vaccine has been shown to be protective in limited studies in other high-risk groups, including those with HIV infection.

Relatively few prospective trials have assessed inactivated vaccine efficacy in children. In one randomized, controlled trial in healthy children aged 6 through 23 months, vaccine efficacy was 66% (95% CI, 34%–82%) in the 1st year, but efficacy could not be assessed in the 2nd year due to a very low influenza attack rate. In an early efficacy study comparing LAIV and TIV over 5 years in children, IIV-3 had 77% efficacy against culture-confirmed H3 and 91% efficacy against H1. In a large field trial conducted at multiple international sites in children 3 to 8 years old, IIV-4 was shown to have efficacy of 59% in prevention of PCR-confirmed influenza and 74% efficacy against moderate to severe influenza.

Two large studies have evaluated the addition of MF59 to inactivated vaccine in children. In the first randomized placebo-controlled study done in children 6 to 72 months of age, the efficacy of IIV-3 against PCR-confirmed influenza was 43% and that of the MF59 adjuvanted vaccine was 86%. In a second study done in a population in which most children had previously been vaccinated, MF59 adjuvanted vaccine efficacy was similar to that of unadjuvanted vaccine in the entire study population but was 31% better than standard vaccine in the subpopulation 6 to 23 months of age,[151] consistent with observations of greater adjuvant effect in immunologically naïve

populations.

Live Attenuated Influenza Vaccine

LAIV was demonstrated to be efficacious in the prevention of influenza in a 2-year, randomized, placebo-controlled trial conducted in 1,314 children 15 to 74 months of age. Efficacy against culture-confirmed influenza illness in the 1st year of this trial was 95% against influenza A/H3N2 and 91% against influenza B. In the 2nd year of the trial, the H3 component of the vaccine (A/Wuhan/93) was not a close match with the predominant H3 virus that season, A/Sydney/95. However, the efficacy of LAIV against this variant was 86% (95% CI, 75%–92%),[7] suggesting that LAIV can induce protective immunity against drift variants. Overall, the efficacy of LAIV to prevent any influenza illness during the 2-year period of surveillance in this field study was 92% (95% CI, 88%–94%). The overall efficacy of LAIV against culture-confirmed influenza among children 6 to less than 36 months who were attending day care was shown to be 85% and 89% in the 1st and 2nd year of the study, respectively. Studies done in Asia have reached similar conclusions, with an efficacy of LAIV compared to placebo of between 64% and 84% over multiple seasons, depending on the antigenic match with the vaccine.

Relatively, few placebo-controlled trials of the efficacy of LAIV have been conducted in adults. In the human challenge model, cold-adapted and IIVs were of approximately equal efficacy in prevention of experimentally induced influenza A (H1N1), A (H3N2), and B. The combined efficacy in preventing laboratory-documented influenza illness due to the three wild-type influenza strains was 85% for LAIV. In a randomized, controlled study in healthy persons aged 1 through 64 years, of whom most of the participants were adults, the efficacy of a prelicensure, bivalent preparation of LAIV for preventing culture-confirmed influenza A illness in adults was 85% (95% CI, 70%–92%) for H1N1 and 58% (95% CI, 29%–75%) for H3N2. LAIV was also evaluated in a large study against clinical endpoints performed in 4,561 healthy working adults. In this study, the effectiveness of LAIV in preventing severe febrile respiratory illness of any cause during the influenza season was 29%.

Effectiveness (Results of Observational Studies)

Many recent studies have utilized a test-negative, case-control design, in which individuals meeting a particular case definition are tested for influenza using a highly sensitive and specific diagnostic test, and the vaccination exposure of test-positive cases and test-negative controls is determined. Large surveillance networks have been established in Canada, the United States, Europe, and Australia for purposes of making interim and end-of-season estimates of vaccine effectiveness. Studies using this design have shown variable results with estimates generally ranging from as low as 20%, or in some cases, no effectiveness, to as high as 60% to 70%. Updated results of vaccine effectiveness studies in the United States are available at https://www.cdc.gov/flu/professionals/vaccination/effectiveness-studies.htm.

While the various networks vary in their study design and the specific selection criteria for subject inclusion, a few overall generalizations can be stated. Failure to detect vaccine effectiveness has typically occurred in studies with very low prevalence of influenza in the study population, or in years with substantial antigenic mismatch between the vaccine and circulating strains but even in situations of antigenically matched viruses, vaccine effectiveness remains in the 50% to 60% range. In some cases, these viruses have been shown to have substantial changes on a HA sequence level despite appearing well matched by traditional HI tests.

Most studies have not enrolled enough subjects in a single season to make age-specific estimates of vaccine effectiveness. However, there is a trend toward decreased vaccine effectiveness in elderly, not surprising given their diminished immune response to vaccination. After accumulating cases over several seasons, it is possible to use the same test-negative case-control design to demonstrate vaccine effectiveness of approximately 60% against influenza-related hospitalization in a population of community-dwelling older adults. Among hospitalized patients, vaccinated individuals have lower rates of ICU admission and in-hospital deaths.

The ability to compare the effectiveness of different vaccines using observational approaches depends on the extent to which various vaccines are being used in the study population, so complete information is not always available. In a cohort study based on Medicare beneficiary data in the United States, the use of high-dose vaccine was associated with a significantly greater reduction in influenza-related deaths among seniors in a year in which H3N2 viruses predominated, but not in a year of primarily A(H1N1)pdm09

virus.[125] In a case–control study among elderly individuals in Canada, MF-59 adjuvanted vaccine also appeared to be more effective than standard-dose unadjuvanted vaccine.[146]

Effects of Prior Vaccination

Recent studies of influenza vaccine effectiveness using the test-negative design, as well as other study designs, have suggested that vaccine effectiveness is decreased in those who are yearly vaccine recipients, compared to those who receive vaccine for the first time this year. These findings would be consistent with very early observations made in a boy's boarding school, referred to as the "Hoskins effect." However, not all studies have shown a negative effect of prior vaccination. The effects seem to be greatest when this season and the previous season vaccine components are similar to each other but the circulating virus is a mismatch.[128]

The immunologic mechanisms that might be responsible for the negative effects of prior vaccination are not known. Individuals with higher prevaccination antibody levels tend to have lower magnitude responses to vaccination although still typically achieving very high levels of antibody. Prior vaccination might result in memory responses that preferentially recognize shared epitopes and not new epitopes that are present in antigenically drifted viruses, representing a form of back boosting.[30]

Because at least one component of the vaccine changes each year, there is not practical solution to influenza control using current vaccine strategies other than annual vaccination. Further research to understand the magnitude and mechanisms of putative negative effects of prior vaccination will clearly be important in improving influenza control.

Comparisons of Live and Inactivated Vaccines

While relatively few randomized direct comparisons of the efficacy of live and inactivated vaccines have been performed, the available studies are consistent with the observed effects of age and prior influenza experience on immunogenicity. When these vaccines have been compared in young children 12 months through 59 months of age, LAIV has shown consistently superior protection, with an approximately 50% greater protective efficacy than inactivated vaccine.

In contrast, studies that directly compared the vaccines in adults have suggested that the vaccines have similar efficacy or that IIV is slightly more efficacious than live vaccine. In one three-armed study, the efficacy of LAIV compared to placebo for prevention of laboratory-confirmed influenza in healthy adults was 57%, while the efficacy of the IIV was 77%, but the difference between the two vaccines was not statistically significant. In a subsequent season in the same population, the absolute efficacies of IIV and LAIV were 68% and 36%, respectively. In an effectiveness assessment in the US military, the effectiveness of IIV against medical visits for pneumonia or other influenza-related diagnoses was higher than that of LAIV, except for personnel who had not been vaccinated in previous years.

When the H1N1 component of LAIV was replaced by a virus with the HA and NA of an A/California/09 virus following the pandemic, there was a substantial decrease in effectiveness of LAIV, particularly against H1N1.[13] This poor effectiveness was repeatedly demonstrated in the United States and to a lesser extent in other countries. The reasons for the diminished effectiveness of this formulation are not completely known but may be related to the replication fitness of the specific H1N1 virus, increasing levels of background immunity in the vaccinated population, or other factors. However, as a result, use of LAIV in the United States was not recommended by the Advisory Committee on Immunization Practices (ACIP) for several years. Subsequently, the H1N1 component has been updated with a virus (A/Slovenia/2093/2015) that appears to generate stronger immune responses, and use of LAIV has resumed. No information is available regarding the efficacy or effectiveness of this new formulation at this time.

Secondary Protection

Generally, individuals at the highest risk for influenza complications may also be compromised in their ability to respond to vaccination. There has been considerable interest in potential strategies to protect such individuals indirectly by preventing illness and viral transmission within highly susceptible populations that probably play a role on community transmission, such as schoolchildren. Several studies have suggested that this may be possible. During the 1968 pandemic, it was observed that the incidence of respiratory illness during the period of influenza A circulation among unvaccinated adults was substantially lower in a community in which

schoolchildren were immunized than in a community with no school immunization. Influenza B was not contained in the vaccine, and during a subsequent influenza B epidemic, there was no difference in adjusted respiratory illness rates in adults in the two communities. In a recent study, closed agricultural communities of Hutterites were randomized to vaccination of schoolchildren with influenza vaccine or with hepatitis A vaccine as a control. In the subsequent influenza A epidemic, the rate of laboratory-documented influenza A in unvaccinated adults residing in school-vaccinated communities was reduced by 61% (95% CI, 8%–83%) compared to adults in unvaccinated communities.[84] Vaccination of children in day care has been reported to reduce the rates of febrile respiratory illnesses in unvaccinated household contacts. Observations in Japan, where it appeared that substantial fluctuations in overall influenza-related mortality (occurring mostly in the elderly) were directly related to the rate of school-age influenza vaccination, also support a potential role for school vaccination in protection of elders. A retrospective study conducted in Japan demonstrated that universal vaccination of schoolchildren reduced the number of class cancellation days and absenteeism when compared with years during which the immunization program was abandoned.

A critical target group for vaccination is health care workers. At a minimum, universal vaccination of heath care workers will reduce workplace absences and prevent disruptions in care. In addition, there is supportive evidence that vaccination of health care workers reduces the risk of nosocomial influenza in hospitals. In nursing homes, vaccination of staff reduces mortality in residents independently of the vaccination status of the residents themselves.

Maternal Immunization

Infants less than 6 months of age are at substantial risk for influenza-related morbidity but are too young to receive influenza vaccine. One strategy to protect vulnerable infants is maternal immunization, with protection mediated by both transfer of maternal antibody as well as reduced potential for contact with an influenza-infected mother. In a multiple randomized studies of maternal immunization, infants born to mothers immunized with influenza vaccine have had substantially lower rates of laboratory-documented influenza in the first 6 months of life than did infants born to mothers

immunized with control vaccine.[138] Similarly, in a retrospective case-control study, the frequency of influenza immunization was substantially lower in the mothers of infants hospitalized with PCR-confirmed influenza than in mothers of infants hospitalized who were PCR negative, with an estimated protective effect of 92%.

Recommendations for Vaccine Use

Current US recommendations are for routine annual influenza vaccination of all individuals aged 6 months and above. Ideally, vaccine should be administered by October, but later vaccination can still be beneficial if the seasonal epidemic has not yet occurred. Recommendations for influenza vaccine in the United Sates are updated annually by the Centers for Disease Control and Prevention.[45]

Vaccines for Pandemic Influenza

As described earlier, there have been multiple observations of human infection with avian or swine influenza viruses with novel HA and/or NA subtypes, and there continues to be concern regarding the potential of such viruses to acquire the ability to transmit efficiently from person to person and result in the next human influenza pandemic. In addition to active ongoing surveillance, there have been substantial efforts to prepare for such a pandemic by developing potential pandemic vaccines in advance. Because seasonal vaccines are licensed for use in all age groups and have substantial evidence of safety and efficacy, pandemic preparedness efforts have generally focused on development of pandemic formulations of seasonal vaccines, including inactivated and live varieties. Several of these have undergone advanced clinical development and have been licensed or approved for emergency use based on a favorable safety and immunogenicity profile.

A large number of inactivated H5 and H7 vaccines have been developed and tested in humans. These vaccines have included egg-derived, cell culture–grown, and recombinant HA vaccines similar to the approaches taken for seasonal influenza. Extensive clinical trials have generally shown that these vaccines are well tolerated but, when administered without an adjuvant, poorly immunogenic. Generation of potentially protective immunity, as

measured by serum HI and neutralizing antibody responses, requires a two-dose schedule and the use of doses substantially higher than those used for seasonal vaccines. When responses are seen, they are typically limited in breadth and predominantly focused on the homologous antigen. Limited studies of whole virion vaccines have suggested slight improvements in immunogenicity.

Oil-in-water emulsions such as MF59 and AS03 have allowed much lower doses of pandemic vaccines to be used successfully. With these adjuvants, substantial immune responses have been seen at doses as low as 3.75 μg of antigen, compared to the need to use 45 or 90 μg of unadjuvanted vaccine, allowing for the generation of a much larger supply of vaccine in the event of a pandemic. In addition, responses after adjuvanted vaccine are typically more broad, with higher titers of antibody recognizing antigenic variants of the vaccine subtype. A number of other adjuvants have also been tested with pandemic vaccines and also show effective improvement in response. Limited studies have suggested that the use of an adjuvant is much more important with the first dose of vaccine. However, even with adjuvants, inactivated pandemic vaccination will likely require a two-dose schedule, imposing significant operational challenges to a pandemic response.

Despite the relatively poor immunogenicity of these vaccines, multiple studies have shown that even unadjuvanted pandemic vaccines may induce long-lasting immune memory, demonstrated by vigorous responses to subsequent booster doses many years later. Such responses can be demonstrated even in subjects who did not respond to the primary series. These studies have also suggested that priming and boosting with antigenically variant HAs can also generate strong responses to revaccination. Hence, prepandemic priming,[42] potentially limited to high-risk groups, could be considered to prepare for a possible H5N1 pandemic.

Live attenuated pandemic vaccines have also been evaluated in clinical trials. Evaluation of pandemic live vaccines is complicated by the concerns regarding potential transmission of the vaccine virus, possible reassortment with cocirculating human influenza viruses, and potential generation of virulent human viruses with novel HA or NA surface proteins. Therefore, these studies have been conducted under isolation conditions to prevent possible transmission outside the study and consequently have been somewhat limited in size.

Surprisingly, all of these studies have shown very limited replication of the pandemic vaccine viruses on either the A/Ann Arbor or the A/Leningrad backbone. Vaccine virus shedding occurs in a minority of susceptible recipients and, when it is detected, is almost invariably of limited magnitude and short duration. Because immune correlates of protection afforded by seasonal live vaccines have not been determined, it is not possible to draw definitive conclusions regarding the relevant immunogenicity of pandemic formulations of these vaccines. However, measurable serum or mucosal immune responses occur rarely.

Similar to the findings with inactivated vaccines, pandemic formulations of LAIV appear to induce long-lasting immune memory despite the lack of measureable immune response to the initial immunization.[112,131] These observations have caused some to suggest that the most effective use of vaccines for pandemic control would be prepandemic vaccination, in which the population would be vaccinated with a prototypic H5, H7, or other threat subtypes prior to a pandemic, and then boosted with an antigenically matched virus should a pandemic occur.

Strategies for More Broadly Protective Vaccines

For a variety of reasons previously outlined, there is considerable interest in the development of influenza vaccine approaches that could generate more broadly protective immunity, potentially providing protection against multiple antigenic variants within a subtype or possibly even providing protection against multiple subtypes. Several approaches have emerged in pursuit of this goal (for a recent review, see [Reference28]).

In contrast to the globular head of the HA, the stalk, or HA2 region, remains relatively conserved from season to season. Stalk-directed antibody or stalk-reactive B cells are seen most frequently when individuals are exposed to a novel influenza virus, such as after infection with H5N1 or A(H1N1)pdm09 viruses in 2009. Stalk-specific antibodies are capable of mediating virus neutralization by inhibiting HA-mediated fusion. In addition, these antibodies can mediate antibody-dependent cellular cytotoxicity. Therefore development of vaccines to induce stalk antibodies is one of the prime strategies for more broadly protective vaccines. Both chimeric approaches, where several doses of a vaccine in which the HA1 domain is derived from a novel subtype, and the stalk remain the same, and stalk-only

constructs are in development.

The influenza NA has also been explored as a potential target for more broadly protective vaccines. The rate at which mutations accumulate in the NA appears to be less than that in the HA, suggesting that vaccines that induced substantial NA-specific immunity would continue to provide protection against drifted viruses and would need updating less often than HA-centric vaccines.

The third envelope protein, the M2, has also been identified as a potential target since the extracellular domain (M2e) is fairly well conserved among human influenza A viruses. The mechanism of protection by M2e antibodies also involves antibody-dependent cellular cytotoxicity in M2e antibody–mediated protection. Multiple platforms have been used to induce antibody specific for M2e, which have induced variable levels of M2e antibodies in humans.

Vaccines designed primarily to elicit cellular antibodies often contain mixtures of peptides computationally identified as cellular target epitopes. Immunization of humans with a mixture of linear peptides has been reported to induce cellular immunity and prime for subsequent vaccine responses. Such epitopes could be delivered by mixtures of peptides or by live viral vectors, such as vaccinia. Virus-like particles and gamma-irradiated whole virus have also been evaluated for their ability to induce cellular immune responses.

PERSPECTIVES

Over the last decade, we have witnessed several important developments in influenza virology. HPAI viruses, which in the past caused transient, local outbreaks, have now expanded their geographic range and become enzootic in parts of Asia and the Middle East, with frequent introductions into Europe. In several studies, recombinant H5 viruses have been shown to acquire respiratory droplet transmissibility in ferrets; based on these results, the pandemic potential of these viruses should not be discounted. In 2013, novel influenza viruses of the H7N9 subtype emerged in China and have caused greater than 1,500 human infections with a case fatality rate of approximately 40%. The recent poultry vaccination campaigns in China may have controlled

this outbreak. The last decade has also seen major efforts to improve influenza vaccine efficacy including the development of broadly protective ("universal") vaccines; several concepts are being pursued, and first candidates are now being tested in clinical trials. Moreover, we have witnessed the development and approval for human use of a novel class of antivirals to influenza, that is, inhibitors of the viral polymerase complex. While progress has been made in several areas of influenza virus research, key questions remain: How can we better predict the pandemic potential of newly emerging influenza viruses? And how can we better understand the antigenic evolution of human influenza viruses, so that vaccines can be ready before appreciable numbers of people get sick?

CHAPTER **16**

Bunyavirales: The Viruses and Their Replication

John N. Barr • Friedemann Weber • Connie S. Schmaljohn

Introduction
History and classification
- *Hantaviridae* family
- *Nairoviridae* family

INTRODUCTION

The *Bunyavirales* order includes 12 families of single-strand RNA viruses with genomes that are typically composed of two or three (but sometimes even up to eight) segments with negative sense or ambisense coding strategies. The families are *Arenaviridae*, *Cruliviridae*, *Fimoviridae*, *Hantaviridae*, *Leishbuviridae*, *Mypoviridae*, *Nairoviridae*, *Peribunyaviridae*, *Phasmaviridae*, *Phenuiviridae*, *Tospoviridae*, and *Wupedeviridae* families. This large and diverse group of viruses, generically termed "bunyaviruses," infect a broad range of natural hosts including mammals, reptiles, birds, plants, and arthropods. Certain bunyaviruses are pathogenic for humans, but most are not known to infect or cause disease in humans. Bunyaviruses have numerous characteristics consistent with those required for emerging pathogens, such as error-prone polymerases, segmented genomes, persistent infection cycles in the vector organism, and widespread host distribution, which provide opportunities for genetic drift and shift and spillover to new hosts. In this chapter, we describe characteristics of the four traditional virus families within the *Bunyavirales* order that include important human pathogens. We briefly describe characteristics of the other families, with the exception of the Family *Arenaviridae*, which is addressed in a separate chapter.

HISTORY AND CLASSIFICATION

The order takes its name from Bunyamwera virus (BUNV), which was isolated originally from *Aedes* mosquitoes in the Semliki Forest, Uganda, during a yellow fever study in 1943[414] and which was subsequently associated with a mild febrile illness in humans known as Bunyamwera fever. BUNV is the prototype of the order, and remains an important research model; it was the first bunyavirus whose genome was completely sequenced,[106,247] and was the first segmented genome negative-sense RNA virus that was generated entirely from cloned DNA.[54,367] From these beginnings, the *Bunyavirales* order now contains approximately 500 named viruses aligned to almost 300 species and as such is one of the largest of all virus taxonomic groupings.

At the time of the isolation of BUNV, arboviruses were categorized according to their serological characteristics, which led to the establishment of classical arbovirus groups A, B and C. While viruses within groups A and B were later included in the *Flaviviridae* and *Togaviridae* families, further virus discovery along with detailed serological analyses[294] led to the expansion of group C arboviruses into the Bunyamwera supergroup,[69] which consisted of viruses that could be linked by repeatable serologic cross-reactions.[61]

The family *Bunyaviridae* was formally established in 1975,[339] and in 1980 the International Committee on Taxonomy of Viruses (ICTV) approved the creation of the *Bunyavirus* genus, along with *Uukuvirus*, *Phlebovirus*, and *Nairovirus* genera that contained viruses morphologically and biochemically similar but antigenically distinct.[42] The discovery of a novel group of rodent-borne viruses and another group of plant-infecting viruses with conforming molecular properties, respectively, led to the creation of the *Hantavirus* genus in 1985, and the *Tospovirus* genus in 1991, and in the same year, further studies demonstrated a close biochemical similarity between uukuviruses and phleboviruses, resulting in their combination into the *Phlebovirus* genus.[60] The *Bunyavirus* genus was renamed *Orthobunyavirus* in 1995, to provide distinction between members of the respective genus and family taxa,[107] and thus a taxonomic structure with five distinctive genera was established.

Assignment of species to one of these genera was based upon multiple factors; a lack of serologic cross-reactivity with members of other genera, the patterns of sizes of virion proteins (Table 16.1) and genome segments (Table 16.2), gene expression strategy (Fig. 16.1), and conserved terminal nucleotide sequences of the genomic RNAs (Table 16.3).

However, both further virus isolations as well as implementation of large-scale meta-transcriptomic sequencing projects[257, 403, 464] have dramatically increased the membership of the family, and revealed the previously unseen scope of bunyaviral genetic diversity. A measure of this diversity is that the previous and defining bunyavirus characteristic of a trisegmented, single-stranded RNA genome of negative- or ambisense polarity is no longer a distinctive property shared by all members of this order, with members of the newly-incorporated *Tenuivirus* genus (*Phenuiviridae* family) possessing up to 6 RNA segments, and members of the *Emaravirus* genus (*Fimoviridae* family) possessing up to eight. Instead, taxonomic assignments can be made solely based on viral nucleotide sequences, and in the case of bunyaviruses, their current phylogeny is primarily based on the sequence of conserved motifs within the viral RNA dependent RNA polymerase (RdRp). It should

be noted that many of these newly classified viruses have not been isolated, and thus biochemical and molecular characteristics, as well as information about their natural history and pathogenesis are as yet unknown.

Consequently, in 2016, the ICTV *Bunyaviridae* study group initiated a taxonomic revision to incorporate the many unclassified bunyavirus-like species that could not be assimilated within the established five genera scheme, and to place all related viruses within a new high level overarching taxon, namely the *Bunyavirales* order. This involved the renaming and expansion of previous genera into family taxa, creation of four additional families containing newly identified species with invertebrate and plant hosts, as well as inclusion of the *Arenaviridae* family. Of these 12 families, 5 represent vertebrate-infecting bunyaviruses: the *Hantaviridae, Nairoviridae, Peribunyaviridae*, *Phenuiviridae*, and *Arenaviridae* families. The first four of these will be discussed in this chapter, as these groupings contain the vast majority of bunyavirales members for which molecular and biochemical information has been gathered. For historical reasons, the *Arenaviridae* family will be discussed separately in chapter 18.

These taxonomic assignments should be regarded as being in a state of flux. Implementation of further large-scale sequencing projects involving diverse vertebrate, invertebrate, and plant hosts will aid in deciphering the complex evolutionary relationships between the bunyaviruses to fill the gaps that currently exist in the phylogenetic tree, and it is certain that further changes will be made to their taxonomy.[56,305,315,316]

Table 16.4 lists notable members in the families within the *Bunyavirales* order and includes the traditional bunyaviruses. A brief description of the genera within the four families follows.

	Zucchini lethal chlorosis virus	Zucchini lethal chlorosis virus	SA	*F. zucchini*	Plant

Hantaviridae family

More than 100 small mammal species, to include rodents, shrews, moles and

bats, have been found to host hantaviruses in nature.[283] Very recently, using a large-scale meta-transcriptomic approach, hantavirus-related gene sequences were also identified in reptiles, ray-finned fish, and jawless fish.[220] To date, all human pathogens in this family are carried by rodents and transmitted through aerosol exposure and occasionally by bite. The current taxonomy of the trisegmented negative-sense RNA virus family *Hantaviridae* includes 4 subfamilies (*Actantavirinae*, *Agantavirinae*, *Mammantavirinae*, *Repantavirinae*), 7 genera, approximately 50 viral species, and 70 named viruses.

Orthohantavirus genus

Hantaviruses infecting mammals are included into the *Mammantavirinae* subfamily, with the *Orthohantavirus* genus (family *Hantaviridae*, order *Bunyavirales*) constituting all of the important rodent-borne human pathogens. The type species of the *Orthohantavirus* genus is Hantaan virus (HTNV), which was named after a small river close to the location where the virus was first identified.[245] The discovery of hantaviruses traces back to the early 1950s when United Nations troops were deployed during the border conflict between North and South Korea. More than 3,000 cases of an acute febrile illness were seen among the troops, about one third of which exhibited hemorrhagic manifestations, with an overall mortality of 5% to 10%.[102,245] The disease was initially termed Korean hemorrhagic fever but is now referred to as hemorrhagic fever with renal syndrome (HFRS). Despite considerable effort, it took about 25 years until the field mouse, *Apodemus agrarius*, was identified as the rodent reservoir, and HTNV was eventually isolated from the lungs of this animal.

During the course of the early studies in Korea, it became clear that HFRS cases were also occurring in urban areas. Years of investigation finally demonstrated that the urban cases in Korea, China, and Japan were associated with infection with Seoul virus (SEOV), which is hosted by the rats *Rattus norvegicus* and *R. rattus*.[243,245,426] For more than 50 years, a similar, but generally milder, disease termed nephropathia epidemica (NE) was described in various parts of Scandinavia.[298] Following the isolation of HTNV, the virus was shown to react with sera from patients with convalescent phase NE.[298]

This led to the discovery of Puumala virus (PUUV) as the cause of this form of HFRS and the bank vole, *Myodes glareolus*, as the virus host. A fourth pathogenic hantavirus, Dobrava virus, was isolated from *Apodemus flavicollis* in Slovenia and causes severe HFRS in central and southeastern Europe and in European Russia.[317]

The most recent major event in the history of hantaviruses was the discovery of hantavirus pulmonary syndrome (HPS) in the southwestern United States in 1993.[297] A cluster of cases was first identified in New Mexico, which presented with a "flu-like illness" (i.e., fever, headache, muscle aches, chills, and so on), but rapidly progressed to a more severe respiratory disease with bilateral pulmonary infiltrates, respiratory failure, shock, and death, occurring approximately 2 to 10 days after onset of illness in almost 50% of the cases.[213] Within a couple of weeks of the initial outbreak, a newly identified virus, Sin Nombre virus (SNV), was shown to be the cause of HPS, and the rodent reservoir was shown to be the common deer mouse, *Peromyscus maniculatus*.[76,297] Within the next several years, HPS was shown to occur throughout the Americas from Canada to Patagonia, and was found to be caused by numerous hantaviruses, associated with various diverse rodent species.

Further genera of the Mammantavirinae subfamily

The genus *Thottimvirus* contains two shrew-borne viruses. Thottapalayam virus was isolated from an Asian house shrew (*Suncus murinus)* in Southern India although it was not recognized as a hantavirus until several years later.[65] Imjin virus was isolated from a musk shrew (*Crocidura lasiura*) shrews in the demilitarized zone of Korea.[350] Neither of these shrew-borne hantaviruses are known to be pathogenic to humans.

The name of the genus *Mobatvirus* is an amalgamation derived from "moles" and "bats." The prototype virus, Nova virus, was first detected in 2009 in archival liver tissue of the European mole (*Talpa europaea*) in Hungary.[202] Complete L-, M- and S- segment nucleotide sequences of a Nova virus strain circulating in Belgium demonstrated that this virus was related to, but highly divergent from, the orthohantaviruses and thus was placed into a new genus of the family.[236] The other two viruses in the genus, Laibin and

Quezon viruses, have been detected in bats, and complete genome sequences have been determined.[18,470]

The *Loanvirus* genus contains currently a single virus, Longquan virus. The virus was detected in intermediate horseshoe bats (*Rhinolophus affinis*) in China. Although it is phylogenetically distinct from other hantaviruses, it has not yet been isolated or characterized.[151]

Nairoviridae family

The *Nairoviridae* family comprises trisegmented negative-sense RNA viruses grouped into *Orthonairovirus*, *Shaspivirus*, and *Striwavirus* genera. Of these, the *Orthonairovirus* genus is the largest with 15 discrete species that are mostly maintained in tick hosts, but isolations have also been made from mosquitoes and midges. In contrast, the members of the *Shaspivirus* and *Striwavirus* genera were identified in spiders and water striders, respectively (Table 16.4). Information of these viruses outside of nucleotide sequence data is currently lacking, and consequently this text will focus on viruses within the *Orthonairovirus* genus.

The *Orthonairovirus* genus was named after Nairobi sheep disease virus (NSDV), which was originally isolated in Nairobi, Kenya, in 1910 by inoculation of sheep with the blood of sheep with acute gastroenteritis.[289] The virus causes fatal disease in sheep and goats and is present throughout various parts of Africa, and also India where it is known as Ganjam virus. The most important orthonairovirus from a human health perspective is Crimean–Congo hemorrhagic fever virus (CCHFV), which was first recognized in the Crimean peninsula in the mid-1940s, when a large outbreak of severe hemorrhagic fever among agricultural workers was identified. The outbreak included more than 200 cases with a case/fatality of about 10%.[78] Cases exhibiting similar disease were later reported throughout the European and central Asian republics of the former Soviet Union, to include Romania, and Bulgaria. However, the virus was first isolated in 1956 from a patient with a 1-day fever in Kisangani, Democratic Republic of Congo.[411] It was some years before the connection was established, but subsequent serologic studies and virus isolations from Asia and Europe revealed that the viruses from the different outbreaks and geographic regions were essentially the

same virus, which then became named CCHFV.[70,79] CCHFV is now endemic in over 30 countries across Africa, Asia, Europe and the Middle East,[38] with outbreaks centered around southeastern regions exhibiting highly variable case/fatality rates of up to 30%.

Peribunyaviridae family

The *Peribunyaviridae* family is the largest within the *Bunyavirales* order and includes four genera of tri-segmented negative-sense RNA viruses: the *Orthobunyavirus*, *Herbevirus*, *Pacuvirus*, and *Shangavirus* genera. Of these, 82 of the 89 species belong to the *Orthobunyavirus* genus, which is the only genus in this family to include animal and human pathogens, with select members associated with arthropod-borne hemorrhagic fevers with severe or fatal disease potential.

The Orthobunyavirus genus

The largest genus of bunyaviruses is the *Orthobunyavirus* genus (family *Peribunyaviridae*, order *Bunyavirales*), which contains almost 200 named viruses that are found throughout the world.[3,391] Almost all of these viruses are transmitted by mosquitoes and have amplification cycles in a variety of vertebrate hosts.[61] Among important orthobunyavirus human pathogens are La Crosse virus (LACV), which causes pediatric encephalitis; Oropouche virus (OROV), which causes a debilitating febrile illness; and Ngari virus, which causes hemorrhagic fever. In contrast, Aino, Akabane, Cache Valley, and Schmallenberg viruses are examples of viruses causing disease in domestic animals (Table 16.4).

Classification of orthobunyaviruses has proven to be complex. The majority of viruses have been placed in one of 20 serogroups based on serologic relatedness of complement-fixing antibodies (mediated by the N protein) and hemagglutinating and neutralizing antibodies (mediated by the glycoproteins), although a number of viruses classified into the *Orthobunyavirus* genus are currently not assigned to any of these serogroups.[3,391] The 20 serogroups are Anopheles A, Anopheles B, Bakau, Bunyamwera, Bwamba, California, Capim, Gamboa, Group C, Guama, Koongol, Mapputta, Minatitlan, Nyando, Olifanstlei, Patois, Simbu, Tete,

Turlock, and Wyeomyia. Serologic relatedness varies within a serogroup and is further complicated by the occurrence of natural reassortant viruses (Fig. 16.2), such that viruses may be more related to members of one group or another depending on the assay used.[59]

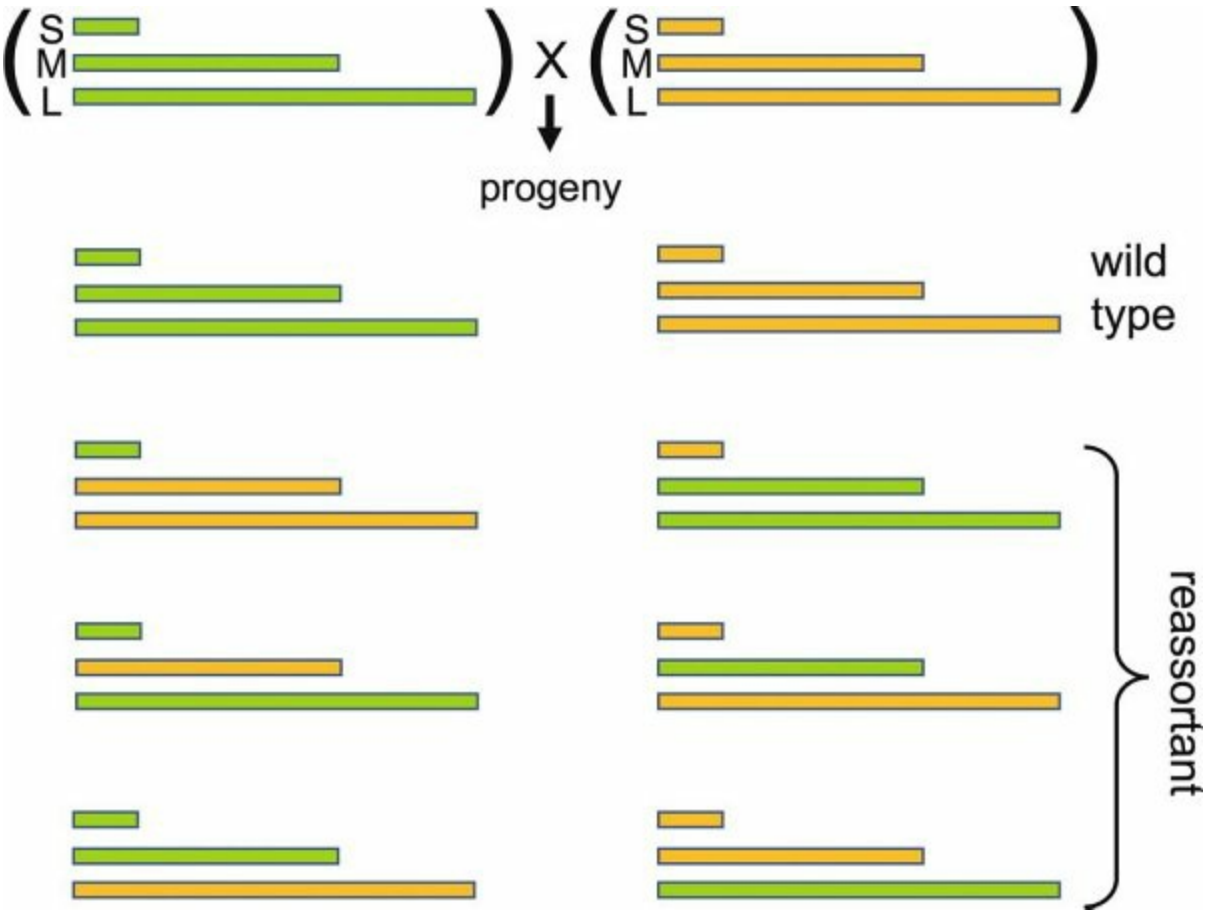

FIGURE 16.2 Reassortment of bunyavirus genome segments. When a cell is coinfected with two genetically compatible bunyavirus strains (parent 1 and parent 2), eight different genotypes can be represented in progeny virus: the two parental genotypes and six reassortant genotypes, each with two segments from one parent and one segment from the other parent.

Molecular genetic studies comprising all three genome segments of the orthobunyaviruses have been conducted on viruses in 13 of the serogroups,

namely Anopheles A, Bunyamwera, California, Capim, Gamboa, Group C, Guama, Koongol, Mapputta, Nyando, Simbu, Tete, and Turlock,[52,99,132,150,304,305,374,391] as well as several ungrouped orthobunyaviruses.[260,365] In many cases the S genome segment encodes two proteins, N and, in an overlapping reading frame, a small nonstructural protein termed NSs. N and NSs proteins are translated from the same viral messenger RNA (mRNA) molecule as the result of alternate AUG-initiation codon selection.[43,109] However, viruses in the Anopheles A, Anopheles B, Capim, Guama, Koogol, Mapputta, Tete, and Turlock serogroups as well some ungrouped orthobunyaviruses do not show evidence of having an NSs ORF.[132,391]

Phenuiviridae family

The *Phenuiviridae* family comprises a diverse collection of viruses grouped into 15 genera that infect vertebrates, invertebrates, and plants. Of these 15 genera, only 2 contain viruses known to be associated with significant human and animal disease, namely the *Phlebovirus* and *Banyangvirus* genera. These viruses possess trisegmented, partially ambisense RNA genomes and have been the primary focus of phenuivirus research to date. The other 13 genera comprise plant and arthropod viruses for which biochemical and molecular data are currently lacking.

Phlebovirus genus

The *Phlebovirus* genus (family *Phenuiviridae*, order *Bunyavirales*) contains more than 80 viruses, classified into 10 species. Phleboviruses orginated in ticks, and evolved into tick-borne and dipteran-borne viruses that are present throughout the world.[276] Most dipteran-borne species are associated with phlebotomine sandflies, hence the genus name *Phlebovirus* (see Table 16.4). However, there are prominent exceptions, such as Rift Valley fever virus (RVFV), a medically and agriculturally important virus in Africa, which is primarily associated with *Aedes* species mosquitoes, and the tick-borne apathogenic Uukuniemi virus (UUKV).[277]

RVFV, the type species, was first isolated in 1930 by Daubney et al. from an infected newborn lamb as part of an investigation of a large epizootic of

disease causing abortion and high mortality in sheep.[90] Large RVFV epizootics in various areas of sub-Saharan Africa have been noted since that time, and clinically compatible outbreaks have been retrospectively identified as far back as 1912.[103] Several decades passed before serologic and molecular similarities to phlebotomine fever viruses were noted. Sandfly fever Sicilian virus (SFSV), one of the most widespread phleboviruses, and Sandfly fever Naples virus (SFNV) were first isolated from American troops with febrile illness in the Palermo region of Sicily, Italy in 1943 and Naples, Italy in 1944, respectively, by inoculation of acute-phase sera into human volunteers and passage in newborn mice.[373] Outbreaks of compatible human illness in the Mediterranean region date back to the time of the Napoleonic Wars, and association of the disease with sandflies was suggested as early as 1905.[171]

Banyangvirus genus

The *Banyangvirus* genus (family *Phenuiviridae*, order *Bunyavirales*) contains the type species Huaiyangshan banyangvirus (better known as severe fever with thrombocytopenia syndrome virus (SFTSV) or Henan fever virus (HNFV),[469,472] which is prevalent in East Asia. The related Heartland virus (HRTV) is endemic in the United States.[281] Both viruses are tick-borne and are highly pathogenic.

Tospoviridae family

The Family *Tospoviridae* has only one genus, the *Orthotospovirus* genus, which includes 18 species of plant-infecting trisegmented ambisense RNA viruses[168,271] that are transmitted propagatively by at least 15 different species of thrips[461] of the *Thysanoptera* order[309,457] with the western flower thrip *Frankliniella occidentalis* identified as the primary vector. Several tospoviruses are now recognized as being of significant agricultural importance, inflicting massive losses in economically important crops, in major part due to the wide plant host range of *F. occidentalis* as well as the broad distribution of this vector across North and South America, Australia, Europe, and the Middle East.[142,342]

The history of the tospoviruses goes back to 1915, with the recognition of

a spotted wilt of tomatoes in Australia,[57] and then the subsequent isolation in 1930 of tomato spotted wilt virus (TSWV), from which the genus gained its name[230] and which remains the prototype of the genus. By the late 1940s, TSWV infections were greatly reduced in the United States and Western Europe due to pesticide use controlling the onion thrips, *Thrips tabaci*, which was likely the primary vector at that time. The geographic spread during the 1960s and 1970s of *F. occidentalis* led to a rapid expansion of TSWV[457] which is now known to be global in distribution, and it is found throughout agricultural areas in warmer climate zones and prevalent in greenhouse cultivations in more temperate areas. In contrast to the other genus members, TSWV has an unusually wide host range, with more than 925 plant species, including 82 botanical families, reported to be susceptible to infection. These include several important crops such as peanuts, peppers, tobacco, potatoes, peas, tomatoes, celery, lettuce, and ornamental flowers, with annual crop losses amounting to more than a billion dollars.[318]

VIRION STRUCTURE

Under the electron microscope, negatively stained bunyaviruses appear in most cases spherical to pleomorphic, 80 to 120 nm in diameter, and display surface glycoprotein (GP) projections of 5 to 10 nm, which are embedded in a lipid bilayered envelope approximately 5 to 7 nm thick (Fig. 16.3). Cryo-electron microscopic and tomographic techniques combined with computational three-dimensional reconstruction revealed the structures of virions at a resolution of about 2 to 3 nm (Fig. 16.4). Virions of BUNV orthobunyavirus (family *Peribunyaviridae*) are pleomorphic and approximately 108 nm in diameter.[51]

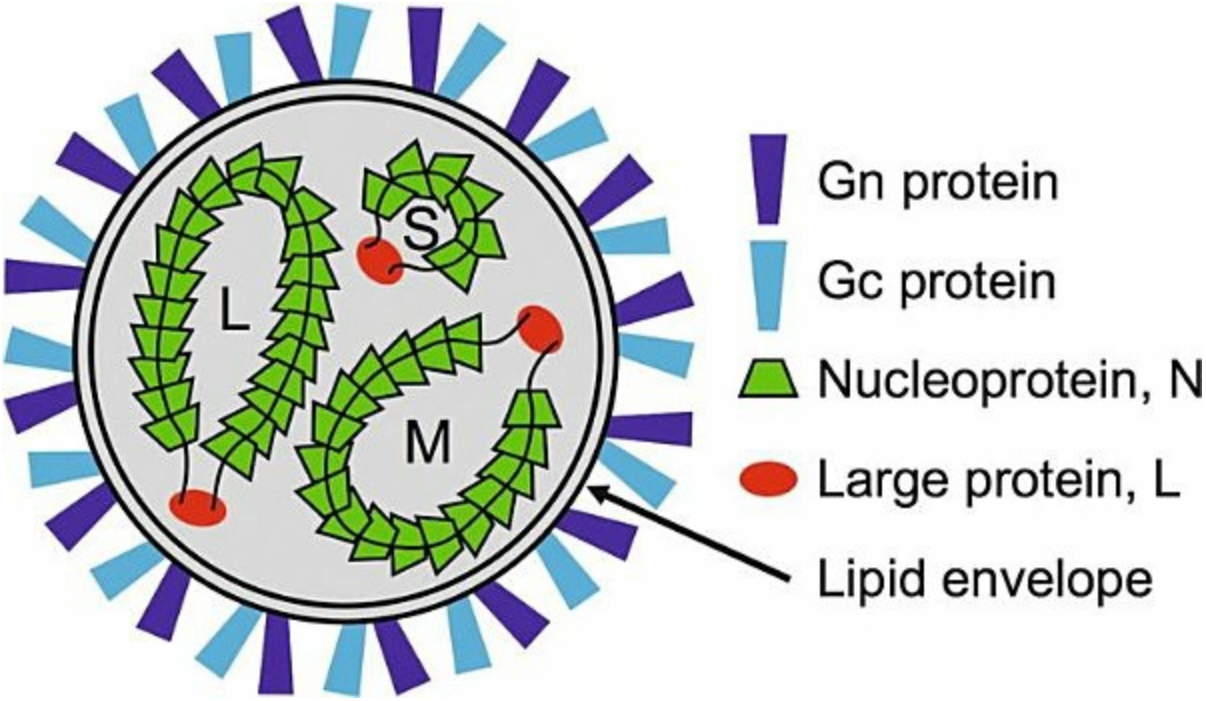

FIGURE 16.3 Schematic of a bunyavirus virion. The genome segments (commonly *S*, *M*, and *L*) are encapsidated by nucleocapsid protein (*N*) to form ribonucleoprotein complexes (RNPs), and together with the viral *L* protein (RNA dependent RNA polymerase, RdRp) are packaged within a host cell–derived lipid envelope modified by insertion of the viral glycoproteins Gn and Gc. Note that there is no matrix protein.

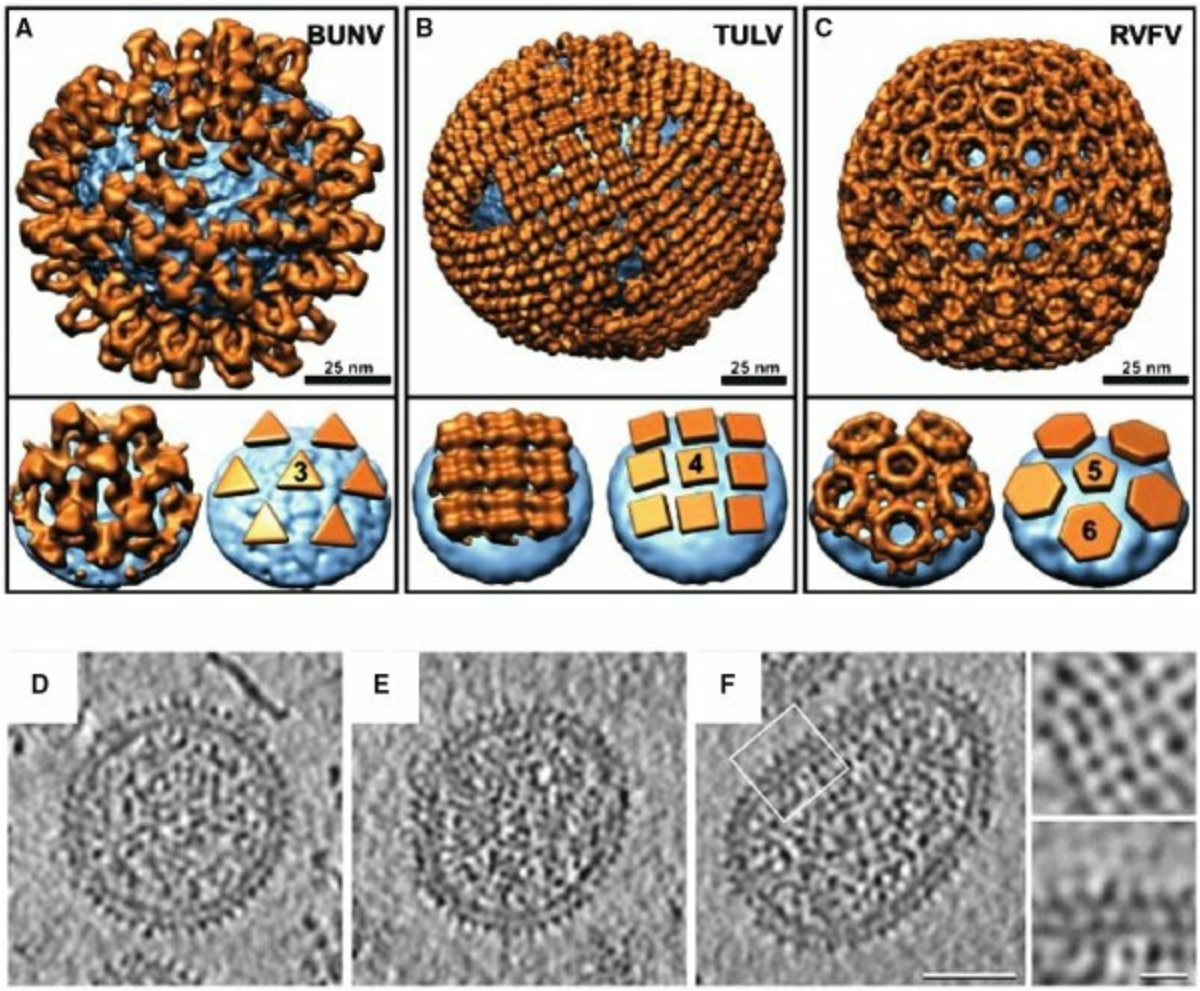

FIGURE 16.4 Structural diversity of bunyavirus surface glycoprotein architectures. A–C: Structures of Gn–Gc glycoprotein spikes (*orange*) are shown mapped onto the membrane surface (*cyan*) of **(A)** an orthobunyavirus (Bunyamwera virus; BUNV), **(B)** a hantavirus (Tula virus; TULV; EMD-170411), and **(C)** a phlebovirus (Rift Valley fever virus; RVFV; EMD-15507). At the bottom of each panel, a close-up view of a glycoprotein spike cluster (*left*) and a schematic representation of the spike arrangement (*right*) is shown. Symmetries of individual spikes are annotated. **D–F:** Central tomographic sections of three Hazara nairovirus (HAZV) virions, with fourfold symmetry of spikes shown in a tangential section. Scale bars represent 50 nm. (**Panels A–C** from Bowden TA, Bitto D, McLees A, et al.

Potassium is a trigger for conformational change in the fusion spike of an enveloped RNA virus. *J Biol Chem* 2018;293(26):9937–9944.)

Although several studies reported hantaviruses to be highly pleomorphic with spherical particles of 135 nm median diameter and tubular particles up to 350 nm long and approximately 80 nm in diameter, more recent EM and cryo-EM observations reveal a mostly spherical morphology, suggesting that mechanical stress likely contributed to earlier reports of pleomorphism.[35,170,180]

Virions of RVFV and UUKV phleboviruses (family *Phenuiviridae*) are distinct from all other bunyaviruses thus far characterized in that they are not pleomorphic but instead possess T = 12 icosahedral symmetry with mean diameters of approximately 100 and 125 nm, respectively.[122,181,313] The surface projections are thought to consist of equimolar heterodimers of the two viral GPs. They interact with each other to form family-specific surface morphologic units, namely 110 hexameric and 12 pentameric rings that form the well-defined and symmetric virions characteristic of this genus.[163,181,313,392] Whether this icosahedral symmetry is also a property of members of the other genera within the *Phenuiviridae* family is unknown, although electron microscopic images of SFTSV and HRTV (*Banyangvirus* genus) particles show regular, uniformly sized particles with similarity to phleboviruses.[281,472]

Orthobunyavirus virions (*Peribunyaviridae* family) have tripod-like GP spikes arranged with threefold symmetry in patches with gaps in between.[51] The surfaces of HTNV and Tula hantavirus (TULV) display spike projections with fourfold symmetry, and each spike contains four molecules of both glycoproteins. The fourfold symmetry is proposed to be maintained by homo-oligomerization of Gn and by interactions between Gn tetramers that interconnect to Gc dimers with one dimer at each face of the square-like spike.[35,170,180]

This localized architecture is also seen in the nairoviruses, with patches

of spikes exhibiting fourfold symmetry and extending in a discontinuous manner over the virion surface.[35,180,256,343]

To date, structural analyses of viruses within the *Tospoviridae* family to a similar resolution have not yet been reported, although negative-stain EM has confirmed the presence of GP projections, which are observed as a characteristic fringe.[284]

The viral GP spikes represent both the cell attachment and membrane fusion machinery, responsible for the merging of viral and cellular envelopes during the entry process (see later) and these must be active only at the appropriate stage of the virus multiplication cycle. Stage-specific activation is achieved by the induction of GP conformational changes that are both pH dependent and ion dependent and are driven by the biochemical properties of the milieu present within various cellular compartments through which viruses must pass during entry. pH- and ion-dependent conformational changes have been visualized for orthobunyaviruses, phleboviruses, and nairoviruses,[51,163,313,343] and it is suggested that such changes expose hydrophobic regions on Gc that facilitate fusion between the viral and endosomal membranes during viral entry, a mechanism observed for other enveloped viruses that enter cells via the endocytic pathway. In addition, specific lateral interactions between spike complexes are thought to induce membrane curvature during the budding process.

In contrast to the features on the virion exterior, the content of the virion interior is poorly resolved. Cryo-electron tomography reveals the presence of electron density consistent with the filamentous RNA segments in the form of ribonucleoprotein (RNP) complexes[51,97,181,256] and the proximity of this density located very close to the inner face of the viral envelope suggests a possible interaction with the cytoplasmic tails of one or both of the glycoproteins.[35,180,181,313,355] The precise architecture of bunyaviral RNPs within virions remains unclear, presumably due to their flexibility that complicates subtomogram averaging.

GENOME STRUCTURE AND ORGANIZATION

Viral Genome

The bunyavirus genome comprises two to eight single-stranded RNA segments, and at all stages of the multiplication cycle, these RNAs are enwrapped in the cognate N protein to form an N-RNA complex known as an RNP. For the classical trisegmented bunyaviruses within *Hantaviridae, Nairoviridae, Peribunyaviridae, Phenuiviridae, and Tospoviridae* families, these segments are designated according to their relative sizes: large (L), medium (M), and small (S). In contrast, for viruses with more than three segments, a numerical system is used. All segments sequenced to date possess a short stretch of up to 9 contiguous complementary nucleotides at their extreme 3′ and 5′ termini, with these being highly conserved among viruses within a family, but being distinct from those of viruses in different families (Table 16.3). Some degree of interterminal base pairing of these nucleotides is predicted to allow formation of stable panhandle structures, possibly driving the circularization of bunyaviral RNAs, and this suggestion is supported by direct visualization of purified RNPs by electron microscopy, as well as biochemical and genetic evidence (see later section).

Electron microscopic analysis of segments released from phlebovirus, orthobunyavirus, and nairovirus virions reveal pseudocircular structures,[332] again consistent with 3′ and 5′ terminal interactions, described above. These RNPs do not exhibit obvious helical symmetry, which is in stark contrast to those belonging to members of the *Mononegavirales* order for which their RNPs form compact and often rigid helices that assemble into rod-like structures.[370] Instead, bunyaviral RNPs appear highly flexible and with diameters on the order of 10 nm. In some instances the RNPs appear as "beads on a string," implying N protein monomers contact adjacent monomers only. In other instances, localized regions of compact helical symmetry are evident, suggestive of interactions between N monomers on successive turns of an ordered helix.[20,118,355,358,450]

At least one each of the individual RNPs must be contained in a virion for infectivity; however, equal numbers of nucleocapsids may not always be packaged in mature virions, as suggested by various reports of nonequimolar ratios of L, M, and S RNAs in natural virions or of elevated segment numbers in recombinant virions containing additional, artificial segments.[44,182,459,460] Unequal complements of the RNPs may contribute to the size differences of

virions observed by electron microscopy[35,431] and also argues against a selective packaging mechanism that several segmented RNA viruses from other taxonomic orders (like influenza viruses) appear to possess.[47,301] Whether a segment selection mechanism exists for other newly classified bunyaviruses with as many as eight segments remains to be determined.

In addition to RNPs containing virion-sense RNA (vRNA), certain viruses in the *Phlebovirus* genera and *Tospoviridae* family encapsidate small amounts of complementary sense (cRNA or antigenome). The phlebovirus UUKV was found to contain S- but not M-segment cRNA, and the tospovirus TSWV had both M and S cRNAs in virions.[228,408] For the orthobunyavirus LACV, S-segment cRNA was detected in virions synthesized in insect cells, but not in mammalian cells.[348] Interestingly, the phlebovirus RVFV encapsidated all three cRNA gene segments, and, as will be described later (see "S-segment products"), at least one of the cRNA genes may have a role in early replication processes.[187]

Coding Strategies of Viral Genes

All bunyaviruses follow a common strategy in which mRNAs for their structural proteins (N, Gn/Gc, and L) are transcribed from their vRNA, whereas their nonstructural protein mRNAs can be transcribed from either their cRNA or vRNA strands. Therefore, some viruses in the order *Bunyavirales* use only a negative-sense coding strategy, while others use a combination of negative-sense and also ambisense coding strategies (Fig. 16.1). For either of these strategies, the bunyaviral RdRp is capable of transcribing only one mRNA molecule from each cRNA or vRNA template, and the ability to alternatively promote either negative-sense or ambisense transcription is dictated by specific 3′ and 5′ terminal nucleotides that constitute the transcription promoter[29] such that viruses that utilize an ambisense transcription strategy possess transcription promoters in both vRNA and cRNA strands. For all bunyaviruses studied to date, their vRNA segments conform to a common arrangement in which nontranslated sequences containing transcription and replication promoters flank one or more open reading frames (ORFs) within a single transcriptional unit. In the following section, the coding strategies of only bunyaviruses that possess trisegmented genomes (S, M, and L) will be described, due to the current lack

of detailed information concerning the strategies of bunyaviruses with more than three segments.

S-Segment Strategies

Without exception, the S segment of all bunyaviruses encodes the corresponding viral nucleocapsid protein (N). While the S segment of some bunyaviruses expresses only the N protein,[287] in many instances, the S segment also has the capacity to express a second protein, known as NSs (nonstructural, S), either from an alternative ORF[43] (Fig. 16.1), or from an ORF accessed by ambisense transcription. The various bunyavirus NSs proteins exhibit low sequence similarity, but all have common functions relating to the mitigation of host innate immunity and apoptosis (see below). The presence of NSs in virus-infected cells was demonstrated for several members of the *Orthobunyavirus* genus[105] and, as only one S segment mRNA species is transcribed in orthobunyavirus-infected cells,[71] it was deduced that N and NSs were generated by alternative start codon recognition by leaky ribosome scanning[99,109] confirmed by rescue of NSs knock out BUNV from cDNAs.[55] In general, the S segments of members of the *Peribunyaviridae* family are the shortest within the order, although there are exceptions; Brazoran orthobunyavirus has a long S segment corresponding to its uncharacteristically large N protein[237] with a long C-terminal extension of unknown function.

Hantaviruses and nairoviruses encode larger N proteins than do viruses in other families, and so their S segments are also correspondingly larger (Table 16.1; Fig. 16.1).[275,385] Some hantaviruses (e.g., SNV, PUUV, TULV, Prospect Hill virus [PHV] and Andes virus [ANDV]), have second ORFs within their cRNAs, and a corresponding NSs protein has been detected in PUUV-, ANDV-, and TULV-infected cells.[189] For ANDV, expression of NSs was proposed to result from leaky scanning of the translation initiation codon for N.[441] An NSs protein has also been detected in CCHF orthonairovirus-infected cells[27] and it is thought to be translated from an NSs-specific mRNA generated by ambisense transcription, and to induce apoptosis.

The S segments of phleboviruses, banyangviruses, and tospoviruses are

ambisense, with N mRNAs transcribed from the genomic vRNA strand, and NSs mRNAs transcribed from the complementary cRNA strand (Fig. 16.1).[91,183,469,472] This dictates that expression of NSs relies on the presence of cRNA within cells, and it was first postulated that replication of the infecting S-segment vRNA was required to provide this cRNA template. Consistent with this, for the phlebovirus UUKV, N was detected at 4 to 6 hours after infection, whereas NSs did not appear until 2 hours later.[409,436] Likewise, the mRNA for NSs of the tospovirus TSWV was detected in infected plant cells 15 hours later than for N.[418] In addition, and consistent with a need for vRNA replication prior to NSs expression, studies with the phlebovirus Punta Toro virus (PTV) demonstrated that protein synthesis inhibitors arrest production of NSs mRNA, but not N mRNA.[185] In contrast, studies with the phlebovirus RVFV demonstrated the presence of cRNAs of all three RNA segments in purified virions, removing the need for a replication step prior to the access of ambisense ORFs. Moreover, mRNA for the NSs protein was detected as early as 20 minutes after infection, concomitant with the appearance of mRNA for N, suggesting that for RVFV the ambisense-encoded NSs mRNA is transcribed from incoming cRNA strands.[187]

M-Segment Strategies

Sizes of bunyavirus M segments range from approximately 3,600 to 5,300 nucleotides (Table 16.2). All bunyavirus M segments encode a single polyprotein precursor from a single ORF that is subsequently processed by cellular peptidases to yield at least two envelope GPs (Fig. 16.1) These GPs were previously designated G1 and G2 based on relative migration of the glycoproteins in polyacrylamide gels, but are now named Gn and Gc, referring to the amino-terminal or carboxy-terminal position of the proteins within the precursor.[238] As described below, it is becoming increasingly clearer that the functions of the Gn and Gc proteins are conserved among the bunyaviruses.

Some, but not all, bunyaviruses encode additional polypeptides from their M segments. For orthobunyaviruses, nairoviruses, and phleboviruses a nonstructural protein known as NSm is cleaved from the M-segment polyprotein precursor during the processing of Gn and Gc.

The roles of these NSm proteins are not yet clearly defined; genetically engineered RVFV lacking NSm was found to induce more extensive apoptosis than did one with NSm, and the expression of NSm significantly inhibited the cleavage of caspase 8 and 9 induced by staurosporine, indicating that the NSm protein suppresses apoptosis.[465] In addition, the detection of BUNV NSm in the proximity of virus assembly sites within the Golgi apparatus, as well as the activity of NSm knock out BUNV mutants, suggests the orthobunyavirus NSm may play a role in altering local cellular architecture to establish replication factories.[121]

In contrast, members of the plant-infecting *Tospoviridae* family express an NSm protein using an ambisense transcription strategy in which a subgenomic mRNA is transcribed from the cRNA template.[227,240] The tospovirus NSm protein is readily detected in infected plants and is the only M-segment nonstructural protein in the *Bunyavirales* order to have a clearly defined role, which is as a movement protein (see "M-Segment Products," below).

L-Segment Strategies

Without exception, the bunyavirus L segment encodes the RdRp, or L protein. The L segments of hantaviruses, orthobunyaviruses, phleboviruses, and banyangviruses are of similar size (~6,500 nucleotides), whereas those of tospoviruses and nairoviruses are considerably larger (~9,000 and 12,000 nucleotides, respectively; Table 16.2). All L segments of viruses in the order, except for arenaviruses, which are not discussed in this chapter, use conventional negative-sense coding strategies (Fig. 16.1) and there is no evidence for additional coding regions in either the cRNA or vRNA.[106,108,177,229,292,382]

STAGES OF REPLICATION

The principal stages of the replication process for viruses in the *Bunyavirales* order are illustrated in Figure 16.5 and are summarized in the following:

1. Attachment, mediated by an interaction of viral proteins and host receptors

2. Entry, predominantly by receptor-mediated endocytosis
3. Uncoating, by acidification of endocytic vesicles, and fusion of viral membranes with endosomal membranes
4. Primary transcription of viral-complementary mRNA species from genome templates using host-cell–derived primers and the virion-associated polymerase
5. Translation of S-, M- and L-segment mRNAs
    - cotranslational cleavage of M-segment polyprotein and postranslational cleavage of precursors for some viruses
    - dimerization of Gn and Gc in the endoplasmic reticulum (ER)
6. Membrane-associated RNA replication
    - synthesis and encapsidation of cRNA to serve as templates for vRNA or, for ambisense genes, templates for subgenomic mRNA
    - genome replication
7. Morphogenesis
    - localization of N in budding compartments
    - transport of dimerized Gn and Gc to the Golgi
    - glycosylation
    - acquisition of modified host membranes, generally by budding into the Golgi cisternae
8. Fusion of cytoplasmic vesicles containing viruses with the plasma membrane and release of mature virions
    - More rarely, some viruses in some cell types have been observed to bud directly from the host cell plasma membrane.

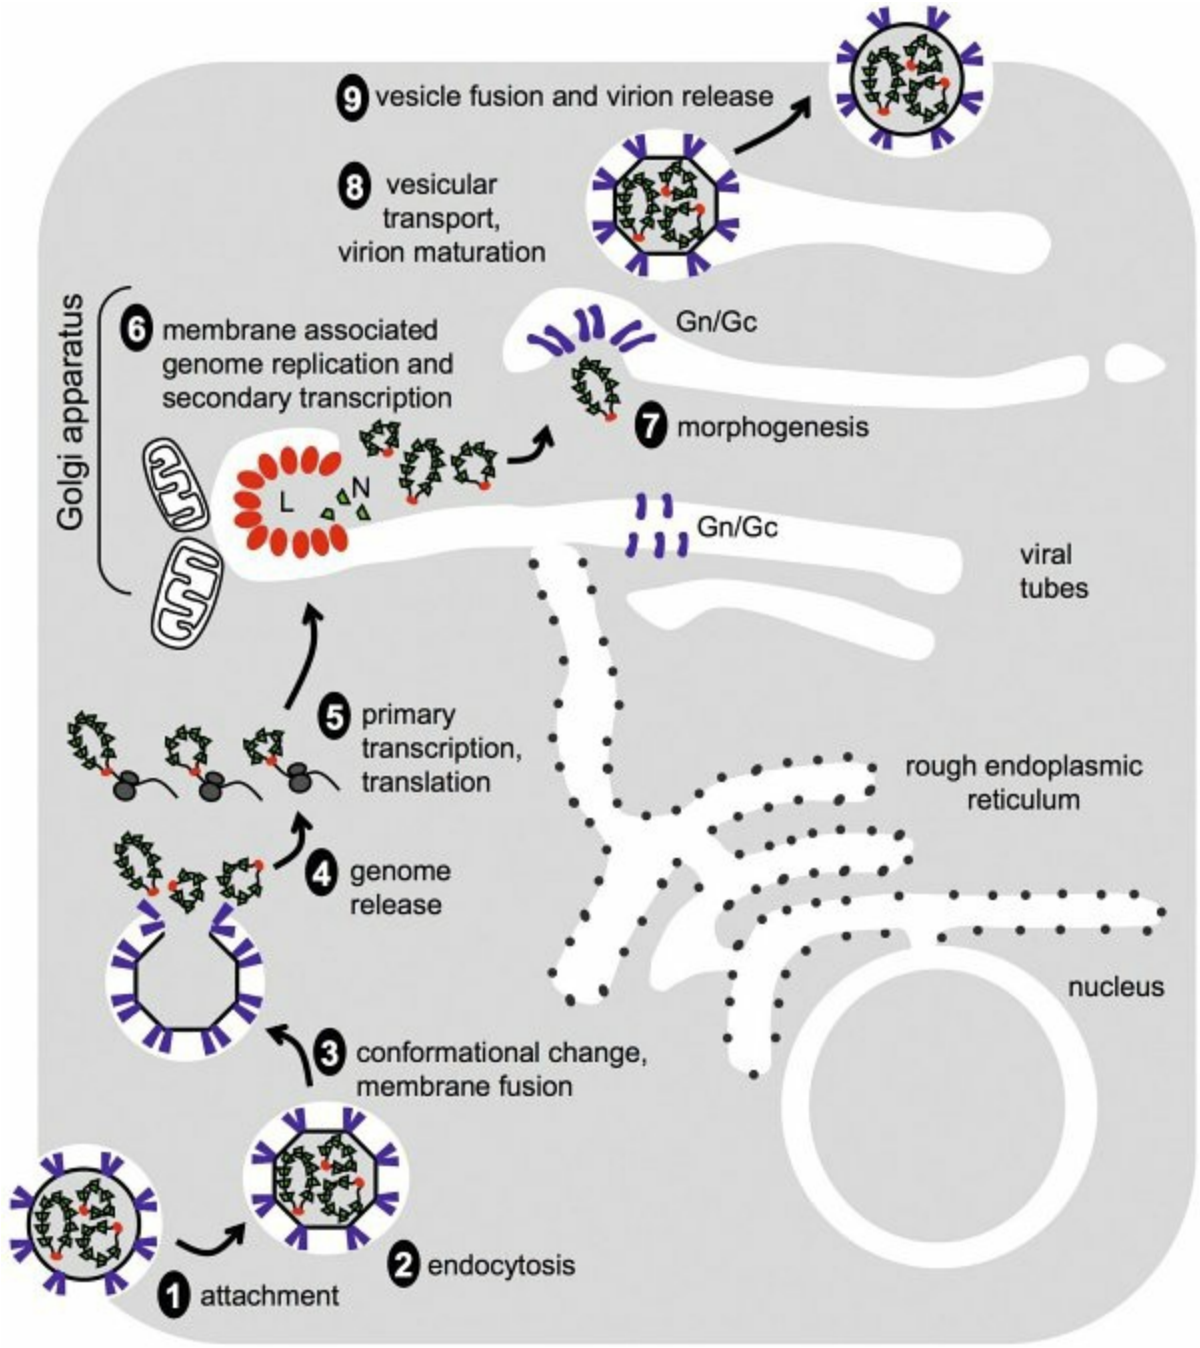

FIGURE 16.5 General virus multiplication scheme for members of the order *Bunyavirales.* Steps in the replication cycle are the following: *1*. Attachment, mediated by an interaction of viral proteins and host receptors; *2*. Receptor-mediated endocytosis; *3*. Uncoating, by acidification of endocytic vesicles, and fusion of viral membranes with endosomal membranes; *4*.

Primary transcription of viral-complementary messenger RNA (mRNA) species from genome templates using host-cell–derived primers and the virion-associated polymerase; *5*. Translation of L, M, and S mRNAs, cotranslational cleavage of the M-segment polyprotein, dimerization of Gn and Gc in the endoplasmic reticulum (ER); *6*. Membrane-associated RNA replication, synthesis, and encapsidation of cRNA to serve as templates for vRNA or, for ambisense genes, templates for subgenomic mRNA, genome replication; *7*. Morphogenesis including transport of the structural proteins to the Golgi, glycosylation of Gn and Gc, budding into the Golgi cisternae; *8*. Migration of Golgi vesicles containing viruses to the cell surface, fusion of vesicular membranes with the plasma membrane, and *9*, release of infectious virions. Some viruses in some cell types can bud both into intracellular vesicles and also from the plasma membrane.

Attachment and Entry

Viral Attachment Proteins and Cellular Receptors

The mechanisms by which bunyaviruses gain access to the host cell cytoplasm appear similar to those reported for many other enveloped viruses. The first step involves an interaction between cell surface exposed receptors, and the bunyaviral Gn and/or Gc glycoproteins. The presence of neutralizing and hemagglutination-inhibiting sites on both the Gn and Gc proteins of phleboviruses and hantaviruses[19,209] suggests that both proteins may be involved in attachment. However, it is more likely that both are needed due to conformational requirements that depend on dimerization of Gn and Gc.

In general, Gc appears to be the primary attachment protein for orthobunyaviruses in mammalian cells, mosquito cells, and mosquitoes.[160,216,427] Consistent with this view, expression of M-segment products of three orthobunyaviruses demonstrated that Gc, but not Gn, could affect attachment and entry when tested in a cell-to-cell fusion assay and a

pseudotype transduction assay.[335] However, the amino terminal half of BUNV Gc ectodomain is not required for infection of cultured mammalian cells,[399] and this region can be replaced by green fluorescent protein (GFP) allowing the creation of viable viruses expressing chimeric Gc-GFP in their virions.[404]

For tospoviruses, the envelope GPs are required only for infection of their arthropod vectors, as evidenced by the ability of envelope-deficient mutants to replicate in plants after mechanical transmission but their inability to infect thrips.[362] In addition, analysis of reassortant viruses demonstrated that mutations that disrupted the Gn-Gc ORF of TSWV ablated transmissibility by thrips.[412] These studies provide indirect evidence that the L-polymerase protein remains associated with ribonucleocapsids and is active despite the absence of intact virions.

Although there are no specific reports of Gc being the attachment protein of tospoviruses, functional homology to the Gc proteins of other bunyaviruses was proposed based on amino acid sequence homologies detected for iris yellow spot virus.[84] In contrast, however, a study with a soluble, truncated form of TSWV Gn produced by recombinant baculoviruses showed binding of this protein to epithelial cells in the midguts of thrips, suggesting that Gn could mediate attachment in these hosts.[456] Similar results were reported earlier with the orthobunyavirus LACV, in that virions treated with a protease that cleaved Gc but not Gn exhibited increased binding to the insect vector midgut but reduced binding to cultured mammalian or mosquito cells.[267] Given that both of these systems use a Gn protein in the absence of Gc, it remains to be determined whether Gn functions for attachment when in its native conformation on virions.

Host cell receptors have not been identified for most viruses in the order; however, pathogenic and nonpathogenic hantaviruses were shown to use β3 and β1 integrins, respectively, to enter endothelial cells.[133] This finding was suggested to relate to pathogenesis, in that binding of hantaviruses to integrins might disrupt their ability to regulate cell-to-cell adhesion and result in the vascular permeability characteristic of hantaviral diseases.[134] For two HPS-causing hantaviruses, ANDV and SNV, the human asthma-associated

gene protocadherin-1 was identified as an essential determinant of entry and infection in pulmonary endothelial cells. Hamsters genetically engineered to remove the gene were resistant to a normally fatal infection by ANDV.[193] In addition to these entry determinants, decay accelerating factor (DAF)/CD55, a glycosylphosphatidylinositol (GPI)-anchored protein, has been shown to mediate HTNV and PUUV entry across the apical membrane of polarized epithelial cells,[232] and gC1qR/p32, a 32-kD glycoprotein that interacts with complement protein C1q, binds HTNV and mediates infection of cultured A549 lung cells.[77]

Several phleboviruses and banyangviruses, including RVFV, UUKV, SFSTV, PTV, and Toscana virus (TOSV), have been shown to use the C-type lectins DC-SIGN or L-SIGN (also known as DC-SIGNR) as receptors for infecting dendritic cells or liver sinusoidal endothelial cells, respectively. DC-SIGN was also found to be required for both binding and internalization of UUKV, whereas L-SIGN only promoted binding.[8,174,248,265] In addition, DC-SIGN has been implicated as a receptor for CCHFV and LACV.[174,425] Other factors identified to promote bunyavirus infection include heparan sulfate for RVFV and TOSV, nucleolin for CCHFV, and a thrips midgut 50-kDa protein for TSWV.[8]

Aside from the requirement of specific host gene products, many bunyaviruses have been shown to be highly sensitive to perturbation of cholesterol biosynthesis pathways for their entry,[218,330,407] and it has been postulated that cholesterol modulates virus entry by facilitating the interaction of the viral fusion machinery with target endosomal membranes.[437]

Entry of the Viral Genome into the Host Cytoplasm

Shortly after attachment, viruses in the *Phlebovirus* and *Orthonairovirus* genera were observed in phagocytic vacuoles.[110,372] This suggested a mode of viral entry similar to that first described for alphaviruses in which the virus is endocytosed in coated vesicles, and inhibitor studies have confirmed this to be so for the animal-infecting bunyaviruses. Orthobunyaviruses, hantaviruses, and nairoviruses enter by clathrin-mediated

endocytosis,[130,199,381,407] and HTNV proteins were shown to colocalize with clathrin in confocal immunofluorescence studies.[199] Although clathrin-mediated endocytosis appears to be most common for bunyaviruses, other entry mechanisms have been reported, to include caveolae-mediated endoctytosis and macropinocytosis for RVFV,[167] and undefined nonclathrin as well as clathrin-mediated entry routes for the hantaviruses SNV and ANDV.[75] Likewise, UUKV phlebovirus has been found to enter cells predominately in a clathrin-independent manner.[266]

After endocytosis, acidification of the endocytic vesicles is thought to promote a conformational change in Gn and/or Gc that facilitates fusion of the viral and cellular membranes, thereby allowing the viral genome in the form of an RNP with its associated polymerase access to the cytoplasm. Consistent with pH-dependent fusion and entry, infection by several bunyaviruses was shown to be blocked by treatment with ammonium chloride to prevent endosomal acidification.[191,335,381,401] Additional indirect support for membrane fusion as a mode of entry came from experiments demonstrating the ability of viruses in the family to mediate syncytia formation at low pH.[119,145,191,308,335,401,458]

Of the bunyaviruses studied to date, most appear to traffic through the early endosomes (EE) to the more acidic late endosomes (LE) where fusion is triggered.[264] Infection by CCHFV, as well as UUKV and certain hantaviruses, have been reported to use functional microtubules, which are known to be required for directing LE toward the nucleus.[406] CCHFV and LACV, however, have both been found to infect cells in the absence of Rab7, a critical component of LE fusion, indicating that the viruses do not traffic to LE[130,175] Instead, CCHFV was found to enter the cytosol via multivesicular bodies just prior to transitioning from EE to LE.[405] In addition to a role for low pH in virus entry, the use of inhibitors of specific cellular ion channels has shown that the concentration of potassium ions within specific cellular compartments also influences bunyavirus entry[179] (Fig. 16.6). Biochemical analyses suggest that the escape of RNPs from endosomes requires an influx of potassium ions that depends on the activity of cellular potassium ion channels, located within endosomal membranes. Structural studies show that

elevated levels of potassium ions directly influence the conformation of the viral Gn/Gc spikes, activating their fusogenic properties, which likely promotes fusion between virion and endosomal membranes.[343] Potassium channel blockade prevents virus escape, and virions are trafficked to later compartments within the endosomal pathway, or lysosomes, where they are inactivated by low pH.[179]

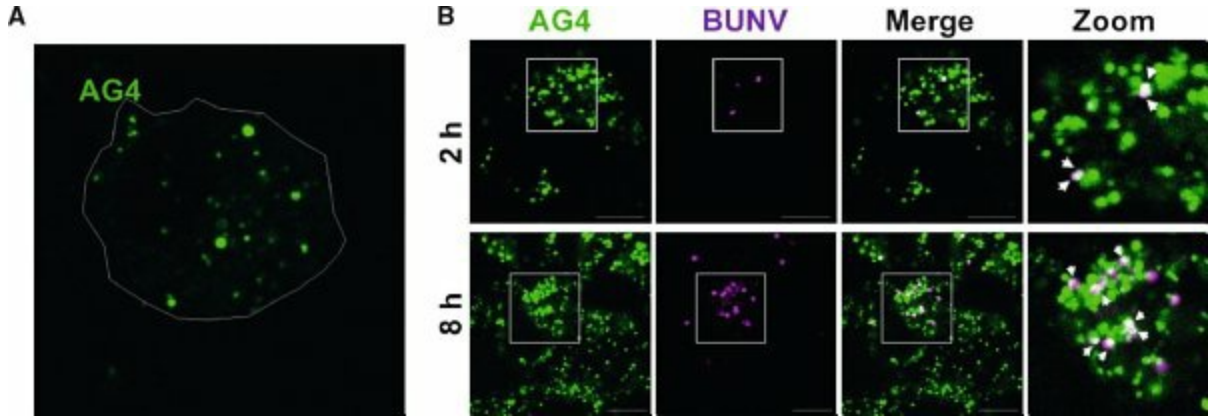

FIGURE 16.6 BUNV traffics through endosomes containing K^+ ions. A: K^+-containing vesicles can be labeled with the membrane-impermeable K^+-specific fluorescent probe Asante potassium green-4 (AG4), the membrane-permeable form of which has previously been used to monitor cytoplasmic [K^+]. AG4 (10 μM) was added to A549 cells for 40 minutes to allow endosomal uptake, and live cells were imaged. Representative images are shown ($n \geq 100$ cells). Scale bar = 10 μM. **B:** A549 cells were infected with a fluorescently labeled BUNV in the presence of AG4 (10 μM) to allow virus penetration into cells, and live cells were imaged 2 or 8 hours postinfection. Images are representative of ≥50 cells. (Taken from Hover S, Foster B, Fontana J, et al. Bunyavirus requirement for endosomal K+ reveals new roles of cellular ion channels during infection. *PLOS Pathog* 2018;14(1):e1006845.)

High-resolution structural studies (see below) have revealed that the bunyaviral Gc proteins have characteristics similar to those of class II fusion proteins identified for positive-sense RNA viruses in the *Flaviviridae* and *Togaviridae* families,[131] raising interesting questions concerning the evolution of these virus groups. Such proteins have internal fusion domains known as fusion loops, as opposed to terminal fusion peptides found for the class I fusion proteins. Experimental support for this finding was obtained by demonstrating interaction of the fusion loop postulated for the Gc protein of the hantavirus, ANDV, with artificial membranes.[435] In addition, several lines of evidence indicate that the Gc of orthobunyaviruses is involved in membrane fusion. Protease sensitivity assays, detergent partitioning experiments, and antibody-binding studies suggest that Gc undergoes a conformational change at pH conditions where fusion is observed.[144] Mutational analyses of a hydrophobic region (residues 1,066–1,087) of LACV Gc that is well conserved among different orthobunyaviruses[84] supported this notion,[191,336] and the residues flanking the predicted fusion peptide in BUNV Gc (residues 1,058–1,079) were shown to be structurally critical for the conformational change in Gc that occurs during the fusion process.[399] LACV Gc alone, however, when expressed from recombinant vaccinia viruses, could not cause cell fusion, suggesting that an association of the two GPs may be needed for activation of the fusion machinery,[191] and mutations in the cytoplasmic tail of BUNV Gn severely affected fusion activity indicating that Gn must also play an important role in this process.[401] Likewise for HTNV, both Gn and Gc were required to achieve surface expression and cell-to-cell fusion activity.[308] Recombinant LACV carrying mutations in the Gc fusion peptide was impaired for growth in both mammalian and insect cells but were still neurotoxic to neuronal cells, implying that the fusion peptide is a determinate of neuroinvasiveness but not necessarily neurovirulence.[415]

Transcription and Replication

After release of the virion-associated segments from within the virus particle, the initial RNA synthetic event is primary transcription in which each vRNA is transcribed as a complementary mRNA by the RNP-associated RdRp. *In*

vitro experiments showing transcriptional activity of permeabilized purified virions as well as atomic structures show that the RdRp is located at the vRNA termini of each RNP segment while still inside the infecting particle, positioned alongside the transcription promoter.[138,323] Thus, it can commence primary transcription upon release into the cytosol.

Studies with hantavirus N protein suggest that N participates in transcription initiation by facilitating dissociation of the RNA panhandle and by subsequently remaining attached to the 5′ terminus of the RNA, thereby freeing the 3′ terminus for RdRp interactions. Furthermore, N was suggested to be important for replication by acting as an RNA chaperone and transiently and continuously unfolding the RNA to allow it to form more stable structures.[285] A role for N in both transcription and replication is also evident by analysis of the behavior of BUNV N proteins carrying specific mutations, either in a minigenome assay or in the context of virus infection.[20,104,448] BUNV N mutants could be divided into two groups, those that were defective in antigenome synthesis but not mRNA transcription, and those that were replication defective but transcription competent, suggesting that different domains within N are associated with different RNA synthesis activities.[104] The mechanism by which residues in N modulate template activity requires elucidation; one possibility is that transcription and replication require different binding partners that interact with distinct regions on the N protein, or alternatively that these mutations result in subtle conformational changes in N that modulate its function.

Genome Promoters

The template for bunyavirus transcription and replication is not naked RNA but instead is an RNP in which the RNA is enwrapped with the corresponding N protein to form a flexible assembly that is resistant to RNase digestion.[100,262,288,356] Extensive analysis of the RNA synthesis activity of model RNA segments from members of the *Phlebovirus* and *Orthobunyavirus* genera have revealed that nucleotides within the 3′ and 5′ nontranslated regions of these RNPs contain signals for both mRNA transcription and genome replication. Furthermore, targeted mutagenesis of these regions has helped define the roles of individual nucleotides in promoting these activities. For the phleboviruses RVFV and UUKV, the first

13 or the first 10 nucleotides, respectively, of the 3′ end of the genome are sufficient for RNA synthesis activity,[120,340] whereas for the orthobunyavirus BUNV, at least 17 nucleotides at each of the termini are required for detectable levels of RNA replication.[288]

For BUNV, studies have suggested that at the extreme 3′ and 5′ termini, precise nucleotide sequence rather than complementarity is required to form the RNA synthesis promoters. A striking example is in the role of the conserved nucleotide mismatch located among a run of otherwise perfect complementary residues, which is a common feature of many bunyaviruses. Saturation mutagenesis showed that this 3′ position 9 must be a U residue in order to signal maximal transcription, and this signaling ability was completely independent of the corresponding 5′ position 9[32]; thus, arguing against the need for interterminal cooperation within these initial nucleotides.

However, for BUNV and other orthobunyaviruses, there is considerable evidence in support of a counterargument, suggesting 3′ and 5′ terminal interactions are important; Firstly, the precise nucleotides that form the BUNV transcription promoter have been identified and shown to constitute nucleotides within both 3′ and 5′ termini,[29] a finding that implies the polymerase must contact both termini during transcription initiation.[31,223] Secondly, genetic manipulation of model BUNV segments revealed RNA synthesis was promoted only when potential interterminal interactions within terminal-distal nucleotides (residues 12–15) were maintained, independent of specific nucleotide sequences.[31] In addition, inter-terminal secondary structures were identified in virion-associated RNAs following psoralen cross-linking.[172,348]

Interestingly, the recently solved crystal structure of the orthobunyavirus LACV RdRp in complex with 3′ and 5′ terminal RNAs suggested that the termini interact with separate sites on the polymerase surface. Nucleotides 1 to 8 of the 3′ end bind as a single extended strand whereas 5′ nucleotides 1 to 10 form an intraterminal stem-loop “hook” structure,[138] suggesting that interaction between the two termini may not actually be due to interterminal base pairing, but instead mediated by the polymerase (see below). However, it is possible that the existence of inter- and intraterminal interactions are not mutually exclusive, and both forms may be required at different stages of the

virus replication cycle. Thus, it is likely that some regions of the 3′ and 5′ termini form sequence specific signals, whereas other sequences form signals based on structure. Moreover, by setting progressive terminal deletions it was found that the minimal BUNV RNA replication promoters comprise 17 nucleotides from each end,[288] but that production of infectious virus also requires additional segment-specific sequences in the untranslated regions (UTRs),[263] presumably for activities other than RNA synthesis such as virus assembly.

The *in vivo* importance of intact termini was also suggested by a study in which terminally deleted RNAs were shown to accumulate during the establishment of persistent infections with the hantavirus, SEOV. It was hypothesized that as deletions accrued, fewer replication-competent genomes were present, leading to a down-regulation of the replication processes, and possibly to persistence.[282] Similar deletions were found on the termini of ANDV M and L, but not S genes, leading to a speculation that differences observed in the relative abundance of Gn and Gc compared to N could reflect down-regulation of M-segment expression from genes without intact termini.[314]

Primed mRNA Synthesis (Cap Snatching)

Like influenza viruses, viruses in the *Bunyavirales* order prime mRNA synthesis with capped oligoribonucleotides that are scavenged from host mRNAs (Fig. 16.7). However, unlike influenza viruses, which take primers from newly synthesized mRNAs in the host cell nucleus, members of the order *Bunyavirales* use primers cleaved from host cell mRNAs in the cytoplasm. Work with influenza virus has shown that cap snatching requires both cap-binding and endonuclease activities, which are encoded within different polymerase subunits. For bunyaviruses, generation of the capped primers is accomplished by an endonuclease domain belonging to the PD-D/ExK superfamily of cation-dependent nucleases[95,117,176,219,290,323,357,359,368,446] and in all bunyavirales members examined thus far, the endonuclease domain resides within the N-terminus of the respective proteins. Comparison of endonuclease domains from segmented negative-stranded RNA viruses revealed them all to possess structural similarity, but two distinct classes were apparent: one with a canonical catalytic histidine (His+) as exemplified by

influenza virus and bunyaviruses and another class in which this histidine is replaced by an acidic residue (His-), typified by the arenaviruses.[117,176,357] In contrast to the endonuclease domain, no cap-binding domain has yet been identified for any bunyavirales member, although comparison between the segmented architecture of the influenza virus RdRp alongside the monomeric bunyavirales L protein suggests it is likely to reside within the C terminus. It is also thought that the distance between the cap-binding and endonuclease domains dictates the length of the snatched primer. In the case of the bunyaviruses, this appears to fall within a characteristic range for viruses within the different families, with mean lengths of between 10 and 20 nucleotides.[50,74,98,129,197,338,410] In the case of influenza virus, the endonuclease is sequence specific, with the RNA cleavage event preferentially occurring between 10 and 13 nucleotides downstream of the cap, at a G residue.[89] There is some evidence to suggest that the site of bunyaviral primer cleavage may also be sequence dependent, with certain snatched primer sequences being selected over others. During TSWV transcription, the TSWV mRNAs acquired 5′ extensions with a preference for cleavage at an A residue.[98] It was suggested that this preference was due to a need for base pairing at the ultimate U residue of the TSWV gene segments. Consistent with this, later studies indicated that double- and triple-base complementarity to nucleotides at the ends of the tospovirus gene segments were preferred, even more than the single complementary residue.[439]

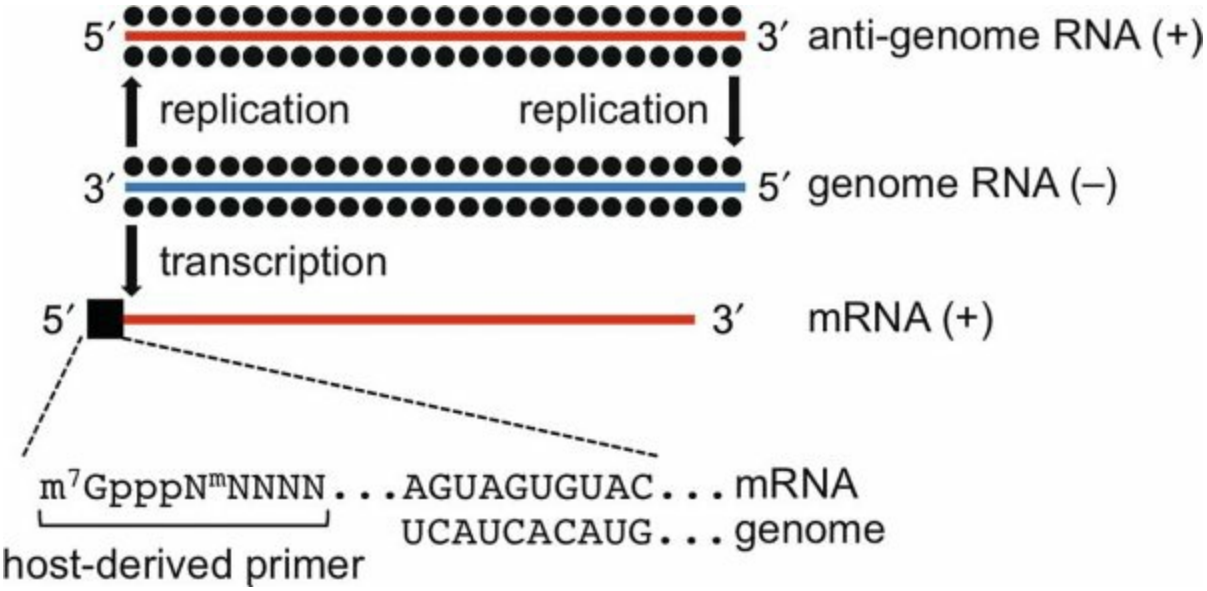

FIGURE 16.7 Transcription and replication scheme of negative-sense bunyavirus genome segments. The genome RNA and the positive-sense complementary RNA known as the antigenome RNA are found only as ribonucleoprotein complexes and are encapsidated by N protein (●). Segments are shown as linear RNA molecules for simplicity, whereas all available evidence suggests the active templates for RNA synthesis are circularized by noncovalent terminal interactions. The messenger RNA (mRNA) species contain host-derived primer sequences at their 5′ ends (■) and are truncated at the 3′ end relative to the virion RNA (vRNA) template; the mRNAs are neither polyadenylated nor encapsidated by N protein. The sequence at the 5′ end of an orthobunyavirus mRNA is shown.

Other viruses in the order also have nucleotide or nucleotide motif preferences for endonuclease cleavage of capped primers. These preferences vary among the families and genera, and sometimes even among viruses within a genus. A preferred primer sequence, or a favored nucleotide at the site of cleavage due to a need for limited base pairing with the viral genome, appears to be a common feature of primed transcription for bunyaviruses. In one study, the 3′-terminal nucleotides of the scavenged host primers often

were similar to the 5′-terminal viral nucleotides.[197] It was proposed that after transcription of two or three nucleotides of the nascent mRNA, the viral polymerase slips backward on the template before further elongation, resulting in a partial reiteration of the 5′-terminal sequence. An extension of this concept, termed “prime and realign,” was proposed for mRNA transcription of hantaviruses.[129] According to this model (Fig. 16.8), priming by host oligonucleotides with a terminal G residue would initiate transcription by aligning at the third nucleotide of the viral RNA template (C residue). After synthesis of a few oligonucleotides, the nascent RNA could realign by slipping backward two nucleotides on the repeated terminal sequences (AUCAUCAUC) (Table 16.3), such that the G becomes the first nucleotide of the nontemplated 5′ extensions (Fig. 16.8). The frequent deletion of one or two of the triplet repeats in hantaviral mRNA supports this sort of slippage mechanism and suggests that sometimes the initial priming might start at the C residue of the third triplet in the conserved sequence rather than at the C of the second triplet.[129]

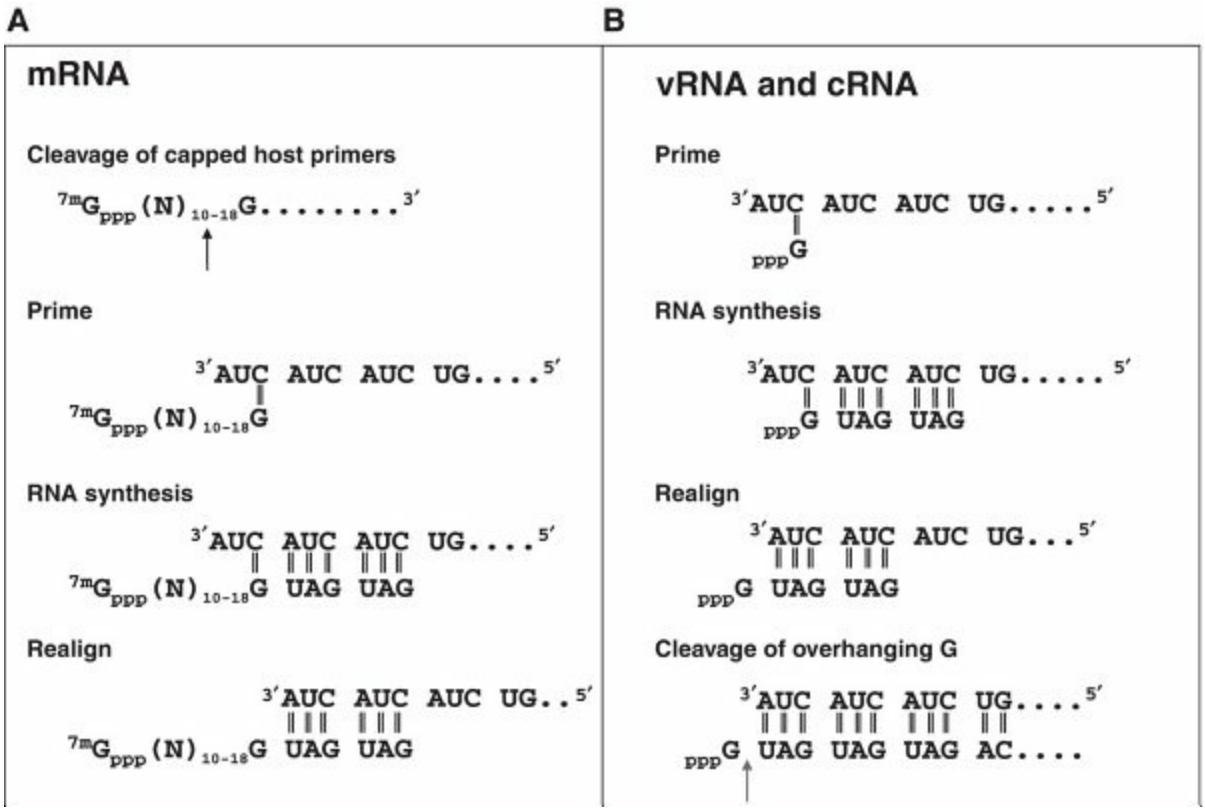

FIGURE 16.8 Prime- and- realign models for primary transcription and genome replication as illustrated to occur for a hantavirus. [129] **A:** Primed messenger RNA (mRNA) transcription. According to this model, priming by host oligonucleotides with a terminal G residue would initiate transcription by aligning at the third nucleotide of the viral RNA template (C residue). After synthesis of a few nucleotides, the nascent RNA realigns by slipping backward two nucleotides on the repeated terminal sequences (AUCAUCAUC), such that the G becomes the first nucleotide of the nontemplated 5′extension. **B:** Nonprimed transcription of vRNA and cRNA. In the model, transcription initiates with pppG aligned at the third nucleotide (C residue) of the template RNA. After synthesis of several nucleotides, polymerase slippage realigns the nascent RNA such that the initial priming G residue overhangs the template, but is subsequently removed (perhaps by nucleolytic activity of the L protein) leaving a monophosphorylated U residue at the nascent 5′ end.

A problem that the bunyaviruses must overcome is in locating sufficient capped mRNAs to support viral transcription. In the case of hantaviruses and phleboviruses, evidence has been presented that one such source may be cytoplasmic processing bodies (P bodies) that contain much of the RNA decay machinery where 5′ caps are sequestered, including the canonical mRNA decapping enzyme Dcp2. In the case of RVFV, a genome-wide RNAi screen in insect cells identified Dcp2 as a viral restriction factor, possibly reducing the pool of available capped mRNA substrate and thus restricting RVFV gene expression.[178] In the case of hantaviruses, the N protein accumulates in P bodies where it is thought to bind to the 5′ cap of cellular mRNAs to protect them from cell-mediated degradation, also maintaining the pool of cellular messages for subsequent use as cap substrate.[157]

Transcription Termination

The mRNAs transcribed by the nonsegmented negative-stranded RNA viruses resemble host cell mRNAs in that they are 5′ capped and possess 3′ poly(A) tails, and mRNAs generated by the segmented negative-stranded influenza virus also fit this description. However, this does not appear to be the case for most members of the *Bunyavirales* order; while their 5′ ends are capped, their 3′ ends do not in general possess 3′ poly(A) tails.[1,325,436] The only instance where a poly(A) tail has been identified on a bunyavirales transcript is the M-segment mRNA from SNV hantavirus,[182] which also contains a U-tract that in nonsegmented negative-sense RNA viruses is the template for reiterative transcription coupled to termination.[33,389] In all other instances where bunyaviral mRNA ends have been identified, the 3′ end has mapped to either the vRNA 5′ end, indicating run-off transcription,[182] or alternatively, putative transcriptional termination signals.[7,30,188,239]

Transcription termination is well studied for members of the orthobunyavirus group, for which synthesis of M- and S-segment mRNAs terminates between 40 to 100 nucleotides before the end of the genome RNA template, and L-segment mRNAs thought to be terminated by run-off.[85,86,112,198,324] By using a system in which the RNAs generated from mutated S segments were directly visualized, the transcription termination signal for the orthobunyavirus BUNV was mapped to a 33-nucleotide region within the 5′ nontranslated region of the S segment[30] with a 6-nucleotide motif, 3′-GUCGAC-5′, being particularly critical for termination signaling. Interestingly, a second redundant termination signal was also identified further downstream, with the related sequence, 3′-UGUCG′-5′, and a similar motif was observed within the BUNV L, but not the M segment.[30] Detailed experimental mapping of BUNV M and L mRNA termination sites has not been reported. The finding that there were no U-rich regions in the transcription termination signal of BUNV was consistent with the absence of 3′ poly-A tails on the mRNAs.

Comparison of these S-segment sequences with those of other orthobunyaviruses revealed a high degree of conservation, suggesting that similar motifs may also function for transcription termination throughout the genus, at least for S segments. A cross-genus comparison of orthobunyaviral

mRNA 3′ ends also revealed the presence of sequences with the potential to form short stem loop structures, outside of the conserved hexanucleotide sequence.

In contrast to the orthobunyaviruses that perform strictly negative-sense transcription, viruses that use an ambisense transcription strategy, such as the phleboviruses and tospoviruses (and also arenaviruses—see chapter 18), possess segments with a different arrangement of *cis*-acting signals. One of these differences is a centrally located untranslated sequence known as the intergenic region (IGR). Although the IGR sequences are diverse across the various families, they mostly possesses the potential to form stem-loop secondary structures,[214] and previous work has suggested these structures may play a role in transcription termination.[80,91,111,148,149,410] However, the likelihood of hairpin formation in the IGRs of RVFV, TOSV, and SFTSV phleboviruses has been questioned[7] and detailed mapping of mRNA termination sites for the corresponding N and NSs mRNA showed that the 3′ ends contained most of the intergenic sequence and indeed overlapped each other.[7] Furthermore, termination occurred for both mRNAs at the same motif, 3′-$C_{1\text{-}3}$GUCG/A-5′, which was also identified as the termination signal in the negative stranded M segment. Two copies of this motif were identified in the ambisense S segment, one in vRNA (genome) and one in the cRNA (antigenome), and thus it was proposed that transcription termination was signaled by a specific sequence motif rather than a secondary structural element. The similarity between this phleboviral termination signal and that identified for orthobunyaviruses described above is striking and points toward a common mechanism.

Sequences within the 3′ nontranslated regions of bunyaviral mRNAs have been shown to enhance mRNA translatability,[46,442] possibly providing functions that are normally associated with the canonical mRNA poly(A) tail and its synergistic association with the 5′cap.[127] While the precise identity or function of this enhancing element are currently unknown, one possibility is that the secondary structures found within most bunyaviral mRNA 3′ ends are involved.[46]

Bunyavirus transcription is unique among negative-sense RNA viruses in that it requires ongoing protein synthesis,[28,325,346,347,349,444] a finding that at face

value appears incompatible with the presence of a virion-associated transcriptase. In the absence of protein synthesis, only short transcripts are produced *in vivo* and *in vitro*, although if the *in vitro* reaction is supplemented with rabbit reticulocyte lysate, full-length RNAs are synthesized. The translational requirement is not at the level of mRNA initiation, but rather during elongation or, more precisely, to maintain transcriptase processivity. A model to account for these observations suggested that in the absence of ribosome binding and protein translation, the nascent mRNA chain and its template could base-pair, thereby preventing progression of the transcriptase.[37] The translational requirement (Fig 16.9) was formally proven using BUNV model templates containing translational stop codons[28] in which the presence of in-frame stop codons within the transcriptional unit reduced polymerase processivity, with termination events occurring at specific locations resembling transcription termination signals. In contrast, out of frame stop codons had no influence on polymerase processivity, and transcription termination signals placed immediately downstream of stop codons were unrecognized. Taken together, these observations are consistent with a model in which the translocation of a ribosome along the nascent mRNA alters RdRp processivity, in particular in the recognition of consensus or spurious transcription termination signals. Similar findings have been reported for RVFV[239] and thus orthobunyaviruses and possibly phleboviruses appear to have adopted a mechanism whereby transcription and translation are coupled, a feature commonly found in prokaryotes but rare in eukaryotic cells where these processes are compartmentalized. The dependence of transcription on translation has an important implication for the very first stages of the cytosolic phase of the virus replication cycle, as upon release from the infecting virion the bunyaviral RNP/polymerase complex must first sequester ribosomes in order to maintain polymerase processivity and commence primary transcription. How this is achieved is currently unknown.

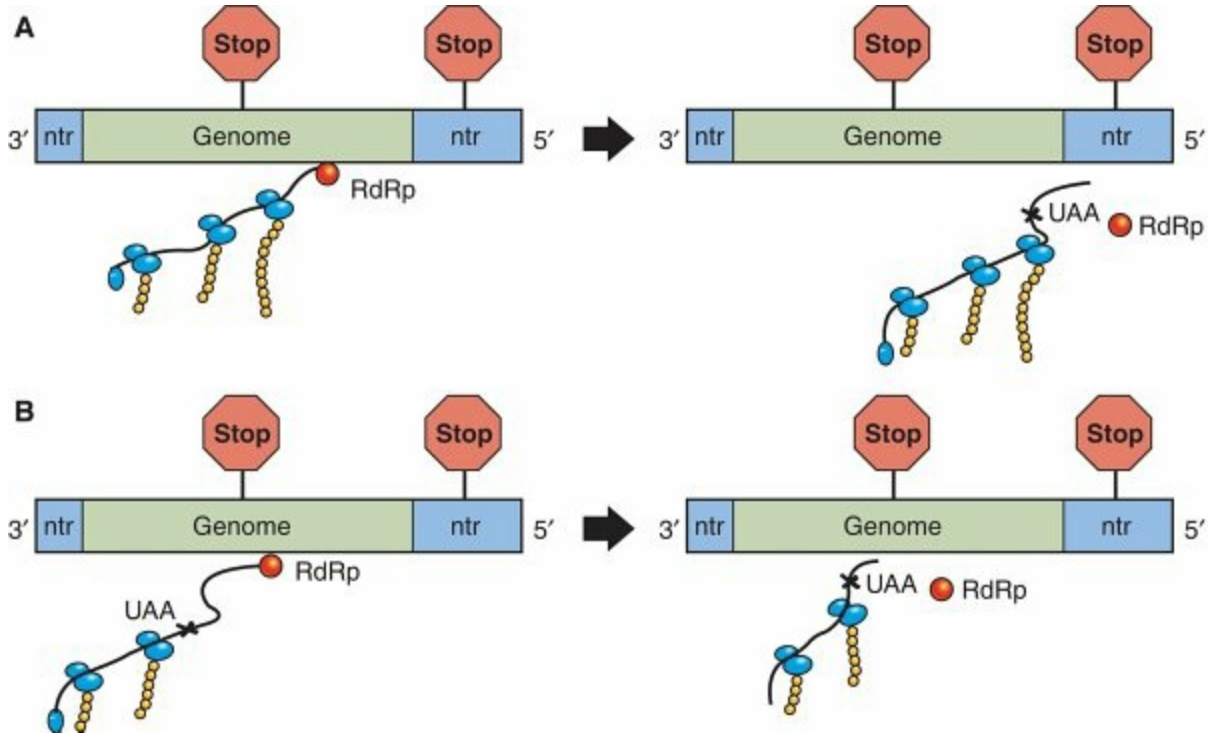

FIGURE 16.9 Model of obligatorily coupled bunyavirus transcription and translation. A: Transcription of full length mRNAs requires on-going translation to allow translocation of ribosomes along the nascent mRNA. Transcription termination signals (shown as STOP signs) within coding regions (green) are not recognised by the RdRp, whereas transcription termination signals within the ntr (blue) are active, leading to generation of the mRNA 3′ end. **B:** When translation is prevented by the presence of in-frame stop codons within the mRNA, ribosome translocation is blocked and previously unrecognised transcription termination signals are now active. Ribosome translocation is proposed to suppress the activity of spurious or cryptic transcription termination signals. (Redrawn from Barr JN. Bunyavirus mRNA synthesis is coupled to translation to prevent premature transcription termination. *RNA* 2007;13:731–736.)

Genome Replication

The first RNA synthesis activity performed within the infected cell by the bunyaviral RdRp is primary transcription, in which short capped RNA oligomers are used to prime mRNA synthesis. However, at a later stage of the infection, the RdRp must commence RNA replication, for which the RdRp is thought to initiate primer-independent RNA polymerization at the precise 3′ end of the template to produce a full-length copy of the template. The molecular mechanism that regulates this switch from primary transcription to genome replication has not been defined for any member of the *Bunyavirales* order, and other fundamental differences between replication and transcription actvities, such as the ability of the nascent strand to be encapsidated or terminated, remain unexplained. It is established that bunyavirus genome replication and subsequent secondary transcription are prevented by translational inhibitors such as cycloheximide, which indicates that continuous protein synthesis is required for replication of the genome. Although not proven, it is likely that synthesis of N is required for genome replication, as described for other negative-strand RNA viruses such as the rhabdovirus, vesicular stomatitis virus, and the paramyxovirus Sendai virus. For these viruses, supply of N protein for encapsidation of new replication products was proposed as a critical component that mediates the transcription–replication switch, and other possibilities have now been suggested.[302]

A prime-and-realign model was also postulated for the nonprimed transcription of hantaviral vRNA and cRNA, except that transcription would initiate with pppG alignment at the third nucleotide (C residue) of the template RNA. After synthesis of several nucleotides, polymerase slipping would realign the nascent RNA such that the initial priming G residue would overhang the template. It was further theorized that nucleolytic activity of the L protein might remove the overhanging G, leaving a monophosphorylated U residue at the nascent 5′ end. The presence of the monophosphorylated U on HTNV RNA was experimentally demonstrated[129] (Fig. 16.8).

Indirect evidence suggesting that a prime-and-realign method of initiation is used by phleboviruses was obtained by using a reconstituted transcription system to study the polymerase recognition sequence at the 3′ termini of the ambisense S-segment RNA of RVFV. In those studies, mutational analysis of the terminal nucleotides revealed that the first 13 nucleotides are required for polymerase recognition, but that one of the two terminal dinucleotides

(UGUG) could be removed without deleterious effects on transcription.[340] These data also suggested that realignment is not a prerequisite for transcription initiation. In contrast, a recent study using the BUNV minigenome system showed that the viral polymerase was able to repair both insertions and deletions in model template RNAs, although this did not appear to involve the prime-and-realign mechanism.[447]

Schematics of transcription and replication based on information above are presented in Figures 16.7 and 16.10.

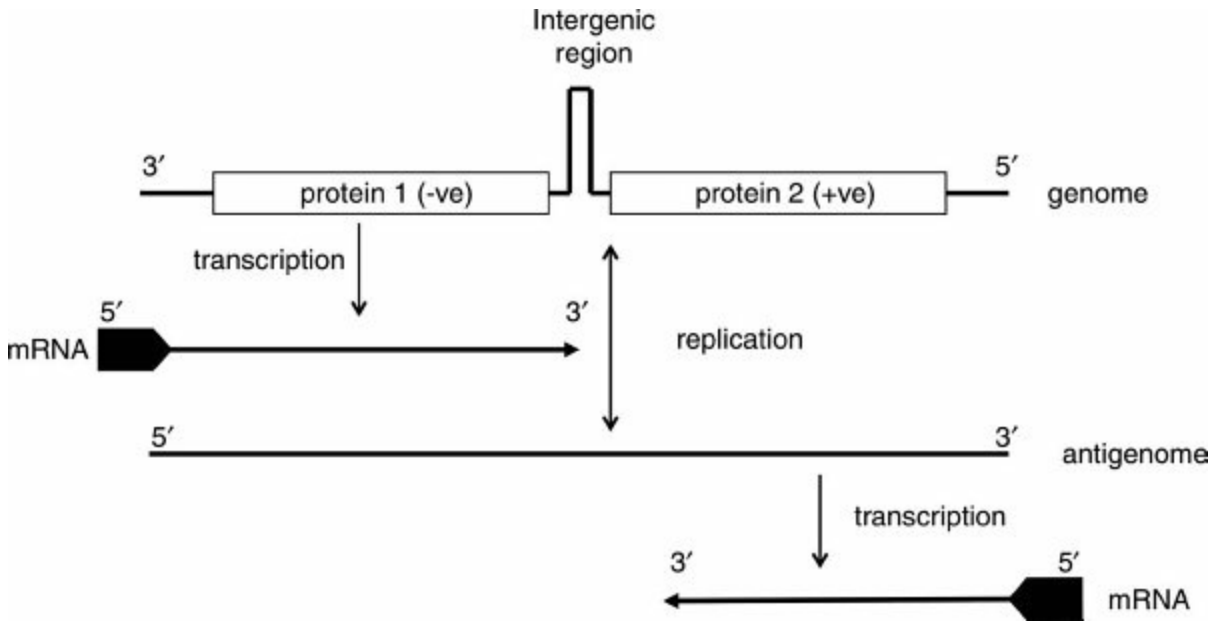

FIGURE 16.10 Transcription and replication scheme of ambisense-sense bunyavirus genome segments. The genome RNA encodes proteins in both negative- and positive-sense orientations, separated by an intergenic region that for some viruses has the potential to form a hairpin structure. The proteins are translated from specific subgenomic messenger RNAs (mRNAs), with the mRNA-encoding protein 2 transcribed from the antigenome RNA after the onset of genome replication.

Encapsidation Signals

The existence of specific RNA signals that drive the formation of RNPs has been proposed only for hantaviruses, as described above. For all other bunyavirales members, RNA sequence signals that drive specific interaction between viral RNAs and the cognate N protein have been proposed based on secondary structure predictions, but not formally identified. The observation that BUNV RNPs functional for RNA replication can be assembled with as few as 17 nucleotides from each of the 3′ and 5′ termini argues that if RNP encapsidation signals existed they would reside within these short UTRs.[288] Interestingly, a stem loop structure comprising these nucleotides was predicted to form in the BUNV 5′ UTR, and proposed to bind N, as demonstrated by *in vitro* gel shift binding assays.[312] However, it is also plausible that no such encapsidation signals exist, and instead, selective encapsidation of viral templates is driven by proximity of solely these RNAs to N protein in viral replication factories, as well as the ability of the polymerase to interact with N,[104] thus, ensuring encapsidation occurs simultaneous with polymerization.[138] In support of this proposal, the recent high-resolution crystal structures of many bunyaviral N proteins do not provide any structural basis for sequence specificity that would favor the interaction between terminal sequences over any other. Work with BUNV has also suggested the terminal UTRs play an important role in segment packaging into virions, whereas the coding regions do not.[225] Mutational analysis of the BUNV M segment revealed a conserved sequence within nucleotides 20 to 33 of the 5′ end of vRNA that was critical for maintaining the segment during serial passage of virus-like particles (VLPs).[225] Variable packaging efficiencies were noted for the L-, M-, and S-segment–derived minireplicons, and packaging appeared to be independent for each.

Host Factors

Beyond the need for host-derived primers for initiating mRNA synthesis, little is known about the role that host factors might play in viral replication. One putative host transcription factor is an approximately 40-kD protein isolated from the main insect vector of TSWV, and it was shown to bind to the viral RdRp at its C-terminus and to the viral RNA at its N-terminus.[92] Both this protein and reticulocyte lysates were needed for RNA synthesis *in vitro*, indicating that other cellular factors are also required. Expression of

this protein in mammalian cells rendered them permissive to TSWV replication.[92] As is the case for a number of other negative-strand RNA viruses, heat-shock protein 90 (Hsp90) appeared essential for LACV replication in that virus yields were diminished in cells treated with Hsp90 inhibitors like geldanamycin due to destabilization of the viral L protein.[82]

Translation and Processing of Viral Proteins

Viral polypeptides are synthesized shortly after infection, with S and L mRNAs translated on free ribosomes and M mRNAs translated on membrane-bound ribosomes. Expression products vary among the genera, and even within a genus.

S-Segment Products: N and NSs

The N protein is the most abundant viral product in virions and infected cells, and while the most prominent role of N is in the encapsidation of viral replication products, it is becoming clear that N plays several other important structural roles in the viral multiplication cycle. For example, N interacts with Gn and Gc, postulated to mediate virion assembly, and N interacts with L, possibly to drive formation of RNPs and mediate encapsidation. In addition, some of the larger N proteins of the hantaviral and nairovirus groups (Table 16.1) have been shown to possess activities unrelated to RNA binding, such as interaction with a diverse set of cellular proteins relating to translation,[165,195] protein folding[306,429,473] regulators of innate immunity,[13,432] and the cytoskeleton.[16,429]

The high-resolution crystal structures of N proteins from several members of the *Hantaviridae*,[156,310] *Peribunyaviridae*,[20,258,300,358] *Nairoviridae*[67,155,428,449,451] and *Phenuiviridae* families[118,311,354,355] have been solved, with a sole example solved for the tospoviruses (Fig. 16.11). In the case of orthobunyaviruses and phleboviruses (*Phenuiviridae* family), which possess N proteins within the smaller size range (Table 16.1), the solved structures are of both RNA-bound and RNA-unbound multimeric forms, which has revealed important information relating to the mechanism of RNA binding and N–N multimerization. BUNV, LACV, Schmallenberg virus (SBV) and Leanyer orthobunyavirus possess globular N proteins that are

almost entirely alpha-helical in composition, with a positively charged RNA binding groove that bisects a bilobed globular core and primarily interacts with the phosphate backbone of RNA through electrostatic and polar interactions, with each N monomer contacting 10 to 11 nucleotides. Orthobunyavirus N proteins possess flexible N- and C-terminal arms that each contact one adjacent monomer, thus providing the basis for multimerization. The RNA is buried deep within the binding cleft, on the inner face of the multimer forms, with the bases inaccessible from the outside, thus requiring transient dislocation of the RNA from N in order for the polymerase to copy the RNA template. The orthobunyaviral N proteins all have a tendency to form predominantly closed and planar tetrameric rings when generated in heterologous expression systems, with a diameter that closely matches that of the assembled RNP extracted from virions. However, the tetramer unit is unlikely to represent the RNP building block in this closed form, and the relevance, if any, of this multimer in the replication cycle is unclear. The extended N- and C-terminal arms permit considerable flexibility in the assembled N multimer, which is also seen in RNPs purified from viruses, that while being uniformly circular are heterogenous in their overall morphology (Fig. 16.12).

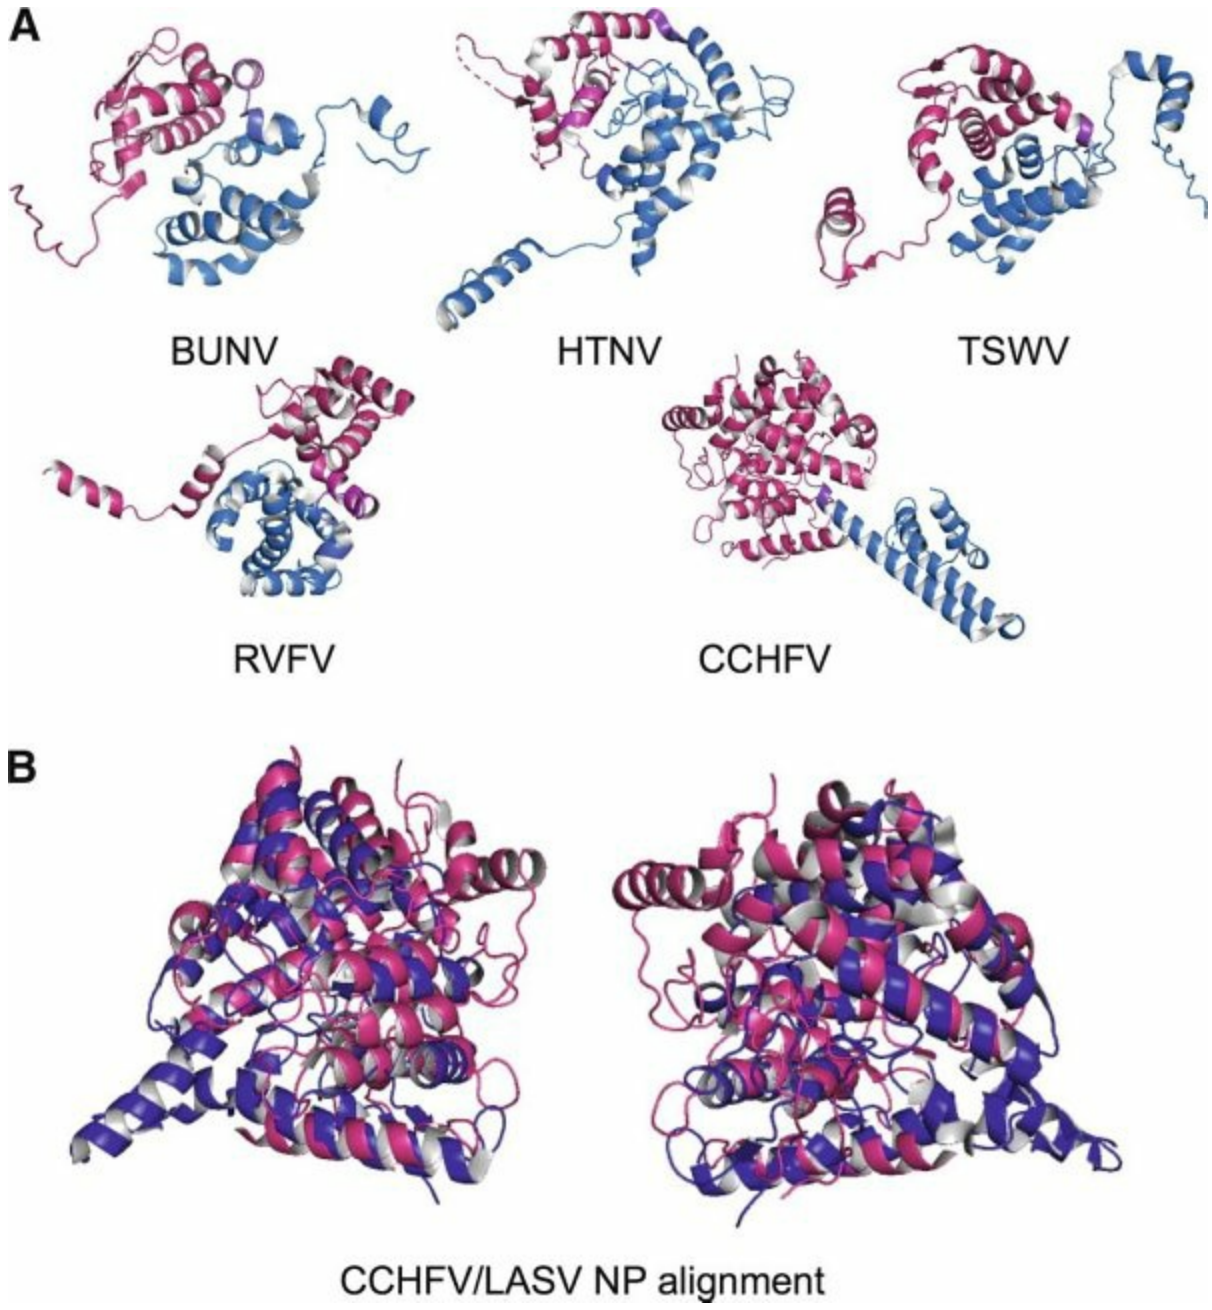

FIGURE 16.11 Crystal structures of N proteins from prototypic members of five families within the *Bunyavirales* order. A and B: BUNV peribunyavirus, HTNV hantavirus, TSWV tospovirus, RVFV phenuivirus and CCHFV nairovirus structures shown as ribbons with the N terminal lobe in *pink* and C terminal lobe in *blue*. Enlarged structural alignments of CCHFV and Lassa arenavirus nucleoproteins, with one alignment rotated 180 degrees.

Ribbon models drawn with Pymol using PDB codes as follows: BUNV 4IJS; HTNV 5FSG; TSWV 5IP1; RVFV 4H5M; CCHFV 3U3I. (Figure courtesy of Francis Hopkins, University of Leeds, UK.)

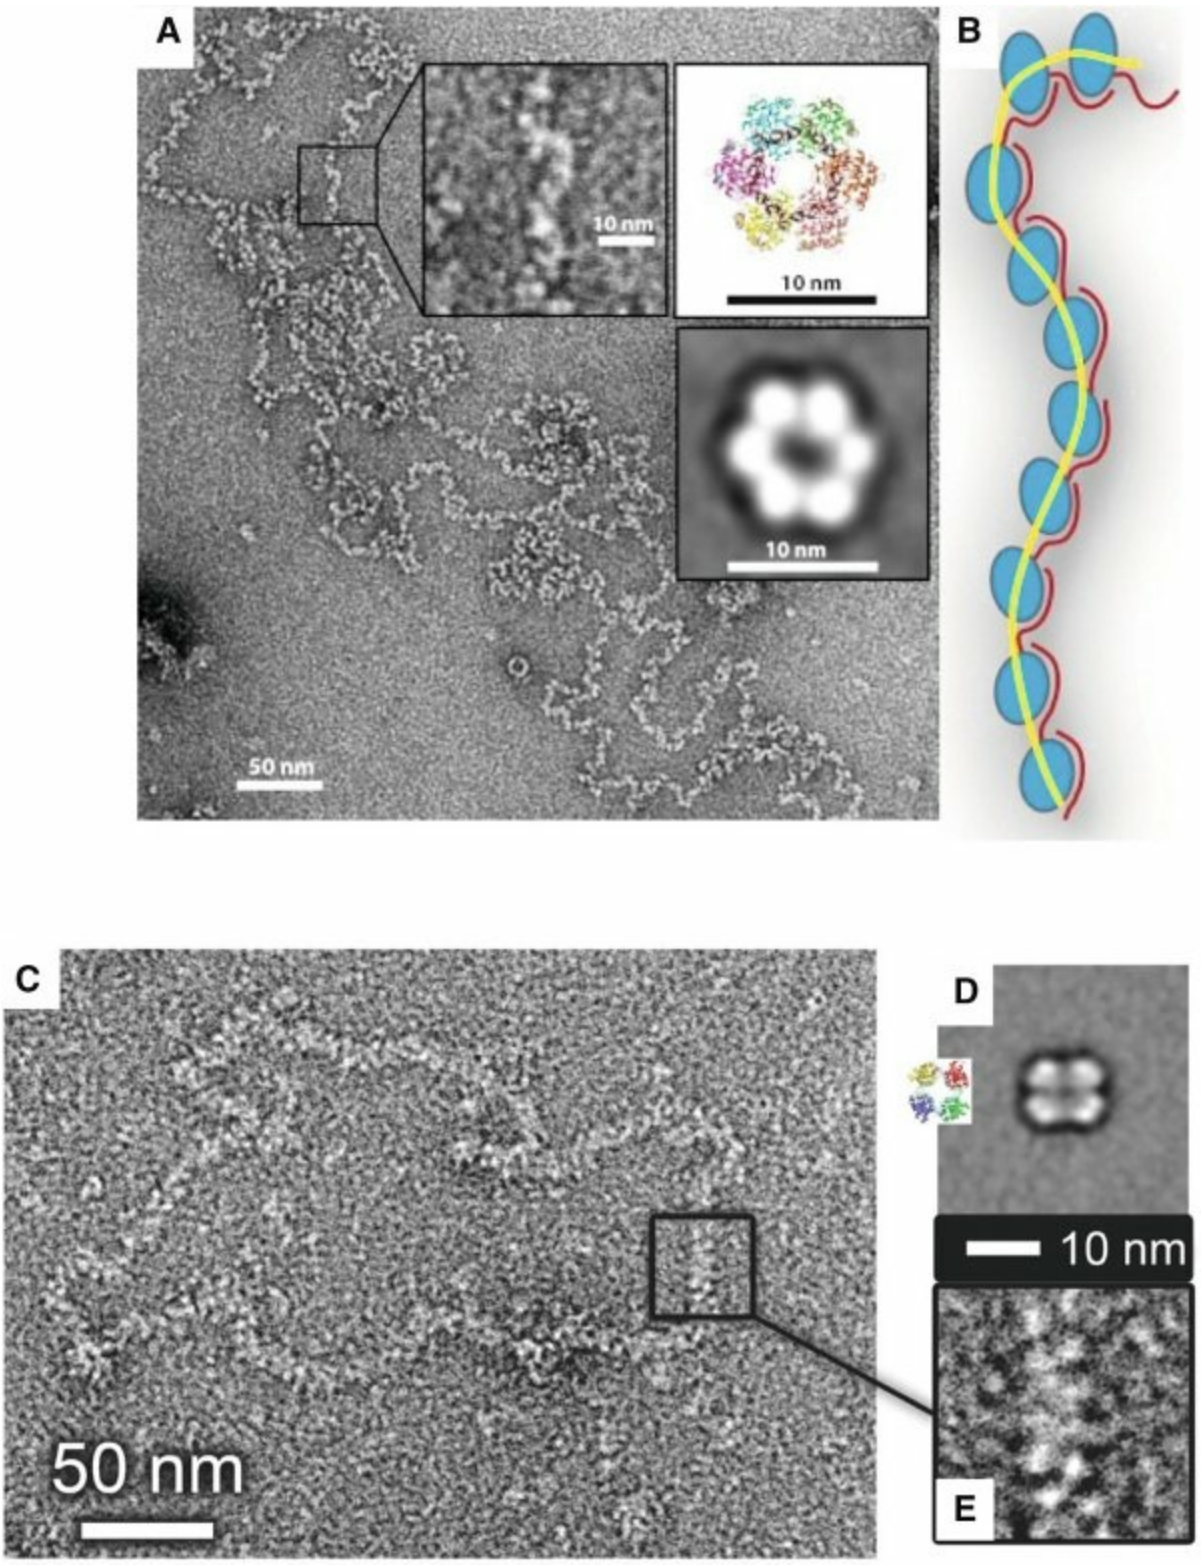

FIGURE 16.12 Bunyavirus RNPs adopt different morphologies. A: Rift Valley fever virus (RVFV) RNPs purified

from infected cells and visualized by negative staining reveals a highly flexible morphology, represented in diagrammatic form **(B)** as a series of NP monomers that each only contacts one adjacent neighboring monomer through the N-terminal arm (*red*). The dimensions of the hexameric N ring are inconsistent with the monomer providing the RNP building block. **C:** A negatively stained Bunyamwera virus (BUNV) L-segment RNP purified from virions appears more rigid, with straight sections (one example is boxed). **D,E:** The diameter of the RNP is more similar to that of N tetramer rather than the monomer, suggesting differences between RVFV and BUNV RNP assembly strategies.

The members of the *Tospoviridae* family also possesses relatively small N proteins (Table 16.1), and the crystal structure of the type species TSWV reveals a very similar overall fold to that of the four orthobunyaviruses described above,[154,226] with somewhat reduced structural similarity with N from TOSV and RVFV phleboviruses, and SFTSV from the *Banyangvirus* genus, described below. As with orthobunyaviruses, N–N multimerization is mediated through extended and flexible N- and C-terminal arms that contact adjacent monomers, with a C-terminal helix providing additional interprotomer contact, suggested to make TSWV RNPs more stable during inter–plant cell transport. Solution of the structure of the TSWV N co-crystalized with nucleic acids albeit at low resolution[226] revealed a high degree of similarity with the SBV orthobunyavirus RNA-binding groove.

The N proteins of phleboviruses RVFV and TOSV exhibit a tendency to form hexamers in solution, and structural analyses show both possess highly flexible N-terminal arms but a C terminus that lies against the globular body and not in contact with adjacent N molecules.[118,311,354,355] This different oligomerization strategy compared with orthobunyaviruses and tospoviruses may explain the different morphologies of the respective RNPs extracted from infected cells or virions, with phleboviral RNPs appearing more flexible (Fig. 16.12). In the case of apo-N from RVFV, the N-terminal arm lies on the monomer surface to sterically block the RNA-binding groove, and this

interaction has been proposed to autoinhibit the interaction of monomeric N with RNA, possibly preventing its association with nonviral RNAs. However, upon N–N multimerization the N-terminal arm relocates to interact with an adjacent N monomer within a hydrophobic cleft, thus exposing the RNA binding groove and providing a mechanism where multimerization and RNA binding are mechanistically coupled. The TOSV N protein co-crystalized with RNA as a series of staggered hexamers, and it has been proposed that RNA binding induces an upward shift in the position of adjacent N monomers, transitioning a planar ring into one with proto-helical properties.[311] In yet another twist of the virus family tree, the phlebovirus N protein exhibits structural similarity to the RNA-binding capsid protein of positive sense RNA plant viruses from the potyvirus genus, implying a shared genetic origin, perhaps as a consequence of the shared arthropod phase of their respective replication cycles.[4]

Despite exhibiting little in the way of nucleotide sequence similarity, the crystal structures of the SNV, HTNV, and ANDV hantavirus N proteins reveal distant structural homology between orthobunyaviral and phleboviral N proteins, sharing the same gross structural architecture that constitutes a bi-lobed globular core that is bisected by an RNA binding groove[156] flanked by flexible N and C terminal arms,[310] with the N-terminal arm forming a coiled coil domain.[48] Interestingly, HTNV N shows partial but close structural homology with tumor suppressor PDCD4, which has been shown to interact with eIF4A,[72] possibly to promote preferential translation of hantaviral mRNAs.

The N proteins from members of the *Nairoviridae* family share no discernable structural homology to N from the orthobunyavirus, hantavirus or phlebovirus groups, and instead display considerable structural homology with N proteins from members of the *Arenaviridae* family,[67] recently incorporated into the *Bunyavirales* order. Rather than being bilobed, with flanking flexible arms, the nairovirus N proteins possess a globular core linked to a stalk (or arm) by a flexible loop. The N and C termini do not extend away from the globular core, and are instead located on its surface and thus are unlikely to mediate intersubunit interactions that drive assembly of RNPs. Instead, N–N multimerization is proposed to involve contact between the tip of the arm domain of one monomer and the base of the globular

domain of a neighboring molecule. Interestingly, in the case of several nairoviruses, the residues that are involved in this interaction at the tip of the arm domain constitute a conserved caspase-3 cleavage site, at which site many of these N proteins are cleaved.[205,449] Recently, the rescue of CCHFV lacking this DEVD motif was shown to be highly attenuated in tick cells, although not in mammalian cell lines, suggesting an important role for this site in the context of infection.[376] As none of the nairoviral N proteins have been crystallized in complex with RNA, the location of the RNA binding surface is unclear, and no positively charged deep groove is evident. However, the above mentioned structural similarity with arenavirus N proteins, for which the RNA binding surface is known, suggests that RNA is bound within a positively charged crevice that extends from the beginning of the arm domain to the base of the globular domain.

How the crystal structures of N monomers or closed multimers relates to that of N in virion-associated RNPs is unclear. However, in LACV, N crystallized in a superhelical form, with a diameter in close agreement to that of assembled RNPs purified from virions, suggesting this structure may be physiologically relevant, revealing how N monomers interact to build an extended multimeric chain (Fig. 16.13). Similarly, the CCHFV N was crystallized as antiparallel superhelical chains, revealing N–N interfaces that may play important roles in assembly of native RNPs[449] (Fig. 16.13). Insight into the mechanism of orthohantaviral N–N multimerization and RNP formation was provided by the cryo-EM structure of full-length recombinant HTNV N, expressed in insect cells, which forms rigid helical filaments with a diameter similar to that of virion-associated RNPs[21] (Fig. 16.13). The terminal arms of each monomer contact each other through subdomain exchange, and also contact the core domains of neighboring monomers. While these terminal arms are connected to the globular core by flexible hinges, each monomer contacts a total of six other protomers within the helical assembly, contributing to the rigidity of the structure. In contrast, native hantaviral RNPs are circular, indicative of considerable flexibility and suggesting that N within such RNPs must undergo other conformational rearrangements absent in the recombinant filaments.

For all these bunyaviral N proteins, the mechanism of RNA encapsidation during genome replication is poorly understood, although the recent solution of crystal structures of many N proteins as well as the LACV RdRp[138] provide some important clues, from which an excellent working model has arisen. This model posits that the RNA template transiently dissociates from N during polymerization to expose the RNA bases for copying, and the nascent replication product is encapsidated as it emerges from the RdRp exit channel by addition of single N monomers.

The S segments of viruses in the *Phlebovirus* and *Orthotospovirus* genera and some viruses in *Orthonairovirus*, *Orthobunyavirus*, and *Orthohantavirus* genera encode NSs proteins in addition to their N proteins. Sizes of NSs range from 10 kD for orthobunyaviruses and orthohantaviruses to more than 50 kD for orthotospoviruses (Fig. 16.1). As the name suggests, the various bunyaviral NSs proteins are nonstructural and possess diverse roles that can be broadly described as suppressors of innate immunity (see below), with the best-studied example being NSs from the phlebovirus RVFV. RVFV NSs is a major pathogenicity factor, with both naturally occurring and engineered variants of RVFV lacking NSs unable to inhibit interferon production and thus being apathogenic in mice. RVFV NSs accumulates in the nuclei of infected cells where it forms large and dense fibrillar structures (Fig. 16.14)[424] comprising NSs as well as multiple nuclear proteins including p44 and XPB of TFIIH, as well as SAP30 and YY1[241,242] although it is not clear whether filament formation is required for the NSs function.

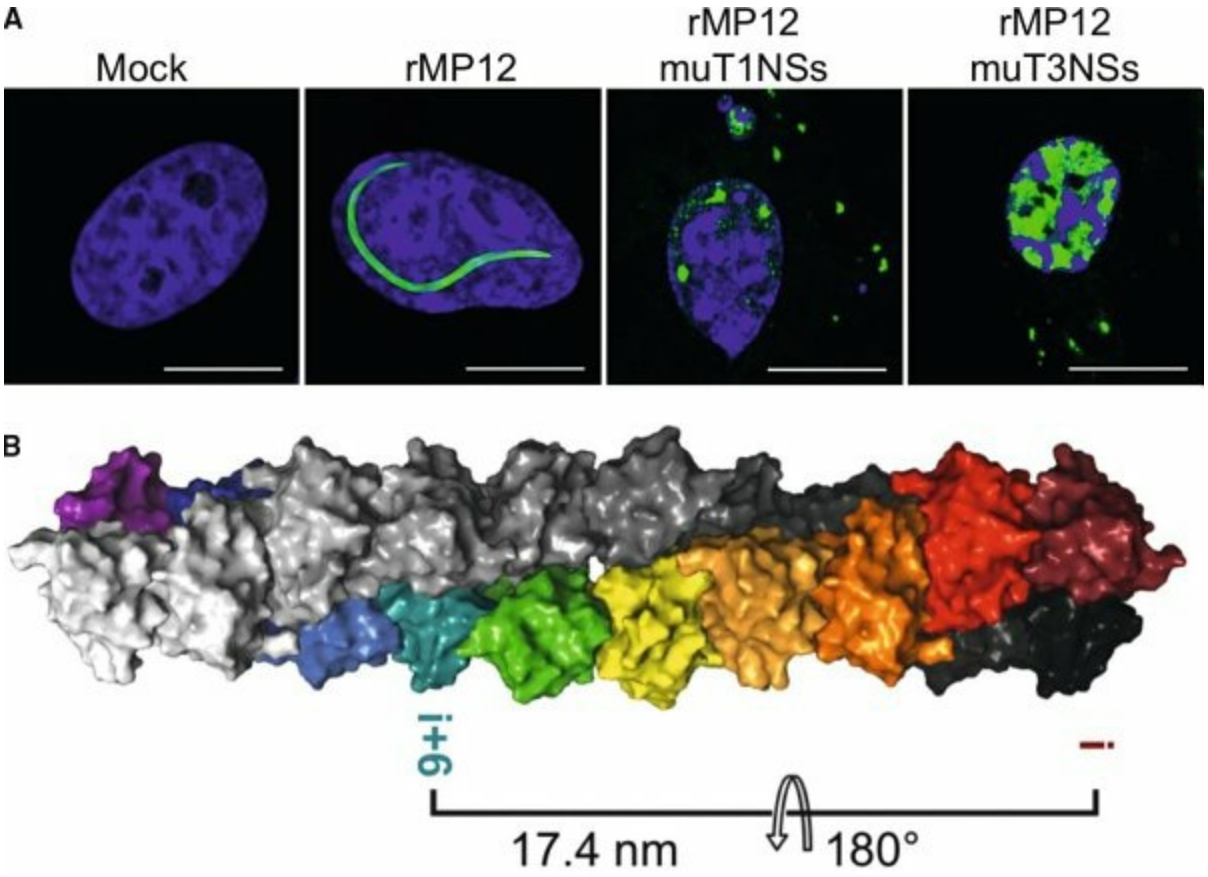

FIGURE 16.14 Rift Valley fever virus NSs protein accumulates in the nucleus as an ultrastructural filament. A: BHK cells infected with Rift Valley fever virus (RVFV) were stained with an anti-NSs antibody showing fibrillar structures in the nucleus. NSs fibrils do not form during infection with recombinant RVFV expressing NSs with alterations at critical fibril interfaces. **B:** Surface rendered model of the double helical NSs filament, with individual monomers alternatively colored, and with 6 monomers per 180-degree turn. (Figures taken from Barski M, Brennan B, Miller OK, et al. Rift Valley fever phlebovirus NSs protein core domain structure suggests molecular basis for nuclear filaments. *eLife* 2017;6:e29236.)

The structure of a soluble core domain of RVFV NSs (NSs ΔN-ΔC) missing terminal residues 1 to 83 and 248 to 265 revealed a novel all-helical

fold, which formed double helical fibrils within the crystal lattice, stabilized by multiple interfaces[34] (Fig. 16.14). The dimensions and architecture of these fibrils were comparable with fibril bundles that build up the characteristic nuclear filaments, and structure-guided mutagenesis of NSs ΔN-ΔC multimer interfaces allowed critical residues in filament formation to be identified. The ability of NSs ΔN-ΔC to form filaments in virus-infected cells shows the termini are dispensable for this activity but conflicts with the finding that NSs binds p62 through a conserved C terminal Ω*X*a*V* motif (deleted in NSs ΔN-ΔC) that is also proposed to be required for filament formation.[88]

Comparing the deduced amino acid sequences of NSs for five different phleboviruses revealed similarities of only 17% to 30%.[143] However, comparison of the NSs gene sequences for a number of strains of a single phlebovirus, RVFV, showed that certain areas were highly conserved.[377] These data suggest that there may be a strong evolutionary pressure to maintain distinct portions of the NSs for individual viruses but that the remainder of the protein can diverge without affecting the function of NSs.

As RVFV NSs is expressed by ambisense transcription, it requires the cRNA template for protein production. Earlier work suggested that the NSs of phleboviruses and tospoviruses were only synthesized after onset of viral replication at later times of infection, required to generate the cRNA template. However, recent work with RVFV indicates that virions can encapsidate S-segment cRNAs and that these incoming cRNA RNPs can serve as templates for transcription of NSs mRNA.[187] The outcome of this is that NSs is expressed early in infection, in agreement with reports that innate immunity is activated upon entry of RNPs.[454] Also, the NSs of three orthobunyaviruses all inhibited BUNV RNA synthesis in a dose-dependent manner in a minireplicon system.[453] These results were suggested to indicate a function for NSs in regulating the activity of the RdRp, in addition to their role in interferon antagonism, apoptosis, host-range determination, and gene silencing described below.

M-Segment Products: Gn, Gc, and NSm

Without exception, the bunyaviral M segment encodes a glycoprotein

precursor (GPC) that is cotranslationally cleaved by various proteases to generate two viral envelope glycoproteins (GPs), Gn and Gc, and following heterodimerization, these form the viral spikes involved in virus entry. However, there are significant differences among the bunyaviruses in the way the GPC is processed, and also in the GPC-derived products that are generated.

M-segment gene products have a high cysteine content of approximately 4% to 7%, with the positions of these residues being highly conserved within families, suggesting that extensive disulfide-bridge formation may occur and that the positions may be crucial for determining correct polypeptide folding. The secondary structure of the proteins is also involved in immunogenicity, as indicated by the finding that neutralizing or protective epitopes are often nonlinear.

All M-segment polyproteins display variable numbers of predicted transmembrane regions, and a hydrophobic sequence at the carboxy-terminus, indicative of a membrane anchor region. Therefore, the M-segment translation products of viruses in the order *Bunyavirales* are typical class 1 membrane proteins, with their N terminus exposed on the surface of the virion and a membrane anchor within the C terminus, with a small number of C-terminal residues potentially exposed within the virion interior.

The Gn and Gc proteins of all characterized bunyaviruses possess asparagine-linked oligosaccharides. Examination of the oligosaccharides attached to the Gn and Gc proteins of orthobunyaviruses revealed that Gc has mostly high-mannose glycans, whereas Gn contains both complex and a novel intermediate-type oligosaccharide.[269,303,395] In contrast, the GPs of hantaviruses were found to be mostly of the high-mannose type.[384] These findings indicate that the proteins are incompletely processed through the Golgi. This is likely related to retention of Gn and Gc in the Golgi, where assembly occurs, discussed more fully below.

In some orthobunyaviruses, nairoviruses, and phleboviruses, but not hantaviruses,[386] processing of the GPC generates an additional nonstructural protein known as NSm, and the characteristics and functions of this module are discussed below. In addition, some nairoviruses further process GPC to generate additional polypeptides that are proposed to have other nonstructural roles, also described below.

The GPC polyprotein of bunyaviruses is not seen in infected cells, and has been observed only by *in vitro* translation of RNA transcripts in the absence of microsomal membranes.[436] For orthbunyaviruses, hantaviruses,[261] and phleboviruses, both Gn and Gc are preceded by signal peptide (SP) sequences, and therefore, cleavage of the polyprotein precursor is likely mediated cotranslationally by host signal peptidase (SPase) in the ER.[114] In the case of BUNV orthobunyavirus, the GPC constitutes a single ORF with Gn, NSm, and Gc modules arranged in that order,[113] and being released by SPase cleavage at their respective N termini. Cleavage at the Gn/NSm boundary was shown to occur at an internal SPase cleavage site located within domain 1 of NSm, releasing pre-Gn in which the SP was still attached to the Gn C-terminus (Pre-Gn).[394] The SP was cleaved from the C terminus of pre-Gn to yield Gn by further processing by signal peptide peptidase (SPP) in the ER. The function of NSm remains unclear; its hydropathy profile suggests that it is a membrane-bound protein, and expression studies demonstrated that it localizes to the Golgi along with Gn and Gc.[246] Although a function for this protein has not been identified, localization studies suggest that it might be involved in facilitating virion assembly in the Golgi.[121,400]

Release of the Gn, Gc, and NSm proteins from the GPC of the insect-borne phleboviruses also involves SPase cleavage, although in the case of RVFV, the protein modules are arranged with the NSm module located at the N terminus of the GP, thus in the order NSm, Gn, Gc (Fig. 16.15). Nucleotide sequence studies revealed five in-frame translation initiation codons (AUG) upstream of the N-terminus of Gn. Mutational analysis of those codons indicated the fourth and the fifth AUGs to translate Gn and Gc. Whilst NSm was found to originate from the second AUG and a 78-kDa polypeptide, representing uncleaved NSm and Gn, was translated from the first AUG.[166] Pulse-chase experiments revealed no precursor–product relationship between the 78- and 14-kDa proteins; therefore, it appears that use of the first and second AUGs, respectively, is what dictates generation of these proteins.[63] Both the 14-kDa NSm and the 78-kDa polypeptide are found in abundance in RVFV-infected cells,[64] suggesting that they might play a role in replication or morphogenesis. A RVFV mutant rescued with M-segment mutations ablating NSm expression was indistinguishable to wild-type in its growth

characteristics, suggesting NSm was dispensable for RVFV multiplication.[139]

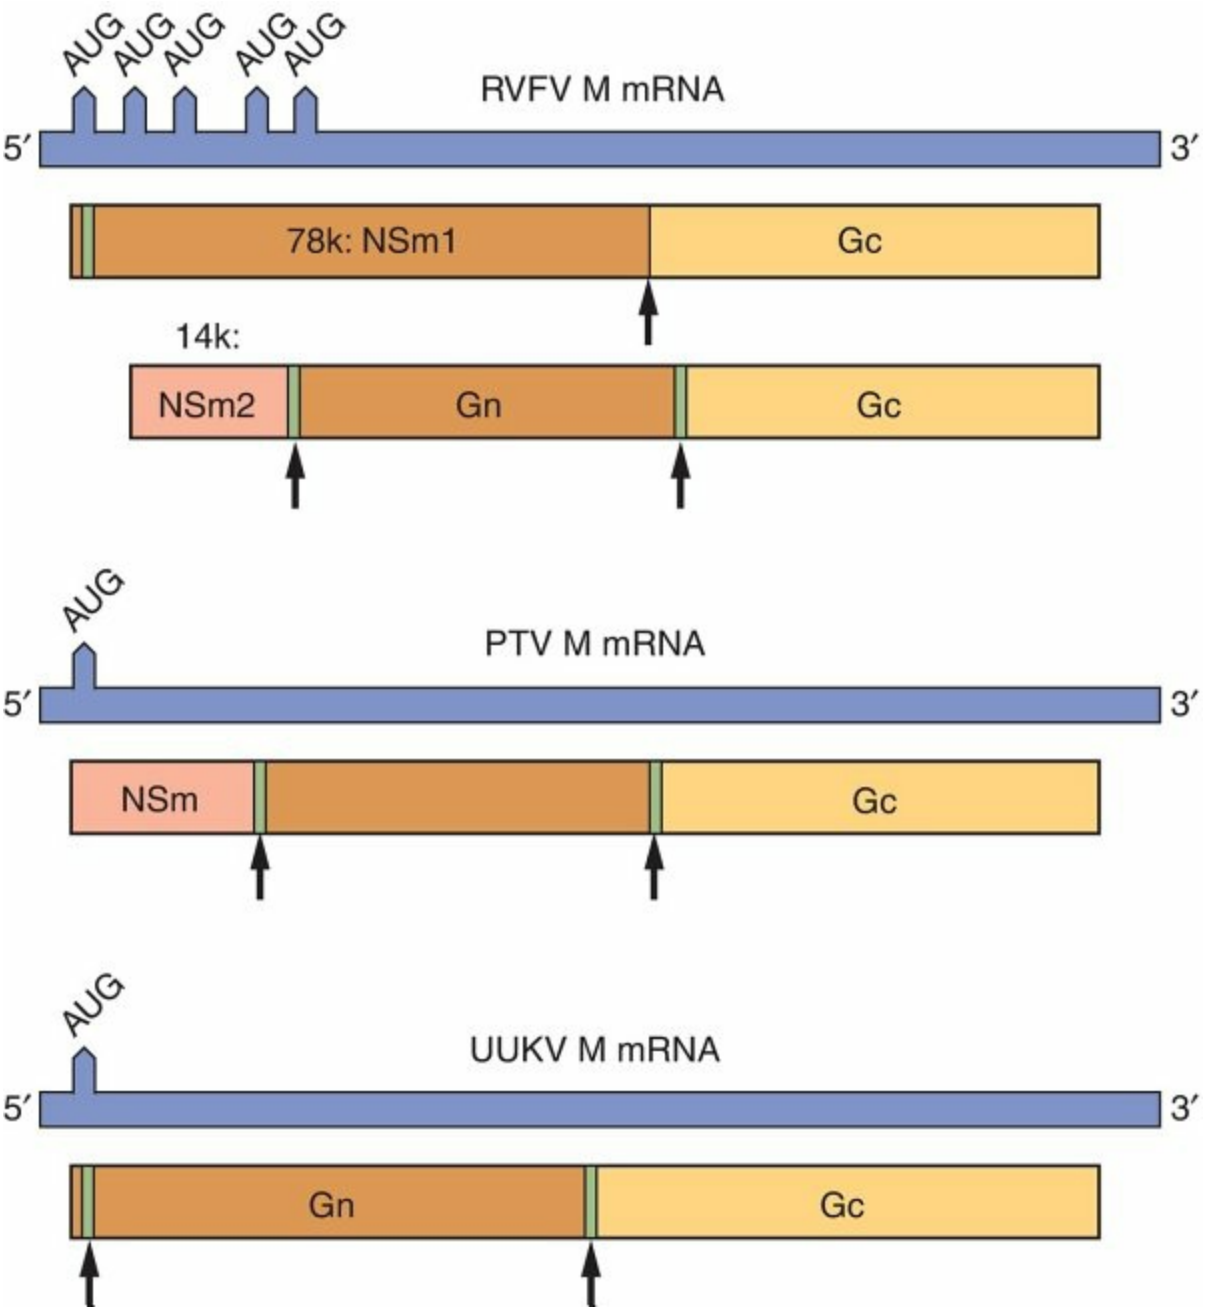

FIGURE 16.15 Expression of phlebovirus M-segment encoded gene products. Schematic representation of the gene products, AUG codons (*lollipops*), and proteolytic cleavage sites (*arrows*) of the M segments of Rift Valley fever virus (RVFV), Punta Toro

virus (PTV), and Uukuniemi virus (UUKV).

An even larger NSm (~30 kDa) is cleaved from the amino terminus of the M-segment polyprotein of the phlebovirus, PTV (Fig. 16.15). *In vitro* expression studies indicated that both envelope GPs could be produced in the absence of the NSm coding region,[279] but other studies to evaluate the use of the 13 potential translation initiation codons present in the NSm coding information have not been reported. No homology between the NSm proteins of PTV and RVFV was apparent.[184]

In contrast to the mosquito-borne phleboviruses PTV and RVFV, the tick-borne phlebovirus UUKV does not produce an NSm (Fig. 16.15). The first (and only) initiation codon preceding sequences of the envelope GPs is located 17 amino acids upstream of the amino terminus of Gn[366]; hence, the Gn protein of UUKV appears to be analogous to the 78-kDa NSm–Gn fusion product produced by RVFV (although there is no obvious sequence homology of these predicted products). Until a function can be assigned to NSm, it is impossible to determine whether UUKV replicates in the absence of such a function or accomplishes whatever function is required without removal of a portion of the amino terminus of Gn.

Alternative GPC processing pathways have also been identified, with nairoviruses relying on proteases other than signalase for their GPC processing events (Fig. 16.16). The nucleotide sequences of Dugbe virus (DUGV), CCHFV, and NSDV M segments reveal the presence of characteristic Gn and Gc modules, as well as NSm.[274] However, studies using CCHFV demonstrate the Pre-Gn moiety is extremely large at approximately 140 kDa, suggesting additional coding capacity.[11,39,378,379,445] Studies show PreGn is further processed to the mature 37-kDa Gn by cleavage with a cellular secretory pathway protease, SKI-1, early in the secretory pathway at a consensus motif, RRLL.[378,445] SKI-1 cleavage generates a subprecursor of two other polypeptides that is cleaved by a furin-like protease at a later stage in the secretory pathway.[378] This cleavage site is completely conserved among several CCHFV strains, suggesting that it has importance for viral replication or pathogenicity.[378] The amino-terminal portion of this

subprecursor is a highly variable (among CCHFV strains) polypeptide with mucin-like characteristics, including numerous serines, threonines, and prolines and predicted extensive O-linked glycosylation. The carboxy-terminal portion of the subprecursor is a 38-kDa nonstructural polypeptide. After furin cleavage, secreted proteins GP38, GP85, and GP160 and the mucin-like protein are produced, and it is presumed these products reflect extensive O-linked glycosylation differences. Although the PreGc precursor also possesses a SKI-1–like cleavage motif, SKI-1 cleavage could not be demonstrated for this protein, so it is likely that a related enzyme is responsible for the processing to yield mature Gc.[378] The importance of furin cleavage in this processing pathway was confirmed by experiments with rescue of a CCHFV mutant lacking a functional furin site,[40] which was highly attenuated in infectious virus production. While the role of the mucin-like domain is unknown, GP38 appears in a secreted form and has been proposed to act as an immune decoy.[378]

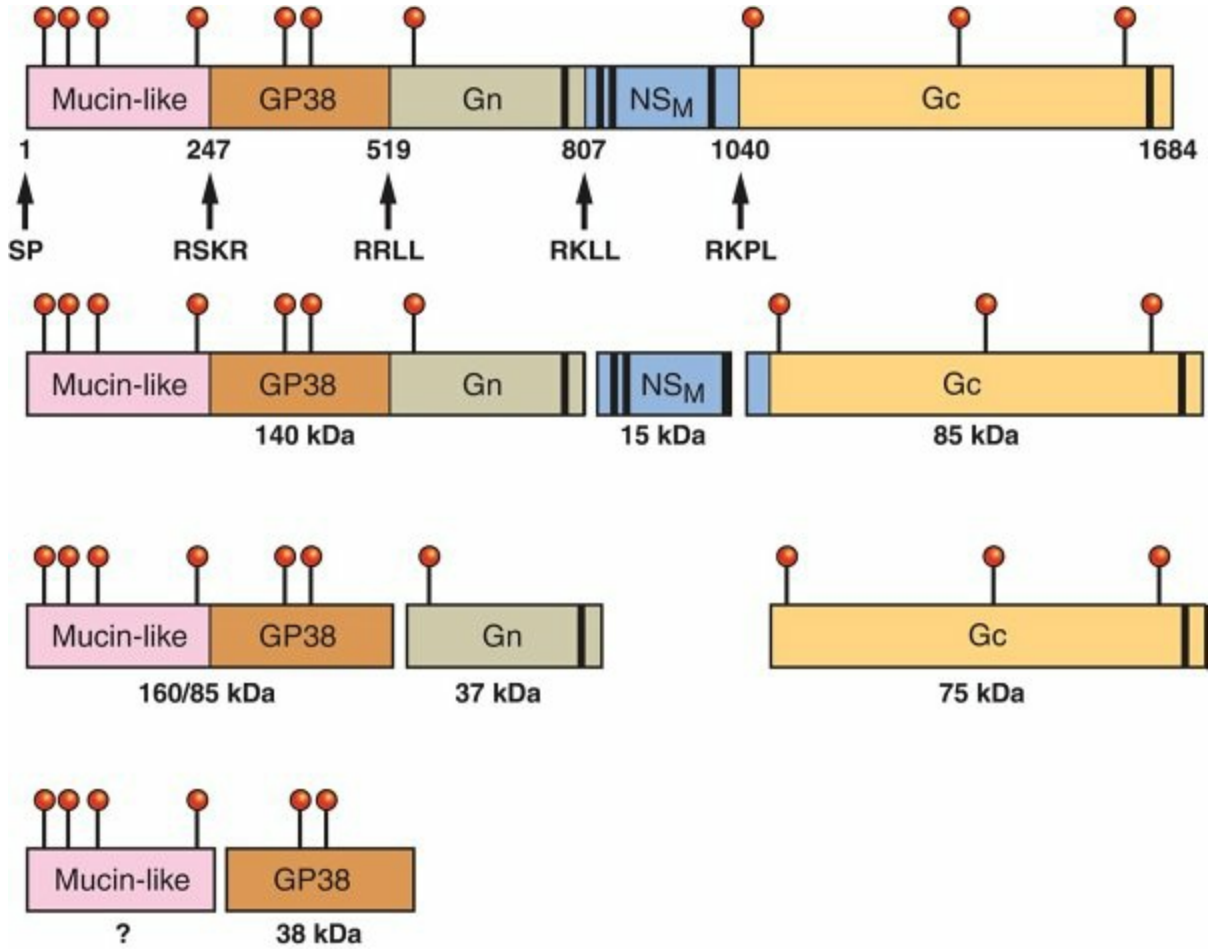

FIGURE 16.16 Processing of the nairovirus M-segment–encoded polyprotein. *Arrows* indicate the known and predicted cleavage site positions and their sequence motifs. *Lollipop shapes* represent predicted N-linked glycosylation sites. Cleavage events are represented sequentially, and the protein products and their sizes are indicated (*middle* and *bottom panels*). *Black bars* represent transmembrane (hydrophobic) regions. Amino acid positions are based on Crimean–Congo hemorrhagic fever virus (CCHFV) strain IbAr 10200. (Modified from Bergeron E, Vincent MJ, Nichol ST. Crimean-Congo hemorrhagic fever virus glycoprotein processing by the endoprotease SKI-1/S1P is critical for virus infectivity. *J Virol* 2007;81:13271–13276.)

Unlike all other viruses in the family, the NSm protein of tospoviruses is translated from an ambisense mRNA.[228] It is also the only NSm protein in the family to have a definitively assigned function. By subcellular fractionation of infected plants, or in thin-section immunoelectron microscopy studies, the NSm of TSWV was found to be present in cell wall–containing fractions or associated with aggregates of nucleocapsids and with the plasmodesmata.[230] Expression of the NSm protein in plant cells or insect cells revealed that the protein first appeared near the cell surface and later as tubular structures protruding from the cell surface. In infected leaf tissues, the tubules were observed only in the plasmodesmata.[420] These findings are characteristic of proteins able to aggregate into plasmodesmata-penetrating tubules that allow cell-to-cell movement of the virus across the cell walls in infected plants. In several other studies, the TSWV NSm protein was shown to have additional characteristics of plant movement proteins, including sequence similarity, expression during the early stages of infection, and RNA-binding activity. Formal proof of this function was obtained from experiments in which NSm of TSWV was able to complement cell-to-cell movement of a movement-defective tobacco mosaic virus vector.[251] This expression system was also used to show that NSm alone induced tubule formation in protoplasts and induced TSWV-like symptoms in *Nicotiana benthamiana*, and separate domains within NSm have been mapped for each of these functions.[254] More recently, the TSWV NSm protein has been shown to be physically associated with the endoplasmic reticulum (ER), which extends throughout plants via the ER-desmotubule, providing the basis for TSWV movement and dissemination.[116] NSm was found to be expressed in its natural thrip insect vector, but did not aggregate into tubules, leading to the suggestion that NSm might only have a role in the plant portion of the tospovirus replication cycle.[421]

As described above, the viral spikes must perform multiple roles including interaction with host entry factors during virus binding, as well as mediating the fusion of viral and endosomal membranes, thus releasing the RNPs into the cytosol (Fig. 16.17). Recent structural analyses of several bunyaviral Gn/Gc spikes using both crystallography and cryo-EM techniques has provided important insight into these critical virus activities, and has illuminated the molecular basis of these functions. The fusogenic component

of all bunyaviral Gn/Gc heterodimer resides within Gc, all of which are class-II fusion proteins comprising predominantly beta-sheet secondary structural elements. Crystal structures of the phlebovirus RVFV and SFTSV Gc proteins in pre- and postfusion confirmations[94,162] characterized the conformational changes predicted to occur during pH triggered fusion, as well as identify the potential histidine residues involved in pH-sensing activities, and the hydrophobic fusion loops.

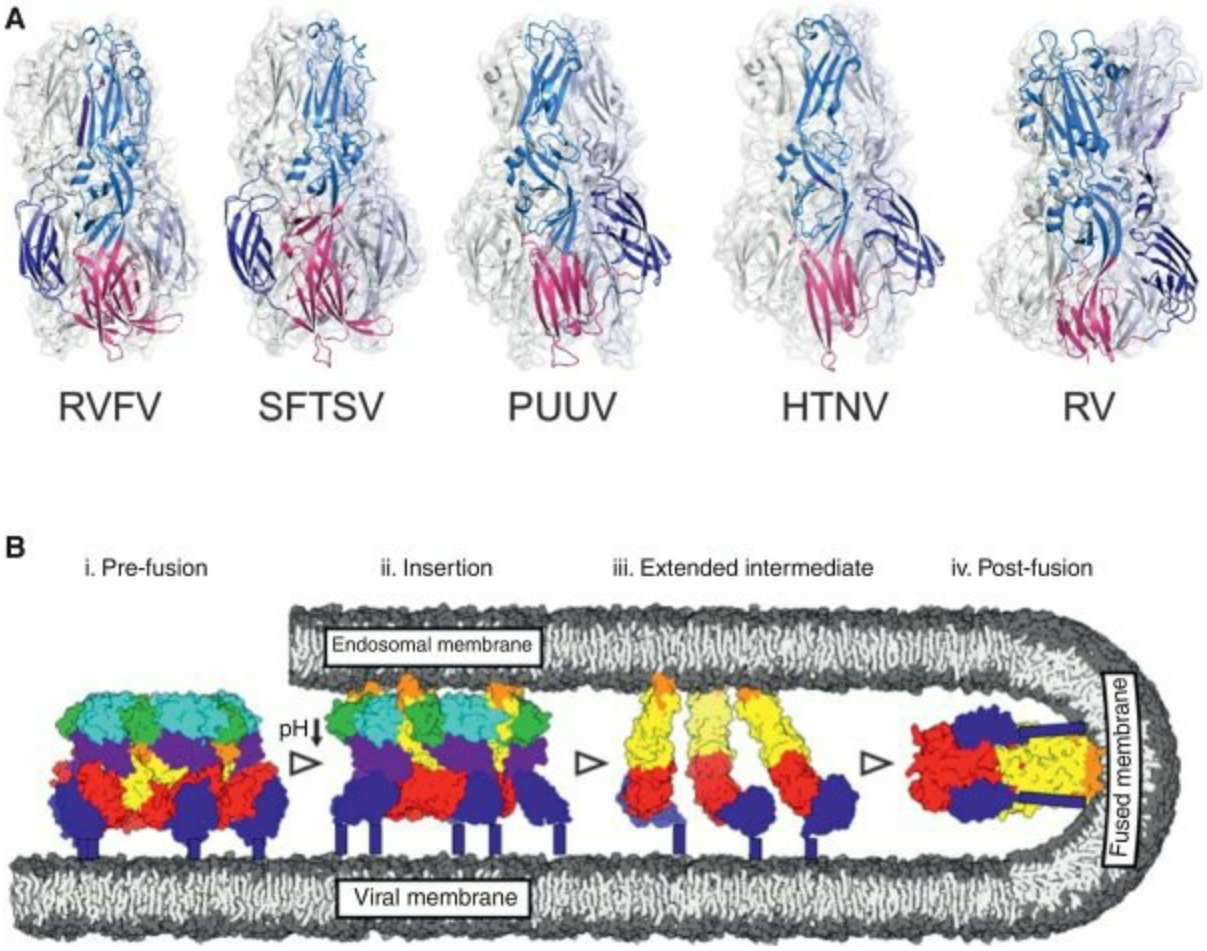

FIGURE 16.17 Structure and function of bunyavirus spikes. A: Crystal structures of Gc from RVFV, SFTSV and PUUV from the *Phlebovirus* genus, HTNV from the *Hantavirus* genus, and rubella virus from the *Togaviridae* family of positive-sense RNA viruses. Ribbon structural models drawn with Pymol using PDB codes as follows: RVFV 6EGU; STFSV 5G47; PUUV RJ81; HTNV 5LJZ;

RV 4ADG. (Figure courtesy of Francis Hopkins, University of Leeds, UK.) **B:** Model for fusogenic activation of phleboviral Gn/Gc spikes in response to the lowered pH of endosomal compartments. In (*i*), Gn/Gc heterodimers on the virus surface, with Gn domains A, B and the beta-ribbon colored teal, green and purple, respectively located on top of Gc domains I, II, and III colored red, yellow, and blue respectively. The Gc fusion loops are buried and colored orange. In (*ii*), the biochemical changes that occur during transit through the endosome network induce conformational change, whereby Gn domains move to the side, as Gc domains extend exposing the fusion loops of each monomer at its apex, to insert into the target membrane. In (*iii*), the Gn/Gc moieties dissociate, allowing redistribution of Gc, leading to further conformational changes that culminate in formation of Gc trimers within the fused membrane. (Schematic taken from Halldorsson S, Li S, Li M, et al. Shielding and activation of a viral membrane fusion protein. *Nature Commun* 2018;9:349.)

By solving the crystal structure of RVFV Gn and docking the resulting Gn/Gc structural model into a cryo-EM derived structural model of the RVFV spike envelope, the location of Gn and Gc on the virion surface was determined, which confirmed the existence of Gn/Gc heterodimers, and defined their interacting interfaces.[163] By comparing the structures of Gn/Gc heterodimers with and without the provision of biochemically relevant lipids at low pH, the conformational changes associated with membrane interaction were observed, which revealed exposure and insertion of the Gc fusion loop in concert with a dramatic conformational shift of Gn. These findings suggested that in the prefusion state, Gn shields the hydrophobic fusion loop of Gc, blocking premature fusion until the appropriate cellular compartments are reached. Gn conformational changes allow extension of Gc and insertion of the fusion loop into target membranes, driving subsequent fusion events. The fusion event is facilitated by the ability of Gc to sequester glycerophospholipid head groups within a binding pocket under the fusion

loop that participate in polar interactions, thus stabilizing the inserted fusion loop.[152]

Similar conformational changes in Gn and Gc structure have also been described for Hantaan and Puumala hantaviruses, which share significant structural similarity despite their different geographic origins.[8,153,364,463] As for phlebovirus Gn/Gc assemblies, lowered pH induces dramatic conformational changes, allowing dissociation of the Gn/Gc lattice that is proposed to stearically facilitate the extension and insertion of the Gc fusion loop into the host cell target membrane. As for phleboviruses, Gn has been proposed to provide a shielding role to Gc, with structural rearrangements of the hantaviral glycoprotein lattice in response to appropriate biochemical cues resulting in exposure of the fusion loop, and its availability for insertion into target endosomal membranes.

L Segment Product: L Polymerase Protein

As their name suggests, bunyavirus L proteins are large, with those of the *Peribunyaviridae*, *Hantaviridae*, and *Phenuiviridae* families possessing molecular weights around 240 kDa, whereas members of the *Tospoviridae* and *Nairoviridae* families are somewhat larger, around 330 to 450 kDa respectively (Fig. 16.1). To mediate both primed synthesis of mRNAs, as well as nonprimed synthesis of vRNA from cRNA templates, these RdRps must possess numerous enzymatic activities including endonuclease, transcriptase, replicase, and probably cap-binding.

All RdRps for which the structure has been solved adopt a canonical RdRp fold, often described as a right hand with a palm, fingers and thumb domains containing catalytic core motifs,[17,196,235,292] and the recently described crystal structure of a near full-length construct of LACV L (Fig. 16.18) (residues 1–1,750; 77%) is no exception to this.[138] The LACV RdRp possesses much structural similarity with the RdRp from the segmented negative stranded influenza virus, and alignment of the two molecules shows that the PA, PB1, and PB2 subunits can be mapped head-to-tail onto the LACV structure, in that order.[474] The central RdRp core domain of LACV L (residues 760–1,432) maps to IAV PB1 and constitutes the palm, fingers, fingertips, and thumb features. In LACV, this central RdRp core is buttressed

by substantial extensions: on one side by a N-terminal region (residues 1–759) corresponding to PA, and on the opposite side by a C-terminal region that aligns with the N-terminus of PB2 (PB2-N) constituting LACV residues 1,433–1,750. The C terminal residues of the LACV L (1,751–2,263) were not represented in the LACV L expression construct, but likely correspond to the C terminal portion of PB2, which includes a cap-binding domain, although the existence of cap-binding activity or an associated domain in any bunyaviral RdRp has yet to be confirmed.

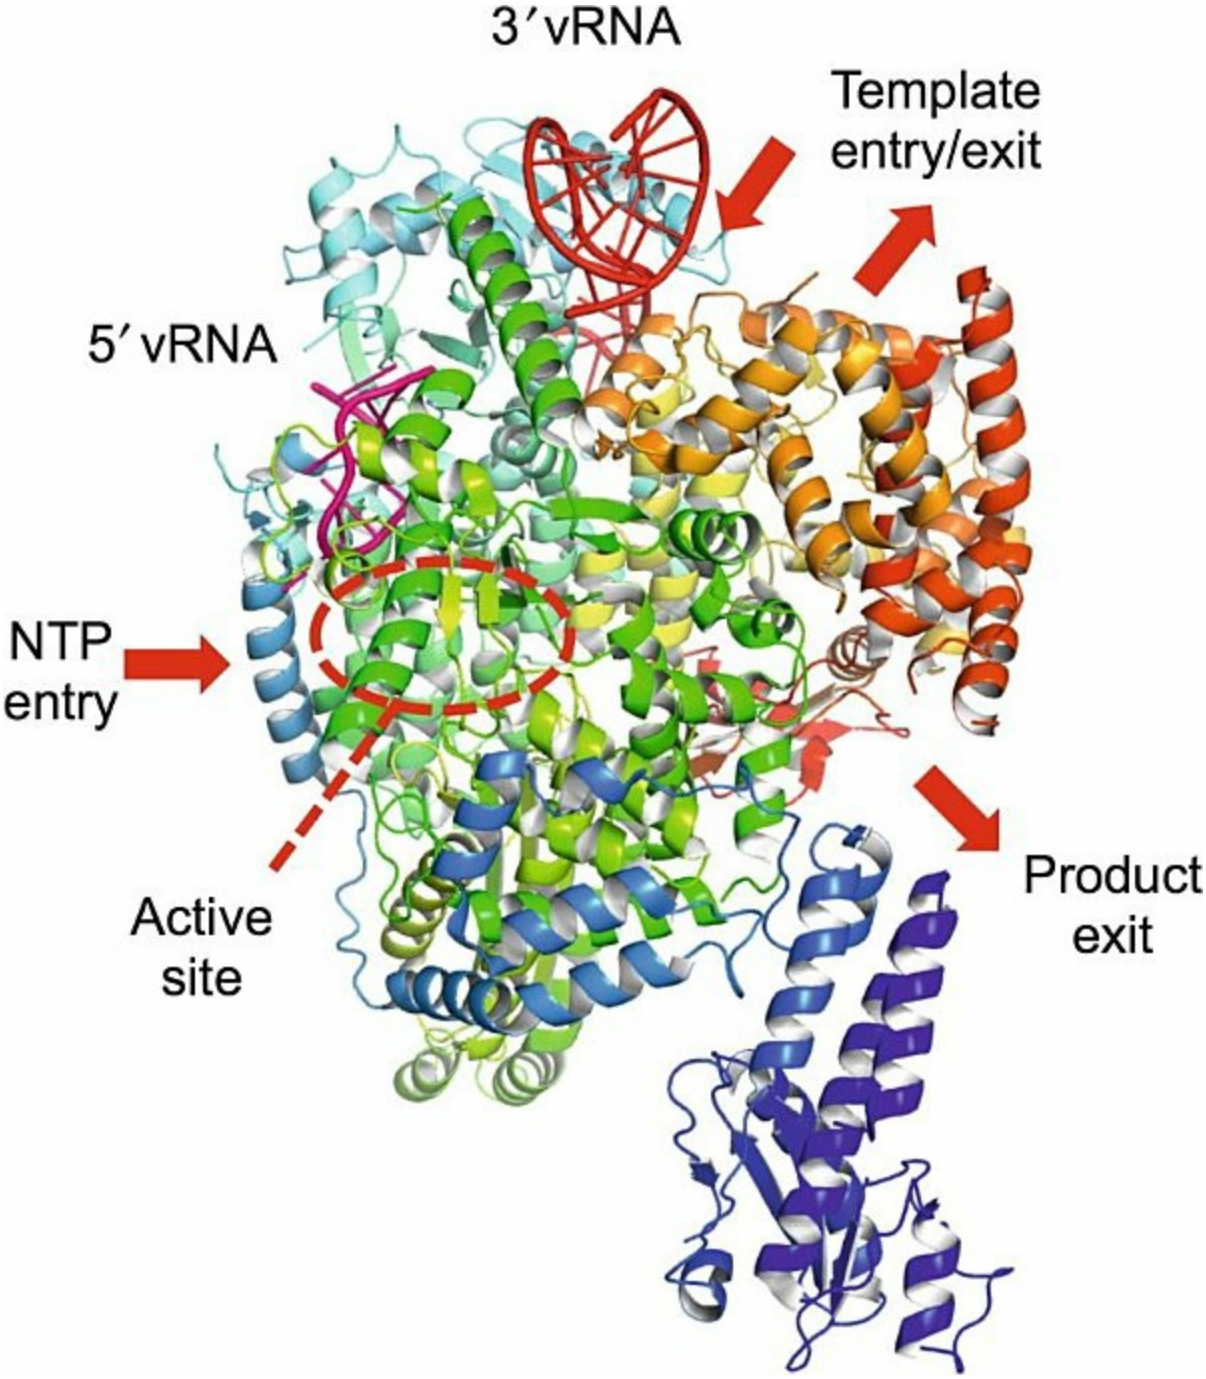

FIGURE 16.18 The crystal structure of the LACV RNA-dependant RNA polymerase (RdRp). The RdRp is shown bound to RNAs constituting 3′ and 5′ vRNA sequences, with *red arrows* showing entrances to tunnels that permit entry and exit of template, product, and NTP substrate, and the active site is marked with a *red dashed oval*. (Structural model drawn using Pymol from PDB code

5AMQ, and annotated with information from Gerlach P, Malet H, Cusack S, et al. Structural insights into Bunyavirus replication and its regulation by the vRNA promoter. *Cell* 2015;161(6):1267–1279. doi: 10.1016/j.cell.2015.05.006. Figure courtesy of Francis Hopkins, University of Leeds, UK.)

The N-terminus of the LACV L protein (residues 1–184) contains the endonuclease domain, responsible for generation of the capped RNA primers, and bears a high degree of structural similarity to the influenza virus endonuclease within PA.[96,474] Both endonucleases are members of the PD-(D/E) × K cation–dependent superfamily, and structural, bioinformatic, and functional analyses indicate that viruses in all the other *Bunyavirales* families contain a similar domain,[95,117,176,219,290,357,359,368,446] suggesting a common origin of the cap-snatching process of segmented negative sense viruses. The LACV endonuclease is linked to the rest of the PA-like region by an extended flexible linker (residues 185–270) that may permit significant mobility of this domain. Residues 271 to 759 can be divided into two lobes, one of which interacts in a sequence-specific manner with the two vRNA termini at separate binding sites, while the other buttresses the thumb and palm of the RdRp core. Within the central PB1-like RdRp core (residues 760–1,432), the palm domain comprises conserved polymerase motifs A-D, while the fingers represent motif F. Together, these regions build up the internal active site chamber, within which the active site is located and accessed by four solvent accessible tunnels. Two of these are assigned as template entry and exit tunnels, which are adjacent and force the template through an internal path approximately 20 nucleotides in length, passing alongside the active site. The confined dimensions of the polymerization chamber do not permit the formation of an extensive template/product hybrid, and instead the strands are forced to separate, with the nascent RNA product exiting the complex through the third tunnel, the product exit channel, with the fourth channel assigned to rNTP entry. The proximity of the template entry and exit channels potentially allows the RNA to be extracted and replaced within the N protein RNA binding groove within the RNP without breaking N–N interactions nor exposure of the RNA (Fig. 16.18). Access of the capped RNA oligomers to prime transcription are postulated to enter the active site

through the product exit channel, as is the case for influenza virus, facilitated by the flexibility of the endonuclease linker.

This first high-resolution structure of the bunyavirus RdRp has allowed an elegant model to be proposed, which describes the concerted events involved in bunyavirus RNA replication (Fig. 16.19). Critical features of this model include transition of an inactive preinitiation RNA-L complex into an active form by relocation of the 3′ vRNA end, the ability of RNA to transiently dissociate from N without disruption of the N–N multimeric chain, and the association of the nascent replication product with a second polymerase with associated N, thus ensuring encapsidation of the newly synthesised RNA strand, and maintaining the replication competance of the subsequently formed RNP. Cap-dependant mRNA transcription will likely involve major mechanistic differences, allowing access of the capped oligoribonucleotide to the active site, preventing encapsidation of the nascent RNA and thus allowing recognition of transcription termination signals that are presumably within the nascent transcript.

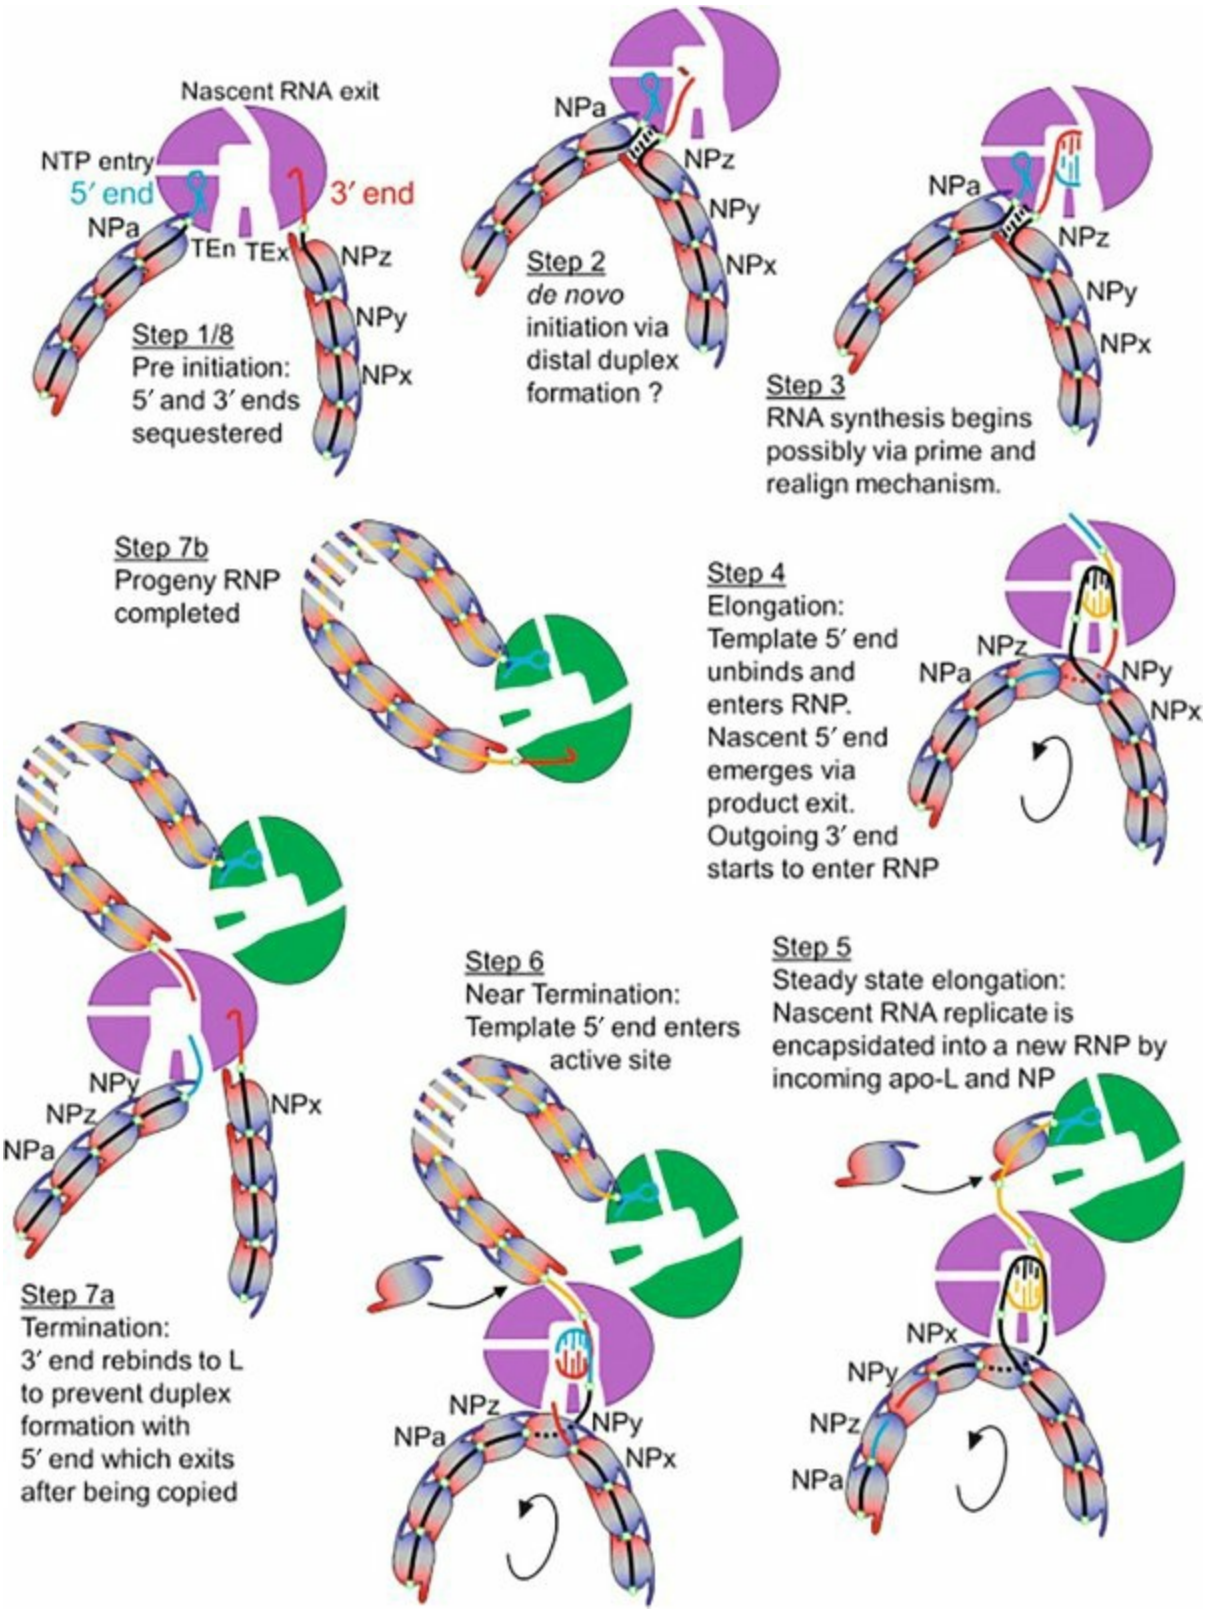

FIGURE 16.19 Model describing bunyavirus RNA replication.

The initial RNP cartoon (step1/8) shows the resident polymerase (*purple*) in its preinitiation state with vRNA 3′ (*red*) and 5′ (*cyan*) sequences bound at sites on the polymerase surface. Tunnels for template entrance (TEn), template exit (TEx), nascent RNA, and NTP entry are marked. NP molecules are represented as circles with N- and C- terminal arms, bound to 11 nucleotides of RNA forming the RNP chain. In step 2, the 3′ vRNA end becomes relocated in the active site, and in step 3, cRNA synthesis begins, and in step 4, the nascent cRNA emerges from the RNA exit channel. The proximity of TEn and TEx allow only a short RNA sequence to enter the active site, and thus the disruption of the RNA-NP template is minimal and may affect only one or two NP monomers. In step 5, an apo-L (*green*) complete with bound NP recruits the newly synthesized 5′ end, allowing encapsidation to commence. Further NP molecules join the growing cRNA strand, until the 5′ end of the template passes through the active site, to rebind on the surface of the encapsidating (*green*) polymerase, shown in steps 6 and 7a. All 3′ and 5′ ends relocate to surface-bound locations, the newly name cRNA complete with resident RdRp can generate further vRNAs, and the cycle can begin again, step 7b. (Figure adapted from Gerlach P, Malet H, Cusack S, et al. Structural insights into Bunyavirus replication and its regulation by the vRNA promoter. *Cell* 2015;161(6):1267–1279. doi: 10.1016/j.cell.2015.05.006.)

The significantly larger L proteins of nairoviruses possess identifiable motifs of both the endonuclease and catalytic core domains, although these are located further toward the C terminus of the molecule than in the other bunyaviruses.[95,176] Bioinformatics analysis revealed that the N terminus of the DUGV L protein contained a motif characteristic of cysteine proteases of the ovarian tumor (OTU) protein superfamily,[272] which were also subsequently

identified in CCHFV[177,217] along with a C2H2 zinc finger domain, and motifs corresponding to a leucine zipper and the active site of topoisomerase 1. The OTU domain acts to remove both ubiquitin (Ub) and also the Ub-like protein IFN-stimulated gene 15 (ISG15) from various cellular target substrates that serve as antiviral signaling platforms, thus it acts as both a deuquitinating enzyme (DUB) and also a de-ISGylase,[6,62,125,192,438] although sequence and structure variation is high and not always are both these activities realized.[101] The crystal structure of the CCHFV OTU revealed structural similarity to DUBs of both eukaryotic and viral origin, and revealed the molecular basis for Ub and ISG15 cross-substrate specificity. The catalytic activity of the OTU domain is not required for the RNA polymerase activity by CCHFV in a minigenome system[39]; however, it is essential for infectious virus production[388] with the catalytic knock out C40A mutant CCHFV being nonviable. In contrast, CCHFV mutants with reduced Ub or ISG15 binding were highly attenuated for growth in IFN-competent cell lines.

Morphogenesis

Transport of Viral Proteins

In contrast to other negative-strand RNA viruses, bunyaviruses usually mature within cells by budding at smooth membranes of the Golgi. The plant-infecting members of the family, the tospoviruses, also appear to assemble in the Golgi; however, it was suggested that instead of budding, there is a coalescence of Golgi membranes around the RNPs.[215] Budding at membranes other than those associated with the Golgi have been reported for some viruses; for example, the hantaviruses, SNV, and Black Creek Canal virus (BCCV), and the phlebovirus RVFV were found to bud from the plasma membrane as well as in the Golgi in some cells.[12,353] The reason(s) for maturation of bunyaviruses in the Golgi complex as opposed to the more usual mode of viral morphogenesis (budding at the plasma membrane) are not understood completely; however, important clues have been obtained by studying the viral proteins' transport to, and retention in, the Golgi.

Golgi Targeting and Retention

Expression of M gene segments of representative bunyaviruses demonstrated that Gn and Gc are targeted to the Golgi in the absence of other viral components. When expressed individually, Gn is able to exit the ER, but Gc remains in the ER for the orthobunyaviruses, phleboviruses, nairoviruses, and tospoviruses.[41,217,238,278] For hantaviruses, neither protein exits the ER when expressed separately.[371,396] For all studies to date, the signal for Golgi transport has been localized to Gn and complexing of Gn and Gc in the ER is necessary for efficient transport of Gc to the Golgi. Although ER retention signals have not been identified on Gc for most viruses, the phleboviruses have a characteristic carboxy-terminal ER retention motif (KKXX, where K = lysine and X = any amino acid).[140] Evidently, this signal can be overcome when Gn and Gc oligomerize. For BUNV, the Golgi localization and retention signal was mapped to the transmembrane domain of Gn.[402] The Golgi localization signal for the phleboviruses PTV and RVFV was identified within the transmembrane domain plus 10 (PTV) or 28 (RVFV) amino acids of the cytoplasmic tail.[140,278] The Golgi localization signal of another phlebovirus, UUKV, was found to be within a 30–amino acid peptide of the cytoplasmic tail.[15]

Similar expression studies with M-segment constructs of HTNV indicated that the ability of Gn to transport Gc to the Golgi requires the presence of the complete signal sequence of Gc. This suggests that the Gc signal peptide remains attached to the Gn cytoplasmic tail. This signal alone, however, is apparently not sufficient for Golgi targeting because M-segment constructs that maintained the Gc signal peptide but had other internal deletions in Gn or Gc failed to reach the Golgi. These results were interpreted to indicate that the correct conformation of the oligomerized Gn and Gc is also important for Golgi targeting.[386] Consistent with this is the observation that overexpression of SNV Gn resulted in the apparent accumulation of misfolded proteins in aggresomes.[417] In addition, the cytoplasmic tail of Gn was found to be polyubiquitinated when expressed alone, suggesting that it would undergo proteasomal degradation if not complexed with Gc.[135]

For the nairovirus, CCHFV, removal of the transmembrane domain and cytoplasmic tail of Gn did not prevent Golgi targeting, and this soluble truncated Gn was still able to dimerize with Gc and transport both proteins to

the Golgi.[41] In another study, Golgi targeting was dependent on a signal found both in the hydrophobic region of the cytoplasmic tail as well as in the ectodomain[161]; therefore, unlike other bunyaviruses, nairoviruses appear to have at least part of their Golgi-targeting signal in the ectodomain, rather than only in the transmembrane or cytoplasmic tail regions of Gn.

Clearly, although there are definite signals targeting the viral glycoproteins to the Golgi, there is no consensus motif or even region of Gn conserved among viruses across the order.

Trafficking Through the Golgi

The Golgi complex consists of several subcompartments, including the cis-, medial-, and trans-Golgi.[221] By using the fungal antibacterial reagent Brefeldin A, which inhibits transport of proteins out of the ER and causes a redistribution of the Golgi component to the ER, the GPs of the phlebovirus PTV were found to be localized in the cis and medial Golgi membranes.[36] Similar redistribution of Gn and Gc from the Golgi to the ER were observed following Brefeldin A treatment of cells infected with vaccinia virus recombinants expressing the M segment of BUNV.[295] Immunohistochemical and electron microscopy studies of the phlebovirus UUKV demonstrated that budding may begin as early as the pre-Golgi intermediate compartment and that virus budding continues in the Golgi stack.[194,375]

Examination of the type and amount of oligosaccharides attached to viral proteins influences trafficking and provides clues regarding the transit of the proteins through the Golgi compartments. For example, shortly after primary glycosylation of nascent proteins at the ER, oligosaccharides are susceptible to cleavage by endoglycosidase H (endo-H), an enzyme that cleaves only high-mannose residues. Later, after removal of glucose residues at the rough ER, migration of the GPs to the smooth ER and Golgi, trimming of residues, and attachment of peripheral sugars, the oligosaccharides are no longer susceptible to endo-H cleavage. Therefore, acquired resistance to endo-H generally indicates that the proteins have been processed through specific Golgi compartments as described earlier (see “M-segment products”). For the nairovirus CCHFV and the hantavirus HTNV the GPs remain endo-H sensitive, suggesting that they have not been processed through the medial

Golgi.[41,397] In contrast, the GPs of the orthobunyavirus, BUNV become endo-H resistant, so they can be assumed to have moved through the trans-Golgi.[303]

To identify the roles of specific glycosylation sites on trafficking of HTNV GPs, a series of expression constructs were created in which each of the four glycosylation sites that are used on Gn and the single site used on Gc were mutated. Removal of the glycosylation site closest to the amino-terminus of Gn resulted in its inability to exit the ER and for a loss of reactivity with monoclonal antibodies to native Gn.[397] Mutating the third glycosylation site in Gn was also poorly tolerated, and resulted in inefficient Golgi targeting and loss of monoclonal antibody reactivity. In contrast, mutating the single site on Gc or two of the other three sites of Gn were well tolerated. A similar study with BUNV indicated that the single Gn glycosylation site is absolutely required for correct protein folding, trafficking, and infectivity.[395] These data are consistent with results from another study, which will be described below, indicating that the processing of sugars plays a key role in maturation of BUNV.[303]

The time required to convert between endo-H susceptibility and resistance correlates with the time needed for protein transport from the ER to the Golgi. For the phlebovirus PTV, heterodimerization occurred between newly synthesized Gn and Gc within 3 minutes after protein synthesis, and the dimers were found to be linked by disulfide bonds. The dimeric Gn–Gc proteins were observed both during transport and after accumulation in the Golgi complex.[36] For another phlebovirus, UUKV, it was found that the transport of Gn and Gc from their site of synthesis on the rough ER through the Golgi occurred at an estimated two to three times slower rate than that of most viral membrane GPs destined to be transported to the plasma membrane.[126] That is, endo-H resistance was achieved at 45 and 90 to 150 minutes for Gn and Gc of UUKV,[233] compared to 15 to 20 minutes for the hemagglutinin protein of influenza virus or the G protein of vesicular stomatitis virus. The finding that UUKV Gn and Gc have different transport kinetics (i.e., Gn is incorporated into virions 20 minutes faster than Gc) suggests that the dimers may arise from different precursor proteins, possibly because faster-folding Gn cannot dimerize with slower-folding Gc until Gc has reached its correct conformation.[462] In this same study, the Gn and Gc

proteins of UUKV were found to exit the ER quickly, but did not enter the Golgi for 15 to 20 minutes. These findings suggest that the Gn and Gc proteins may dimerize in an intermediate compartment between the ER and Golgi.[462]

The NSm proteins are not known to play a role in transport or Golgi retention. For representative phleboviruses and orthobunyaviruses, expression of Gn and Gc in the absence of NSm had no effect on their transport to the Golgi; however, when the entire M segments were expressed, NSm co-localized to the Golgi with Gn and Gc, suggesting an interaction of these proteins before their exit from the ER.

Assembly

For assembly to occur, N, L as well as Gn and Gc must move to the same intracellular location. For the hantavirus, SEOV, N could first be observed approximately 2 hours after infection and accumulated as scattered granules in the cytoplasm. Although N was not observed in the Golgi, it could be observed to surround the Golgi by 24 hours after infection.[204] The N proteins of the nairovirus CCHFV and the hantavirus BCCV were both observed in the perinuclear region of infected cells, and both were found to bind to actin.[16,352] Disrupting the cellular actin network by treatment with cytochalasin D reduced the assembly of infectious CCHFV, suggesting a role for actin in transporting N to the site of virion assembly. For BCCV, the N protein was found to be peripherally associated with Golgi membranes, suggesting that the RNPs are recruited to the Golgi for assembly.[417] In contrast, the CCHFV N protein was not found in association with Golgi membranes; therefore, it is unclear where the actual assembly site is for nairoviruses, and it was suggested that some sort of novel structure close to the nucleus might be involved.[16] Immunofluorescence and cell fractionation studies showed the L protein of TULV associated with perinuclear membranes[234] with partial co-localization with Golgi matrix protein GM130. Similarly, an epitope-tagged L protein expressed from a recombinant BUNV was also identified within the perinuclear region, and cell fractionation studies showed L to be distributed in both cytosolic and microsomal fractions.[398] These studies pointed to bunyaviruses establishing membrane-

associated virus factories, similar to those described for flaviviruses, and this was confirmed by detailed electron microscopic analysis of BUNV-infected cells, which identified viral replication occurring in membranous structures built around the Golgi complex (Fig. 16.20). These comprised repetitive units of Golgi stacks, mitochondria, components of the rough ER, and virus-derived tubular structures with a globular head.[375] The viral polymerase and N protein were found mainly in the globular head, and viral RNPs were released from disrupted, purified tubes.[121] Viral tubes contain cellular proteins such as actin and myosin I, and both tube assembly and viral morphogenesis were sensitive to drugs that affect actin. Advanced imaging and three-dimensional (3D) reconstruction of infected cells showed that the tubes link cellular organelles, for example, mitochondria, to the Golgi and interact with intracellular viral forms, thereby providing a route for cellular factors required for genome replication. Based on these observations a model has been proposed (Fig. 16.21) whereby viral RNPs are transported from sites of replication in the globular domain to the cytoplasm where they condense on Golgi membranes modified by the insertion of Gn and Gc, and promote budding of immature particles into Golgi-derived cisternae that separate from Golgi stacks. Further studies using the orthobunyavirus OROV showed that Golgi membranes become remodeled by using the cellular ESCRT (endosomal complex required for transport) machinery.[26] As already mentioned, localization studies with BUNV suggest that the nonstructural protein NSm might be involved in facilitating virion assembly in the Golgi.[121,400]

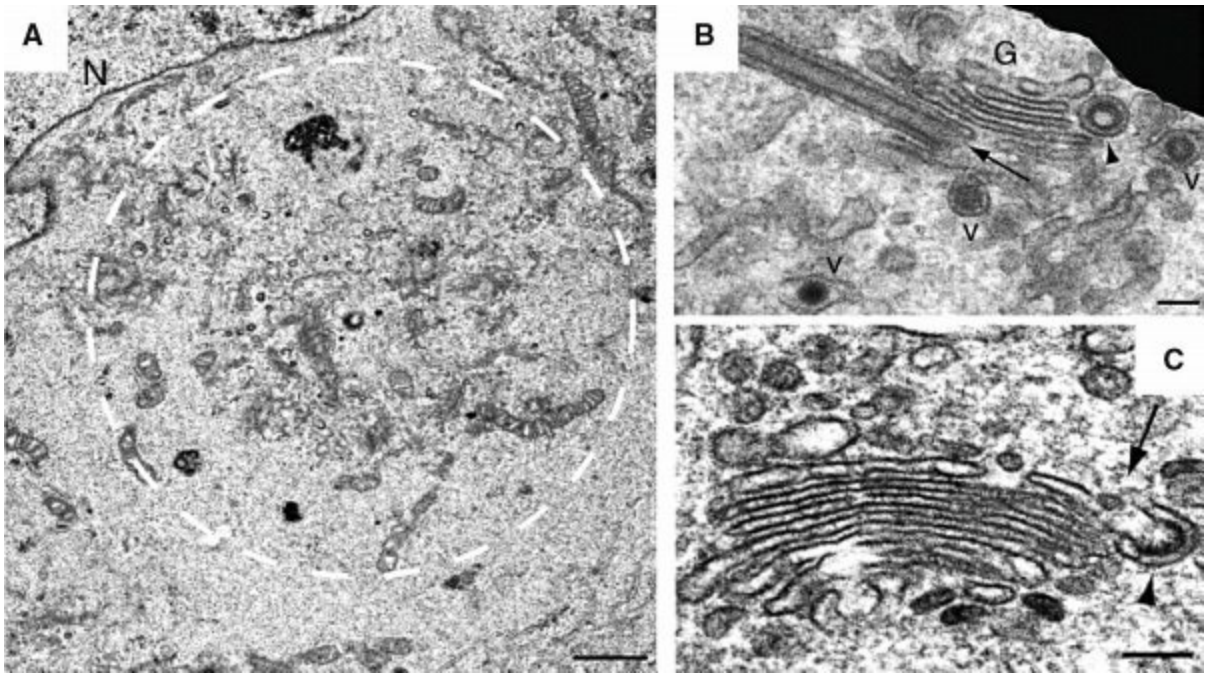

FIGURE 16.20 Visualization of viral factory in Bunyamwera virus (BUNV)-infected BHK cells by electron microscopy. A: Viral factory (*dashed white circle*) shows groups of organelles near the nucleus (N). **B:** Higher magnification shows longitudinal (*arrow*) and transverse (*arrowhead*) sections of tubular structures in Golgi stacks (*G*). Virus particles (*V*) are also seen. **C:** Tubular assembly with a bigger globular domain (*arrow*). N, nucleus; G, Golgi stack; V, virus particle; scale bar represents 1 μm in **(A)** . (Modified from Fontana J, Lopez-Montero N, Elliott RM, et al. The unique architecture of Bunyamwera virus factories around the Golgi complex. *Cell Microbiol* 2008;10:2012–2028.)

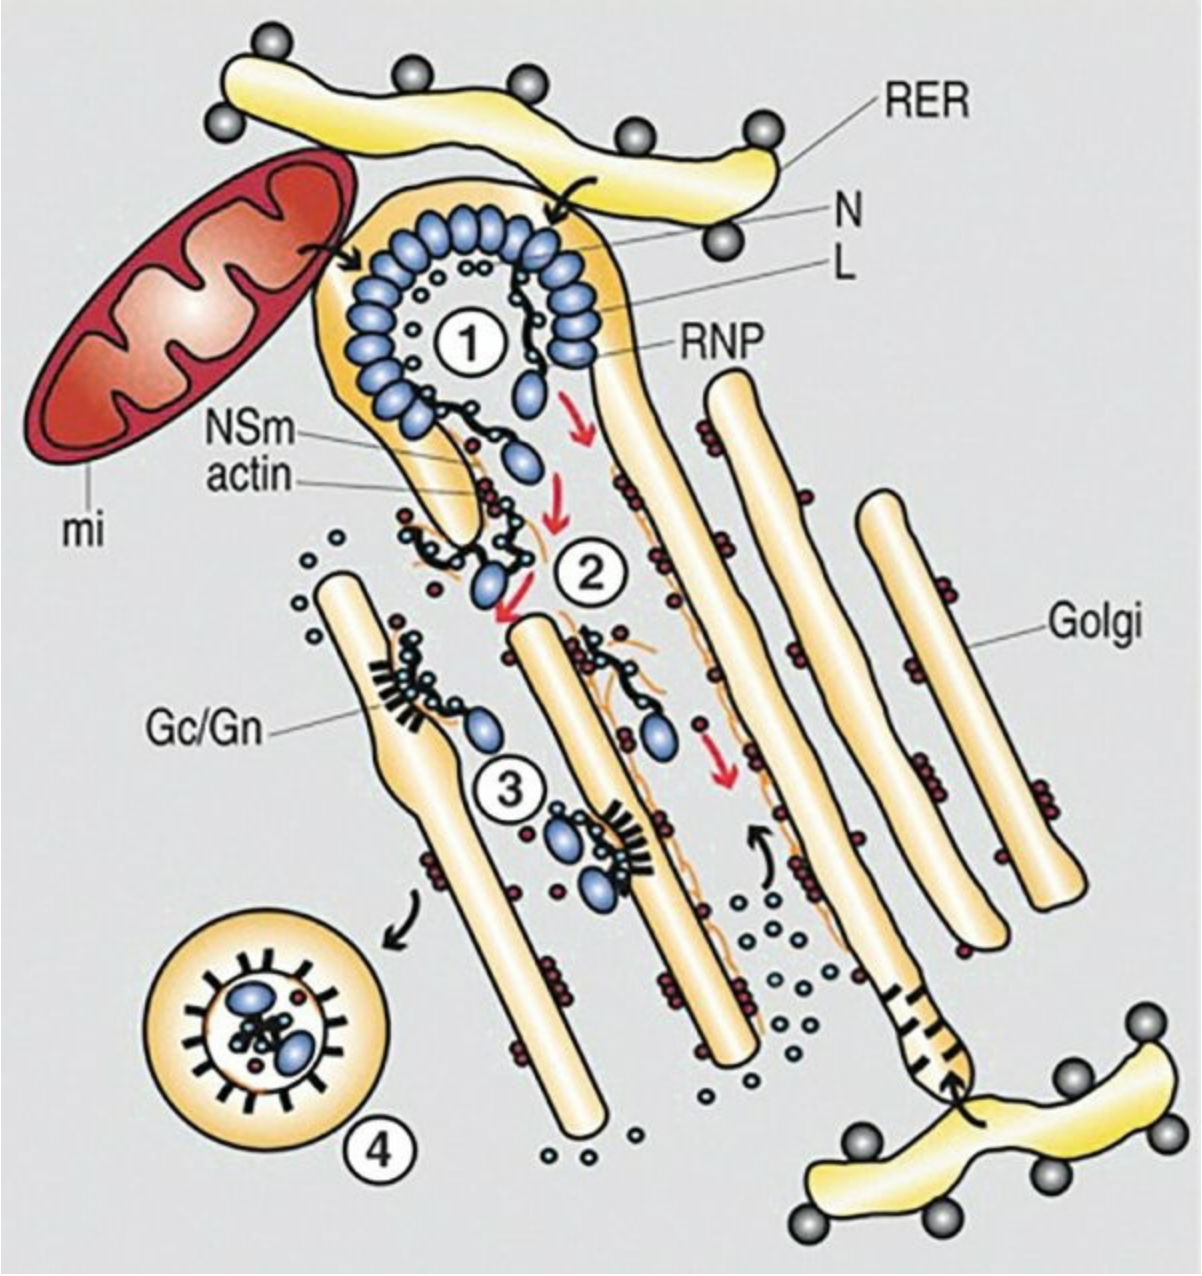

FIGURE 16.21 Model for the functional structure of viral tubes integrated in the Bunyamwera viral factory. Viral tubes assemble in association with Golgi membranes using endogenous actin and polymerized NSm as scaffold. Tubes attach to rough endoplasmic reticulum (*RER*) cisternae and mitochondria that provide cell factors needed for viral replication and assembly. Viral polymerase (*L*) concentrates in the globular domain. Replicated viral RNA (*1*) gets protected by interaction with N molecules,

abundant around Golgi membranes and inside tubes. N molecules enter the tubes through their openings to the cytoplasm. With the help of actomyosin-based motors, assembled ribonucleoprotein complexes (*RNPs*) then travel toward the cytoplasm (*2*), where they bind to the cytoplasmic domains of viral glycoproteins (*Gc/Gn*) concentrated in the nearby Golgi membranes. Budding events (*3*) lead to new viral particles that incorporate some amounts of the scaffold NSm protein and actin inside. Assembled immature viral particles are then ready for maturation and secretion (*4*). (Redrawn from Fontana J, Lopez-Montero N, Elliott RM, et al. The unique architecture of Bunyamwera virus factories around the Golgi complex. *Cell Microbiol* 2008;10:2012–2028.)

Unlike most other negative-strand RNA viruses, bunyaviruses do not have a matrix (M) protein to link the integral viral envelope proteins and their nucleocapsids and to act as the nucleating step for assembly. The absence of an M protein suggests a direct interaction between the ribonucleocapsids, which accumulate on the cytoplasmic side of vesicular membranes, and viral envelope proteins, which are displayed on the luminal side.[422] Electron microscopy of cells infected with the phleboviruses PTV or Karimabad virus revealed that RNPs and spike structures (i.e., viral envelope GPs) were present only in regions of Golgi membranes where budding appeared to be occurring, and not on adjacent areas of the same membrane, suggesting a transmembranal interaction of N with Gn or Gc.[413] Direct evidence for the requirement of the cytoplasmic tails of both glycoproteins has been obtained using VLP production assays.[401]

The signal directing the RNPs to the budding compartment has not been identified for most bunyaviruses. For hantaviruses, however, N was shown to interact with the cellular proteins, SUMO-1 (small ubiquitin-like modifier-1) and Ubc9 (SUMO-1 conjugating enzyme 9) in yeast two-hybrid systems.[208,246,270] For HTNV, the interaction occurred at a four–amino acid motif, MAKE, located at amino acid positions 188 and 189 of N, and mutation of this motif prevented transport of N to the perinuclear region,

suggesting a role for this interaction in directing N to the site of assembly.

Excess RNPs of hantaviruses, tospoviruses, and nairoviruses were found to accumulate in large cytoplasmic inclusions, suggesting that only RNPs that interact with the envelope proteins are transported to the Golgi. Although not yet defined, it is likely that the transmembrane domains of Gn or Gc that are exposed on the cytoplasmic face of the membrane are involved in this interaction. Candidate transmembrane regions have been predicted from hydropathic characteristics of derived amino acid sequences representing the envelope proteins of all bunyaviruses examined to date. Direct examination of a phlebovirus by enzymatic digestion of exposed proteins embedded in intracellular membranes demonstrated that approximately 12% of Gn or Gc was exposed on the cytoplasmic face of membranes in infected cells and was accessible to digestion. A large protease-resistant fragment was identified, which was presumably sequestered in the membrane in a manner that rendered it safe from enzymatic digestion.[413] These enzyme-resistant fragments may therefore represent transmembrane regions of proteins, which could provide the interaction between RNPs and the cellular membranes required for envelopment. The predicted cytoplasmic tails on Gn have also been suggested to be logical candidates for interacting with the ribonucleocapsids.[361]

Tospovirus assembly and release in plants may differ from those processes of other viruses in the *Bunyavirales* order. A model was proposed in which Golgi membranes with integral viral envelope proteins wrap around RNPs. These particles may then fuse with each other or with ER membranes to release single enveloped particles into the cisternae.[215] Mature virions accumulated within the ER cisternae likely remain there until ingested by thrips.

Transport and Release

After budding into the Golgi cisternae, virions apparently are transported to the cell surface within vesicles analogous to those in the secretory pathway. The release of virus from infected cells presumably occurs when the virus-containing vesicles fuse with the cellular plasma membrane (i.e., by normal exocytosis). Numerous viruses in the family have been observed late in infection within vesicles or in the process of exocytosis by electron

microscopy, and more recently by light microscopy of BUNV expressing a Gc-GFP fusion protein (Fig. 16.22). In polarized cells, the phleboviruses PTV and RVFV show differing release characteristics, in that no marked polarized release could be detected for RVFV whereas PTV was released primarily from the basolateral surfaces.[73,141] In contrast to these phleboviruses, the hantavirus BCCV was released from the apical surface.[353] Such polarized release of viruses might be important for disseminating virus during natural infection to produce a systemic disease. Release of tospoviruses from insect cells probably occurs via secretory exocytosis similar to that of animal-infecting members of the family.[461]

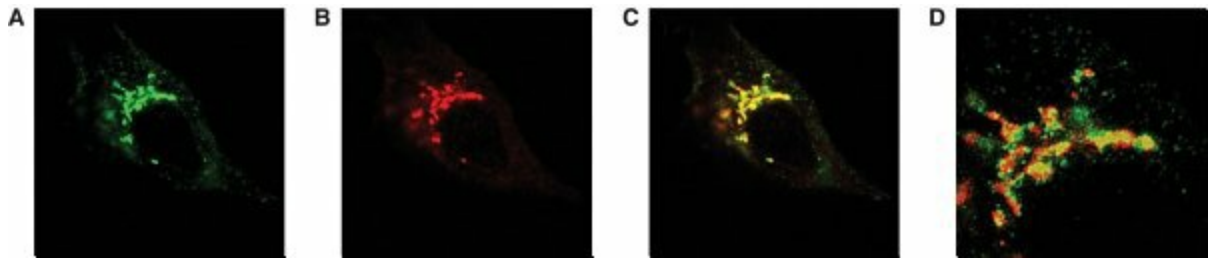

FIGURE 16.22 Bunyavirus budding at the Golgi. BSR-T7/5 cells, BHK-derived cells constitutively expressing T7 RNA polymerase, were infected with a recombinant Bunyamwera virus (BUNV) expressing a Gc-GFP (*green* fluorescent protein) fusion protein (*autofluorescence* shown in **A**) and co-stained with antibodies to the Golgi marker GM130 (in *red* in **B**). Colocalization between Gc proteins and the Golgi protein is shown in *yellow* in the merged images (**C**), and an enlarged image is shown in **D** . (From Shi X,van Mierlo JT, French A, et al. Visualizing the replication cycle of Bunyamwera orthobunyavirus expressing fluorescent protein-tagged Gc glycoprotein. J Virol 2010;84(17):8460–8469. doi: 10.1128/JVI.00902-10. EFFECTS OF VIRAL REPLICATION ON

HOST CELLS

Cytopathic Effects

The cytopathic effects observed in cultured cells infected with bunyaviruses vary widely, depending on both the virus and the type of host cell studied. Most bunyaviruses are capable of alternately replicating in vertebrates (or plants for tospoviruses) and arthropods, and generally they are cytolytic for their vertebrate/plant hosts but cause little or no cytopathogenicity in their invertebrate hosts. Hantaviruses have no known arthropod vector, and generally cause persistent infections in their hosts and in cultured cells. Little is known about hantaviruses from fish and reptiles, as only gene sequences have been detected for these thus far. Some bunyaviruses display a narrow host range, especially for arthropod vectors. Although the reason for this has not been defined completely, studies on variant and revertant LACV orthobunyaviruses have suggested that the specificity was related to Gc, probably at the level of viral attachment to susceptible cells.[427] In natural infections of mammals, viruses are often targeted to a particular organ or cell type. For example, orthobunyaviruses such as LACV appear to be neurotropic[321]; the phlebovirus RVFV is primarily hepatotropic[329]; and the hantavirus HTNV persists in rodent lungs.[244] It will be interesting to determine whether this targeting is due solely to host-cell receptors or to other factors such as differences in effects on host-cell metabolism in targeted cell types versus the unnatural situation in cultured vertebrate cell lines.

Host-Cell Metabolism

In vertebrate cells, orthobunyaviruses and some phleboviruses were found to cause a reduction in host-cell protein synthesis, which became more prominent as the infection progressed. For example, by 5 hours after infection, cells infected with BUNV at high multiplicity showed reduced levels of host protein synthesis, and by 7 hours there was almost no synthesis.[327] RVFV-infected cells displayed reduced host protein synthesis, which gradually became more pronounced from 4 to 20 hours after infection.[320] In contrast, a reduction in host protein synthesis did not occur,

even late in infection, with another phlebovirus, UUKV, or with the nairovirus DUGV,[331,436] both of which are transmitted by ticks rather than mosquitoes. Hantaviruses not only cause no detectable reduction in host macromolecular synthesis[383] but routinely establish persistent, noncytolytic infections in susceptible mammalian host cells, a finding consistent with their nonpathogenic persistence in their natural rodent hosts.[244]

The arthropod-borne members of the family, like most other arboviruses, cause little detectable cytopathology in mosquito cell cultures, and viral persistence is readily established. Unlike cultured vertebrate cells, mosquito cells infected with the orthobunyavirus, Marituba virus, displayed no reduction in host macromolecular synthesis; therefore, viral infection apparently does not drastically interfere with normal cellular processes.[68] One suggested reason for this is that, in arthropod cells, excess viral proteins do not accumulate in the cells but rather are more efficiently processed into mature virions.[296] Another possibility is that viral transcriptase may be less active in arthropod cells than in mammalian cells and that the endonuclease activity of the polymerase (which is used to acquire transcriptional primers) is detrimental to host-cell messages. A reduced level of activity of the viral transcriptase would, therefore, produce less damage to host-cell messages and consequently to protein synthesis.[369]

Persistence, in both insect and mammalian cells, can be mediated by defective interfering (DI) viruses. Conventional DI particles, which displayed deletions only in L, were described for orthobunyaviruses and tospoviruses. The L deletions identified both in the TSWV and BUNV DI particles were in-frame, thus allowing translation of truncated L polypeptides.[93,322] Persistent infections of viruses in the family have also been described that do not involve typical DI particles, but instead are caused by infection with temperature-sensitive and plaque morphology mutants.

Host-Cell Responses and Viral Suppression

Interferon-Stimulated Genes and Gene Products

A first line of host defense against viruses is the innate immunity mechanism mediated by the type I interferon (IFN) pathway. Type I IFN (also called

IFNα/β) is produced in, and secreted from, infected cells, and in neighboring cells activates the expression of hundreds of ISGs whose gene products directly or indirectly inhibit virus replication. IFN induction is mediated by the recognition of pathogen-associated molecular patterns (PAMPs) by cellular receptors.[333] Two RNA helicases, RIG-I and MDA5, are intracellular receptors that are activated by specific double-stranded RNA (dsRNA) PAMPs, though the dsRNA–binding protein kinase PKR may also assist.[207,334,351,360,390] RIG-I binds short dsRNAs with 5′ triphosphate groups, whereas MDA5 recognizes any long dsRNA. Negative-sense RNA viruses do not produce much of long dsRNA[455] but are strong activators of RIG-I because of the 5′ triphosphorylated dsRNA panhandle on their genome.[454] Activation of RIG-I by binding of RNA initiates a signaling cascade that leads to phosphorylation of the transcription factor IFN regulator factor 3 (IRF-3)[173]; phosphorylated IRF-3 dimerizes, enters the nucleus, and initiates IFN-β mRNA synthesis. Virus replication also activates other transcription factors such as IRF-7, NF-kB, and AP-1, which enhance IFN gene expression. IFN is then produced and secreted by the infected cells. After docking onto its cognate receptor in an autocrine or paracrine fashion, a signaling chain ensues that results in expression of ISG-encoded proteins. These newly made proteins have a myriad of functions, some of which have been characterized with respect to their specific antiviral activity. Major antiviral defense mechanisms concerning bunyaviruses are the Mx proteins, PKR, the 2′-5′ oligoadenylate synthase (2′-5′-OAS)/RNaseL system, ISG20, IFITMs, tetherin, and viperin.

The Mx proteins are IFN-induced cytoplasmic proteins, which belong to a family of large GTPases that function in intracellular trafficking.[164] After viral infection and IFN induction, Mx proteins are rapidly induced and accumulate in the cytoplasm. Human MxA has been shown to inhibit the replication of representative members of the *Orthobunyavirus*, *Orthohantavirus*, *Orthonairovirus*, and *Phlebovirus* genera.[53,123,201,211] Both inhibition of primary transcription and genome replication have been observed.[123,158,361] The MxA protein was shown to bind to the N proteins of LACV, BUNV, RVFV, ANDV, and CCHFV[13,211,222,361] and in LACV-infected cells to redistribute it into membrane-associated perinuclear

cytoplasmic complexes, thus removing the protein from use in viral replication.[222,361] For the orthobunyavirus LACV, MxA inhibits replication in mammalian cell cultures, in mosquito cells expressing the human MxA gene, and in MxA-transgenic mice that lack a functional IFN system.[123,169,286]

Inhibition of the replication of several hantaviruses by MxA protein has been described. ANDV infection of human vein endothelial cells (HUVECs) was found to up-regulate transcription of MxA RNA and expression of MxA protein. Virus replication was required for the induction of MxA, and the virus was found to replicate best in cells with low or no expressed MxA. Comparison of induction of MxA protein for pathogenic and nonpathogenic hantaviruses in HUVECs demonstrated that the nonpathogenic hantaviruses (PHV or TULV) induced an early and vigorous onset of MxA expression, whereas the pathogenic hantaviruses (ANDV or HTNV) induced MxA relatively late (48 hours) after infection.[137,231] In contrast, Vero E6 cells, which lack IFN genes, supported the growth of both viruses. These results suggest that pathogenic but not nonpathogenic hantaviruses can delay the IFN-β-induced antiviral MxA response and allow efficient viral replication early in infection.[231]

To determine whether MxA would be active against tospoviruses in plants, transgenic tobacco plants expressing MxA were created and then challenged with TSWV. No increased resistance to viral replication was observed in the transgenic plants, indicating that expression of human MxA alone is not sufficient to impart virus resistance to plants.[124]

In MxA-deficient systems bunyavirus replication can still be impaired, implying that other ISGs have anti-bunyaviral activity.[14,49,159,307] PKR is a dsRNA-activated inhibitor of translation that was shown to contribute to host resistance to BUNV, whereas the RNA-degrading 2′-5′ OAS/RNaseL system had no effect.[66,423] Moreover, RVFV lacking its NSs protein (see below) is highly sensitive to PKR *in vitro* and *in vivo*.[159,186] ISG20 (Interferon-stimulated gene 20 kDa protein) is a 3′-5′ exonuclease able to inhibit members of the *Peribunyaviridae*, *Hantaviridae*, and *Nairoviridae* families, whereas *Phenuiviridae* of the genus *Phlebovirus* (RVFV) and *Banyangvirus* (SFTSV, HRTV) were not affected.[115] Members of the IFN-induced transmembrane proteins (IFITMs) inhibit cytoplasmic entry of a broad range

of viruses, including LACV (genus *Orthobunyavirus*, family *Peribunyaviridae*), RVFV (genus *Phlebovirus*, family *Phenuiviridae*), ANDV and HTNV (genus *Orthohantavirus*, family *Hantaviridae*), but not CCHFV (genus *Orthonairovirus*, family *Nairoviridae*).[291] Tetherin is a transmembrane protein that, different from the IFITMs, interferes with a late step in replication, the budding of enveloped virus particles from the cell. For orthobunyaviruses like, for example, SBV tetherin was shown to inhibit virus propagation by reducing the amount of GPs in viral particles.[440] Viperin is a member of the radical S-adenosylmethionine enzyme superfamily shown to inhibit BUNV multiplication by an unknown mechanism.[66]

Interferon Antagonism

Viruses encode IFN antagonistic proteins that allow them to overcome the antiviral effects of IFN. Evasion of the IFN response by viruses can occur by preventing IFN induction or by inhibiting IFN signaling and/or the activity of ISGs. IFN antagonism has been demonstrated for the NSs proteins of the phlebovirus RVFV, the orthobunyaviruses BUNV and LACV, and the hantaviruses PUUV and TULV.[189,268,387,468] For the phleboviruses and orthobunyaviruses, NSs proteins were identified as IFN antagonists by comparing wild-type and mutant viruses that do not express NSs. An RVFV mutant, called Clone 13, was naturally occurring, whereas the BUNV and LACV mutants were created by reverse genetics.[45,55,293] The wild-type viruses induced little IFN and were virulent in mice, whereas the NSs-defective viruses were potent inducers of IFN and attenuated in mice. In genetically altered mice that are nonresponsive to type 1 IFN, the mutant viruses were just as virulent as the wild-type parents, indicating that type 1 IFN is the target of NSs.[46,55,452]

Although the orthobunyavirus and phlebovirus NSs have no sequence similarity and are expressed by different coding strategies, they both appear to antagonize host IFN at the level of cellular transcription. For BUNV and LACV, NSs was shown to interfere with the C-terminally hyperphosphorylated (i.e., elongating) state of the RNA polymerase II complex, leading to a down-regulation of host mRNA synthesis.[434,443] This effect was seen only in mammalian cells, not in insect cells, suggesting that

IFN antagonism by NSs might be involved in the lytic infections observed in mammalian cells as opposed to viral persistence in insects.[224] BUNV NSs was shown to interact with the protein MED8, a component of the Mediator complex that is essential for mRNA synthesis.[249] LACV NSs selectively targets the RPB1 subunit of the elongating form of RNA polymerase II for proteasome-mediated degradation, an event similar to that seen during the cellular DNA damage response.[443] RVFV NSs inhibits transcription of IFN mRNA in several ways, firstly by sequestering the p44 subunit of the TFIIH general transcription factor,[241] secondly by proteasomally degrading the p44 subunit of TFIIH via the ubiquitin ligase FBXO3,[200] and thirdly by recruiting the SAP30 repressor factor to the IFN-β promoter.[242] RVFV NSs also interferes with host cell mRNA export from the nucleus, a mechanism most likely contributing to IFN antagonism.[83] The NSs proteins of several other pathogenic phleboviruses and banyangviruses including SFSV, TOSV, PTV, and SFTSV were also shown to efficiently block IFN induction.[146,147,159,299,328,344,363,380,466,467] The mechanisms, however, are quite different. Whereas SFSV NSs masks the DNA-binding domain of IRF-3 to hinder it from IFN promoter binding,[467] TOSV NSs interacts with RIG-I and triggers its proteasomal degradation.[147] PTV NSs affects neither IRF3 nor RIG-I but appears to act as a general host cell shutoff factor similar to RVFV NSs[259,467] SFTSV NSs sequesters a number of components of the RIG-I-dependent antiviral signaling chain (including RIG-I and the IRF-3 kinase TBK1) into inclusion bodies, thus disabling antiviral signaling.[299,380,466] Interestingly, the NSs of the avirulent phlebovirus UUKV is only a weak inhibitor of IFN induction.[363] A similar positive correlation between virulence and IFN antagonism was observed for the NSs-less orthobunyaviruses in the Anopheles A, Anopheles B, and Tete serogroups. The majority of them have not been associated with human disease, and failed to prevent induction of IFN-β mRNA. Tacaiuma virus (Anopheles A serogroup), causing a mild febrile disease in humans, was the exception as it was able to inhibit IFN induction, apparently in an NSs-independent manner.[287]

As described above, some hantaviruses have an additional ORF in the S segment,[337] and evidence for the expression of an NSs protein has been

obtained for PUUV and TULV.[189] The NSs protein was shown to be weakly antagonistic to IFN when overexpressed in cell culture, and the presence of a full-length NSs gave a growth advantage to TULV strains in IFN-competent cells.[190] Both hantaviruses and nairoviruses have 5′ monophosphorylated nucleotides on their genomes, thereby avoiding recognition by RIG-I and hence inducing IFN,[157] although the viruses also encode other countermeasures to innate immunity. The OTU domain in the nairovirus L protein deconjugates ubiquitin and ISG15 from cellular targets, thus antagonizing IFN induction.[25,63,125,192,388] Certain hantaviruses have also been shown to interfere with TNF-*α* induced activation of NF-κB signaling through an interaction between the viral N protein and karyopherin molecules that normally transport the NF-κB subunits from the cytoplasm to the nucleus, thus preventing their use to activate ISGs.[432]

It has been reported that pathogenic hantaviruses do not efficiently activate the IFN response as compared to nonpathogenic hantaviruses, suggesting the presence of an IFN antagonistic gene.[137] The cytoplasmic tail of the Gn glycoprotein (Gn-T) from pathogenic hantaviruses has been shown to down-regulate IFN induction by interacting with TNF receptor–associated factor 3 (TRAF3), an adaptor protein for IRF-3 and NF-kB signaling, whereas Gn-T from PHV fails to inhibit IFN induction.[9,10] However, a recent study showed that the Gn-T of nonpathogenic TULV can also down-regulate IFN induction, but does so in a manner not involving interaction with TRAF3.[280] These data suggest that the pathogenic potential of hantaviruses does not depend on their ability to down-regulate IFN alone. The situation is further complicated by the demonstration that for ANDV, IFN induction is inhibited by coexpression of the GPC and N protein, whereas downstream IFN signaling may be inhibited by either protein.[250] In addition, hantavirus infection of VeroE6 cells was reported to result in induction and secretion of type III IFN (IFN-*γ*).[341,419] Furthermore, the induction of ISGs in epithelial cell lines (e.g., A549 cells) infected with Vero cell grown virus was found to be due to the presence of IFN-*γ* rather than to virus infection.[341]

Cytokines/Chemokines/ITAMs

The host cells' responses to hantaviral infection have been studied in an attempt to understand the mechanism of disease. Hantaviruses cause two serious human disease syndromes: HFRS and HPS. Both HFRS and HPS are believed to result from host immune responses to viral infection, rather than damage caused by the viruses themselves.[212] In both syndromes, vascular endothelial cells show increased permeability, which is believed to contribute greatly to the diseases. Several studies have measured the types of cytokines and chemokines released in response to disease, and these are discussed in the context of viral pathogenesis below. Of note is the presence of immunoreceptor tyrosine-based activation motifs (ITAMs) within the cytoplasmic tails of the Gn protein of hantaviruses. ITAMS are cell-signaling elements involved in regulating endothelial cell function. The presence of these elements in hantaviruses has also been suggested to relate to the dysregulation of endothelial cells during hantaviral infection.[135,136]

Apoptosis

Apoptosis, a type of programmed cell death, has been described for orthobunyaviruses, phleboviruses, nairoviruses, and hantaviruses. Apoptosis usually results from activation of a proteolytic system involving caspases, a group of cysteine proteases that cleave cellular substrate proteins. The role of apoptosis in virus infection can be both supportive and suppressive, depending on the time point of its onset.

Apoptosis caused by a bunyavirus was first noted in cultured cells and brains of newborn mice infected with the orthobunyavirus LACV.[326] The NSs proteins of LACV and related viruses were found to have an amino acid sequence similar to that of a *Drosophila* protein, Reaper, which is involved in regulating caspase activity and can induce apoptosis.[81] Reaper is one of several proteins that are able to bind to a group of proteins, known as inhibitors of apoptosis, which function to control caspase activity.[393] Like Reaper, BUNV NSs proteins were shown to both inhibit cellular protein translation and activate caspase in cell-free extracts. To demonstrate *in vivo* apoptosis, a Sindbis virus replicon expressing NSs was injected into the brains of young mice. The mice developed neuronal apoptosis and died 6 days after infection. A similar mechanism of action for inducing apoptosis by Reaper and orthobunyavirus NSs was proposed because both were shown to

bind to and counteract the effects of a protein known as Scythe, which is an apoptosis regulator.[81] Mosquito cells persistently infected by LACV do not undergo apoptosis.[45] The orthobunyavirus OROV induces apoptosis in HeLa cells that is dependent on virus uncoating and replication, but treatment of cells with a pan-caspase inhibitor did not affect virus production although apoptosis was prevented.[2] The results indicated that the intrinsic apoptosis pathway was triggered by virus replication but apoptosis was not necessary for efficient virus production in cell culture.

Apoptosis was also observed after infection with phleboviruses like RVFV or TOSV.[87] Similar to LACV NSs,[443] the nonstructural protein NSs of RVFV activates DNA damage-response signaling in the nucleus and the apoptosis promoter[23] p53.[24] The nonstructural protein NSm of RVFV, however, suppresses apoptosis.[433,465] For the nairovirus CCHFV, the NSs protein was shown to trigger apoptosis by disrupting the mitochondrial membrane potential,[27] but at early stages of infection CCHFV inhibits apoptosis.[206]

For several hantaviruses, apoptosis was observed in infected cultured monkey kidney (Vero E6) cells,[203,252] in cultured human embryonic kidney cells (HEK-293),[273] and in lymphocytes of HFRS patients.[5] Unlike most infections with hantaviruses, which are generally noncytolytic and persistent, cytopathic effects were observed in the HEK-293 cells infected with hantaviruses, and apoptosis was observed almost entirely in cells adjacent to those actively infected with the hantavirus.[273] In another report, apoptosis was not seen in confluent Vero E6 cells infected with various hantaviruses, and only a few apoptotic cells could be seen when subconfluent cells were infected.[166] Likewise, infection of primary immature dendritic cells or HUVECs with HTNV did not induce cell lysis or apoptosis.[345] These differing results remain to be resolved, but it is likely that they can be attributed to differences in the cells or the condition and passage histories of the cells.

The factors triggering apoptosis for hantaviruses are not generally known. In TULV-infected Vero E6 cells, caspase 8 activation was observed and

apoptosis could be inhibited with a caspase inhibitor.[252] Caspase 8 is one of several caspases that can be induced by the binding of a specific ligand to "death receptors," such as tumor necrosis factor 1 (TNF1) and Fas (also called CD95), which are found on certain cells.[22] Consistent with this, TNF1 was up-regulated at times when apoptosis was apparent in the TULV-infected cells and a Fas-mediated apoptosis enhancer, DAXX, was found to bind to PUUV N proteins.[255] However, in another study, no significant increase in the mRNAs of the TNF superfamily was observed in hantavirus-infected HEK-293 cells.[273]

Stress on the host cell ER is another cellular condition that can trigger apoptosis. TULV infection of Vero E6 cells was noted to activate markers of ER stress, including induction of the chaperone protein, Grp78/bip, which was suggested to be induced by the accumulation of misfolded proteins in the ER.[253] Another cellular stress-response protein, heat shock protein 70, was found to be abundant in postmortem tissues of hantavirus-infected patients and to be up-regulated in VeroE6 cells infected with HTNV.[471] In this study, it was not clear what role the stress protein played in host-cell response to infection. Additional work is needed to identify the many possible factors that can contribute to cellular stress and apoptosis in Bunyavirus-infected cells.

As countermechanisms it was described that HTNV N protein stimulates the degradation of the apoptosis driver p53 via the E3 ubiquitin ligase MDM2,[319] and that HTNV and ANDV interferes with DAXX-mediated apoptosis by up-regulation of IFN-activated counterplayers like Sp100.[210]

RNA Silencing

RNA silencing, or RNA interference (RNAi) was first described for plants as a mechanism to defend against viral infection, but is now known to occur in most eukaryotes. The gene silencing is mediated by short interfering RNAs (siRNAs), which arise from cleavage of dsRNAs, including the replication intermediates of RNA viruses by a host enzyme known as Dicer. The 21 to 25 nucleotide siRNAs become part of a protein complex known as the RNA-induced silencing complex, which recognizes and degrades sequence-specific mRNAs. Some viruses have been shown to produce suppressors to counteract

the gene silencing mechanism. In the family *Tospoviridae*, the NSs protein of TSWV was found to act as a suppressor of gene silencing.[58,430] In addition to the plant-infecting bunyaviruses, siRNA suppression has been observed with the orthobunyavirus LACV, in both mammalian and insect cells, and with the nairovirus Hazara virus (HAZV) in tick cells. As observed for the tospoviruses, the LACV-suppressing activity was localized to NSs, despite the completely different coding strategy used for this protein (i.e., ambisense vs. ORFs).[416] For HAZV, which does not produce an NSs protein, the activity was observed with the S-segment gene in either the sense or antisense orientation.[128]

- Severe Fever with Thrombocytopenia Syndrome Virus

INTRODUCTION

Among the approximately 500 identified viruses belonging to Bunyavirales order, at least 55 are known to cause disease in humans. Among them, Rift Valley fever virus (RVFV), Crimean-Congo hemorrhagic fever virus (CCHFV), severe fever with thrombocytopenia syndrome (SFTS) virus, Heartland virus (HRTV), and a number of hantaviruses and orthobunyaviruses present a significant public health concern due to varying properties, which may include potential for high morbidity and mortality, ability to transmit from person to person, or propensity to cause alarm to the public in outbreak settings. Fortunately, most bunyaviruses that cause human disease exhibit either no or low mortality rates, no human-to-human transmission, and usually restricted geographic distribution.

In this chapter, we review the emergence and reemergence of these high-consequence pathogens and their pathogenesis in both reservoirs and humans. We examine the clinical features of disease and highlight aspects of disease that warrant additional investigation. Viral epidemiology and ecology are summarized, focusing on viral maintenance and distribution in natural reservoirs and human disease incidence. The progress on diagnostics for these viruses is examined, and, finally, as no vaccines or antivirals are currently approved for prevention or treatment, the current state of experimental therapeutics and vaccines is discussed.

HANTAVIRIDAE, GENUS ORTHOHANTAVIRUS

Pathogenesis and Pathology

Reservoirs

Although a significant number of new hantaviruses has been recently discovered in insectivores and bats, all presently known pathogenic hantaviruses are harbored by rodents. Hantaviruses are horizontally transmitted among rodents, primarily through excreta and saliva. Infection of natural reservoirs results in an acute phase with high viremia, followed by prolonged or persistent infection with variable durations of virus shedding in the urine, feces, or saliva; persistent infection can last days to months, or even the rodent's lifespan.

Experimental infection of host rodents indicates that viremia peaks approximately 2 weeks post infection and results in dissemination of the virus throughout the animal. Hantaviruses appear to target primarily endothelial cells, with the highest concentrations of viral antigen observed in the lungs, heart, and kidneys.[52,280] Peak amounts of viral RNA in experimentally infected animals vary, with some animals exhibiting characteristics of super-shedders.[349] The end of viremia correlates with the induction of hantavirus-specific antibodies, which first become detectable around 14 days post infection, peak approximately 50 days post infection, and remain detectable throughout the rodent's lifespan.[228] Neutralizing antibodies are detected after 3 weeks post infection. Infection of the rodent host induces moderate inflammatory responses that are not harmful to the host and that contain the virus without clearing it. The infected endothelium and increased numbers of regulatory T cells (Tregs) that modulate the immune response allow the virus to establish persistence and periodic shedding.[109,110,347,348]

Although naturally infected rodent reservoirs do not display apparent disease symptoms, reduced winter survival and reduced body weights of infected rodents have been reported.[80,101,191] Aggressive behavior has been correlated with increased infection among rodents: older males and animals with more scars are more likely to be seropositive.[138]

Human Infections

In stark contrast to the asymptomatic infection of the primary rodent reservoir species, human hantavirus infection frequently results in hantavirus disease traditionally presenting as one of two main syndromes: hemorrhagic fever with renal syndrome (HFRS) caused by Old World hantaviruses, and

hantavirus pulmonary syndrome (HPS) caused by New World hantaviruses. The pathogenesis of both HFRS and HPS is similar, although the disease manifests in different organs, primarily affecting the lungs in HPS and the kidneys in HFRS. Severe human disease has been attributed to microvascular leakage and inflammation. Humans are infected mainly by inhaling aerosols of the excreta of infected rodents or possibly through rodent bites. Human-to-human transmission can occur but is rare and has only been observed with Andes virus (ANDV) infection.

The cells initially infected by hantaviruses have not been identified, but the major target cells are microvascular (capillary) endothelial cells. Since inhalation of aerosols is the main route of infection in humans, it is tempting to assume that the virus first infects the upper respiratory epithelium or the macrophages and dendritic cells residing in the respiratory endothelium. How the virus passes through the respiratory epithelium to establish systemic infection is not clear, however. Studies in polarized epithelial cell cultures have shown an apical polarized entry and release of hantaviruses,[211,327] but experiments on entry and release of ANDV in primary hamster tracheal epithelial cells indicate bidirectional entry and release of this virus.[334] Apical release would facilitate virus spread into the respiratory tract, but such bidirectional infection and release may be an aspect unique to ANDV infection. In addition to the microvascular endothelium, epithelial cells, human dendritic cells, monocytes macrophages, and likely other cells are susceptible to hantavirus infection. Infected dendritic cells could disseminate the virus through the lymphatic system to lymph nodes and eventually to the vascular respiratory endothelium. As mentioned above, Old World hantaviruses preferentially affect kidney functions, while New World hantaviruses affect the lung. The mechanisms behind this preferential tissue tropism are currently unknown.

Immune response

Hantaviruses have developed multiple mechanisms to limit host cell immune responses early in infection (see details in Chapter 16). Although the extent to which pathogenic and nonpathogenic hantaviruses induce the interferon (IFN) response varies and pathogenic hantaviruses delay the induction of the innate immune responses, that delay alone is unlikely to be the source of differences in pathogenicity. All hantaviruses cause strong and long-lasting

humoral immune responses in patients. Antibodies against the hantavirus N protein can be detected early after the onset of illness, and neutralizing antibodies directed against Gn and Gc develop soon after.[182] In general, generation of high levels of hantavirus-specific IgG early in the disease has been associated with increased chances of survival, and higher amounts of neutralizing antibodies correlate with milder disease.[37,246] Hantavirus infection of dendritic cells *in vitro* induces their maturation, and mature dendritic cells can generate a strong adaptive immune response.[254,323]

Viral RNA is usually detectable in patients' blood during the early stages of disease, and viral load correlates with disease severity.[309,426] At the time of death, viral antigens are detectable in endothelial cell layers throughout the body, but predominantly in lung endothelial cells in HPS patients and in kidney endothelial cells in HFRS patients.[175,434] Interestingly, the numbers of monocytes and dendritic cells in the blood are reduced during the acute phase of hantavirus disease, likely not because of cell death but rather due to redistribution and migration of these cells to the infected tissues.[345] Additionally, soluble CD163, a biomarker of macrophage activation, is elevated in the sera of HFRS patients, correlating with disease severity.[413]

Neutrophils are the first immune cells recruited to the site of inflammation or infection, attracted by IL-8 released by hantavirus-infected endothelium. Activated neutrophils can release reactive oxygen species and serine proteases (degranulation) and form extracellular traps (NETosis). High levels of activated neutrophils and increased levels of histone/double-stranded DNA complexes have been observed in hantavirus patients.[324,346,371] Moreover, neutrophil activation has been correlated with kidney injury in Puumala virus (PUUV) infections in humans.[371]

A strong T-cell response followed by generation of long-lived memory T cells has been well documented in hantavirus infection.[232,252,326,398] CD4 and CD8 T cells obtained from blood samples of patients in the acute and convalescent phases of disease can recognize epitopes from viral N, Gn, and Gc proteins.[116,398] In cases of PUUV infection, proliferating, activated effector CD8 T cells can be seen in the peripheral blood and bronchoalveolar lavage early on the disease course.[232,326] High frequencies of virus-specific CD8 T

cells have been linked to severe disease, suggesting the possibility of immune-mediated pathogenesis.[198,339,384] Early studies also indicate that severity of both HFRS and HPS in humans correlates with specific human lymphocyte antigen haplotypes.[249,278,400]

In general, very strong or very weak T-cell responses can lead to severe disease. The above studies suggest that strong cytotoxic T-cell responses contribute to the pathology of hantavirus disease. However, a protective role of T cells during hantavirus disease has also been reported, with Gn-specific effector memory T cells conferring protective immunity in ANDV-infected patients.[252] A strong CD4 T-cell response against Hantaan virus (HTNV) glycoproteins was also associated with controlling the virus and a better clinical outcome in HFRS cases.[244]

The expansion and long-term maintenance of natural killer (NK) cells has been reported in HFRS patients. NK cells become activated by IL-15 and IL-15Ra expressed by hantavirus-infected endothelial cells and can secrete proinflammatory cytokines such as tumor necrosis factor alpha (TNF-α) and interferon gamma (IFN-γ).[43,56] NK cells and cytotoxic T lymphocytes can eliminate infected target cells by inducing apoptosis. It is apparent, however, that they do not kill hantavirus-infected endothelial cells, since the microvascular endothelium remains undamaged. This is likely due to the antiapoptotic effects of hantaviruses, including the N protein, which protects infected endothelial cells from cytotoxic lymphocyte-induced apoptosis by inhibiting the function of granzyme B and caspase 3.[150,364]

Endothelial cell leakage

Hantavirus infection of the microvascular endothelium and immune cells does not result in a direct cytopathic effect.[434] The progression of the disease, with the associated increase in vascular permeability, is a complex process, with contributions directly from virus replication and from the induced immune responses to hantavirus infection. Studies using primary microvascular endothelial cells have indicated that hantavirus infection and replication alone can trigger pathways that lead to reduced endothelial integrity by down-regulating vascular endothelial cadherin (VE-cadherin or CD144), an essential component of adherence junctions, or ZO-1, an

essential component of tight junctions.[210,356] Hantavirus N protein alone can influence vascular permeability of the endothelium by activating cellular RhoA GTPases.[144] The interaction between pathogenic hantaviruses and their cellular receptor β3 integrin can also sensitize the endothelium and cause vascular hyperpermeability in response to added permeability factors like vascular endothelial growth factor (VEGF-A). The binding of VEGF-A to its receptor VEGF-R2 induces down-regulation of VE-cadherin, resulting in increased vascular permeability. Indeed, increased VEGF-A concentrations have been reported in serum, pulmonary edema fluid, and urine samples collected from patients.[136,245,295] Hantavirus infection can also activate the kallikrein–kinin system to release bradykinin, another potent permeability factor that can cause vascular leakage.[382]

A dysregulated immune response causing strong inflammation is believed to be another main contributor to hantavirus disease. The infected endothelium becomes activated and orchestrates a series of events by secreting various cytokines and chemokines and by up-regulating adhesion molecules that attract immune cells like neutrophils, NK cells, and $CD8^+$ T cells that in turn can also produce high levels of proinflammatory cytokines.[375] Numerous *in vitro* experiments and studies of human infection have shown increased levels of proinflammatory cytokines and chemokines, including IL-6, IL-8, and IFN-γ, and permeability factors, such as TNF-α and VEGF.[136,194,268,295] High levels of cytokine production in specific tissues have been identified during hantavirus disease. For example, in HFRS, expression of TNF-α, TGF-β, and platelet-derived growth factor (PDGF) has been observed in the kidneys.[383] Similarly, high levels of cytokine production can be seen in the lungs (but not in kidneys and livers) of fatal HPS cases, suggesting that local cytokine production may play an important role in disease severity.[268] Among the induced cytokines, IL-6 strongly correlates with HPS severity.[13,250] The cytokine and chemokine profiles of HFRS and HPS cases are different, with proinflammatory responses in HPS found to be substantially stronger than in HFRS, likely reflecting the much higher case fatality rates (CFR) generally seen in HPS.[194]

In addition to endothelial cell activation and induction of proinflammatory cytokines, other factors that can contribute to the vascular

leakage seen in hantavirus disease are complement activation and the coagulation system. Complement activation and elevated amounts of SC5B-9, a component of the complement cascade, have been associated with disease severity in HFRS patients.[359] Tissue-type plasminogen activator (tPA), but not its inhibitor PAI-1, is up-regulated in HFRS patients and is possibly responsible for stimulating fibrinolysis. The opposite is seen in severe HPS cases induced by Sin Nombre virus (SNV), in which a strong prothrombotic response with elevated PAI-1 levels has been reported, possibly explaining the absence of hemorrhagic symptoms in HPS.[30,46] Lastly, in addition to activated macrophages, T cells, and NK cells, neutrophils could play a role in vascular permeability by generating NETs and by secreting permeability factors like VEGF and TNF-*α* in the vicinity of the infected endothelium.[346] A proposed model for hantavirus disease is shown in Figure 17.1.

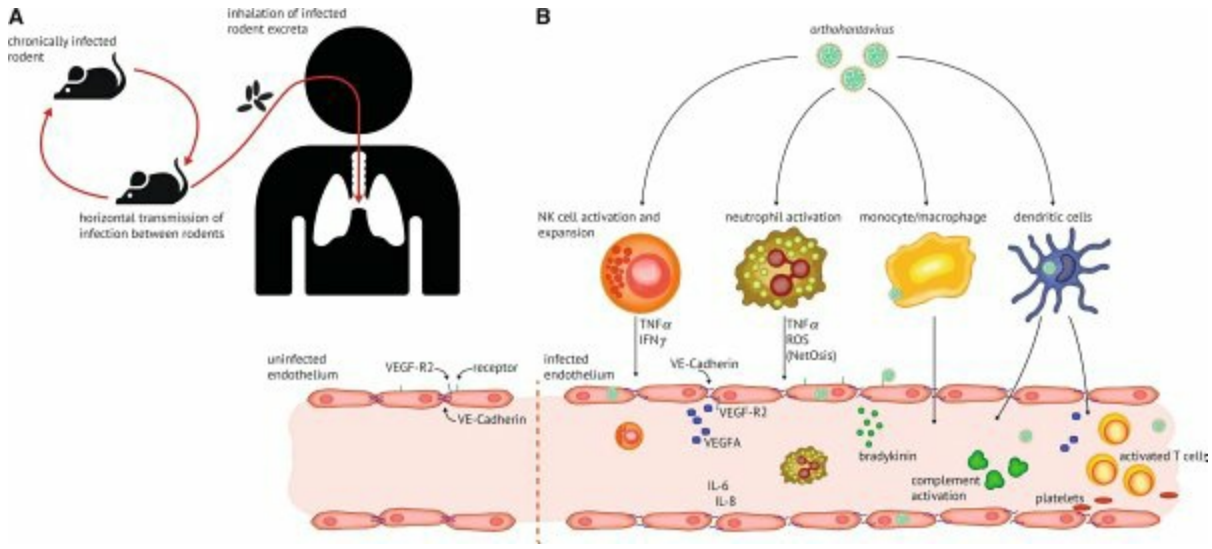

FIGURE 17.1 A: Hantavirus maintenance in the rodent reservoir in nature and transmission to humans. Humans acquire the virus by inhalation of aerosols or dust particles contaminated by excreta of infected rodents. **B:** Proposed model of the steps leading to hantavirus disease-induced vascular permeability. Orthohantaviruses gain access to the vascular endothelium through infected dendritic cells or infected macrophages. Hantavirus

infection triggers both innate and adaptive immune responses. Infection of the endothelium can stimulate pathways that reduce endothelial integrity by down-regulating VE-cadherin and activating Rho GTPases. At the same time, hantavirus-infected endothelial cells produce proinflammatory cytokines and chemokines and up-regulate adhesion molecules on their cell surface, which in turn attract activated natural killer (NK) cells, neutrophils, and T cells to the infected area in addition to infected macrophages and dendritic cells. The activated immune cells secrete more chemokines, cytokines, and other proinflammatory molecules, like TNF-α and reactive oxygen species, resulting in a "cytokine storm." Secretion of potent permeability factors, such as VEGF and bradykinin, can directly disrupt the integrity of the endothelium. Additional factors, like complement activation, may also contribute to vascular leakage.

In addition to microvascular leakage, another prominent feature of hantavirus disease is induced thrombocytopenia (low number of blood platelets). The exact mechanism of this platelet deficiency is not known. However, the presence of normal or increased numbers of megakaryocytes in bone marrow of hantavirus disease patients indicates no deficiency in platelet production. In addition, evidence of fibrinolysis suggests that increased consumption or sequestration of platelets is the possible reason for hantavirus-induced thrombocytopenia.[137,220,221,226,434]

One enduring limitation to studying hantavirus pathogenesis has been the absence of suitable experimental animal models. The first breakthrough came with the discovery that Syrian golden hamsters infected with ANDV develop a disease with characteristics similar to those of human HPS, including interstitial pneumonitis, alveolar edema, mononuclear cell infiltrates in the lung, and high mortality rates.[166,411] However, only immunosuppressed Syrian golden hamsters infected with SNV and other New World hantaviruses can develop HPS-like disease.[60,404] The hamster animal model has been extensively used to study HPS pathogenesis. Depleting B cells, T cells, and

alveolar macrophages does not affect the course of the disease in this model, indicating that these cells may not contribute to the induced pathogenesis. How much we can extrapolate from results in hamsters to human disease remains an open question. Non-human primate (NHP) animal models have been developed for PUUV-induced HFRS and, more recently, for SNV-induced HPS.[147,204,339] In the NHP model of HPS, thrombocytopenia, neutrophilia, eosinophilia, and monocytosis were noted, in addition to the development of an uncontrolled tissue-specific proinflammatory response.[339] Interestingly, depleting neutrophils in mice with severe combined immune deficiency (SCID) infected with HTNV suppresses hantavirus-induced pulmonary edema, highlighting a possible role of neutrophils in hantavirus pathogenesis.[207] Similarly, in a humanized mouse model, neutrophils and functional HLA-A2–restricted CD8 T cells were shown to play an important role in hantavirus-induced pathogenesis.[205]

Pathologic findings in biopsies of kidneys of HFRS patients include mild to moderate interstitial infiltration of lymphocytes, plasma cells, monocytes and macrophages, and polymorphonuclear leukocytes (mainly eosinophilic granulocytes and neutrophils), although the exact mechanism of kidney failure in HFRS patients is still unclear.[383] HPS patients usually develop pulmonary edema, plural effusions, interstitial mononuclear cell infiltrate, edema, and focal hyaline membranes[307,434] (Fig. 17.2).

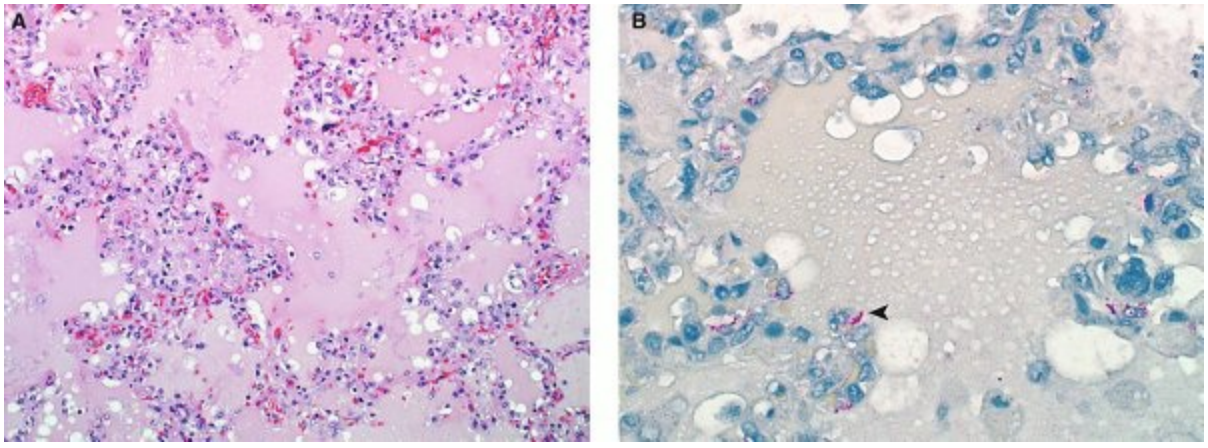

FIGURE 17.2 HPS is characterized by acute pulmonary edema and shock. A: Histological features of a lung section include

interstitial pneumonitis and alveolar edema in a typical case. **B:** Immunostaining of hantavirus antigens in the lung shows that the viral antigen is localized mainly in pulmonary microvascular endothelial cells (in *red*, indicated by an *arrowhead*).

Clinical Features

The main characteristics of hantavirus disease noted upon hospital admission are fever, thrombocytopenia, and acute kidney or lung injury followed by a number of abnormal clinical findings. Hemorrhage is not a common characteristic. Although here we present the clinical features of HFRS and HPS individually, this separation is based mainly on the distinct virus tropism in the 2 syndromes, kidneys in HFRS and lungs in HPS. We now know that pulmonary involvement can be seen in HFRS cases,[410] while petechia, hemorrhage, and renal signs can be observed in HPS cases.[74,161,195] The broad term "hantavirus disease" has therefore recently been proposed to describe the disease caused by hantaviruses.[299] A map of the distribution of pathogenic hantaviruses is presented in Figure 17.3, and a summary of symptoms of HFRS and HPS is presented in Figure 17.4.

FIGURE 17.3 Global distribution of hantaviruses known to be

pathogenic in humans. Hantaviruses cause two main clinical syndromes: hemorrhagic fever with renal syndrome (HFRS) and hantavirus pulmonary syndrome (HPS). HFRS is seen primarily in Europe and Asia, while HPS occurs mostly in the Americas.

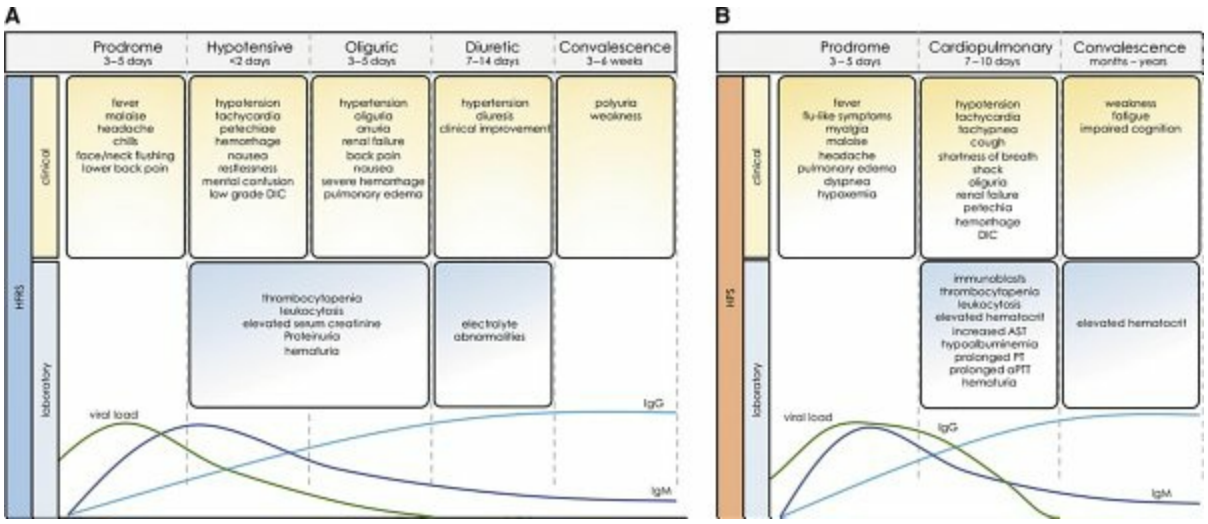

FIGURE 17.4 A: An outline of the main clinical manifestations and laboratory findings in severe HFRS. **B:** An outline of the main clinical manifestations and laboratory findings in severe HPS.

The incubation period before the onset of HFRS symptoms typically lasts 2 to 3 weeks. Initial symptoms of severe HFRS are high fever, headache, malaise, chills, and prostration, which last 3 to 5 days. Flushing of the face and neck and conjunctival and pharyngeal injection (indicating capillary dilation) are frequently observed. Increased capillary permeability is likely responsible for the retroperitoneal edema and lower back pain often described. This febrile phase is followed by a hypotensive phase lasting several hours to days, characterized by marked thrombocytopenia and often by petechial hemorrhage. Many patients exhibit low-grade disseminated intravascular coagulation (DIC). Approximately 10% to 15% of patients show some degree of shock around this time, which improves within 12 to 48 hours as blood pressure returns to normal, or as the patient becomes hypertensive. Oliguria may occur, and, historically, renal failure contributes to about half of all HFRS deaths. Recovering patients undergo a phase of

diuresis that may last several months. Not all patients go through all the stages described; some rapidly progress to death within a few days, whereas others skip some phases of the disease or exhibit very mild symptoms that may not be recognized as HFRS. However, this progression tends to be seen with the most severe forms of HFRS caused by (HTNV) and Dobrava (DOBV) viruses, which are associated with 5% to 15% case fatality rate (CFR). HFRS associated with Seoul virus (SEOV) is usually milder, with a mortality rate of 1% to 2%.[199] HFRS associated with PUUV is the mildest form of the disease, with a mortality rate of less than 1%. In PUUV-associated HFRS, phases of the illness are generally less pronounced and symptoms are milder, with hypotension rather than shock, petechiae rather than frank hemorrhage, and relatively mild renal involvement.

Similarly to HFRS, HPS also begins with a 2- to 3-week incubation period (though longer incubation times have been documented) followed by rapid onset of acute disease. In SNV-caused HPS, the first 4 days often include fever, myalgia, malaise, headache, and gastrointestinal symptoms. Patients frequently present for medical attention with the onset of pulmonary edema, dyspnea, and hypoxemia. These features, together with the hemoconcentration that is frequently observed, are presumably linked to viral infection of the microvascular endothelial cells surrounding the lungs, which leads to increased permeability and fluid leakage into the lungs. Bilateral pulmonary infiltrates are often visible on chest x-rays. Deterioration of the patient's condition is often very rapid, with death occurring within 1 to 3 days of hospital admission in almost 40% of the cases. Clinical laboratory tests frequently reveal thrombocytopenia and prolonged partial thromboplastin time. Hypotension and shock can be prominent at this stage. A very similar clinical picture is seen in HPS cases caused by other viruses found in rodents of the *Sigmodontinae* subfamily. HPS cases have been associated with infection by Monongahela virus, which is related to SNV; New York virus; Bayou virus; Black Creek Canal virus (BCCV); and ANDV and the related Oran, Lechiguanas, Hu39694, Laguna Negra, Juquitiba, Araraquara, and Castelo dos Sonhos viruses. BCCV and Bayou virus infection generally leads to more renal involvement and elevated serum creatine phosphokinase. Renal failure also appears to be common with Oran virus-associated HPS in northern Argentina.[230] Flushing and petechiae, and frank hemorrhage, have been observed in some HPS patients infected with

ANDV in Argentina and Chile, respectively.

Epidemiology and Ecology

The geographic distribution of hantaviruses and the epidemiologic patterns observed for HFRS and HPS reflect the distribution and natural history features of the rodent hosts of these viruses (Fig. 17.2). Epidemiologic data accumulated since the 1950s for a variety of hantaviruses, including HPS-associated hantaviruses, suggest that human-to-human virus transmission does not generally occur, and that virtually all human infections are acquired by exposure to infected rodent excreta. A notable exception is in ANDV-associated HPS, in which human-to-human transmissions have been demonstrated.[256,294,419]

In general, hantavirus disease incidence is higher in males than in females. However, a number of reports have shown that the CFR in females is higher than in males in particular age groups. The disease is rare in pediatric populations.[203,247,255] A short summary of each hantavirus family relative to epidemiology and ecology is described below.

HTNV and HTNV-like viruses (Amur/Soochong) are found in various parts of China, South Korea, and Far Eastern Russia, in *Apodemus agrarius mantchuricus*, a mouse common in the region's agricultural fields, and *Apodemus peninsulae*.[184] Adult humans in rural areas (e.g., farmers, forest workers, or troops stationed in the field) are the most at risk of infection. HFRS cases peak in the fall, likely reflecting a mixture of factors, including increased abundance of virus-infected mice coinciding with increased human activity in the fields associated with harvest of crops, as well as movement of rodents into human dwellings as winter approaches.[225] Most HNTV HFRS patients are 20 to 50 years old, while cases in children younger than 10 are uncommon.[79,227] Males are more likely than females to become infected, consistent with predominant exposure being in the fields rather than in the homes. HTNV-related HFRS is most prevalent in China, where approximately 100,000 cases are reported each year; 300 to 900 HFRS cases are estimated to occur in Korea and in Far Eastern Russia annually.

SEOV is associated with the domestic rats, *Rattus norvegicus* and *Rattus rattus*,[227,372] and is distributed worldwide due to the recent global spread of

rats to port cities and beyond through international shipping. A related virus, Thailand virus, is found in *Bandicota indica* rodents in Thailand but is not known to cause human disease. SEOV is the only hantavirus known to cause disease in urban areas, as other hantaviruses are associated with rodents that predominantly inhabit rural areas. Cases of SEOV contracted from pet rodents by humans are becoming more frequent in the last decade and have been reported both in Europe and North America.[127,193,380] SEOV-related HFRS cases in general tend to be more moderate than those associated with HTNV, with mortality rates approximately up to 1%.[83] Unlike HTNV-related HFRS, cases of SEOV-related HFRS occur year-round. The annual number of cases is unknown, as figures for SEOV- and HTNV-related HFRS are often not separated. However, Chinese reports suggest that SEOV-related HFRS cases in urban areas of several provinces have been growing since the discovery of the virus in 1981.

In Europe and Scandinavia, most cases of HFRS are caused by infection with PUUV. Particularly in Scandinavia, the disease is referred to as nephropathia epidemica (NE) and is usually milder than HTNV-associated HFRS. PUUV is hosted by the bank vole, *Myodes glareolus*. In Sweden and Finland, the number of cases in rural residents usually peaks in November and January, although cases in urban residents appear to peak in August, likely correlating with vacationing in summer cabins in rural areas. A male-to-female case ratio of approximately 2:1 is seen, and the disease is rare in children.[61] Local epidemics usually reflect increased local bank vole densities, which tend to cycle with a 3- to 4-year periodicity. Approximately 30% of PUUV infections result in reported disease, based on data from areas of Finland with high surveillance for disease.[61] In addition, antibody prevalence rates of up to 20% can be seen in known endemic areas in northern Sweden.[171] PUUV-associated disease in Belgium, northeastern France, and Germany occurs mainly in autumn and spring, and the extent of activity reflects the alterations in the size and structure of bank vole communities.[312] Large PUUV-associated HFRS outbreaks are periodically recorded in several areas of European Russia, particularly Udmurtia and Bashkortostan. A genetically distinct PUUV-like virus has also been identified in *Clethrionomys rufocanus* voles in Far Eastern Russia and on Hokkaido Island, Japan, but is not known to be associated with human

disease.[192] Likewise, several additional hantaviruses are associated with other subfamily *Arvicolinae* rodents but are not known to cause human disease. For example, Topografov virus is present in lemmings in Arctic regions of Russia, and at least 5 hantaviruses are associated with various Old and New World rodents of the *Microtus* genus.

Dobrava virus (DOBV) also causes a considerable number of severe HFRS cases in Europe, particularly in the Balkan countries.[25,298] The primary rodent reservoir of DOBV is *Apodemus flavicollis*, which is widely abundant in this region. Variants of DOBV, such as Saaremaa and Kurkino viruses, can be found in *A. agrarius* (a subspecies distinct from that which carries HTNV in Asia), which is of greater abundance in more northern areas; Sochi virus is found in *Apodemus ponticus* in Southern Russia.[108,358] DOBV and Sochi genotypes cause severe illness with CFR of 9% to 15%.[212,296] Although *A. flavicollis* does not frequent houses and other man-made structures, it will often enter campsites or places where food may be present. Unlike HTNV-associated HFRS, most DOBV-associated HFRS cases occur in the late spring and summer months, when human activity in rural areas is greatest. Epidemics of disease are seen at times when rodent populations increase. Seroprevalence rates in humans can be high in rural areas; for instance, antibody positivity rates of up to 14% were seen in mountainous areas of northern and western Greece.[15]

Since the discovery of SNV and HPS in 1993,[283] numerous other hantaviruses have been detected in New World rodents of the *Sigmodontinae* subfamily. In North America, SNV is by far the most important cause of HPS[267] and is present in deer mice (*Peromyscus maniculatus*, grasslands form) throughout western and central United States and Canada.[267] The initially identified cluster of HPS cases occurred in the Four Corners region (meeting point of New Mexico, Arizona, Colorado, and Utah) in 1993; while the majority of subsequent cases have occurred in the southwestern United States, some have now been recorded in 32 states and 4 Canadian provinces. SNV-infected deer mice have been detected throughout most of this range, which stretches from the Yukon peninsula to Mexico and from California to the Appalachian mountains in the eastern United States and Canada.[265,267] A survey of 2,500 individuals in high-risk groups, such as persons with

occupations that would bring them in close contact with rural rodents, found hantavirus-specific antibodies in only approximately 0.5% of those sampled,[409] suggesting that human SNV infections are rare.[435] Clusters of cases appear to be generally associated with local increases in infected deer mice populations. HPS cases peak in late spring and early summer. More cases in the United States have occurred in males, with a mean age of 37 years (range 6 to 83 years). Retrospective studies suggest that the disease had gone unrecognized since at least 1959.[129]

Through December 2018, 784 HPS cases have been reported in the United States, with a CFR around 35%. Since the Four Corners outbreak in 1993, the second largest SNV outbreak, with 10 cases and 3 deaths, was identified among overnight visitors at the Yosemite National park in 2012.[288] Several other hantaviruses are capable of causing HPS in the United States. The forest form of deer mice (*P. maniculatus nubiterrae*), found predominantly throughout the Appalachian mountain range extending from Georgia to eastern Canada, harbor a genetically distinct SNV-like virus referred to as Monongahela virus.[267,366] Monongahela virus has been associated with several HPS cases in the eastern United States. The white-footed mouse, *Peromyscus leucopus* (eastern haplotype), hosts another SNV-like virus, New York virus, responsible for some HPS cases in the northeastern United States.[160,172]

Other sigmodontines also harbor HPS-associated hantaviruses in the United States, such as BCCV, which was associated with a single HPS case in southern Florida and is hosted by the cotton rat, *Sigmodon hispidus* (eastern form).[328] The genetically distinct western form of *S. hispidus* hosts another hantavirus, Muleshoe virus.[329] Bayou virus was discovered in 1994, associated with a fatal HPS case in Louisiana,[273] and subsequently was shown to be hosted by the rice rat *Oligoryzomys palustris* and present throughout the range of the rodent.[394] Bayou virus was also associated with a nonfatal HPS case in Texas.[161] Although HPS associated with BCCV and Bayou virus is still predominantly a pulmonary disease, more renal involvement has been seen in those cases than in classic SNV-associated HPS.[161,196]

The confirmation of an HPS case in Brazil in late 1993 marked the

beginning of a wave of discovery of HPS cases and associated hantaviruses throughout South and Central America.[188,241] In addition to Brazil, Argentina, Bolivia, Brazil, Chile, Ecuador, Paraguay, Panama, Uruguay, and Venezuela have also reported HPS cases. Rodents carrying viruses similar to SNV have been found in Colombia, Costa Rica, and Mexico but have not been associated with disease in humans.

The high prevalence of hantavirus-specific antibodies in the general population in some areas of South and Central America differs considerably from the epidemiologic picture seen in North America, where seropositivity rates of 0.2% or less are seen. For instance, high rates of hantavirus-specific antibodies have been detected on surveillance of general populations in regions of Paraguay (40%), Salta province in Argentina (17%), and Los Santos province in Panama (13%).[126,423] These data suggest more frequent exposure of people to hantaviruses in these areas and more asymptomatic or subclinical infections than seen with North American hantavirus infections.

Phylogenetic analysis of rodent-borne hantaviruses and their reservoir hosts indicated that their evolutionary trees largely overlapped, with a limited number of exceptions, suggesting that these viruses may have coevolved with their hosts over 20 to 30 million years.[317] The recent discoveries of hantaviruses in moles, shrews, and bats complicates the evolutionary history of hantaviruses. In addition to codivergence with their rodent hosts, cross-species transmission and geographic expansion could have also played an important role in hantavirus evolution, shifting the time frame of hantavirus–host coevolution to hundreds of millions of years.[163,318] Thus, while HPS and many hantaviruses have only recently been discovered, phylogenetic analysis clearly indicates that these viruses are of ancient origin.

Diagnosis

Clinical differential diagnosis of HFRS and HPS cases can be difficult due to the nonspecific early symptoms in both types of disease. Early signs of severe HFRS can be easily confused with those of leptospirosis, typhus, pyelonephritis, poststreptococcal glomerulonephritis, an acute abdominal emergency, or other hemorrhagic fevers.[227] In areas of China, Korea, Far Eastern Russia, Europe, and Scandinavia where HFRS is known to occur, a

febrile patient presenting with thrombocytopenia and renal symptoms should be questioned about potential rodent exposure and tested for evidence of hantavirus infection. In the Americas, the early stages of HPS are easily confused with influenza and are thus extremely difficult to recognize. However, fever and myalgia and a history of potential rural rodent exposure together with the appearance of acute onset shortness of breath and findings of thrombocytopenia, leukocytosis with left shift (higher ratio of immature-to-mature neutrophils), and atypical lymphocytes would suggest HPS.[287] A peripheral rapid blood screening test has been developed and evaluated to quickly and inexpensively detect HPS based on five peripheral smear criteria, including thrombocytopenia, the presence of a left shift, hemoconcentration, lack of toxic changes, and the presence of immunoblasts.[106,209]

Laboratory diagnosis

Antibodies against hantaviruses are invariably seen in patient sera around the time of onset of illness. Laboratory analysis of the presence of virus-specific antibodies has historically included indirect fluorescent antibody testing. Serology is broadly used to detect hantavirus antibodies in patient sera. Acute diagnosis is best achieved by IgM capture enzyme-linked immunosorbent assay (ELISA) using either hantavirus-infected cell slurries or recombinant nucleocapsid proteins as antigen with appropriate negative controls.[115,124,214] Such assays have been shown to be highly sensitive, rapid, and inexpensive. Considerable cross-reactivity among related hantaviruses is seen, so inclusion of a limited number of antigens representative of various viruses (e.g., SNV, PUUV, and HTNV) allows detection of virtually all acute hantavirus infections. The disadvantage of the cross-reactivity of the assay is the inability to precisely identify the virus based on a positive result. Western blot assays utilizing recombinant nucleocapsid proteins or GPs have also been effectively used for acute diagnosis, particularly of New World hantaviruses and can provide additional insights into the identity of the virus.[162,182]

Virus isolation from acute clinical specimens is an almost impossible task, and only a few human virus isolates exist despite a plethora of newly discovered hantaviruses and available genome sequences. The exact reason for the difficulty of isolating hantaviruses is unknown but is likely related to

the presence of a strong immune response at the time of disease onset, including serum-neutralizing antibodies. Given the frequent difficulties in obtaining infectious virus, reverse transcriptase-polymerase chain reaction (RT-PCR) assays have been used effectively to complement the serological assays. RT-PCR is used in acute diagnosis to detect viral RNA in the blood, serum, or tissue samples of patients and allows detailed genetic comparison of hantaviruses.[241,283,298] Given the potential for false positives due to cross-contamination, RT-PCR is not recommended as the sole means of establishing a hantavirus diagnosis, and a combination of RT-PCR and IgM/IgG ELISA is still the most appropriate way to establish for hantavirus diagnosis. Virus-specific real-time RT-PCR assays, in addition to microarrays and next-generation sequencing, are more expensive and complex techniques for laboratory diagnostics but are certainly gaining ground[407] (reviewed in ref.[212]).

Immunohistochemistry on formalin-fixed or paraffin-embedded tissue samples from fatal cases can be useful in identifying hantavirus infection by detecting viral antigens.[434] Additionally, small fragments of virus genomic RNA can be detected by RT-PCT to establish a postmortem diagnosis of hantavirus infection.[157]

Prevention and Control

The primary means of preventing hantavirus infection is by reducing exposure to rodents. Effective measures include rodent-proofing homes, correctly storing food, airing seasonally closed cabins, and appropriately disinfecting and removing trapped rodents and rodent droppings.[139,170] In addition, public awareness and proactive public health educational efforts should target high-risk groups.[24,229] Yet for some occupations and for the residents of rural areas, avoiding rodent exposure is not an option. The lack of nosocomial and person-to-person transmission reported during virtually all hantavirus outbreaks (with the exception of ANDV) suggests that spread to medical personnel or case contacts is usually not a concern.

As for many viral infections, the development of a safe, effective, and inexpensive vaccine is needed.[344] However, the high genetic and antigenic diversity of hantaviruses poses a considerable challenge for the development

of a multivalent, broadly protective vaccine that would be efficacious against most of the pathogenic hantaviruses. In addition, cross-protection vaccine studies are hard to perform, since currently animal models are available for only a few hantaviruses. A broad vaccine to prevent HFRS is needed purely because of the thousands of HFRS cases reported annually. Indeed, several different inactivated virus vaccines for HTNV and SEOV have been developed in Asia. These include antigens derived from virus-infected rodent brain and inactivated with formalin or beta-propiolactone. Upon vaccination, these antigens induce a weak neutralizing antibody response, and multiple booster doses are needed to elicit protective immunity.[167,367,427] Several monovalent and bivalent anti-HTNV and anti-SEOV tissue culture-derived inactivated vaccines have also been produced in China,[167] some of which may have high efficacy. In addition, a number of recombinant DNA approaches to vaccine development has been investigated.[343] The most advanced among them is a DNA vaccine composed of a mixture of HTNV and PUUV M segments; it was found to be safe and able to elicit neutralizing antibody responses in the majority of human participants in a phase I clinical trial.[168]

HPS caused by various hantaviruses remains a rare sporadic disease despite its high mortality rate. HPS vaccines can be useful against local epidemics but are unlikely to be broadly used because of the low frequency of HPS cases. This scenario could change in the future if the frequency of cases increases or if ANDV human-to-human transmission becomes more frequent. HPS prototype vaccines based on DNA and VSV platforms expressing the virus glycoproteins have shown promising results when tested in the hamster model.[59,319]

A neutralizing antibody response appears to be a strong correlate of protection from severe disease. Thus, passive immunotherapy has been tested as treatment for HFRS and acute HPS. Passive transfer of sera from convalescent patients has shown a modest survival benefit.[406] Recently, 2 potent neutralizing human monoclonal antibodies engineered from HPS patient sera have shown efficacy when administered as a monotherapy or as cocktail in the hamster model.[134] Similar results were also obtained using human polyclonal antibodies produced by DNA vaccination of transchromosomal bovines.[169] Antibody therapy could be developed as

hantavirus disease treatment in the future.

Based on the hypothesis that HPS and HFRS are caused by an excessive host proinflammatory immune response, steroid treatments have been tested. However, in a double-blind, randomized controlled clinical trial in Chile, high concentration of methylprednisolone produced no significant clinical benefit in HPS patients in comparison to untreated controls, underscoring the complexity of this disease and the difficulty for successful immunotherapeutic intervention.[405] On the other hand, the immunotherapeutic icatibant, a bradykinin receptor antagonist, has been successfully used to treat 2 patients with severe PUUV infection.[14]

The only antiviral that has been used to treat hantavirus disease in humans is ribavirin. Ribavirin effectively suppressed HTNV replication in tissue culture and in animal models,[173] thereby promoting clinical trials in HFRS and HPS patients; promising results were reported in HFRS.[174,335] Although ribavirin treatment has shown activity against ANDV in an HPS animal model, no effect was seen in human trials in the United States and Chile when treatment was initiated during the symptomatic phase of infection.[78,264,338]

Current treatment of hantavirus disease is limited to intensive supportive care, including hemodialysis and mechanical ventilation. Extracorporeal membrane oxygenation, used in very severe cases of HPS in order to maintain a sufficient supply of oxygen, increased overall survival of patients.[420]

NAIROVIRIDAE

The most important human pathogen in the family Nairoviridae is CCHFV within the genus *Orthonairovirus*. Other Nairoviridae viruses of human concern are Dugbe virus (DUBV), Erve virus (ERVEV), and Nairobi sheep disease virus (NSDV). DUBV was first isolated in 1964 in Nigeria from *Amblyomma variegatum* ticks and causes a benign febrile illness in humans.[422] DUBV has been recovered from a wide range of ticks, domestic cattle, mosquitoes, and *Culicoides* in Western Africa; however, serosurveys

did not reveal wide spread human infections. ERVEV was isolated in 1982 from a white-toothed shrew (*Crocidura russula*) in the Erve river valley in northern France.[95] The virus has been found in Czech Republic, France, Germany, and the Netherlands. Very little is known about the involvement in human disease although it has been suspected to cause severe headache and intracerebral hemorrhage in humans. Nairobi sheep disease is a noncontagious, tick-borne infection of sheep and goats characterized by hemorrhagic gastroenteritis, abortion, and high mortality rates and is found in East and Central Africa. NSD virus has been isolated from sick patients in Uganda, as has the identical or closely related Ganjam virus from febrile patients in India, but their importance in terms of human disease is currently unclear.[253]

Crimean-Congo Hemorrhagic Fever Virus

Distribution and Significance

The human disease was first described as Crimean hemorrhagic fever (CHF) in 1944 in the Crimean peninsula, although the virus isolation took until 1967. In 1969, Jody Casals showed that an agent that had been isolated in the Belgian Congo (present Democratic Republic of the Congo, DRC) in 1956 and designated "Congo virus" was identical to CHF virus, leading to its current designation of CCHFV.[73] Today, we know that the virus is extensively distributed in wild and domestic animals, birds, and ticks through countries in Africa, Southeast Europe, the Middle East, Africa, and the Indian subcontinent (Fig. 17.5). As a result, CCHFV is the most widespread of all tick-borne viruses and second most widespread hemorrhagic fever virus after dengue virus. Nevertheless, human cases are typically sporadic and found in geographically circumscribed endemic foci within countries. The incidence of confirmed CCHF cases have markedly increased within the last two decades, Turkey, Iran, India, Southern Russia, and some Balkan countries. There is a concern about the increasing geographic spread of the disease illustrated by the recent report of CCHF cases in Spain.[370] It has been hypothesized that the increasing case numbers and geographic spread are a result of changes in environment and climate, land use/agricultural practices, and movement of livestock or migratory birds influencing the tick–virus–host

dynamics ultimately changing the epidemiology of the disease.[35,120,121]

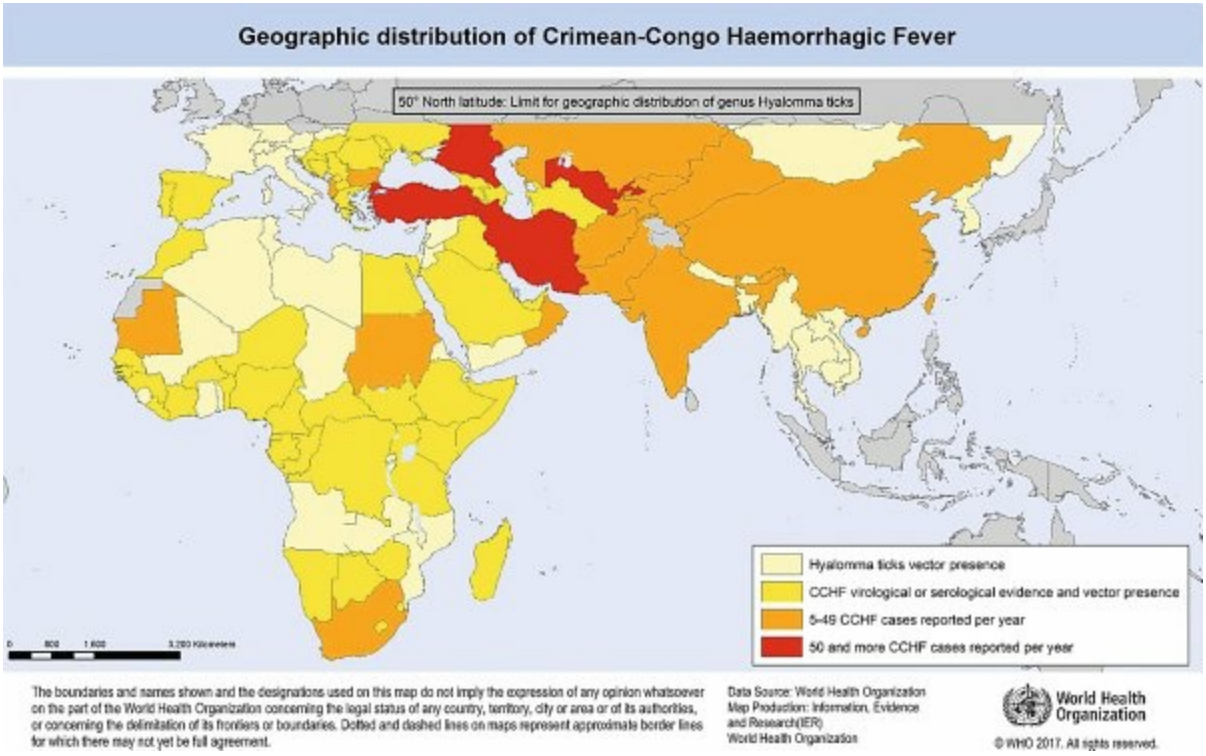

FIGURE 17.5 Geographic distribution of Crimean-Congo hemorrhagic fever virus (2017). (Figure © WHO 2017 All rights reserved.)

Epidemiology and Epizootiology

CCHFV transmitted to humans typically through tick bite or crushing of engorged tick and in some cases through direct contact with blood of viremic vertebrate hosts including livestock and humans (Fig. 17.6). In nature, CCHFV circulates in enzootic tick-vertebrate-tick cycle. Since neither the infected tick vector nor the infected vertebrate host show any signs of infection, this cycle perpetuates undetected. Ticks are virus vector and reservoir; once infected, they remain infected throughout their lifespans; the virus is maintained through transstadial (i.e., passing the virus through the various stages of the life cycle, from larva to nymph to adult) and transovarial transmission (i.e., horizontal transmission to the next generation) in several

species of ixodid (hard) ticks, accompanied by a seasonal bursts of amplification each spring and summer, when the ticks transmit the virus to mammals while taking the blood meals required for their maturation and for egg production (Fig. 17.6). The resulting viremia in mammalian animal hosts is transient. Humans are dead end hosts and the only host that shows overt signs of disease and human cases typically occur singly or sporadically in rural areas. The epidemiology of CCHFV reflects the complex ecology and geographic distribution of the ixodid tick hosts of the virus, particularly those of genus *Hyalomma*.[117,164] Although CCHFV has been isolated from approximately 30 different tick species, evidence is lacking as to whether they truly represent vectors or merely reflect the isolation of virus from engorged ticks that have fed on a viremic vertebrate host. Only some ticks of three genera, *Hyalomma, Dermacentor, and Rhipicephalus*, have actually been shown to be capable of transstadial transmission of CCHFV following feeding on a viremic host.[133] Transovarial transmission of CCHFV has also been shown to occur with some of the tick species in these genera. Moreover, the overall global pattern of geographic distribution of CCHFV cases corresponds most closely with the distribution of *Hyalomma* ticks, suggesting their principal role as vector.

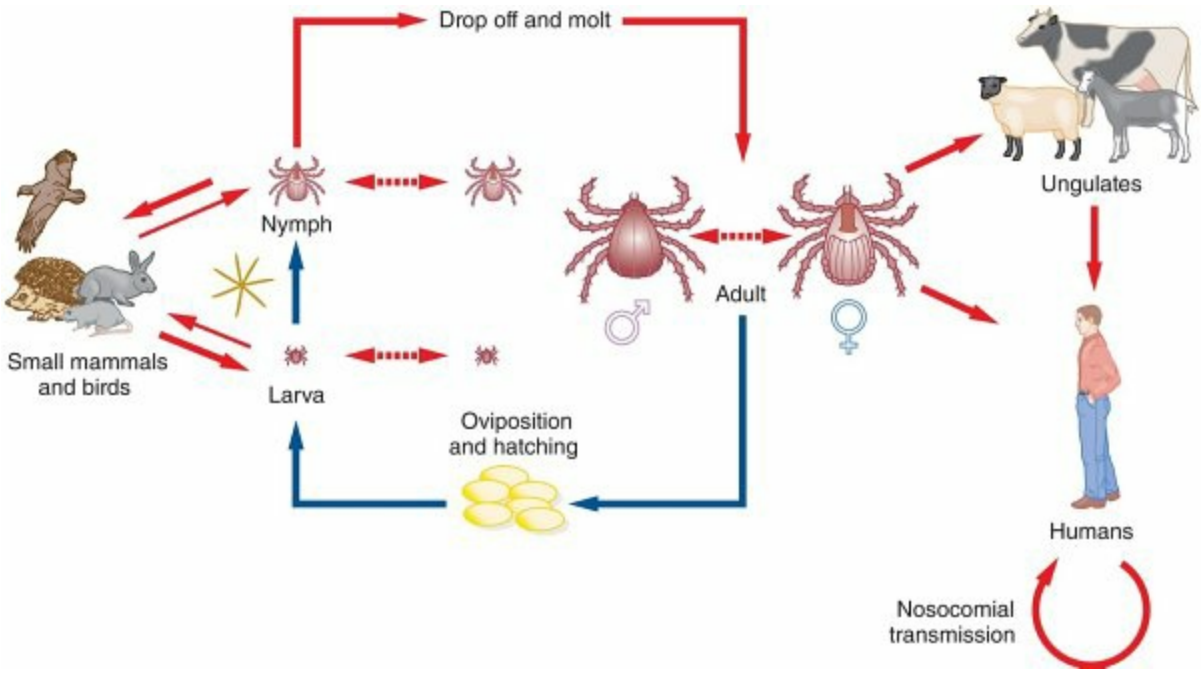

FIGURE 17.6 Life cycle of *Hyalomma* spp. ticks and vertical

and horizontal transmission of CCHFV. The course of the tick life cycle is indicated with *blue arrows*. Upon hatching, larvae find a small animal host for their first blood meal (hematophagy). Depending on the tick species, the larvae either remain attached to their host following engorgement and molt in place (two-host ticks) or fall off and molt (three-host ticks); this transition is marked by an *asterisk*. The nymphs then either continue to feed on the animal on which they molted (two-host ticks) or attach to a new small animal (three-host ticks). Upon engorgement, nymphs of all species drop off their host and molt into adults. Adult ticks then find a large animal for hematophagy and mate while attached to the host. After taking a blood meal, the engorged females drop off and find a suitable location for ovipositing. During the tick life cycle, there are a number of opportunities for virus transmission between ticks and mammals (*solid red arrows*) and directly between ticks, through cofeeding (*dashed arrows*). For each form of virus transfer, the thickness of the *red arrow* indicates the efficiency of transmission. Infection of humans can occur through the bite of an infected tick or through exposure to the body fluids of a viremic animal or CCHF patient.

Reported CFR have been broad, ranging from 3% all the way to 100%. The variation in rates could be explained by differences in treatment, data sampling and diagnostics capabilities between outbreaks, as well as difference virulence of CCHFV strains. For instance, it has been suggested that the CCHFV strain AP92, originally isolated in and endemic in Greece, shows a lower virulence than other CCHFV strains due to the lack of clinical cases in Greece. Recently, strains very closely related to AP92 have been found in neighboring countries and have been detected in clinical cases. Turkey has overall the largest case numbers with a CFR just under 5%. CRFs in other countries for example Kosovo (34%) are higher. It is not known why this is the case.

Only limited information is available on CCHFV infections in special

populations. CCHF appears to be associated with more severe disease in pregnant women with an overall CFR or 34%; however, the overall prevalence is very low and only few cases have been examined.[320] CCHFV infection of pregnant women can lead to spontaneous abortion, and the overall prognosis for the fetus is poor. The prevalence of CCHF in children is lower than in adults, and the disease is generally milder with lower fatality rates, although the full range of clinical features can be seen.[389] This might be due to the fact that the proinflammatory chemokine levels in children seemed to be not as often elevated as in adults.[18]

As one would expect based on the epidemiology, most cases are among individuals (e.g., shepherds, ranchers, and abattoir workers) living or working in close contact with livestock (e.g., sheep, goats, cattle, or ostriches) in endemic areas. Cases are usually start to occur in the early summer until early fall. Nosocomial outbreaks with cluster of cases have also been reported in several regions, with infection of medical personnel following treatment or surgery on an unsuspected CCHFV case.[35] This usually occurs when awareness of CCHF presents is low among medial personal not proper personal protective measures are taken.

Recent studies indicate that the human seroprevalence in enzootic areas of the disease can be as high as 90% with patients reporting no disease.[44,149,357] This could be an indicator for a much greater number of subclinical CCHFV infections as previously thought. A Russian study showed that one of every five infected people develops CCHF.[140]

The CCHFV genome has unique properties (see molecular chapter). For example, the M and L segment are significant larger than other bunyavirales and the function of many domains remains to be determined. CCHFV displays a great degree of sequence diversity among strains, with divergence of 20%, 22%, and 31% in the S, L, and M segments, respectively.[94] This suggests that significant genome and protein diversity is tolerated while maintaining fitness in the invertebrate vector and the vertebrate host. The sequence diversity is driven by genetic drift due to an error-prone polymerase as well as recombination and reassortment; although the latter two are considered rare events.[35,158] Reassortment and recombination could potentially have a significant influence on the virulence of CCHFV strains as

described in a study from South Africa.[64] More subtle antigenic difference within the CCHFV group have been defined using monoclonal antibodies,[2] but it is unclear how such variation affect the virulence across or the cross-protection among viruses in vertebrate hosts.

Clinical Features

Although *Hyalomma* ticks feed on a range of vertebrate hosts, humans are the only species that have been described to show overt signs of disease. As discussed above, an indeterminate number of CCHFV infections in humans take their course asymptomatically or as a mild form.[44,149,357] Symptomatic CCHFV infections mostly take a characteristic course with four distinct phases: incubation, prehemorrhagic, hemorrhagic, and convalescence period (Fig. 17.7).[164] The incubation period likely depend on the mode of virus acquisition and viral dose and can range from 1 to 13 days. Following tick bite, the incubation period is usually short, up to 5 days.[35] However, determining the exact time when patient was bitten by a tick is difficult especially since tick saliva contains pharmacologically active substances that numb the bite site, and many tick bites go unnoticed. Humans can also become infected by crushing of engorged or semiengorged ticks percutaneously or through contact with mucous membranes. The incubation period following blood-borne transmissions from viremic animals or human patients most likely depends largely on the viral titers in the blood but is usually 5 to 7 days. No studies have defined the infectious dose or the stability of CCHFV in blood. Studies conducted in South Africa showed a time to onset of disease after exposure to tick bite was 3.2 days, 5 days following exposure to blood or tissue of livestock, and 5.6 days after exposure to blood of infected human beings.[378] The prehemorrhagic period is characterized by the sudden onset of fever (39°C–41°C), headache, malaise, myalgia, and dizziness, and in some patients nausea, diarrhea, and vomiting. Flushing of the face, neck, and chest, congested sclera, and conjunctivitis are also commonly noted.[197,274] Virus can be detected in the blood at this point. On average, the prehemorrhagic period lasts for 3 days (range: 1–7 days) and fever persists for 4 to 5 days.[117] The hemorrhagic period develops rapidly, usually begins between the 3 to 5 day of illness and is short (2–3 days). The

first evidence is petechiae and ecchymosis in the skin and mucous membranes. Bleeding from other sites, including the vagina, gingival bleeding, and cerebral hemorrhage, have been reported.[197,378] The most common bleeding sites are the nose, gastrointestinal system (hematemesis, melena, and intra-abdominal), uterus (menometrorrhagia) and urinary tract (hematuria), and the respiratory tract (hemoptysis).[165,274] Atypical presentations of bleeding are also seen. Hepatomegaly and splenomegaly have been reported to be occurred in one-third of patients.[117,165] Several studies have shown that viral loads directly correlate with disease outcome and disease severity. Viral loads corresponding to greater than 10^8 genome equivalents/mL indicate a fatal outcome, while lower viral loads elicit a less severe disease course.[341] Deaths generally occur on day 5 to 14 of illness and are attributed to cardiovascular disturbances and multiorgan failure (MOF). The convalescence period usually begins in survivors about 10 to 20 days after the onset of illness and can take up to a year. During this period, generalized weakness, tachycardia, temporary hair loss, polyneuritis, difficulty breathing, xerostomia, impaired vision, hearing loss, and memory loss have been reported.[378] Thrombocytopenia, leukopenia and raised levels of aspartate aminotransferase (AST), alanine aminotransferase (ALT), lactate dehydrogenase (LDH) are hallmark features of CCHF infection. Furthermore, coagulation tests such as prothrombin time and activated partial thromboplastin (APTT) time are prolonged. In some patients, DIC develops. In that case, platelet counts fall significant further and the level of fibrin degradation products and D-dimers increases. Clinical data indicate that viral load, thrombocytopenia, elevated prothrombin time ratio, and APTT likely play a central role in disease progression and severity.[104,341] No standardized case definition exists internationally and many countries have their own case definitions.[251]

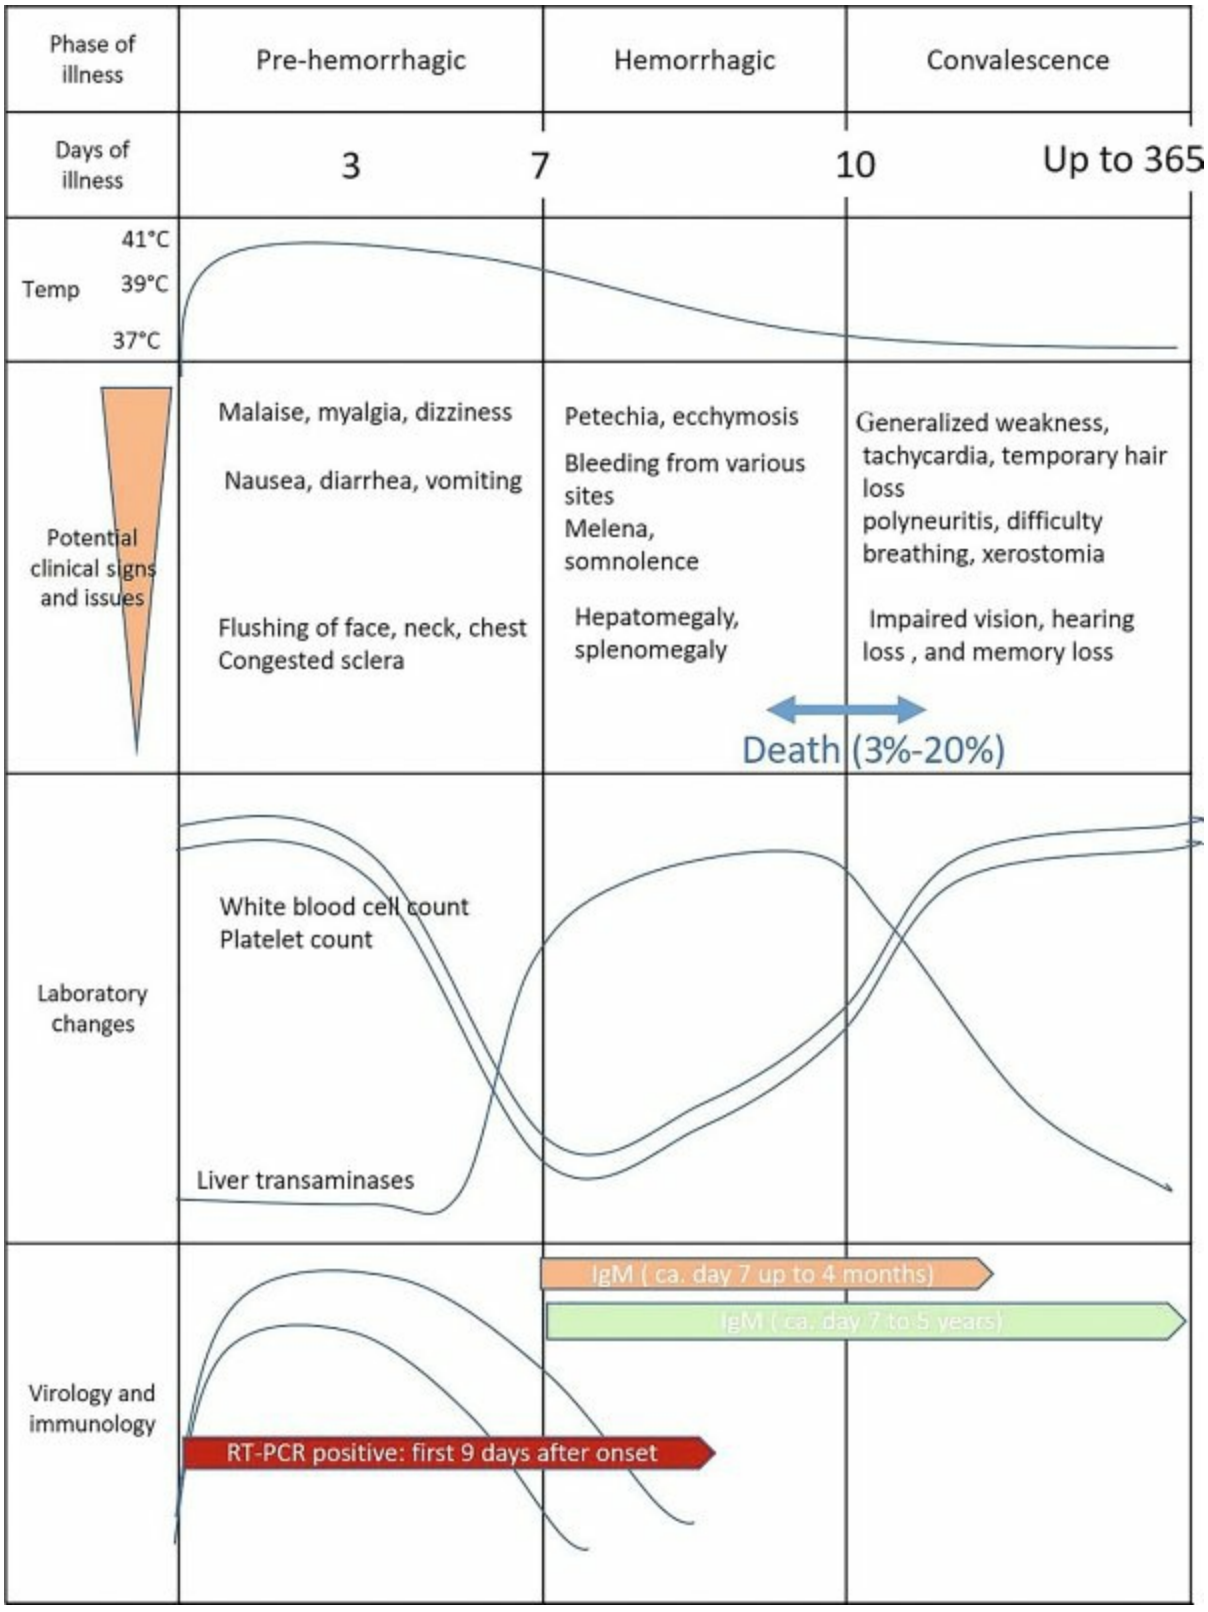

FIGURE 17.7 Clinical presentation of Crimean-Congo hemorrhagic fever in humans. See text for detailed description.

Pathogenesis and Pathology

We only have a very limited understanding of the pathogenesis of the disease mainly due to sporadic nature of human cases, the requirement to work in maximum biocontainment with the virus, and the lack of suitable animal models. What is known is pieced together from a clinical pathology and biomarker studies in patients during the course of the disease and a very limited number of necropsies. Findings from cell culture studies and immunocompromised animal studies lend some support to the findings and fill few knowledge gaps.[35] One of the big questions in CCHF research remains while in contrast to the inapparent infection characteristic of CCHFV infection of other vertebrate hosts, human infections often result in severe hemorrhagic fever. The sequence of events in those severe cases is largely as follows (Fig. 17.8). During attachment and feeding, the tick will introduce the virus into the skin. It is unknown when the tick after attachment will transmit the virus, and what virus titers are transmitted.[133] Studies with other tick-borne pathogens have shown that the immunomodulatory components in the tick saliva that facilitate tick attachment can be exploited by the pathogen to enhance infection.[289] This might explain a shorter incubation period after tick bite compared to human-to-human transmission; however, it remains to be determined for CCHFV as there are certain confounding factors, for example, tick bites go unnoticed sometimes. In addition to tick bite, CCHFV can also be transmitted from contact with the blood of infected animals during the slaughter process, through crushing of engorging ticks feeding on animals, or in a nosocomial setting.[117] On introduction of the virus into the dermis or mucosa, there is likely local primary replication mainly in resident mononuclear phagocytes followed by blood- and lymph-borne spread of the virus either in infected cells or not cell associated to the major organs where secondary replication occurs.[85,310,333] From there the virus is seeded back into the bloodstream to cause viremia. At this point, virus can also be shed from the blood into saliva and urine.[45] Little is known regarding host cell receptor use or factors driving cell and tissue tropism in the host. The systemic spread of CCHFV is aided by the virus ability to evade or suppress the innate immune response (see molecular chapter for more details).[417] The liver seems

to be the main target organ in the systemic phase, where high levels of replication take place.[379] Histopathologic studies have been limited to a small number of human cases.[65,189] The most consistent microscopic changes in the liver tissues were eosinophilic necrosis, Councilman bodies, and Kupffer cell hyperplasia.[65,189] A spectrum of severity of hepatic damage was identified ranging from mild necrosis with occasional Councilman bodies to more severe necrosis with extensive damage of hepatic lobules (Fig. 17.9). Hepatic injury is also reflected by high levels of transaminases in the blood of patient during the hemorrhagic phase. Viral antigen could be detected focally in hepatocytes and Kupffer cells (Fig. 17.10). The main findings in other tissues included prominent splenic lymphoid apoptosis and depletion, and interstitial pneumonia. CCHFV was also detected in endothelial cells. Congestion, edema, and focal hemorrhage and necrosis are seen in most organs. Many of these findings have been supported by studies in immunocompromised mice, which model rather the most severe form of the disease.[34,36,442] Proinflammatory cytokines play a key role in the pathogenesis and severity of the disease. A range of clinical studies measured elevated levels of number of cytokines and chemokines in the blood of CCHF patients with TNF-α, IL-6, IL-8, and IL-10 being associated with severe disease.[300] These findings are by *in vitro* and *in vivo* studies. This suggests that a host-driven inflammatory response, mediated through an imbalance in cytokine and chemokine production, is the cause of severe disease progression. Proinflammatory cytokines, platelet aggregation, and activation of the intrinsic coagulation cascade probably lead to an altered vascular function making bleeding in different organs common in CCHF patients. Increased levels of vascular adhesion markers such as ICAM-1 and VCAM-1 have been detected in cell culture studies as well as in clinical studies.[21,86] The humoral and cell-mediated immune responses to clear CCHFV infection remain poorly defined. One study showed higher levels of NK cells in CCHF patients with severe disease, whereas another study contradicted these findings and found higher levels of cytotoxic T cells instead.[4,428] Both IgM and IgG antibodies are usually detectable approximately 5 to 7 days after the onset of illness and reach maximum levels in survivors by the 2nd or the 3rd week after disease onset and are detectable until at least 3 years after infection.[35,76] Antibody responses are rarely detectable in fatal cases. Lastly, it has been suggested

that genetic makeup such as HLA type or polymorphisms in TLR10 or IFNA expression could play a role in the disease severity.[3,114,202] Recently, an immunocompetent nonhuman primate model was reported in which cynomolgus macaques infected with CCHFV hallmark signs of human CCHF with remarkably similar viral dissemination, organ pathology, and disease progression as humans.[151] This model holds a lot of promise to fill knowledge gaps and needs to be further evaluated.

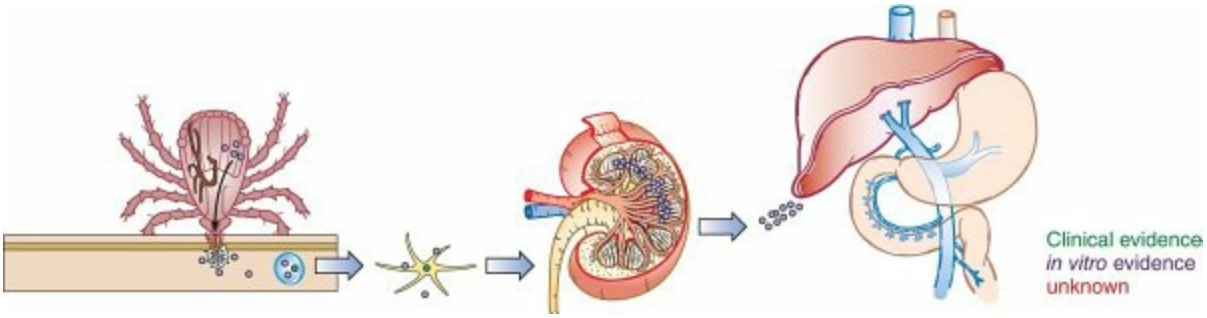

FIGURE 17.8 Transmission and dissemination of CCHFV after tick bite. CCHFV is introduced into the skin through tick bite. It is unclear at what time after tick attachment the virus is transmitted and how much virus is transmitted. Initial cell targets are most likely dermal dendritic cells, Langerhans cells, and in the skin residing macrophages in which the virus replicates. From here, the virus most likely spreads to the local draining lymph node; however, hematogenous spread is conceivable as well. The role of tick saliva in this process and if the dissemination occurs through free or cell bound virus remains unknown. Subsequent to local replication, the virus will spread systemically targeting cells in liver and spleen as well as myeloid cells in the blood where secondary replication occurs.

Diagnosis

Differential

Clinical differential diagnosis of CCHFV varies in the different regions where the disease is known to occur and can be difficult in early stages. In general, the disease can be suspected for patients presenting with a rapid onset of severe influenza-like symptoms and known exposure to tick bite or contact with blood or tissues of potentially infected livestock or humans. The early stages can be confused with sandfly fevers in regions where the diseases overlap, and leptospirosis, Omsk hemorrhagic fever, other viral hemorrhagic fevers (yellow fever, HFRS, Ebola), tick typhus, and mycotoxicoses can appear similar in the more advanced hemorrhagic phase of the illness. Although presentation is not pathognomonic, clinical values can be helpful in diagnosis when CCHF is suspected, with leukopenia, thrombocytopenia, and elevated liver enzymes frequently being present early in the disease.[117,379]

Laboratory

Due to the requirement of high or maximum biocontainment laboratories to work with CCHFV, virus isolation is only used when facilities are available and is not the typical used to for the first-line diagnosis since it is also time consuming.[35] CCHFV antigen detection ELISAs from patient acute phase sera have been developed and are also performed.[35,62,117] For CCHFV isolation, i.c. or intraperitoneal inoculation of patient acute phase blood samples into newborn mice is probably most sensitive, although quicker results can be obtained by inoculation into susceptible tissue culture cells, such as Vero cells, followed by fluorescent antibody staining.[352] Rapid laboratory diagnosis of CCHFV can be achieved by nucleic acid detection and several RT-PCR, real-time RT-qPCRs, and Lamp assays have been

developed.[47,63,103,135,240,293] Advantageous is that the sample can be inactivated before the assay is conducted. Commercial kits are used in some countries, but most countries rely on in-house established assays, and there is no internationally standardized nucleic acid test.[125] The virus, its genome, and antigen are usually detectable up to 1 to 2 weeks after onset of illness. Serological diagnostic is typically done by ELISA or indirect fluorescence assay (IFA), and several serological assays for human or animal sera have been developed.[125,297,340] Fatal cases rarely show significant antibody responses. However, in those destined to survive, IgM and IgG antibodies are frequently detectable after about a week of illness. Studies have shown that IgM can be detected up to 4 months and IgG is detectable for at least 3 years.[117]

Prevention and Control

Prevention

There is no vaccine against CCHF available for humans or animals, and anti-Hyalomma tick vaccine is currently available. Prevention therefore is to minimize exposure to the virus by avoiding tick exposure in endemic areas. Treatment of clothing with pyrethroid preparations, which repels and even kills ticks, is highly recommended for those persons likely to come into contact with CCHFV-infected ticks (e.g., slaughterhouse workers, sheep shearers, veterinarians, and others involved with livestock). In addition, habits that avoid virus-contaminated blood or tissues contacting the skin should be practiced (e.g., wearing of gloves and avoiding crushing ticks with fingers). Medical personnel should practice standard barrier-nursing techniques during care of suspected CCHFV patients.

Treatment

Most CCHF cases occur in rural areas often with low infrastructure. Treatment of those patients is by means of supportive and replacement therapy with blood products. When available, ribavirin treatment has been suggested and has been used to treat CCHF patients for more than three decades. Experimental tissue culture and mouse infections have shown that

CCHFV susceptibility to ribavirin treatment. Studies have generally found that ribavirin is beneficial, so long as it is initiated early in the course of illness.[118,119,381] Nevertheless, recent meta-analysis studies question the therapeutic benefit of ribavirin creating uncertainty of its use as a treatment.[186,363] As a result, some investigators have called for randomized controlled trials to be conducted. Two recent animal studies looked at Favipiravir (T-705) treatment and found it to be more efficient than ribavirin,[156,292] making it an interesting new candidate for treatment. There are limited reports on other experimental treatments such as ribavirin combined with plasma exchange transfusion, steroids, or double plasmapheresis with inconclusive results. Administration of immune plasma has been tried on numerous occasions, but its usefulness remains unclear.[148,179,215]

Vaccines

A chloroform-inactivated vaccine prepared from virus-infected suckling mouse brains was developed in the former Soviet Union in 1970 and was used in parts of Eastern Europe. The vaccine is currently licensed in Bulgaria and is given to high-risk personnel in endemic areas such as military personnel as well as medical and agricultural workers. Although the Bulgarian ministry of health reported a four-fold decrease in the incidence of the disease in two decades due to the vaccine, its efficacy remains still not well characterized. Furthermore, it requires a three booster vaccination, and a mouse brain-derived formulation raise concerns about side effects.[102] Multiple CCHFV vaccines have been developed experimentally, with vaccine types such as inactivated whole/purified virus, virus-like particles, vectored vaccines relying on vaccinia and adenovirus platforms, plasmid-based DNA vaccines, and subunit vaccines relying on either plant or insect produced antigens. With few exceptions, these vaccines have all been evaluated with a prime and boost (or multiboost) strategy along with the subunit and inactivated whole virus strategies containing adjuvants. Many of these listed vaccines have been evaluated in either BALB/c, STAT1 K/O, or IFNAR mice, though a consensus animal model for vaccine testing has not yet been established. Immune correlates of protection in these various vaccination strategies, antigenic targets, and animal models have not been uniform and therefore remains largely unknown. The predominant antigenic target has

been whole or components of the glycoprotein precursor with 100% protection observed in vaccinia vectors, though a tandem nucleoprotein plus glycoprotein approach with DNA vaccines and an adenovirus vectored nucleoprotein only have both achieved >70% protection, suggesting both glycoprotein and nucleoprotein components are viable antigenic targets.[102] The lack of an immunocompetent animal model has made the assessment of vaccine candidates difficult. Moreover, immune correlates of protection not very well defined, and recent studies show that in addition to neutralizing, also non-neutralizing antibodies and the cellular response play a crucial role. The sporadic CCHF outbreaks in rural areas raises questions about the feasibility of a human vaccine. Therefore, One Health approaches using reservoir-targeted approaches through veterinary vaccines and acaricides have been suggested.

PERIBUNYAVIRIDAE, GENUS *ORTHOBUNYAVIRUS*

The *Orthobunyavirus* genus is a large genus containing 49 viral species based on the latest proposed taxonomy of the ICTV. However, the viruses can also be distinguished into 18 serogroups based on neutralization (NT), hemagglutination inhibition (HI), and complex fixation assays. Here, we group the viruses based on serogroups. Medically, the most important viruses such as Oropouche virus (OROV), La Crosse virus (LACV), and Jamestown Canyon virus (JCV) can be found in the Bunyamwera, California, and Simbu serogroups. This section will focus on these three serogroups since they contain members that medically most relevant.

Distribution and Significance

Most orthobunyaviruses are transmitted by mosquitoes, although a few have been isolated from tabanids, phlebotomines, ticks, and bedbugs, and have been found in every continent except Antarctica.[316]

Epidemiology

California Serogroup Viruses

LACV is the most significant of the California encephalitis serogroup viruses in terms of causing human disease in the United States, with 60 to 100 cases per year, predominantly in children younger than 15 years of age. There is, however, severe underreporting.[153,187] The primary vector is the forest-dwelling, tree-hole–breeding mosquito, *Aedes triseriatus*, although more recently, and concerning, the virus has also been isolated from the aggressive day-feeing Asian tiger-mosquito, *Aedes albopictus*.[224] *A. triseriatus* is found throughout the northern Midwestern and Northeastern United States, and LACV is maintained in these mosquitoes by transovarial transmission, which allows overwintering of the virus in mosquito eggs.[416] During the summer months, squirrels, chipmunks, foxes, and woodchucks become viremic following LACV infection and are important amplifying hosts.[391,433] The majority of La Crosse encephalitis cases occur in the summer and early fall months when risk of bite from infected female mosquitoes is highest. Historically, LACV infections mostly occurred in the Mississippi and Ohio river basins, with more than 90% of cases coming from Wisconsin, Minnesota, Iowa, Indiana, Ohio, and Illinois,[316] but since the 1980s, more cases have been reported from Appalachia and eastern Tennessee, and between 1987 and 2009, more than 30% of total cases in the United States were from West Virginia.[153] JCV (including the closely related Jerry Slough variety) is also associated with arboviral encephalitis in the United States. The virus is vectored by *Culex inornata* mosquitoes, and several species of Aedes mosquitoes, and is broadly distributed across much of North America. Vertical transmission of the virus has been demonstrated in several Aedes species mosquitoes.[154] White-tailed deer are the most likely vertebrate amplifying host.

Bunyamwera Serogroup Viruses

Bunyamwera virus is present throughout much of sub-Saharan Africa and appears to be an important cause of acute febrile illness in humans. The virus has been isolated from humans in Uganda, Nigeria, and South Africa.[142,206] More recently, Ngari virus has been identified as a reassortant BUNV. This reassortant virus has been associated with hemorrhagic fever cases in Somalia

and Kenya and a large outbreak of acute febrile illness in Sudan.[53,57] In addition, human antibodies reactive with BUNV have been detected in most of sub-Saharan Africa, with high prevalence (up to 82%) being recorded in some locations.[361] Isolation of the virus from several Aedes species mosquitoes has implicated them as the primary vector.[206,361] Antibodies reactive with BUNV have been detected in domestic animals, nonhuman primates, rodents, and birds, and viremias capable of supporting mosquito transmission have been recorded in experimentally infected rodents, bats, and primates.[355,361] However, the role of a potential vertebrate amplifying host is currently unclear. Several additional Bunyamwera serogroup viruses are present in the Americas[281] and are infrequently reported to cause acute febrile illness in humans. Cache Valley virus is found throughout the United States, Canada, and Mexico and often infects sheep and possibly all ruminants; infections have been associated with embryonic and fetal death, stillbirths, and multiple congenital malformations in sheep.[112,258] The virus has caused a fatal encephalitis in a human.[350] It remains unclear whether Cache Valley and serologically closely related viruses may play a role in syndromes of congenital malformations and embryonic losses in humans in North America.[67]

Simbu Serogroup Viruses

Simbu serogroup viruses are global in distribution and are principally vectored by biting midges of the genus *Culicoides*. Since the original isolation of OROV from a febrile patient in Trinidad in the 1950s, the medical importance of the virus has become increasingly evident.[395] OROV has a wide geographic distribution in tropical regions of the Americas. It has been isolated from humans in Panama, Venezuela, Bolivia, and northern Argentina. It is probably much more common than reported, because of its similar clinical presentation to dengue, Zika, and other diseases causing acute nonspecific febrile illnesses. Between 1960 and 2009, at least 500,000 people are thought to have been infected in more than 30 outbreaks.[402] Most of these outbreaks were in relatively urban areas, leading to the suggestion that there are likely separate urban and sylvatic cycles.[97,332] The principal rural vector in

Brazil appears to be the tiny biting midge, *Culicoides paraensis*,[313,332] which breeds in rotting vegetative matter, and seasonal populations can become high in agricultural areas, where build-up of debris such as banana tree stalks or cacao husks may occur (Fig. 17.11).[314]

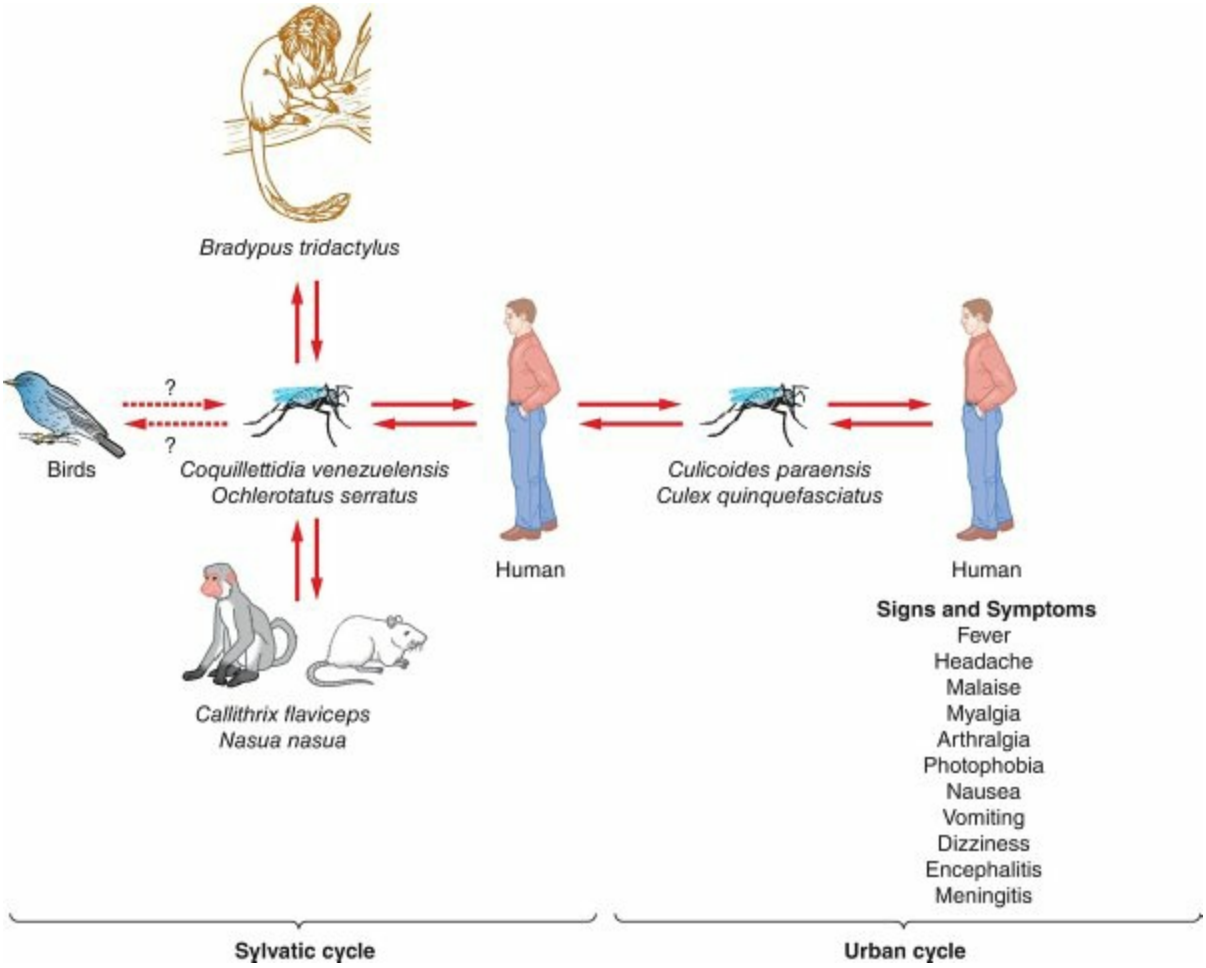

FIGURE 17.11 Transmission cycles of Oropouche virus. (Adapted from Travassos da Rosa JF, de Souza WM, Pinheiro FP, et al. Oropouche virus: clinical, epidemiological, and molecular aspects of a neglected orthobunyavirus. *Am J Trop Med Hyg* 2017;96(5):1019–1030.)

These midges feed predominantly in the early evening hours and are quite anthropophilic. Infected humans develop viremia sufficiently high to

transmit the virus to uninfected midges and appear capable of serving as the vertebrate amplifying host during urban epidemics.[314,395] Serologic data also suggest that primates or sloths, or even birds, may be potential hosts in the sylvatic cycle. There are well-documented outbreaks of OROV in urban areas associated with both *C. paraenesis* and *Culex quinquefasciatus* (Fig. 17.11). The virus has been isolated repeatedly from *C. quinquefasciatus*, and experimental bite transmission has been demonstrated experimentally in this mosquito. Recent phylogenetic studies indicate that four distinct OROV lineages are present in different geographic areas, and that OROV emerged in Brazil in around 1790.[402]

Akabane virus (AKAV) is widely distributed throughout Australasia (Australia, Japan, Korea, Taiwan), the Middle East (occasionally extending as far north as Turkey), and sub-Saharan Africa.[5,11,91] The virus is an important cause of disease in livestock, with periodic outbreaks of abortions, stillbirths, and congenital malformations recorded in cattle, sheep, and goats in Australia, Japan, Korea, Taiwan, Israel, and Turkey, although intriguingly no disease outbreaks have been observed in Africa, despite the widespread presence of the virus.[5] The virus is vectored by midges of the genus *Culicoides*, and although *C. brevitarsis* is the primary vector in Australia,[277] different species are important in Asia and the Middle East.[6,183,217] Unlike LACV, which mainly causes encephalitis in children, JCV appears to predominantly cause disease in adults, although only 15 human cases have been reported since 2004.[330] No information on age depends is available for OROV.

Morbidity/Mortality

For most of the orthobunyavirus infections, no mortality has been reported. Nevertheless, due to the small case numbers, and for some with limited geographic range, under reporting is possible. Cases are usually sporadic. However, several thousand cases of acute febrile illness can occur during OROV epidemics observed throughout the Amazon basin regions of Brazil and Peru.

Clinical Features

The California serogroup viruses, LACV, Jamestown Canyon, and the prototype California encephalitis virus all cause a similar encephalitic disease in humans.[336] Indeed, due to serologic cross-reactivity, many of the early disease descriptions of California encephalitis cases were likely due to JCV or LACV rather than California encephalitis virus, which is now known to be less common.[69] The major difference between the viruses is in age dependence of the spectrum of clinical disease observed, in that LACV infections tend to be more severe in children, whereas JCV infection is more severe in adults. The spectrum of disease ranges from inapparent or mild febrile disease through to fatal encephalitis.[81,261,392] The incubation period is approximately 3 to 7 days. Most cases report sudden onset of fever, followed by stiff neck, lethargy, headache, and nausea and vomiting, and symptoms usually end within 7 days. Approximately half the cases exhibit seizures, and up to 30% develop coma and exhibit a longer disease course. About 65% of patients have meningitis on presentation, with both mononuclear and polymorphonuclear cells present in cerebrospinal fluid. Despite mild neurological symptoms often present at the time of patient discharge, surprisingly little residua is found. The most important sequela is epilepsy, which is observed in approximately 10% to 15% of children, and these are almost always patients who had seizures during acute phase of illness. In addition, about 2% of patients have persistent paresis.[81,152,261]

For OROV, the incubation period is approximately 4 to 8 days, followed by sudden onset of fever, with arthralgia, myalgia, severe headache, chills, photophobia, and prostration. Occasionally, rash, meningitis, or meningismus is seen.[275,315,395] Most of the symptoms resolve within 3 to 5 days, although the myalgia may last 1 or 2 weeks. Viremia is detectable in the majority of patients 2 to 3 days after onset of illness. Approximately half of the patients can exhibit recurrence of some disease symptoms 1 to 10 days after initial recovery.[315,395] OROV is also suspected to be infectious by aerosol, based on reported laboratory infections.[313]

Pathogenesis and Pathology

Human infections with California encephalitis, LACV, or JCV viruses are initiated by the bite of a virus-infected mosquito. The course of the infection

has been extensively modeled in mice.[302] Similar to the human infection, the outcome of the infection in mice is dependent on the age of the animal and strain of virus used, with subcutaneous challenge of newborn mice most closely mimicking the natural human infection. The virus initially spreads from the site of inoculation into striated muscle, which is the major site of replication. It spreads to the plasma, presumably through the lymphatic channels, and the resulting high viremia allows the virus to cross the blood–brain barrier.[181] Mice inoculated intraperitoneally with LACV showed high levels of replication in nasal turbinates, suggesting the virus could enter the central nervous system (CNS) by olfactory neurons.[33] Once in the CNS, the virus replicates in neurons and glial cells, causing considerable neuronal necrosis. Death occurs 3 or 4 days postinfection. In contrast, although rhesus monkeys were highly susceptible to LACV infection, the animals remained asymptomatic and developed neutralizing antibodies.[33] High viremia is essential for neuroinvasion. A monoclonal antibody escape mutant of LACV (V22) showed decreased replication in striated muscle, and hence did not generate sufficient viremia to permit neuroinvasion, but V22 was as neurovirulent as wild-type LACV when inoculated intracranially.[143] A similar distinction between neurovirulence and neuroinvasiveness is implied from observations on recombinant LACV with mutations in the fusion peptide domain of Gc, which showed reduced replication in muscle cells but retained the ability to cause neuronal loss in culture.[365] The lesions observed in the brains of fatal La Crosse encephalitis cases differ from those in infected suckling mice. In humans, and to a large extent in adult mice infected intracerebrally, cerebral edema, perivascular cuffing, glial nodules, mild leptomeningitis, and occasional areas of focal necrosis that are typical of acute severe viral encephalitis are observed. Lesions are mostly in the cerebral cortex, with some in the brainstem.[190] Studies with Tahyna virus and JCV showed strain differences in neuroinvasiveness and neurovirulence in a Swiss Webster mouse model, whereas in rhesus monkeys, no clinical disease was observed but the animals mounted strong neutralizing antibody responses.[31,32]

Infection of natural vertebrate amplifying hosts of these viruses, such as adult chipmunks (LACV) or snowshoe hares (snowshoe hare virus), results in

inapparent infection and viremia sufficient to infect mosquitoes.[351] *A. triseriatus* mosquitoes are the principal vector of LACV, and their experimental infection with California encephalitis serogroup viruses has been studied in detail.[29,386,390,415] Viruses ingested via a viremic bloodmeal infect the epithelial layer surrounding the mosquito midgut. Replication of the virus results in release of the virus across the basal lamina into the hemocele, allowing transport of the virus to tissues throughout the body. Virus infection of mosquitoes other than the principal vector species usually results in poor penetration of the virus across this midgut barrier. Experimental infections using reassortant viruses have shown that virus M genomic segment (encoding the glycoproteins and NSm protein) is an important component in the correct match between virus and host mosquito, which allows efficient transit across the midgut barrier.[29] Once across the barrier, virus replication occurs in a wide variety of tissues, including the ovaries and salivary glands.[386] Release of virus from the salivary glands allows virus transmission from the female mosquito to the vertebrate host during feeding. Mosquitoes begin to be infectious approximately 1 or 2 weeks after ingestion of virus, an interval referred to as the extrinsic incubation period.

The infection of the ovaries is thought to be crucial for virus maintenance in mosquito populations, in that it results in transovarial transmission of the virus from the female to the offspring and allows the virus to overwinter in infected eggs.[416] In addition, LACV-infected females appear to mate more efficiently than uninfected mosquitoes.[131] Male mosquitoes play no role in the vertical transovarial transmission of the virus, or in the horizontal transmission via amplifying vertebrate hosts, as they do not take a bloodmeal. However, the virus is detected in the gonads of transovarially infected males and can result in venereal transmission of the virus horizontally within the mosquito population.[390] This combination of transmission mechanisms allows efficient maintenance of the LACV in *A. triseriatus* populations. Similar processes are thought to function in host mosquito infections with other California serogroup viruses,[397] and results from studies with these viruses and their arthropod hosts serve as a model for understanding virus maintenance and transmission mechanisms for other Bunyavirales viruses.

Aino and AKAV are important causes of disease in livestock, causing epizootics of abortions and congenital defects in cattle, sheep, and goats.[200,201,396] Experimental infections of pregnant cattle or ewes with either virus have been shown to produce viremia, followed by virus replication in the placenta and fetal tissues, and resulting in congenital defects such as microencephaly and hydrocephalus.[201,303,396] Similarly, experimental infection of pregnant hamsters with AKAV results in death of the fetus.[12]

Natural reassortment among orthobunyaviruses is important as it confounds serology and classification of viruses in the genus.[58] A striking example is Ngari virus, a human pathogenic virus in Africa. Ngari virus was isolated during a large human hemorrhagic fever outbreak in 1997 in East Africa.[53] A genetic analysis revealed that Ngari virus is a naturally occurring reassortant between Bunyamwera virus (S and L segment) and Batai virus (M segment).[57] These two viruses do not cause a hemorrhagic disease in humans. As illustrated with Ngari, reassortants may be phylogenetically quite similar to other viruses but quite different phenotypically.

Diagnosis

Laboratory

A wide variety of assays have been used in the diagnosis of infections with viruses of the genus *Orthobunyavirus*, including complement fixation (CF), hemagglutination inhibition (HI), neutralization (NT), immunofluorescence assay, IgM capture ELISA, and RT-PCR.[66,107,146,216,223,321] Diagnosis of California serogroup virus infections relies on serologic methods, as the virus is generally absent from blood or secretions during the phase of CNS disease. The HI test is considerably more sensitive for these viruses than CF, but NT assay or RT-PCR coupled with multiplex nucleotide sequencing is needed for confirmation and subtype identification.[222] The IgM capture ELISA works well for diagnosis of most infections by viruses of the genus *Orthobunyavirus* but has not been widely applied to date.[107,176,350] Virus isolation attempts complement serologic and genetic assays and is best achieved by intracerebral (i.c.) inoculation of suckling mice or infection of susceptible

cells such as Vero cells.

Prevention and Control

Prevention and control is difficult for the mosquito-borne California and Bunyamwera serogroup viruses due to the widespread presence of the mosquito vector hosts and relatively sporadic nature of the associated human or livestock diseases. No vaccines are available for human-infecting orthobunyaviruses. Broad application of insecticides, as carried out in earlier decades, is no longer ecologically acceptable. Relative to human disease, use of fine mesh netting and personal protectants containing *N*,*N*-diethyl-meta-toluamide (DEET) are highly recommended in areas with high risk of people being bitten by virus-infected mosquitoes. Similar vector control challenges exist for the Simbu serogroup viruses vectored by *Culicoides* midges. With the OROV disease in Brazil and Peru, avoiding the build-up of rotting organic debris such as banana tree stalks or cacao husks in agricultural areas may help curtail population levels of *C. paraensis* and reduce the risk of seasonal epidemics.[314] Avoiding exposure (treated netting, DEET repellents) to these midges during their early evening feeding hours is also recommended. Similar protective measures are recommended for AKAV. In addition, a successful formalin-inactivated AKAV vaccine has been developed in Japan using virus-infected hamster lung cell cultures, and a trivalent-inactivated vaccine protective against AKAV, Aino virus (AINOV), and Chuzan orbivirus has been successfully trialed in Korea.[200] With knowledge of the distribution and seasonality of AKAV disease outbreaks, vaccination of at risk animals prior to pregnancy is feasible.

PHENUIVIRIDAE, GENUS *PHLEBOVIRUS*

Rift Valley Fever and Sandfly Group

Pathogenesis and Pathology

Sandfly fever disease is a febrile and occasionally encephalitic illness caused

by viruses belonging to the *Phlebovirus* genus, family Phenuiviridae, which are harbored by phlebotomine sandflies. The main viruses currently known to cause sandfly fever are sandfly fever Sicilian virus (SFSV), sandfly fever Naples virus (SFNV), and Toscana virus (TOSV). Outbreaks of human disease have been identified as early as 1900s in the Mediterranean region. The only known reservoir of these viruses is the competent adult sandfly. There is no direct evidence of a vertebrate reservoir, although antibodies against all sandfly-borne phleboviruses have been detected in a number of animals in the Mediterranean region.[269] *In vitro* experiments have shown that human monocyte-derived dendritic cells and endothelial cells can be productively infected by TOSV and secrete proinflammatory cytokines.[90] Increased proinflammatory and anti-inflammatory cytokine levels have been reported in cerebrospinal fluid of patients with TOSV encephalitic disease.[401] A specific antibody response develops rapidly in human infection and is long-lasting against TOSV. Moderate levels of neutralizing antibodies are maintained for more than a year.[311]

More is known about the pathogenesis and disease of another phlebovirus, mosquito-borne RVFV.[39,50,262] RVFV infections of livestock are often recognized by the onset of “abortion storms” that sweep through livestock-producing areas, with simultaneous acute febrile disease in humans. Humans are infected with RVFV either by mosquito bite or exposure to infected animals. Most RVFV infections in humans result in mild febrile illness, with about 1% to 2% of cases progressing to severe disease. Rift Valley fever (RVF) can present with varying degrees of symptoms, ranging from no symptoms or mild influenza-like illness to severe disease with hepatitis, retinitis, or encephalitis. Direct human-to-human transmission, including nosocomial transmission, has not been observed.[7]

Data from experimental infections and analogies from other arbovirus infections suggest that macrophages and dendritic cells are likely among the first cells infected by RVFV.[141,260] Subsequently, RVFV is transported by lymphatic drainage to the regional lymph node, where local viral replication takes place. The virus then enters the blood, causing primary viremia and spreading to the major organs. The main target organ of RVFV is the liver, and hepatic necrosis is prominent in severe cases. Replication in the lymph nodes, spleen, liver, adrenals, lungs, and kidneys results in high viremia.

Viral load is prognostic of disease outcome: viral loads are 1 to 2 logs higher in patients who succumb to infection than in survivors.[38]

A small percentage of patients with severe disease develops retinitis and/or encephalitis 1 to 3 weeks after the onset of illness, and necrotic foci can be observed in the brain.[271] How RVFV reaches immune-privileged sites like the eye and brain is not known. One possible explanation is that the virus enters the peripheral nervous system and later replicates and spreads through either the systemic or neural route into the CNS, resulting in encephalitis. Disruption of the blood–brain barrier occurs in the late stages of infection, after the virus has been actively replicating inside the CNS.[412]

RVFV replication in cells is highly cytopathic, suggesting that most of the cellular destruction observed in acute illness is likely due to the virus directly killing host cells. In hemorrhagic RVF cases, a complex interaction exists between the virus and both fibrinolytic and coagulation pathways, with increased levels of tissue plasminogen and D-dimers indicative of ongoing fibrinolysis, and decreased levels of P-selectin, ADAMTS13, and fibrinogen during the acute phase of disease.[92] The RVFV NSs protein is a major virulence factor that allows the virus to escape the host innate immune response by down-regulating type I IFN response and shutting down host cell transcription.[243] In both animal models and human cases of RVF, failure to induce an early type I IFN immune response results in severe disease; in NHP models, survival is improved by administration of IFN-α.[270] Patients who succumb to disease often fail to generate RVFV-specific humoral immunity.[38] A strong innate immune response, followed by the generation of high-titer neutralizing antibodies, is currently considered to be a correlate of protection. The role of T cells during human RVFV infection is unclear. In experimental encephalitis in NHPs, survival correlated with higher numbers of activated CD4 and CD8 T cells.[424] Additionally, depleting T cells can worsen the development of RVF encephalitis.[98,155] However, dysregulation of the immune response may contribute to RVFV pathogenesis, and an uncontrolled inflammatory response to RVFV infection correlates with fatal outcome.[180,259,260]

As indicated above, clinical presentation of RVF varies greatly, likely

due to a number of factors. The virus dose and route of exposure may contribute to the disease outcome. Epidemiological studies have shown that direct exposure to sick animals, which usually harbor high viral loads, could lead to severe disease with hemorrhage and encephalitis.[17,248] Experimental intranasal or aerosol infections lead to enhanced neurovirulence with a rapid replication of the virus in the CNS.[100,412]

Human genetic factors could also influence disease progression. Polymorphisms in human genes of the innate immune system have been shown to play a role in disease severity.[159,219] Other underlying conditions and coinfections, like HIV infection, have also been associated with disease severity and fatal outcome.[266]

Susceptibility of livestock to RVFV infection varies considerably depending on a variety of factors, including livestock species and age and the strain of the virus. Pathologic features of the disease in livestock also differ significantly. Leukopenia is frequently seen during the first 3 or 4 days of infection, when fever and viremia are usually highest. Altered serum enzyme levels (e.g., aspartate aminotransferase and sorbitol dehydrogenase), indicative of hepatocyte destruction, are often seen during the acute phase. Leukocytosis frequently occurs in the early phase of recovery. Thrombocytopenia and fibrin thrombi in several organs suggest that disseminated intravascular coagulopathy (DIC) may be a feature of severe disease in livestock, as seen in hemorrhagic infections in humans.[87,377]

RVFV infection of pregnant animals frequently results in abortion of the fetus, and the ability of the virus to cross the placenta to infect the fetus is well documented. Abortions early in the course of infection are probably the result of the high fever associated with the acute phase of illness; later abortions are more commonly the result of direct infection of the fetus, with resulting hepatic necrosis. Until recently, no clear correlation between RVFV infection and miscarriage has been noted in human infections. However, a recent cross-sectional study in hospitalized pregnant women in Sudan indicated a significant association between RVFV infection and miscarriage.[28] In humans, maternal transmission of RVFV to the fetus has only occasionally been documented.[1,20] This lack of widespread human fetal infection is in striking contrast to the classical abortifacient hallmarks of RVF

in other vertebrate species.

Epidemiology and Ecology

Phlebovirus genus

The geographic distribution of SFSV and SFNV closely follows that of their sandfly host, *Phlebotomus pappataci*.[385] This distribution extends from the Mediterranean basin throughout the Middle East and the Arabian Peninsula, north up into areas around the Caucus Mountains, and as far east as Pakistan and India. Sandflies are most numerous in the warmer months, are found at ground level, and feed in the early evenings. Unfortunately, their small size allows them to pass through untreated mosquito netting.

A related phlebovirus, TOSV, is hosted by *Phlebotomus perniciosus* and is found in central Italy, Cyprus, Portugal, and Spain. Relatively high (20%–25%) antibody prevalence rates suggest that human infections with TOSV are widespread and frequent in endemic areas.[54,113] In addition, many acute lymphocytic meningitis and meningoencephalitis cases occurring in the summer months, particularly in children, are attributable to TOSV infection.[55,113,285] SFSV, SFNV, TOSV, and related viruses replicate in their sandfly hosts, and transstadial and transovarial transmission of the virus has been demonstrated.[388] Sexual transmission of TOSV among sandflies has also been shown.[387] The relatively low efficiency of transovarial transmission demonstrated in experimental infections suggests that vertebrate amplifying hosts are required to maintain these viruses in endemic areas. However, although antibodies to TOSV are present in many domestic animals, virus isolation has been unsuccessful, suggesting that these animals do not act as reservoirs.[279] Thus, the identity of amplifying hosts remains uncertain. Data showing that viremic humans can infect *P. pappataci*, together with attack rates as high as 75% and urban outbreaks of sandfly fever, suggest that humans can on occasion serve as the amplifying vertebrate host of these viruses.[337]

The geographic distribution of RVFV covers much of Africa, including Madagascar and portions of the Arabian Peninsula, with most livestock

epizootics reported in East and Southern Africa[218,219,304] (Fig. 17.12). *Aedes* sp. mosquitoes of the subgenera *Aedimorphus* and *Neomelaniconion* are likely the principal RVFV vectors and may maintain the virus in nature through vertical transmission.[233] The ecology of RVFV has been best studied in Kenya, Zimbabwe, and South Africa. In these regions, dambos or vleis, shallow depressions up to several hundred meters across, located near streams and fed by ground water, are thought to play a central role in RVFV epizootics. These dambos flood at times of unusually heavy rainfall, triggering a population explosion in floodwater *Aedes* sp. mosquitoes. RVFV epizootics have also been linked to periods of unusually high precipitation.[234]

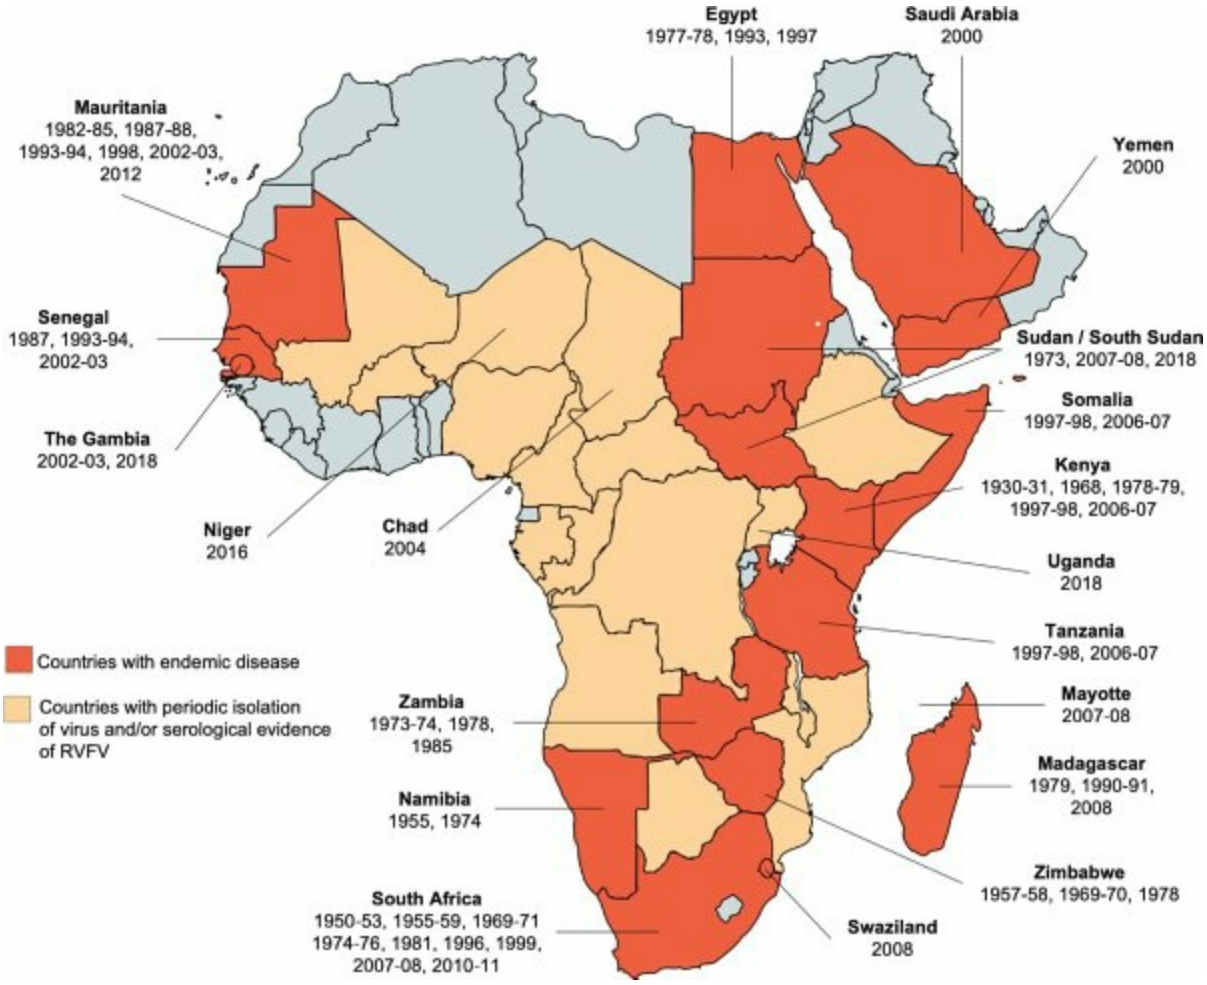

FIGURE 17.12 Geographic distribution of Rift Valley fever virus (RVFV). Countries in which Rift Valley fever (RVF)

outbreaks have been identified are shown in *red*, with the dates of the major outbreaks noted. *Yellow* shows countries with indications of RVFV presence based on livestock serosurveys and identification of periodic cases.

Isolation of RVFV from unfed male and female *Aedes mcintoshi* mosquitoes hatched in a dambo in the endemic area of Kenya during an interepidemic period demonstrates maintenance of the virus between epidemics and transovarial transmission of the virus in these mosquitoes.[233] The transmission cycle of the virus is summarized in Figure 17.13. *A. mcintoshi* is thought to be the principal RVFV maintenance vector in Kenya and Zimbabwe,[376] and these mosquitoes are among the earliest to hatch from eggs after flooding. If the eggs contain virus (passed via transovarial transmission), the hatching mosquitoes are infected and pass the virus on to nearby livestock during feeding, potentially initiating a local epizootic. Viremic livestock act as amplifying hosts that transmit RVFV to other floodwater *Aedes* sp. mosquitoes and to other species including culicines and anophelines, promoting further amplification and spread of the virus. Initiation of such mosquito-virus amplification cycles at dambos throughout a livestock-producing area could give rise to regional, relatively synchronous eruptions of RVFV activity with associated abortion storms across broad geographic areas. Indeed, such eruptions are observed at various intervals in livestock in East and Southern Africa.[304] Although such a scenario is an attractive explanation for the dynamics of explosive RVFV epizootics, longitudinal studies of the vector-virus ecology are necessary to confirm if these factors are solely responsible for the dramatic nature of RVF outbreaks.

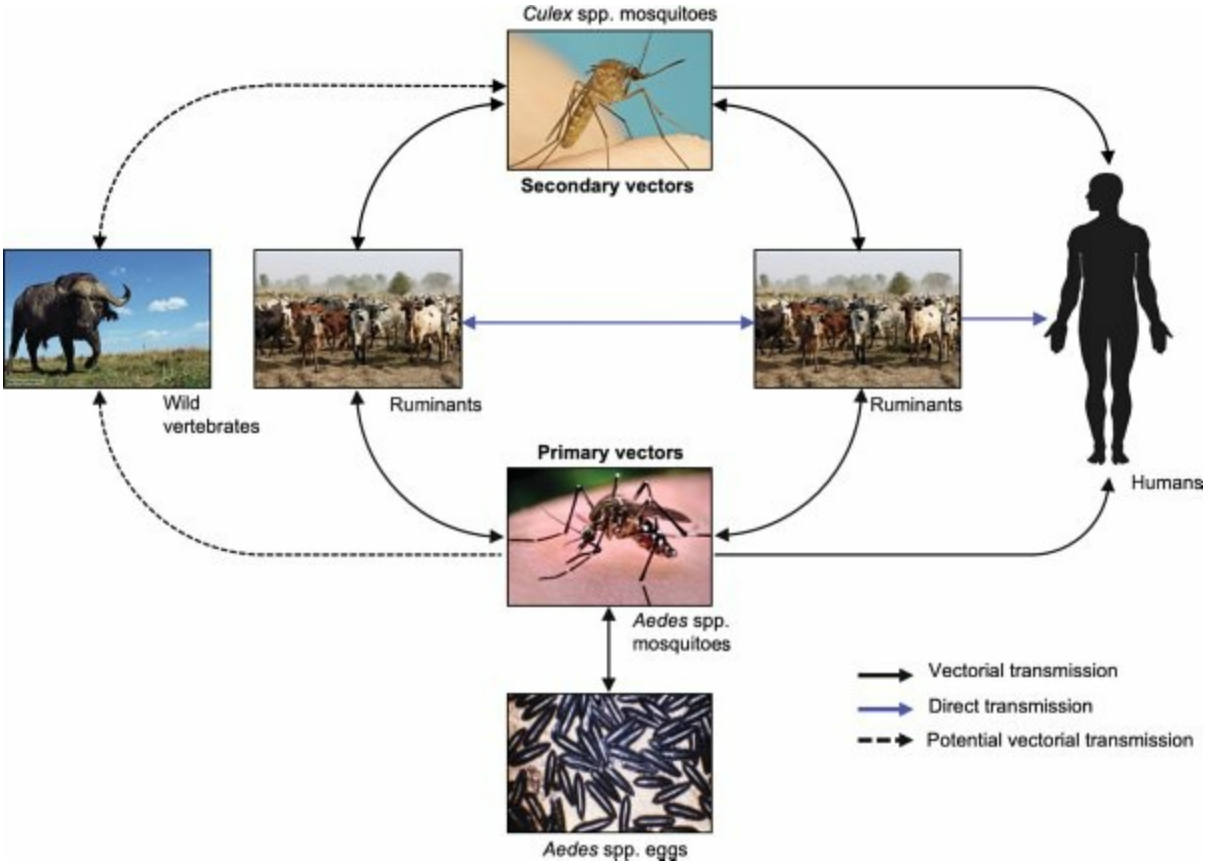

FIGURE 17.13 RVFV transmission cycle. In the enzootic cycle, primary vectors like *Aedes* species mosquitoes maintain RVFV in endemic areas during normal seasonal environmental conditions. The virus is vertically transmitted and can remain infectious in mosquito eggs for prolonged periods of time. During periods of unusual rainfall, secondary vectors, usually *Culex* mosquito species, are responsible for extended dissemination of the virus, causing broad epizootics. Humans become infected either through bites of infected mosquitoes or by exposure to tissues of infected animals. No human-to-human transmission of RVFV has been reported. Solid lines represent an experimentally established transmission route (*arrows* represent direction). *Dashed lines* represent potential vectoral transmission.

Hemorrhagic fever cases in humans are usually seen 1 or 2 weeks after

the appearance of abortions and disease in livestock. While humans are likely infected through bites from infected mosquitoes when vector densities are high, contact transmission from infected animals seems to be most important for human infections.[248,290] People involved in handling births or abortions of livestock and in butchering animals, such as farmers and abattoir workers, are at high risk of infection during epizootics.[77] RVFV is also highly infectious by aerosolization or mucosal exposure. Aerosolization resulted in many infections of laboratory personnel working with the virus before modern biosafety practices were developed,[130,362] but the relative contribution of infectious aerosols or fomites to transmission in natural settings is unclear. Although fewer than 2% of human infections result in serious disease, a substantial number of severe cases can occur given the large scale of some epizootics. For instance, an estimated 27,500 RVFV infections occurred during the 1997–1998 outbreak in the Garissa district of Kenya,[425] and approximately 200,000 human cases with 600 deaths were estimated to have occurred during the outbreak in Egypt in 1977 and 1978. The 2008 RVFV outbreak in Sudan resulted in 698 human cases with 222 deaths, an unusually high CFR of 31.8%. Moreover, the economic effects of RVFV epidemics on animal keepers in endemic areas are devastating; for example, the 2006–2007 outbreak in Kenya resulted in over 7.6 million US dollars in losses from livestock deaths, and the overall monetary loss to the local economy was estimated to be up to 32 million US dollars.[331]

In contrast to the long history of periodic RVFV epizootics in East and Southern Africa, the large RVFV outbreaks in Egypt in 1977 and 1978 and in Mauritania and Senegal in 1987 were more isolated.[436] Retrospective studies showed that RVFV had not been enzootic in Egypt prior to 1977 and its activity disappeared after 1981, only to be reintroduced in 1993.[22] These data suggest that although mosquitoes capable of acting as epizootic vectors (e.g., *Culex* sp.) exist in Egypt, mosquitoes capable of transovarial RVFV transmission are probably absent. RVFV was most likely introduced into Egypt from enzootic areas in Sudan.

The first confirmed RVFV outbreak outside Africa was reported in September 2000, in the western coastal plains of Saudi Arabia and Yemen.[353] Unusually heavy rains and flooding of the foothills of the Asir Mountains

appeared to cause increased mosquito populations and the explosive outbreak in naïve livestock. In Saudi Arabia, 884 hospitalized patients were identified, with 124 deaths.[248] In Yemen, 1,087 cases were estimated, with 121 deaths. The virus associated with this outbreak was almost identical to that associated with earlier RVFV epidemics in East Africa, consistent with the recent introduction of RVFV into the Arabian Peninsula from East Africa.[353] Outbreaks in Madagascar have also been linked to importation of infected animals from East Africa. Additional outbreaks have recently occurred in South Africa, Mauritania, Niger, South Sudan, Kenya, and Uganda.[19,354,369]

Despite its extensive geographic distribution, whole-genome sequencing and phylogenetic analyses indicate that RVFV is a highly conserved virus. Among all the RVFV stains circulating since 1970s, only 4% to 5% genetic diversity is observed at the nucleotide level.[41] Although accumulated mutations can be observed, especially in the virus surface glycoproteins, they do not seem to have resulted in increased RVFV virulence in human populations. Genetic reassortment of virus segments among co-circulating RVFV lineages occurs but is difficult to identify.[26]

Clinical Features

Human infections with sandfly fever viruses result in an acute febrile illness with rapid onset. The incubation period lasts 2 to 6 days and is followed by fever and general malaise, often accompanied by headache, vomiting, photophobia, and back and joint pain.[27,337] The disease is self-limiting, lasting 2 to 4 days before rapid and complete recovery. Leukopenia followed by protracted neutropenia is reported. TOSV infection can start as a mild illness but become neuroinvasive. In very severe cases, seizures, severe meningoencephalitis, deafness, personality changes, and encephalitis, including fatal cases, can be observed (reviewed in ref.[9]).

Experimental RVFV infection of newborn lambs suggests that the incubation period is usually 24 to 36 hours but can be as short as 12 hours.[111] Fever, which is often biphasic, is accompanied by listlessness, lack of appetite, abdominal pain, increased respiration rate, and lack of movement. Mortality rates of over 90% can be seen in animals younger than 1 or 2 weeks of age, with animals rarely surviving beyond 24 to 36 hours after the onset of

illness. Older animals are often less susceptible to RVFV infection, instead presenting peracute or inapparent infection. Mostly older animals develop a febrile acute illness similar to the disease seen in 1- to 2-week-old animals, but with lower mortality rates ranging from 5% to 60%. High and prolonged viremias, widespread tissue damage, vasculitis, hepatic necrosis, and acute renal injury are seen in the more severe cases.[291] Abortions in pregnant animals are frequently observed, with rates varying from 40% to 100%.

Human RVFV infections generally result in a self-limiting, influenza-like illness (Fig. 17.14). However, severe hemorrhagic fever occurs in approximately 2% of cases. In these patients, the reduction of the antithrombotic function of endothelial cells likely initiates intravascular coagulation. The release of procoagulants into the circulation, together with the extensive liver damage[259] (Fig. 17.15) that severely impairs synthesis of coagulation factors and removal of circulating activated coagulation factors, appears to be important factors resulting in DIC in hemorrhagic fever cases.[92, 305, 308] The mortality rate in hemorrhagic cases is up to 65%.

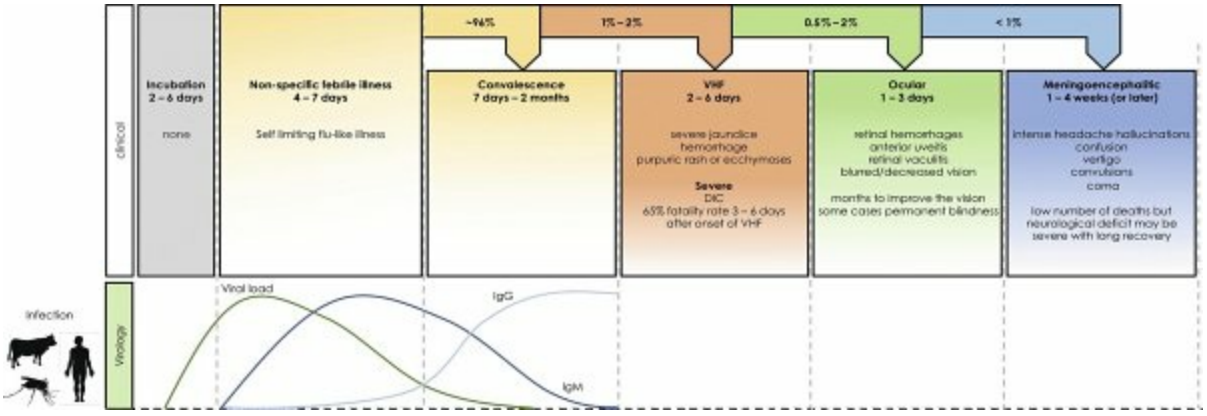

FIGURE 17.14 An outline of the main clinical manifestations and laboratory findings in RVFV human disease.

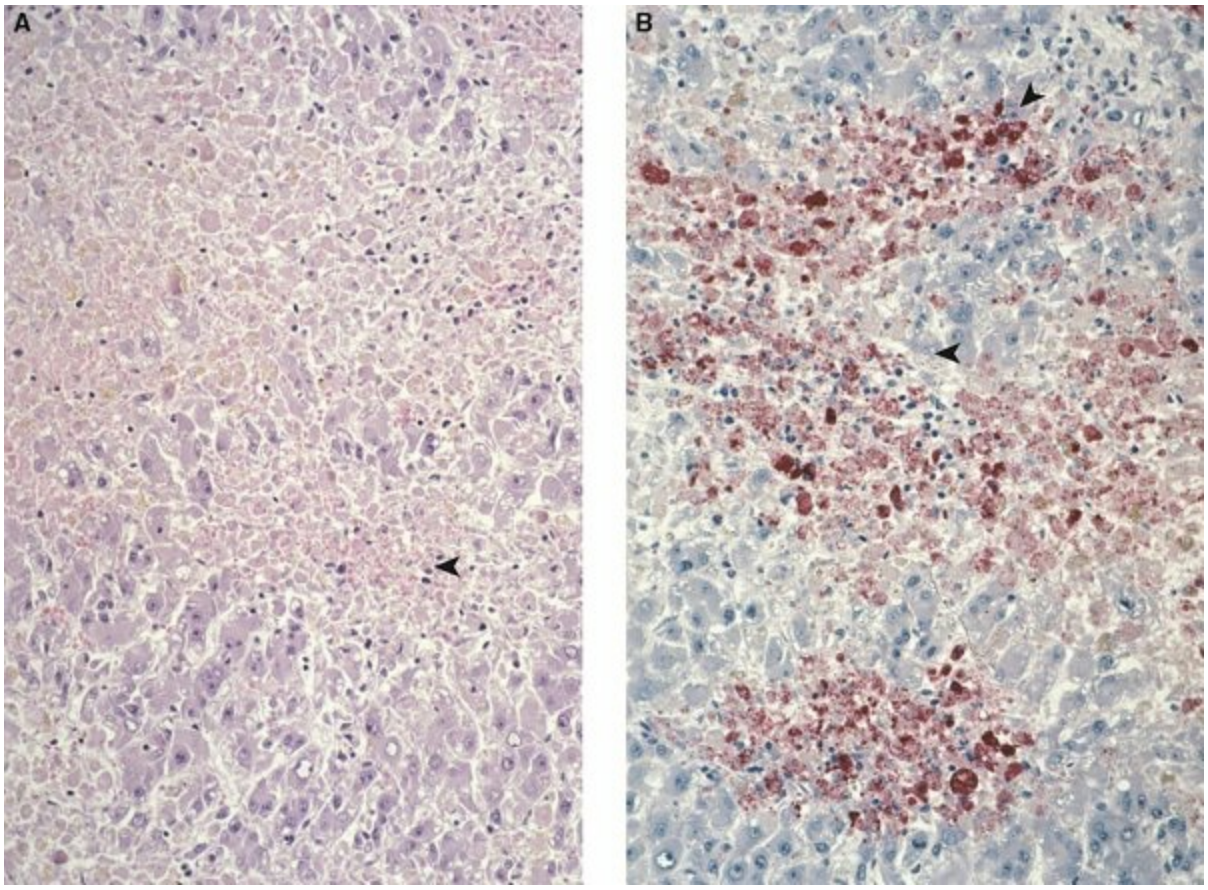

FIGURE 17.15 Clinical findings in RVFV infection. A: Histochemistry of a liver sample from a patient reveals extensive focal necrosis. **B:** Immunostaining of RVFV antigen (in *red*) indicates that the observed necrosis in the liver is mainly due to viral infection (arrowheads point to broader affected area).

In fewer than 0.5% of human RVFV infections, retinitis or encephalitis can be observed 1 to 4 weeks after recovery from the acute illness. Serious vision problems, blurred or decreased vision, or blindness can start developing at the end of either the febrile period or period of severe disease. Retinal hemorrhages, optic disc edema, anterior uveitis, and retinal vasculitis are common findings.[8] It takes several months after infection for vision to improve, and in many cases, it never completely recovers. Encephalitis begins with headache, meningismus, and confusion. Often fever reappears, and hallucinations, stupor, coma, and death may follow. Focal necrosis, which most likely involves direct cell destruction by RVFV, is seen in the

brain. Patients may take months to recover from the neurological sequelae of RVF.[178,262]

Diagnosis

Sandfly fever should be suspected when patients present with a classic "3-day fever" in areas where phlebotomine sandflies are numerous.[113,337] Similarly, TOSV infection should be suspected in patients who develop acute CNS disease during the summer months in rural or semirural areas where phlebotomine sandflies are present.[54,285] Diagnostic confirmation using acute or early convalescent phase samples is readily achieved by virus isolation via intracranial inoculation into suckling mouse or susceptible tissue culture cells or by IgM capture ELISA. In human infections, specific antibody response develops rapidly and is long-lasting. During the acute phase of the disease, RT-PCR or real-time RT-PCR can also be performed in blood or cerebrospinal fluid.[89,403]

Clinical differential diagnosis of RVF cases can be difficult due to the nonspecific early symptoms of disease. Severe cases can be confused with other cocirculating hemorrhagic fevers, including Ebola, Crimean-Congo hemorrhagic fever, dengue, and yellow fever, or with malaria, cholera, meningitis, and a number of other viral and bacterial diseases. Thus, differential clinical diagnosis of RVFV varies depending on the region in question. RVF disease should be suspected in RVFV-endemic regions following abnormally high precipitation, increased rates of abortions in livestock, and appearance of acute influenza-like illness in persons in close contact with potentially infected livestock (e.g., farmers, veterinarians, and abattoir workers). Virologic diagnosis is usually simple given the high-level viremia present throughout the acute phase of illness and the ease of growing the virus by intracranial inoculation into suckling mice or in a wide variety of susceptible tissue culture cells. Serologic testing is also straightforward, particularly if paired sera (one taken during acute illness and the other 1 or 2 weeks later) are available. IgM and IgG ELISAs using inactivated RVFV-infected cell lysates or slurries have proven particularly useful in outbreak investigations.[213,272,399,425] IgM and IgG ELISAs based on recombinant expressed nucleocapsid protein have also been developed.[432] Additionally, a number of sensitive nucleic acid-based assays exist, including RT-PCR, real-

time quantitative RT-PCR, and a multiplex PCR-based macroarray assay.[38,418] Furthermore, immunohistology for detecting RVFV antigen and *in situ* hybridization for detecting RVFV genome in formaldehyde-fixed liver samples can also be used for establishing a RVF diagnosis.[325]

Prevention and Control

The sandfly hosts of SFSV, SFNV, and TOSV have a short flight range and often locomote by hopping, making localized use of insecticide sprays particularly effective around residences. In addition, the use of repellants and treated bed nets and screens is recommended in areas where sandflies are prominent.

No specific treatment is required for the majority of human cases of RVF, which are mild and self-limiting. For severe cases, treatment is currently limited to intensive supportive care, including monitoring fluid and electrolyte balance and renal function, blood pressure, and oxygenation. No effective therapeutics against RVFV have been approved for human use.[23] In experiments using animal models, the antiviral favipiravir has been shown to protect against clinical disease when given within the first 24 hours postinfection, but treatment at 48 hours can result in neurologic disease, with the virus escaping to the brain.[72] Similarly, ribavirin showed antiviral activity in early *in vitro* studies and some therapeutic effect in animal models, depending on the challenge route, but treated animals ultimately succumbed to late-onset encephalitis.[306,342] The combination of the two drugs in *in vivo* studies has shown some efficacy but neither is currently recommended for treating human infections. Studies have been initiated to generate strongly neutralizing monoclonal antibodies against RVFV, which could potentially be used as part of future therapeutic cocktails.[10]

Many human RVFV infections can be avoided by preventing mosquito bites through the use of insect repellents and insecticide-treated bed nets. Currently no vaccines against RVFV have been approved for people or for routine veterinary use outside the endemic areas. Based on the One Health approach, immunization of livestock remains the most effective way to prevent RVFV epizootics and human disease.[40,208] Several vaccines exist for use in livestock. Live attenuated viruses based on the mouse neuroadapted

Smithburn RVFV strain are used in Kenya and South Africa.[70,360] Formalin-inactivated wild-type viruses have also been used in Egypt and South Africa. The modified live Smithburn vaccine produced in cell culture has been shown to be efficacious in sheep but not in cattle, with a single dose inducing lasting immunity in sheep 6 to 7 days after vaccination.[84] However, this vaccine appears to be only partially attenuated, causing abortions or teratology in some pregnant animals.[51,177] Formalin-inactivated vaccines are safer but are expensive, require multiple doses, and induce only short-lived immunity in sheep and cattle.[105] Other candidate live-attenuated vaccines, such as the mutagen-derived MP12 strain; the naturally occurring clone 13, which has a large deletion in the NSs gene; and genetically engineered recombinant viruses lacking NSs and/or NSm protein, or containing 4 instead of 3 genomic segments, have also been evaluated.[42,122,177,421] Other immunization approaches include vectored vaccines, DNA vaccines, non-replicating virus-like particles, and subunit vaccines.[99,123,414] The main problems for vaccinating livestock are the long periods between epizootics and their irregular appearance, which make convincing livestock owners to vaccinate regularly difficult. Recent advances in the use of satellite imagery and surface ocean temperatures to predict regions at increased risk of RVFV activity may allow timely vaccination of animals prior to potential epizootics.[16,234,408]

In RVFV-endemic regions, humans are probably best protected by vaccination of livestock to prevent amplification of virus, thus limiting human exposure and epizootic potential. However, RVF outbreaks are often only detected after the diagnosis of human cases, due to weak animal disease surveillance in resource-poor regions of Africa. Human vaccines are needed for high-risk groups like veterinarians, farmers, and slaughterhouse workers, and for general naïve populations. RVFV is highly infectious by aerosol, as shown by numerous infections of laboratory personnel. To prevent infection, workers at risk of exposure should wear protective clothing to avoid contact with potentially infectious materials and aerosols. Neutralizing antibody response appears to be strongly associated with protection from infection, and since RVFV is highly conserved, a single vaccine should effectively protect against all or most RVFV strains.

SEVERE FEVER WITH THROMBOCYTOPENIA SYNDROME VIRUS GROUP

Severe Fever with Thrombocytopenia Syndrome Virus

Distribution and Significance

SFTS is an emerging tick-borne disease caused by SFTS virus (SFTSV), a novel member of *Phlebovirus* genus. The virus was first reported in the Hubei and Henan provinces of China in 2009. Since then, the virus has been detected in 23 provinces in China as well as South Korea and Japan in 2013 (Fig. 17.16).[430,437] The clinical symptoms were initially considered to resemble those of human anaplasmosis; however, no bacterial DNA was detected in blood samples and instead SFTSV was isolated.[322,430] Phylogenetic characterization of virus isolates revealed that SFTSV is in between from the Sandfly fever group and the Uukuniemi group, indicating that SFTSV forms of a third and novel group within the genus *Phlebovirus*.

FIGURE 17.16 Distribution of severe fever with thrombocytopenia virus.

Epidemiology

Following the identification of the human cases, SFTSV was detected in ixodid ticks of the species *Haemaphysalis longicornis* that were collected from domestic animals where the patients lived. Viral genome analysis revealed that the sequences from ticks were very closely related to those of SFTSV isolates from the patients, implicating this tick species as the main vector.[322,430] A recent study confirmed vector competence of this species and demonstrated its potential as a reservoir.[242] However, SFTSV has been detected in other ixodid tick species with typically lower prevalence levels, and it remains to be shown what role different tick species play in different geographic regions. SFTSV most likely circulates silently tick-vertebrate cycle in nature causing no overt signs of disease in the tick vector and the animal hosts, only human show signs of disease. To determine relevant

animal hosts, studies surveyed SFTSV prevalence in animal hosts in endemic areas. SFTSV RNA or antibodies were found in multiple wild and domestic animals in China, Japan, and Korea including sheep, goats, cattle, pigs, chicken dogs, hedgehogs and rodents.[282,286,438] Nevertheless, it still remains to be determined what animal host plays a crucial role in the perpetuation of the ticks and virus in nature. As a tick-borne disease, the human hospitalizations are linked to the seasonal activity of the tick vector, typically peaking between late spring to early fall. The majority of affected patients are farmers living in wooded and hilly areas working in the fields, demonstrating that agricultural work is a major risk factor. Between 2010 and 2016, the Chinese Disease Prevention and Control Information System reported SFTS cases in 23 provinces with 1,000 to 2,500 cases annually and a cumulative CFR of 5.3%. The highest numbers of reported cases occurred in Henan (37%), Shandong (26.6%), Anhui (14%), and Hubei (12.6%).[238,437] The disease occurs mainly in the elderly population, and death is most frequent in patients over 50 years of age.[238,441] In addition to the tick-borne transmission, human-to-human transmission has also been suggested.

Clinical Features

The incubation time has been reported to be 5 to 14 days, and there is some evidence that the incubation period after tick bite can be shorter versus human-to-human transmission. However, more studies need to be conducted to exclude confounding factors. Patient profiling has shown that the clinical progression of the disease occurs in three stages: fever stage, MOF stage, and convalescent stage (Fig. 17.17).[88,93,132,322,439] The fever stage is characterized by a sudden onset of fever (>38°C), headache, fatigue, myalgia, as well as gastrointestinal symptoms, such as nausea, vomiting, and diarrhea. As the agent's names implies, this stage is also accompanied by marked thrombocytopenia (platelet count of <100,000 per cubic millimeter) as well as leukocytopenia and lymphadenopathy and lasts for up 5 to 11 days. A high viral load can be detected at this stage. The subsequent MOF stage lasts for 7 to 14 days and is defined by progressive worsening organ (liver, heart, lungs, and kidneys) functions all the way to failure in fatal cases or a self-limiting process in survivors.[93,132] In this stage, hemorrhagic presentations (bleeding from mouth mucosa, lungs, and gastrointestinal lumen) and/or CNS

involvement (lethargy, convulsions, and coma) are present. This stage is also characterized by elevated levels of ALT, AST, CK, LDH, and CRP. Coagulation disturbances are also observed, which can lead to DIC. The viral load gradually falls in survivors but remains high in patients who succumb to the disease.[88,439] The key risk factors contributing to a patient's death have been identified as increased viremia, elevated AST, ALT, LDH, CK, and CK-MB levels past the fever stage, and the appearance of CNS symptoms, manifestation of hemorrhagic tendency, DIC and MOF. The convalescence stage in which surviving patients recover starts on average 13 days after disease onset in which clinical and laboratory parameters gradually revert to normal. Although the reported CFR ranges from 6% to 30%, a recent meta-analysis of confirmed patient case studies in China showed an pooled CFR of 16%.[235]

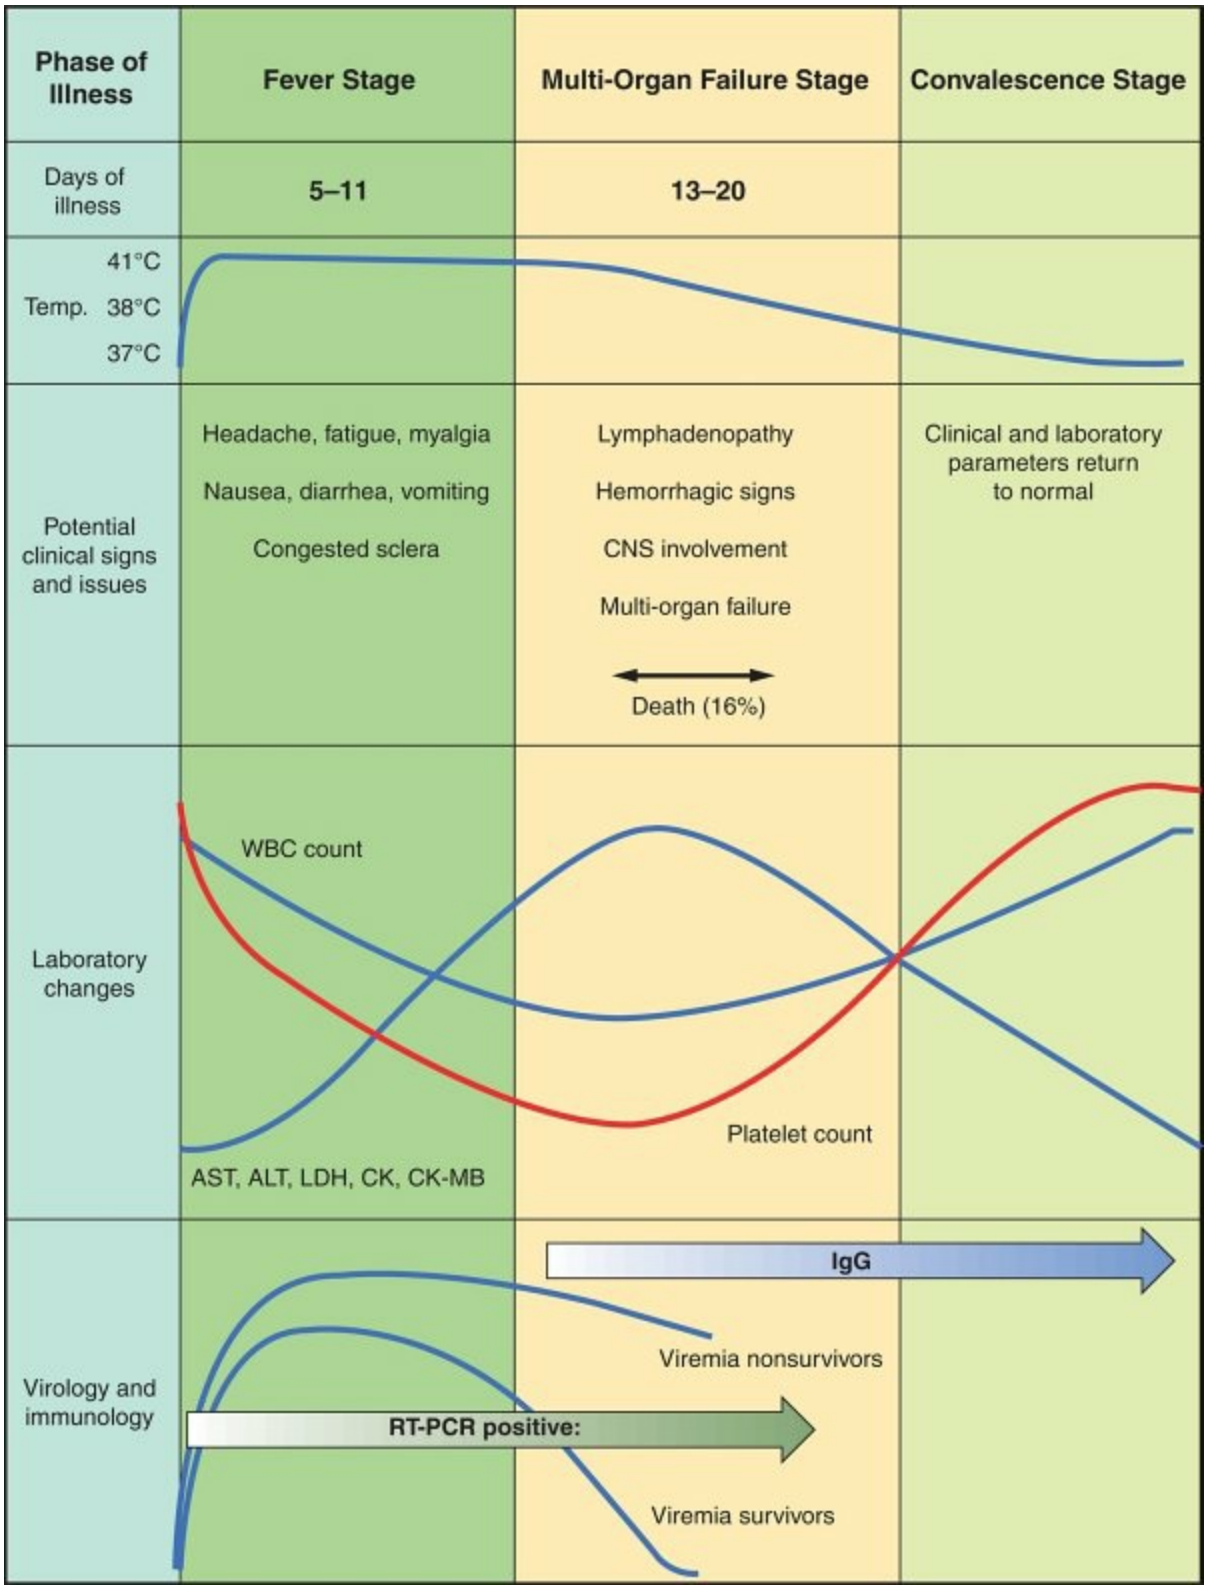

FIGURE 17.17 Clinical findings in SFTSV infection.

Pathogenesis and Pathology

Due to its recent discovery, little is known about the pathogenesis; however, certain aspects might be extrapolated from related viruses with similar disease presentation such as Crimean-Congo hemorrhagic fever. Upon introduction of the virus into the dermis or mucosa, there is likely local replication followed by blood- and lymph-borne spread of the virus to the major organs. A recent study detected SFTSV in multiple organs with the highest titer in the spleen, moderate titers in the kidney, and the lowest titers in lung and heart.[231] Several studies looked at serum levels of cytokines (TNF, IL-6, IL-8, IL-10) and chemokines (MCP-1, IP-10, MIP-1a, G-CSF) in mild and severe cases in a comparative fashion showing that more severe SFTS disease is associated with higher levels of cytokines and chemokines.[93,96,373] This suggests that a host-mediated inflammatory response, through an imbalance in cytokine and chemokine production, might result in a severe disease progression. Furthermore, studies have shown that decrease in leukocyte populations, specifically T cells and myeloid dendritic cells, may be associated with a more severe form of disease.[239,368] Although not thoroughly characterized, it was shown that SFTS survivors develop low level neutralizing antibodies that wane overtime; however, in some patients, they can be detected up to 4 years after SFTSV infection. The study of the SFTS pathogenesis has been hampered by the availability of a suitable animal model.[257] A number of laboratory animals including mice, rats, hamsters, and nonhuman primates have been evaluated in an attempt to model human disease. Immunocompetent animals typically do not show overt signs of disease. In one study, investigators showed thrombocytopenia, leukocytopenia, and elevated liver transaminases, hallmarks of human SFTS, in immunocompetent strain C57BL/6 mice. Viral RNA and histopathological changes were identified in the spleen, liver, and kidney. Consequently, this animal model mimics the aspects of a mild form of SFTS in humans.[440] When the same strain of mice was treated with mitomycin C in order to suppress the immune response, SFTSV challenge was lethal. Similarly, SFTSV challenge in immunocompromised mice (interferon-α or α/β receptor deficient mice) or hamsters (signal transducer and activator of transcription 2 knockout [STAT2 KO]) is typically lethal indicating the importance of the IFN response in controlling virus replication.[145,237,257] In IFN receptor deficient mice, high

levels of SFTSV RNA were found in the brain, liver, kidney, and spleen, and major target tissues of SFTSV appear to be reticular cells in lymphoid tissues of lymph nodes and spleen. No specific cell receptor has been identified.

Diagnosis

The disease presentation is not pathognomonic and can be confused with other diseases. Although patient history such as time of the year, contact with ticks, and geographic location as well as blood chemistry can give clues. Direct diagnosis of the viral RNA in the patient sera can be conducted by conventional RT-PCR or quantitative real-time RT-PCR.[374,429] Infection with SFTSV can also be diagnosed in sera of patients either by detecting the presence of IgM during the acute phase or IgG in convalescent patients. Initially, an IFA was developed and was used for laboratory confirmation. Meanwhile, different ELISA kits have been developed in the effected countries and validated for sensitivity and specificity.[185,431] High levels of neutralizing antibodies are generated during convalescence phase, and virus neutralizations assays can be used to determine antibody titers and specificity.

Prevention and Control

Currently, there is no specific treatment available for SFTSV infection and treatment is symptomatic. Ribavirin has been suggested as a treatment; however, limited studies showed inconclusive effects on disease outcome.[236,301] Favipiravir has been suggested as a treatment, and its efficacy was demonstrated in STAT2 KO hamsters.[145] A clinical trial testing the efficacy of favipiravir is currently ongoing in Japan. No internationally or locally approved vaccines are available. Nevertheless, there has been an increasing number of preclinical studies have been conducted. Limiting tick exposure through individual protective measures such as tick repellents or protective clothing or avoidance of where ticks are common are recommended.

Heartland Virus

Distribution and Significance

In 2009, two farmers in Missouri were independently hospitalized with fever, thrombocytopenia, and leukopenia. Both patients were bitten by ticks approximately 5 to 7 days prior to onset of signs of illness. Collected blood samples were negative for *Ehrlichia chaffeensis* and electron microscopy and next-generation sequencing revealed that the virus was a new members of the bunyavirales, HRTV.[263] Genome sequences from both patients were similar, indicating that both patients were infected independently with the same virus. Further, phylogenetic analysis identified that the HRTV is closely related to the recently identified tick-borne phlebovirus SFTSV in China.[322]

Epidemiology

The phylogenic proximity to SFTSV as well as the patient description of tick bite suggested a tick-borne transmission route. Pools of *Amblyomma americanum* ticks collected on a farm owned by the original case were positive for HRTV.[263] Since then, HRTV has been detected in *A. americanum* ticks in other locations in Missouri. Additionally, the virus has been detected in *A. americium* ticks over multiple years in the same location indicating that HRTV can persist in ticks.[284] As with other tick-borne diseases, human disease occurrence overlaps with the seasonal activity of the ticks, which is typically between late spring and early fall with the peak in June. Serosurveys of domestic and wild animals near the sites of where HRTV-positive ticks were found neutralizing antibodies in white-tail deer, horses, raccoons, opossums, and dogs.[48] Experimental infections of white-tail deer, raccoons, chicken, rabbits, and hamsters demonstrated that they seroconvert to the virus, yet, develop no viremia or signs of disease and are therefore not likely a reservoir for HRTV in nature.[49,82] As of September 2018, over 40 cases have been reported from states in the Midwestern and southern United States.[75] The median age of identified patient is 66 years.[413] The disease distribution overlaps closely with the distribution of *A. americanum* ticks, although some states in which *A. americanum* can be found have not reported the disease. Further studies need to be performed to determine the vector capacity of *A. americanum* and competence of other tick species and potential animal hosts of HRTV with high enough viremia levels to transmit the virus

back to ticks.

Clinical Features

Since the initial two cases, eight additional cases have been reported.[71,128,276] All cases had a sudden onset of fever and the majority of cases presented with fever, fatigue, diarrhea, headache, myalgia, nausea, elevated hepatic aminotransferase levels, marked thrombocytopenia, and leukopenia. In some cases, neurological symptoms such as confusion were also reported. Three of the 10 cases, all male greater than 60 years, were fatal due to MOF. However, two of those three had preexisting comorbidities.

Pathogenesis and Pathology

Due to the limited number of cases and experimental studies, very little is known about the pathogenesis of HRTV and can only be extrapolated from closely related viruses. High levels of IgG antibodies were detected in serum of the initial two patients even up to 2 years.[263] A recent pathology case report from a fatal case detected HRTV antigen in the brain (thalamus), liver (Kupffer cells), pancreas, heart, lung, large bowel, small bowel, kidney, testes, bone marrow, lymph nodes, spleen, and muscle by immunohistochemistry. Evidence of lymphocytic myocarditis with viral antigens was present. In the liver, focal hepatocellular necrosis and Kupffer cell hyperplasia was detected. The kidneys demonstrated hemorrhage, interstitial inflammation, scattered glomerulosclerosis, and acute tubular necrosis with viral antigens present within scattered glomeruli.[128] Another limiting factor in understanding the HRTV pathogenesis is the lack of an immune competent animal model to study the disease seen in humans. Animal studies demonstrated that immunocompetent mice are not susceptible after peripheral or even intracranial or Cynomolgus macaques after peripheral HRTV inoculation.[49,257] A study showed that interferon-$\alpha/\beta/\gamma$ receptor-deficient mice are susceptible to HRTV and indicated the importance of the IFN response in controlling virus replication.[49]

Diagnostics

RT-PCR and serological assays for the detection of viral RNA and antibodies

have been developed. Monoclonal antibodies developed against the nucleoprotein of HRTV are also available.[68, 284, 393]

Prevention and Control

No specific treatment or vaccines are currently available. The treatment remains symptomatic.

PERSPECTIVES

The degree of understanding of the various bunyaviruses and their ability to cause disease in humans varies greatly, depending on the severity of the resulting clinical illness and the impact of each virus to public health. Because of the high level of containment required to work with human pathogens and the stringent restrictions on sharing viruses and clinical specimens, studies of pathogenesis and the development of animal models remain limited. However, progress has been made in many areas, particularly virus detection using next-generation sequencing, outbreak investigations, and development of a number of experimental therapeutics and vaccines. Still, the extensive number of bunyaviruses pathogenic to humans presents multiple future research needs. To highlight just a few: (a) obtaining a better understanding of how bunyaviruses persist in either their arthropod or rodent hosts; (b) sequencing the viruses for analyzing phylogenetics, improving diagnostics, and studying virus evolution (e.g., adaptations resulting in increased virulence or the ability to spill over into new host species); (c) studying pathogenesis, especially in severe human disease; (d) determining how some viruses initially cause a self-limiting disease but eventually reach the brain to lead to severe neurologic disease; (e) characterizing the immune responses responsible for viral restriction and clearance, and determining whether these responses are regulated and protective or dysregulated and damaging to the host; and (f) identifying broad-spectrum antivirals or immunotherapeutics, and developing vaccines for higher incidence and morbidity-associated infections.

Perspective

HISTORY

The first arenavirus, lymphocytic choriomeningitis virus (LCMV), was isolated over 80 years ago from samples from a St. Louis encephalitis epidemic.[330] LCMV was found to be a cause of an aseptic meningitis in humans,[354] and the house mouse (*Mus musculus* Linnaeus, 1758) was identified as the virus's natural reservoir host.[381] By the 1960s, several other viruses had been discovered that shared common morphology,[285] serology,[336] biochemical features, and a natural history of chronic infection of rodent reservoirs, leading to the recognition of the family *Arenaviridae*, named after the granular or sandy (Latin, *arenosus*) appearance of thin sections of virions examined by electron microscopy (EM).[336] In 1956, Tacaribe virus (TCRV) was isolated from phyllostomid Jamaican fruit-eating bats (*Artibeus jamaicensis trinitatis* K. Andersen, 1906) in Trinidad and Tobago, but the virus was not associated with virulence in humans.[92] The discoveries of Junín virus (JUNV) in the late 1950s as the causative agent of Argentinian hemorrhagic fever (AHF),[295] of Machupo virus (MACV) in 1962 as the etiologic agent of Bolivian hemorrhagic fever (BHF),[193] and of Lassa virus (LASV) in 1969 from Lassa fever (LF) patients in Nigeria[125] underscored the pathogenic potential of arenavirus infections of humans (Table 18.1). In the

following years, additional pathogenic arenaviruses have been discovered, including Guanarito virus (GTOV),[346] Sabiá virus (SBAV),[69] and Chapare virus (CHAPV) in South America,[86] and Lujo virus (LUJV) in Africa.[37] As a result of new technologies of deep-sequencing and genome discovery, many new arenaviruses were uncovered in the last decade in mammals. Notably, arenaviruses were also discovered in reptiles (snakes) and fish, representing a significant expansion of the host range of arenaviruses.[168,359,366]

TABLE 18.1 Arenaviruses that are known to be human pathogens

Virus	Abbreviation	Reservoir Host	Geographic Distribution	Disease[a]
Lymphocytic choriomeningitis virus	LCMV	House mouse (*Mus musculus* Linnaeus, 1758)	Worldwide	Lymphocytic choriomeningitis (1C8F)
Lassa virus	LASV	Natal mastomys (*Mastomys natalensis* Smith, 1834)	Western Africa	Lassa fever (1D61.2)
Lujo virus	LUJV	Unknown	Zambia	Other specified arenavirus disease (1D61.Y)
Junín virus	JUNV	Drylands laucha (*Calomys musculinus* Thomas, 1913)	Argentina	Argentinian hemorrhagic fever (1D61.0)
Machupo virus	MACV	Big laucha (*Calomys callosus* Rengger, 1830)	Bolivia	Bolivian hemorrhagic fever (1D61.1)
Guanarito virus	GTOV	Short-tailed zygodont (*Zygodontomys brevicauda* J. A. Allen and Chapman, 1893)	Venezuela	Venezuelan hemorrhagic fever (1D61.3)
Sabiá virus	SBAV	Unknown	Brazil	Other specified arenavirus disease (1D61.Y)
Chapare virus	CHAPV	Unknown	Bolivia	Other specified arenavirus disease (1D61.Y)

[a]According to the World Health Organization's International Classification of Diseases revision 11 (ICD-11).

CLASSIFICATION OF VIRUSES WITHIN THE FAMILY *ARENAVIRIDAE*

Based on phylogenetic analyses of RNA-directed RNA polymerase (L) and nucleoprotein (NP) sequences, members of the family *Arenaviridae* are classified into four genera: *Antennavirus*, *Hartmanivirus*, *Mammarenavirus*, and *Reptarenavirus* (Fig. 18.1). The genus *Mammarenavirus* includes 35 species for 42 viruses. The genus *Reptarenavirus* currently includes five species for eight viruses; the genus *Hartmanivirus* includes one species for

one virus (Haartman Institute snake virus 1); and the genus *Antennavirus* currently includes two species for two viruses. The hosts of mammarenaviruses are mainly rodents (with the exception of TCRV), and infection is generally asymptomatic. Some mammarenaviruses, such as LASV, LCMV, and several viruses of South American origin, can also infect humans and cause severe and sometimes fatal disease. Reptarenaviruses and hartmaniviruses infect (captive) snakes, some of which develop boid inclusion body disease (BIBD). Reptarenaviruses are notable for their surface glycoproteins (GPs), which are more closely related to that of Ebola virus than to those of hartmaniviruses or mammarenaviruses. Hartmaniviruses do not encode the matrix (Z) protein, which is encoded by all known mammarenaviruses and reptarenaviruses. Antennaviruses were discovered in actinopterygian fish and have genomes consisting of three, rather than two, segments. Like hartmaniviruses, antennaviruses do not encode Z.[359]

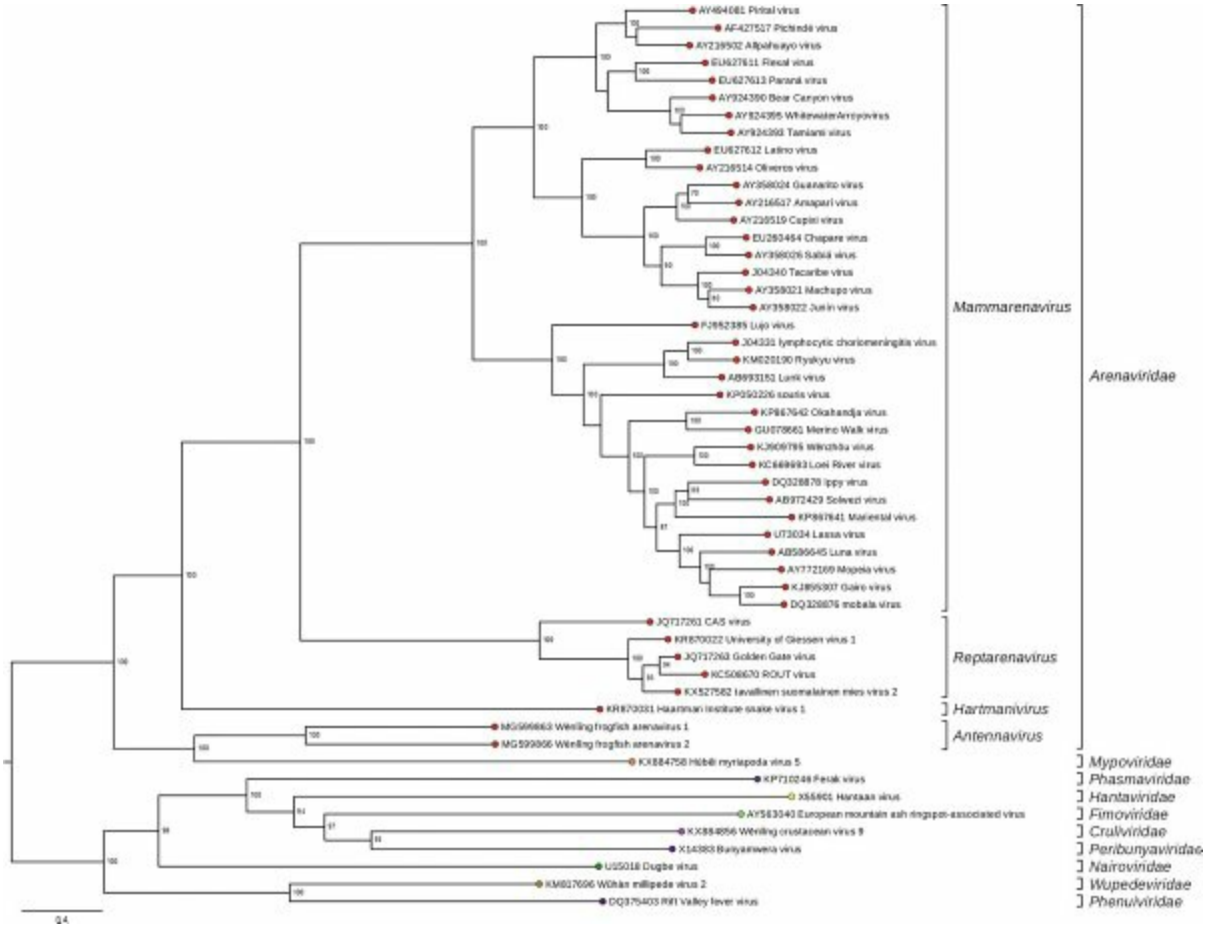

FIGURE 18.1 Phylogenetic relationships of arenaviruses.

Maximum likelihood phylogenetic tree was inferred from probabilistic alignment kit (PRANK) alignment of the complete L amino acid sequences of 43 arenaviruses (*red dots*) assigned to four genera. Representative viruses of other bunyavirus families were also included (*dots in colors other than red*). The best-fit model of protein evolution (LG + G model) was selected using ProtTest 3 (v. 3.4.2). The maximum likelihood tree with 1,000 bootstrap replicates was produced using Randomized Axelerated Maximum Likelihood RAxML (v. 8). The percentage of replicate trees in which the associated taxa clustered together in the bootstrap is shown next to branch nodes (when ≥70%). The tree was visualized using FigTree (http://tree.bio.ed.ac.uk) and is rooted at the midpoint. (Courtesy of Manuela Sironi, Scientific Institute IRCCS E. MEDEA, BosisioParini (LC), Italy.)

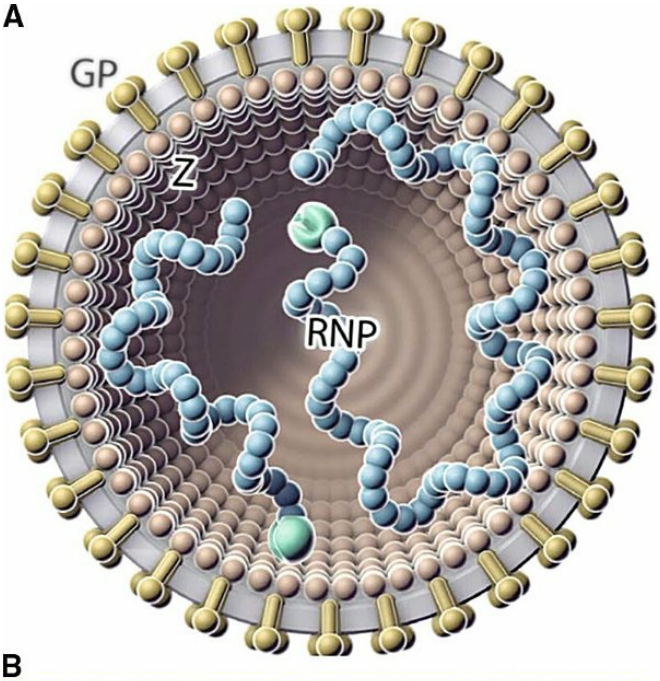
Based on antigenic properties, mammarenaviruses have been divided traditionally into two distinct groups. Old World (OW) mammarenaviruses ("Lassa–lymphocytic choriomeningitis serocomplex") include viruses indigenous to Africa and the ubiquitous LCMV, whereas New World (NW) mammarenaviruses ("Tacaribe serocomplex") include viruses indigenous to the Americas.[47,100,143] This classification is largely consistent with phylogenetic data and muroid rodent host phylogeny, with OW mammarenaviruses infecting murid rodents primarily in Africa and NW mammarenaviruses infecting cricetid rodents primarily in the Americas. This clear-cut dichotomy is under assessment, however, since yet unclassified mammarenaviruses have been discovered in northern three-toed jerboas (Dipodoidea: Dipodidae, *Dipus sagitta* Pallas, 1773) in Mongolia.[320,321,408]

VIRION STRUCTURE

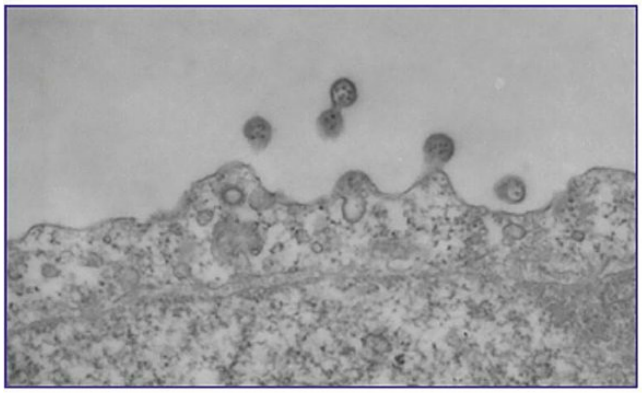
Arenavirions are pleomorphic, ranging in size from 40 to more than 200 nm in diameter[58,187] (Fig. 18.2). The virion's surface is studded with evenly spaced spike projections composed of complexes of the viral glycoproteins

GP1 and GP2. The surface glycoproteins are aligned with subjacent Z and ribonucleoprotein (RNP) densities, which are packed into a two-dimensional lattice at the inner surface of the viral membrane.[187,286] Virions contain the L and S genomic RNAs in helical nucleocapsid structures that are organized in circular configurations, with lengths ranging from 400 to 1,300 nm.[417] The L and S genomic RNAs are not present in equimolar amounts within virions (L:S ratios ~1:2), and low numbers of both L and S antigenomic RNAs are also present within virions. In addition, host ribosomes are documented to be incorporated into virions, but the biological significance of this incorporation remains uncertain.[43,284]

A



B



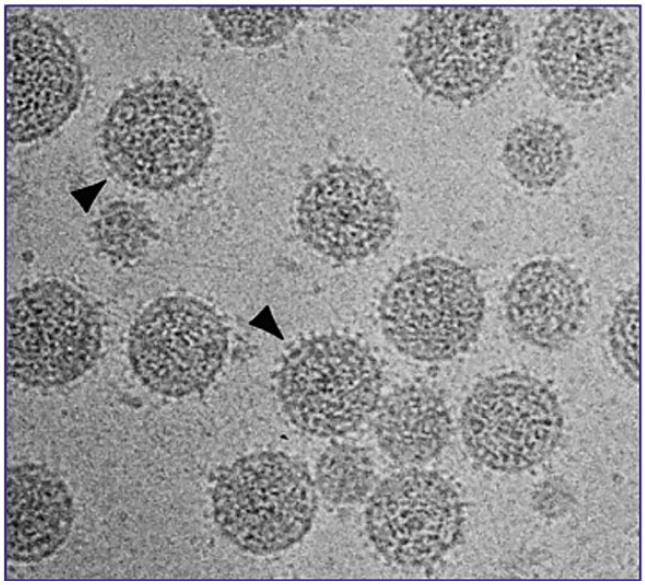


FIGURE 18.2 Arenavirion structure. **A:** Schematic illustration of an arenavirus particle. Shown is the spherical and enveloped (*gray*) particle that is spiked with GPs (glycoproteins; *gold*) around a layer of Zs (zinc-finger matrix proteins, *brown*; missing in hartmaniviruses). The small (S) and large (L) ribonucleoprotein (RNP) complexes inside the particle consist of genomic RNA, nucleoprotein (NP, *blue*) and RNA-directed RNA polymerase (L; *green*). (Courtesy of Fabian de Kok-Mercado and Jiro Wada, IRF-Frederick, Fort Detrick, MD, USA.) **B:***Top panel*: LCMV strain Armstrong release from Vero cells in culture. Particles are visible at several stages of budding and release. Magnification 25,000 times. *Lower panel*: LCMV Armstrong strain, purified and prepared for cryoelectron microscopy. Nominally spherical virions of variable diameter are evident with surface "spikes" that are the glycoprotein complexes (*black arrowheads*). Original magnification ≈ 35,000 times.

GENOME STRUCTURE AND ORGANIZATION

Arenavirus Genomic Organization

Arenaviruses produce enveloped particles with bisegmented (genera *Hartmanivirus*, *Mammarenavirus*, and *Reptarenavirus*) or trisegmented (genus *Antennavirus*) negative-sense (NS), single-stranded RNA genomes. The overall genome organization is well conserved across mammarenaviruses and reptarenaviruses. An ambisense coding strategy is used for the synthesis of two nonoverlapping polypeptides from each of the two genomic RNAs (Fig. 18.3). The term "ambisense" was coined to reflect that both genomic and antigenomic RNAs encode for proteins. This ambisense coding strategy might facilitate temporal control of gene expression of the two genes within

an ambisense RNA genome segment. The open reading frames of these viruses are also separated by a noncoding intergenic region (IGR) with folding predicted to form a stable hairpin structure. The S RNA encodes the viral NP and glycoprotein precursor (GPC). The L RNA encodes the viral RdRp (or L polymerase) and Z.[301,371,382] However, the genomic S and L RNAs do not function as mRNAs and cannot direct translation of GPC and Z, respectively. Unlike other arenaviruses, antennaviruses have a trisegmented (L, M, and S) genome with the M segment coding GPC and an additional hypothetical protein of unknown function. Furthermore, the L segment of hartmaniviruses and antennaviruses lacks the Z open reading frame.

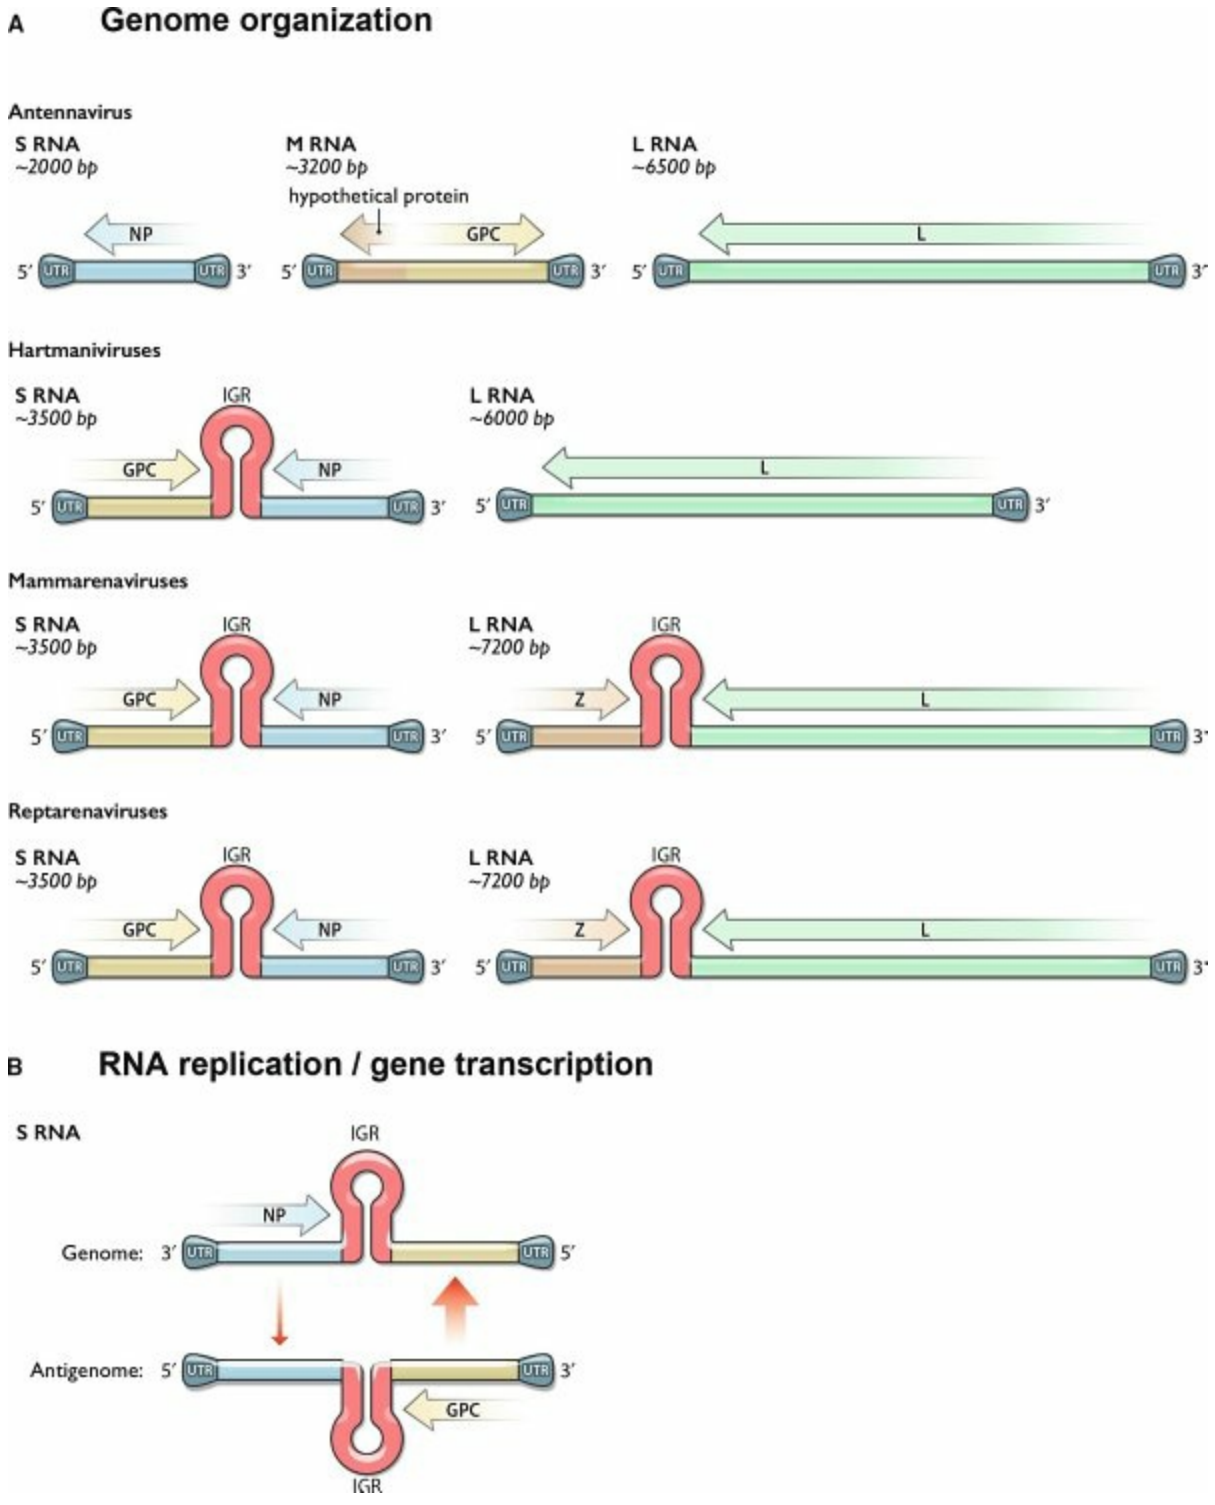

FIGURE 18.3 Arenavirus genome organization. **A:** Schematic representation of the bi- or trisegmented arenavirus genome organization. The 5′ and 3′ ends of all segments (S, [M], and L) are complementary at their termini, likely promoting the formation of

circular ribonucleoprotein complexes within the virion (not shown). GPC, glycoprotein precursor; L, RNA-directed RNA polymerase; NP, nucleoprotein; Z, zinc-finger matrix protein. Open reading frames are separated by noncoding intergenic regions (IGRs), with predicted hairpin structures. **B:** RNA replication and gene transcription of the S segment. The NP gene is transcribed and translated first directly from the negative-sense viral genome. GPC is expressed later, after the S segment has undergone at least one round of replication, from the viral antigenome. A similar strategy is used for transcription and replication of the L segment. There are no direct experimental data examining these steps for antennaviruses and hartmaniviruses. (Courtesy of Fabian de Kok-Mercado and Jiro Wada, IRF-Frederick, Fort Detrick, MD, USA.)

Arenaviruses have highly conserved sequences at the 3′ end of the L and S RNA genome segments, and genome and antigenome RNAs are highly complementary between their 5′ and 3′ termini. This complementarity predicts that both L and S genome segments form panhandle structures.[45] This prediction is supported by EM data showing the existence of circular RNP complexes within arenavirions.[417] This terminal complementarity has been proposed to favor the formation of both intra- and intermolecular L and S duplexes that might be part of the replication initiation complex.[348] For several arenaviruses, a nontemplated G residue has been detected at the 5′ end of progeny genomic RNAs during replication.[136,137]

Arenavirus IGRs are predicted to fold into a stable hairpin structure. Transcription termination of the S-derived NP and GP mRNAs occurs at multiple sites within the predicted stem of the IGR, supporting the view that a structural motif rather than a sequence-specific signal promotes the release of the arenavirus polymerase from the template RNA. There are significant differences in sequence and predicted folded structure between the S and L IGRs, but among isolates and strains of the same arenavirus, the S and L IGR sequences are highly conserved. Some arenaviruses contain one single predicted stem loop within the S IGR, whereas the S IGRs of other

arenaviruses are predicted to contain two distinct stem–loop structures.[45]

Arenavirus Proteins

GPC is a class I fusion protein that is cotranslationally cleaved by cellular signal peptidases to generate a 58–amino acid-long stable signal peptide (SSP) and the immature GP1/2 precursor. The immature GP1/2 precursor is then posttranslationally processed by the cellular protease subtilisin kexin isozyme-1 (SKI-1)/site-1 protease (S1P) to generate the mature virion surface glycoproteins GP1 and GP2. GP1, GP2, and SSP form a tripartite heterotrimeric GP complex that mediates virion receptor recognition and cell entry.[24,310] The SSP has been implicated in the trafficking and processing of the viral envelope glycoproteins and in the GP2-mediated pH-dependent fusion process.[23,350,412, 413, 414, 415] GP1 mediates virion interaction with host cell-surface receptors. GP1 is located at the top of the spike away from the membrane and held in place by ionic interactions with the N-terminus of transmembrane GP2.[46,49,319,322] GP2 directs fusion of virus and host cell membranes, a process that depends on low pH-driven conformational change of GP2 from a metastable prefusion structure to a more stable postfusion six-helix bundle.[106,174,296] GP2 has similarities with fusion-active domains of other viral envelope proteins.[132,411] Crystal structures of the prefusion GP complex of LASV and LCMV[155,159] revealed that compared to other class I viral glycoproteins, LASV GP has some unique structural features with implications for vaccine design.[158]

NP is the most abundant viral polypeptide in both infected cells and virions and the main structural component of the viral RNP responsible for directing RNA genome replication and gene transcription. The C-terminus of NP also counteracts type I interferon (IFN-I).[250, 251, 252] Crystallographic studies identified distinct N- and C-terminal domains within NP of the OW arenaviruses LASV[41,156,317] and LCMV,[403] and similar findings were subsequently documented for the NW arenaviruses JUNV[422] and TCRV.[189] The N-terminal domain contains an RNA-binding site[157] and was proposed to have potential cap-binding activity that could provide the host-derived primers to initiate transcription by the virus polymerase.[317] However, the cap-binding activity of NP remains to be proven. The folding of the C-terminal domain of NP mimics that of the DEDDH family of 3′ to 5′

exoribonucleases similar to the one described for the nonstructural protein 14 of severe acute respiratory syndrome (SARS) coronavirus.[95] Functional studies confirmed the 3′ to 5′ exoribonuclease (exo) activity of LASV NP. The exo activity of NP was proposed to be critical for its anti-IFN activity. However, subsequent studies demonstrated that the exo activity of NP plays critical roles in additional aspects of mammarenavirus multiplication that are yet to be elucidated.[172,250]

Arenavirus L has a central region of conserved motifs characteristically found in the RdRp domains of negative-sense RNA viruses.[313] However, the N- and C-terminal regions do not allow easy identification of RNA helicase or methyltransferase (RNA capping) functions.[387] Residues critical for LASV L function are located both within and outside the predicted RdRp domain.[153,219,221] Mutagenesis of evolutionarily conserved acidic (Asp and Glu) and basic (Lys and Arg) residues within LASV L's C-terminus revealed residues that play a critical role in mRNA synthesis without significantly affecting RNA replication.[221] Bioinformatic analysis revealed that the N-terminus of LASV L has a distant similarity to type II endonucleases.[221] Crystal structures of the N-terminal region of LCMV[283] and LASV L uncovered an endonuclease domain of similar structure to the cap-snatching endonuclease domains of influenza A virus polymerase acidic (PA) and La Crosse virus L. LASV L is organized into three distinct structural domains. At specific amino acid positions, LASV L can be split into N- and C-regions that are able to functionally *trans*-complement each other.[42] In addition, EM characterization of a functional MACV L has revealed a core ring-domain decorated by appendages, which likely reflects a modular organization of the arenavirus polymerase.[207,209]

Mammarenavirus Zs are modestly conserved (below 20%); this similarity is even lower when Z sequences of the recently identified reptarenaviruses are included in alignments. However, three regions within Z have a higher degree of conservation: (a) an N-terminal myristoylation site marked by a highly conserved G motif that is critical for membrane anchoring[303,372] and interaction with other viral proteins,[50,51] (b) a RING domain that binds two zinc ions through three conserved motifs,[31] and (c) a C-terminal region containing proline-rich motifs that constitute, in most cases, functional late-budding motifs. These motifs are similar to those identified in the matrix

proteins of many enveloped RNA viruses and in the group antigen (Gag) proteins of a number of retroviruses. Late-budding motifs mediate protein–protein interactions between viral proteins and components of the endosomal sorting complexes required for transport (ESCRT) within the vacuolar protein sorting (Vps) pathway.[128] Mammarenavirus Zs contain P[T/S]AP- and/or PPPY late-budding motifs in their C-terminal regions, whereas reptarenavirus Zs lack typical canonical motifs. In addition, mammarenavirus Zs contain a highly conserved YxxL motif located within the central RING domain. This motif is not present in reptarenaviruses.

The structure of LASV Z was solved in complex with eukaryotic translation initiation factor 4E (eIF4E) by nuclear magnetic resonance.[392] The N- (residues 1–29) and the C-terminal (residues 77–99) arms flanking the RING domain are disordered, and only the central RING domain is structured. The disordered regions may enable Z to recruit a variety of partners, including promyelocytic leukemia protein (PML), eIF4E, proline-rich homeodomain (PRH) protein, ribosomal P proteins, retinoic acid–inducible gene I protein (RIG-I), and caspases. The interactions of Z with PML protein and eIF4E have been proposed to contribute to the noncytolytic nature of LCMV infection and repression of cap-dependent translation, respectively.[88,392]

Under crystallographic conditions, Z assembles in a dodecameric manner through a head-to-tail dimerization of the RING domain.[160] This assembly involves conformational changes thought to be required for a stable oligomerization, leading to the viral matrix formation. The N- and C-terminal disordered regions do not appear to contribute to the assembly of the oligomeric Z structure, which is consistent with the N-terminus anchoring Z to the membrane and the C-terminus mediating Z's interaction with endosomal components required for moving the maturing virion toward the cell surface. These findings are consistent with Z playing a key role in virion assembly, which is further supported by EM studies indicating that Z bridges the viral RNP to the viral envelope. Z has been also involved in suppression of the host cell type I IFN response via its interaction with RIG-I–like receptors.[108,410]

STAGES OF REPLICATION

Knowledge about the molecular and cell biology of reptarenaviruses, hartmaniviruses, and antennaviruses is rather limited, and therefore the presentation of the arenavirus life cycle is based on information obtained from studies with mammarenaviruses. However, many of the basic principles established for mammarenaviruses will likely also apply for members of the other genera.

Cell Attachment and Entry

Receptor-mediated endocytosis is the main cell entry pathway used by mammarenaviruses (Fig. 18.4). The acidic environment of the late endosome facilitates a pH-dependent conformational change in the GP complex that induces a GP2-mediated fusion step between viral and cell membranes. Following fusion, the viral RNP is released into the cytoplasm where it directs both replication and transcription of the viral genome.[106] *α*-Dystroglycan (aDG), a highly conserved and widely expressed cell-surface receptor for extracellular matrix proteins, is a main receptor for LCMV, LASV, and several other mammarenaviruses.[49,211] In mammals, aDG undergoes complex *O*-glycosylation posttranslational modifications, including the incorporation of a negatively charged sugar polymer called "matriglycan" as a result of the activities of the like-acetylglucosaminyltransferase (LARGE).[416] LARGE-dependent glycosylation is critical for aDG's function as a mammarenavirus receptor.[335] Intriguingly, specific LARGE alleles are positively selected among the Yoruba of Western Africa where LASV is endemic.[341] Pathogenic and nonpathogenic mammarenaviruses use aDG-mediated cell entry, indicating that aDG does not play a direct role in mammarenavirus pathogenesis.

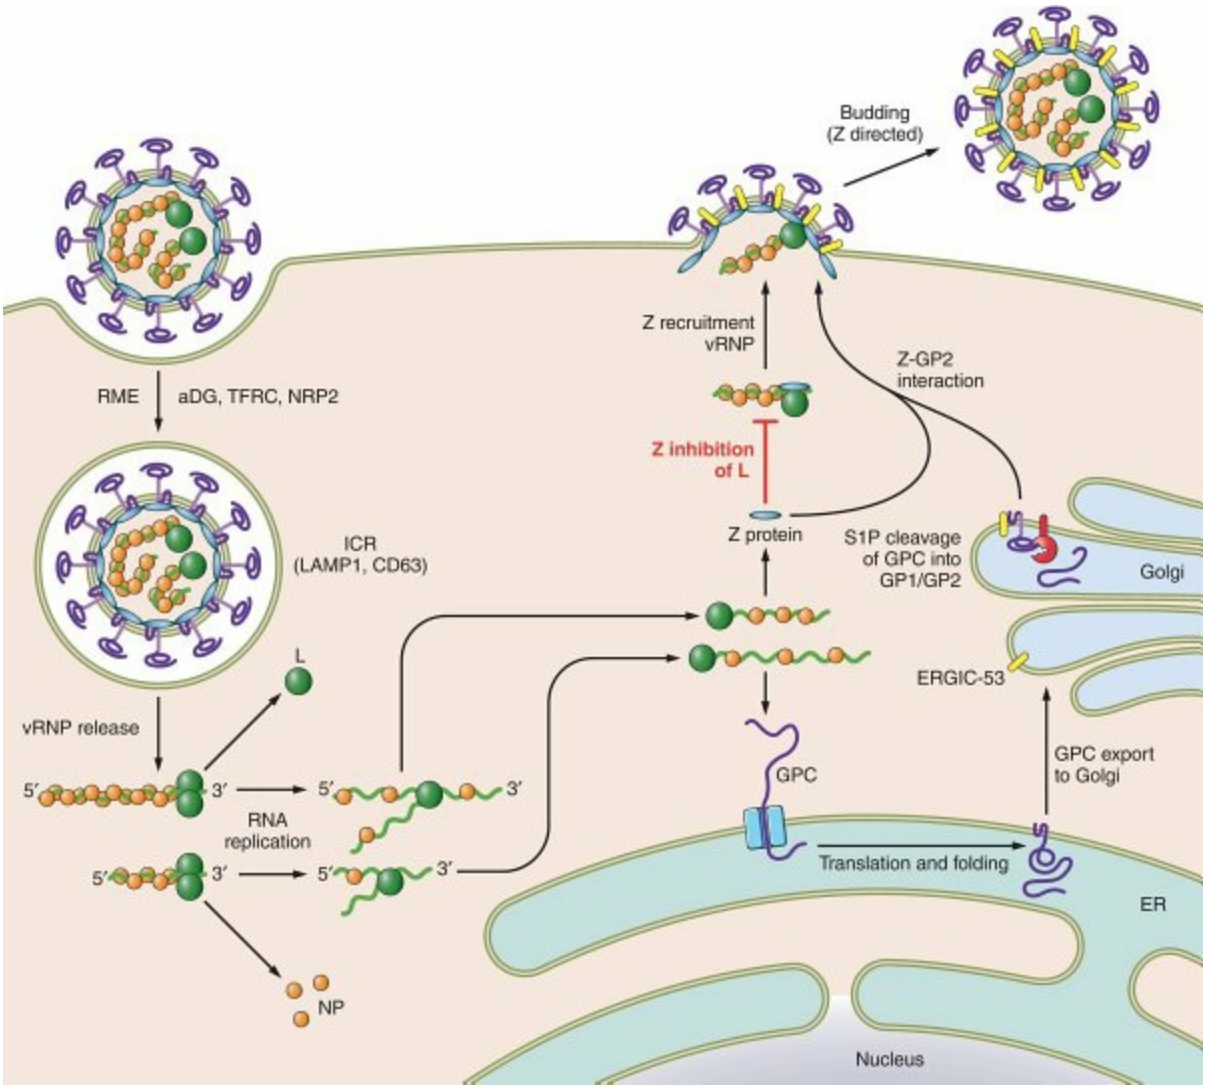

FIGURE 18.4 Mammarenavirus life cycle. Mammarenaviruses enter cells via receptor-mediated endocytosis (RME). Many Old World mammarenaviruses use α-dystroglycan (aDG) as the main receptor. Neuropilin (NRP)-2 is the cell-surface receptor used by the disease-causing Old World mammarenavirus LUJV. Clade B New World arenaviruses use transferrin receptor 1 (TfR1) as cellular receptor. The acidic environment of the endosome triggers a pH-dependent membrane fusion step that results in the release of the viral RNP into the cell cytoplasm where viral RNA genome replication and gene transcription take place. For some arenaviruses, completion of the entry process involves a late

endosomal receptor switch mechanism. The late endosomal resident proteins LAMP1 and CD36 are required for LASV and LUJV cell entry, respectively. Transcription by the viral polymerase complex is initiated at promoters on each 3′ end of the RNA segments, transcribing mRNA encoding NP and L (not shown). Transcription is terminated by structural motifs within the IGR. The virus polymerase complex switches from a transcriptase to a replicase mode and moves across the IGR, generating full-length antigenome (ag) RNAs that serve as templates for the synthesis of the GPC and Z mRNAs. The complete viral genome is also amplified from the agRNA templates. Arenavirus infection induces discrete cytosolic structures for RNA replication. Production of infectious progeny requires that assembled viral RNPs associate at the cell surface with membranes that are enriched in mature viral GP. It is also dependent on the host lectin ERGIC-53, which associates with viral GP and is incorporated into virions. Z plays critical roles in virion assembly and budding. Incorporation of arenavirus GPs into virion particles depends on the interaction of GP with Z. Canonical late-budding motifs found in most mammarenavirus Zs recruit components of ESCRT to promote virion budding.

aDG-mediated LASV entry into human epithelial cells and rapid virus internalization involve macropinocytosis.[178,291] Internalization is independent of dynamin, is dependent on sodium–hydrogen exchangers, and requires the dynamics of the actin cytoskeleton. LASV and LCMV pass through the multivesicular endosome, where the virion–receptor complex undergoes sorting by ESCRT, delivering the viruses to late endosomes.[297] LCMV and LASV GPs have a high binding affinity for aDG, and therefore the unusual endocytotic pathway used by these viruses may reflect the natural cellular trafficking of aDG. Alternatively, binding of GP to aDG could trigger a novel endocytic route for aDG that benefits virion cell entry as previously

documented for other pathogens.[32]

The cellular tropism of LASV and LCMV does not always correlate with the presence of fully glycosylated aDG,[110,393] which may be explained by the cellular expression of secondary alternative receptors, including members of the Tyro3/Axl/Mer and T-cell immunoglobulin (TIM) and mucin receptor families. These receptors can facilitate cell entry by apoptotic mimicry via recognition of phosphatidylserine in the outer leaflet of the virion envelope.[39,111,265] In addition, C-type lectins have been also implicated in LASV cell entry into specific cell types such as dendritic cells (DCs).[140,360,361]

Human transferrin receptor 1 (TfR1) is the main cellular receptor used for cell entry of pathogenic NW mammarenaviruses such as JUNV and MACV.[319,323] Consistent with the use of TfR1 as a primary receptor for cell entry, JUNV enters cells through clathrin-mediated endocytosis.[319] Although TfR1 is internalized and recycled through early endosomes (pH ≈ 6), optimal fusion activity of JUNV GP requires a significantly lower (<5.5) pH. Perhaps, JUNV may redirect TfR1 from its normal recycling pathway into the late endosomes, a process likely influenced by the multivalent nature of the virus particle.

Cell entry of the OW HF mammarenavirus, LUJV, was found to be independent of aDG and TfR1[374] and mediated by neuropilin (NRP)-2, a cell-surface receptor for semaphorins and the tetraspanin protein CD63.[318] Interestingly, NRP-2 is highly expressed on microvascular endothelial cells, and the consequent high susceptibility of the microvasculature to LUJV may explain the extent of coagulopathy observed in LUJV-induced clinical disease.[355] Likewise, expression of NRP-2 on alveolar macrophages may facilitate aerosol transmission of LUJV.[355]

Completion of the cell entry process for some mammarenaviruses involves a late endosomal receptor switch mechanism. For LASV[67,68,179,180] and LUJV,[318] the late endosomal resident proteins LAMP1 and CD36, respectively, are required for cell entry.

Expression and Replication of the Viral Genome

NP and L coding regions are transcribed into a genomic complementary

mRNA (Fig. 18.4). However, the GPC and Z coding regions are not translated directly from genomic RNA but rather from genomic sense mRNAs. These genomic sense mRNAs are transcribed from templates of the corresponding antigenome RNA, which also function as replicative intermediates (Fig. 18.3).

Activation of L's RNA synthesis activity is mediated by (i) structured (double-stranded) 5′ viral RNAs corresponding to the termini of genomic and antigenomic RNAs of both S and L in conjunction with a specific promoter and (ii) the nontemplated G at the 5′-end of the viral genome. Dinucleotide primers also enhance RNA synthesis by MACV, but not LASV, L, illustrating that polymerase complexes from different mammarenaviruses may have some unique features.[207,316,393]

Transcription initiation is performed through a unique mechanism shared by all polyploviricotine viruses called capsnatching. Short fragments of 5′-capped primers composed of four to five nucleotides are “stolen” by the virus polymerase complex from host-cell mRNAs to prime the synthesis of viral mRNAs. This process is thought to be initiated by cleavage of cytoplasmic cellular mRNAs by the endonuclease activity associated with the N-terminus of L that generates 5′-capped primers.[221,327,395] However, the endonuclease activity of any arenavirus L has yet to be experimentally validated. Transcription of NP mRNA was detected in TCRV-infected cells at early times of infection and in the presence of inhibitors of protein synthesis, suggesting that, unlike closely related bunyaviruses, but similarly to orthomyxoviruses, rhabdoviruses, and paramyxoviruses, primary transcription directed by the incoming TCRV RNP can proceed in the absence of translation.[127] The 5′ ends of arenavirus genome and antigenome RNAs each contain a nontemplated G residue that has been proposed to reflect a prime-and-realign mechanism for RNA replication mediated by L.[136,137,324] Recent studies provided biochemical evidence for initiation of arenavirus replication through this mechanism.[393] This prime-and-realign mechanism assumes that arenavirus polymerases initiate, like many other viral RdRps, RNA synthesis *de novo* only with GTP. Accordingly, arenavirus RNA initiation would take place from an internal templated cytidylate. Once the first phosphodiester bond has been formed, the $pppGpC_{OH}$, an uncapped primer, will slip backward on the template and realign, creating a nascent chain whose 5′ end is at position 1 with respect to the template, before the

polymerase resumes downstream synthesis. To maintain a constant length of the genome RNA despite addition of a nontemplated nucleotide at the 5′ end, the polymerase terminates RNA synthesis by removing the last base at the 5′ end of the nascent chain. Arenavirus genome, and antigenome, sequence terminal complementarity combined with the prime-and-realign mechanism for replication initiation generates double-stranded RNAs with overhanging 5′-ppp nucleotides. These structures can escape RIG-I recognition[247] and act as RIG-I decoys,[246] thereby diminishing RIG-I–mediated interferon induction.[149]

Transcription termination occurs within the distal side of the IGR and generates nonpolyadenylated viral mRNAs.[269] The IGR acts as a *bona fide* transcription termination signal for the virus polymerase.[309] Virus replication proceeds in two steps: first the *de novo* (primer-independent) synthesis of an intermediate RNA with positive polarity (cRNA) and second, using this cRNA as template, the synthesis of progeny genomic vRNA with negative polarity.

Using cell-based minigenome (MG) assays for LCMV, LASV,[152] JUNV,[3] TCRV,[228] and Pichindé virus (PICHV),[212] NP and L have been identified as the minimal viral *trans*-acting factors required for efficient RNA synthesis mediated by the virus polymerase. In the case of LCMV, both genetic and biochemical evidence indicate that oligomerization of L is required for polymerase activity.[349] Z is not required for intracellular transcription and replication of an LCMV MG, but rather Z has a dose-dependent inhibitory effect on both transcription and replication of LCMV MG.[70], [71], [72] This inhibitory effect of Z has also been reported for TCRV[228] and LASV.[152] Consistent with these findings, studies using *in vitro* reconstitution of RNA synthesis directed by MACV polymerase have provided evidence that Z, via direct interaction with the polymerase, is able to lock the polymerase in a promoter-bound, catalytically inactive state.[208,209] Transcription of Z mRNA starts at the 3′ end of the L RNA antigenomic segment, once the L antigenomic RNAs have been produced. Low expression levels of Z early during the virus replication cycle facilitate viral RNA replication and gene transcription,[208,209] whereas increased Z expression levels at later times during the arenavirus replication cycle will inhibit viral RNA synthesis and promote virus assembly and budding.[301,371]

Mutation-function analysis of the genome 5′ and 3′ termini using the MG-based assays for LCMV, LASV, and MACV indicates that the activity of the arenavirus genomic promoter requires both sequence specificity within the highly conserved 3′-terminal 19 nt of arenavirus genomes and the integrity of the predicted panhandle structure. This panhandle is formed via sequence complementarity between the 5′ and 3′ termini of viral genome RNAs.[154,302] Mammarenavirus RNA replication and gene transcription are NP dependent, but NP levels do not affect the balance between replication and transcription.[308] MG-based assays confirmed the IGR role as a *bona fide* transcription termination signal, but synthesis of translation-competent viral mRNAs does not strictly require the presence of the IGR.[309]

Assembly and Budding

Assembly and cell release of infectious mammarenavirus progeny require both Z and GPC and the correct processing of GPC into GP1 and GP2 (Fig. 18.4).[222,223,310] Colocalization of all viral proteins for assembly is mediated by Z–L,[208] Z–NP,[362] and Z–GP[51,383] interactions. Mammarenavirus Z is a structural component of the virion, and cryoelectron microscopy structural studies reveal a location of LCMV Z within virions consistent with its role as a matrix protein.[286] In accordance, functional studies have shown LASV and LCMV Zs to be the main driving force of arenavirus budding,[301,371] a process mediated by the interaction of Z's late-budding motifs, PTAP and/or PPPY, with components of the cellular ESCRT complexes.[128] Targeting of Z to the plasma membrane, the location of arenavirus budding, strictly requires myristoylation.[303,372] The cellular cargo receptor endoplasmic reticulum (ER)-Golgi intermediate compartment 53-kDa protein (ERGIC-53) is required for infectious arenavirion production. ERGIC-53 binds to arenavirus GPs, traffics to arenavirus budding sites, and is incorporated into virions. In the absence of ERGIC-53, GP-containing virus particles still form, but they are noninfectious, partially due to their inability to attach to and enter host cells.[204]

PATHOGENESIS AND PATHOLOGY

Pathogenesis of mammarenaviral disease is not well understood. The

pathological findings (gross and light microscopic lesions) found postmortem in patients rarely account for the relative high case-fatality rate (CFR) and severity of disease.[61,98,346,393] Mammarenaviruses typically enter humans in an aerosolized form and are deposited in the lung, where initial viral replication occurs.[80] Antigen-presenting cells (APCs), DCs and macrophages, are prominent targets in the initial stages of infection. The abundance of these cells in the mucosal tissues and skin results in their early infection and amplification of the viruses. The mobility and wide distribution of APCs most likely facilitate mammarenavirus entry into the lymphoid system and their systematic spread to other organs and tissues.[5,142,167,256] Principal target organs, based on virus titers, EM, or viral antigen accumulation at death, include the lymphoid tissue, liver, kidneys, lungs, adrenal glands, and heart. In the case of LASV, the virus has also been recovered from the placenta, mammary glands, and aborted fetal tissues. In the case of AHF, virion-like particles were also observed in the central nervous system (CNS), ovaries, and testes.[73,142,167,256,393] In the case of LCMV, the virus eventually reaches the meninges, choroid plexus, and ventricular ependymal linings, where it replicates to high titers and where the inflammatory response produces the characteristic lymphocytic choriomeningitis (LCM) pathology and signs of meningitis.[30]

In most cases of congenital LCMV infection, the fetus becomes infected transplacentally. After reaching the fetus, the virus exhibits a strong tropism for the fetal brain, where the infection produces its most common and severe pathologic effects, including microencephaly, periventricular calcifications, hydrocephalus, cerebellar hypoplasia, focal cerebral destruction, and gyral dysplasia.[30]

Coagulopathy and Vascular Dysfunction

The extent of hemorrhagic and coagulopathy manifestations differs between pathogenic mammarenaviruses. Hemorrhages are uncommon in LF patients and are primarily limited to mucosal surfaces.[254] In AHF patients, hemorrhage is much more common. Bleeding is typically associated with coagulopathy including thrombocytopenia and platelet dysfunction.[81,120,163] The platelet malfunction may be associated with a yet unidentified plasma inhibitor of platelet aggregation.[76,78] There is no evidence that coagulation

dysfunctions such as disseminated intravascular coagulation or complement activation play a role in mammarenavirus pathogenesis.[81] A recent metabolomics study found that levels of platelet-activating factor (PAF) and PAF-like molecules are lower in the serum of patients with fatal LF than in patients with nonfatal LF. The hemoglobin breakdown products D-urobilinogen and I-urobilin are also reduced in LF patients.[131]

Impairment of vascular function is most likely central for the pathology observed in LASV- and JUNV-infected patients. Edema and pleural and pericardial effusions that are associated with fatal LF cases are most likely due to increased vascular permeability. In both experimentally infected animals and LF patients, the disruption of vascular endothelium function is closely followed by shock and death.[121,234,393] In AHF patients, hemorrhagic disease manifestations are believed to be associated with vascular dysfunction.[210] However, only minimal vascular lesions are detected in fatal human LF and AHF cases and infected nonhuman primates (NHPs).[98] This discrepancy is probably because LASV and JUNV are nonlytic viruses and, as such, do not cause cytopathic effects or cellular damage in infected monocytes, macrophages, and endothelial cells.[139,234]

The mechanism of LASV-induced increase in vascular permeability is yet to be uncovered. A common hypothesis is that virus infection of the endothelium might cause changes in cellular function leading to increased fluid flow and subsequent edema. Infection with other hemorrhage-inducing viruses (e.g., Ebola virus) results in a “cytokine storm” that interferes with the integrity of the vascular endothelium. However, LASV-infected macrophages are not activated and proinflammatory cytokines are not released.[234,240] Recent studies with JUNV-infected endothelial cells reveal perturbation of specific endothelial cell functions, including increased expression of cell adhesion molecules (ICAM-1 and VCAM-1), coagulation factors (von Willebrand factor), and release of vasoactive mediators (nitric oxide and prostaglandin PGI_2) as a consequence of productive viral infection.[139] These studies provide the first possible links to the increased vascular permeability observed in AHF patients, but their relevance *in vivo* remains to be investigated.

Pathology

Macroscopic abnormalities in LF patients include gastric mucosal, renal, and subconjunctival hemorrhages, petechiae, and evidence of increased vascular permeability, such as pleural and pericardial effusions, ascites, and facial, intestinal, and laryngeal edema.[125,328] Microscopic findings reported in patients and in NHPs include multifocal hepatocellular necrosis with weak inflammatory cell involvement, splenic necrosis, necrosis of renal tubular cells, adrenocortical cell necrosis, focal renal interstitial lymphocytic infiltrates, mild mononuclear interstitial myocarditis, alveolar edema with capillary congestion, interstitial pneumonitis, and rhabdomyositis.[125,256,328,393]

The most consistent pathological hallmark of LF in humans is multifocal hepatocellular necrosis. In fatal cases, the extent of necrosis can range from 1% up to 50%. High virus titers in liver tissue correlate with severe hepatitis.[256] However, the degree of hepatic tissue damage is insufficient to cause hepatic failure. In addition, there is no correlation between the degree of hepatic necrosis and chemical indicators of liver damage, such as elevated concentrations of aspartate aminotransferase (AST), alanine transaminase (ALT), and lactate dehydrogenase (LDH) in serum.[256,393] Therefore, LASV-induced hepatitis is not the primary cause of death in fatal cases.

The most common macroscopic abnormality in severe cases of NW mammarenaviral disease is widespread hemorrhage, particularly in the skin and mucous membranes (gastrointestinal [GI] tract), intracranium (Virchow-Robin space), kidneys, pericardium, spleen, adrenal glands, and lungs. Microscopic lesions include acidophilic bodies and focal necroses in the liver, acute tubular and papillary necrosis in the kidneys, and reticular hyperplasia of the spleen and lymph nodes. In cases of BHF, hepatic petechiae are common and the number and size of Kupffer cells are also increased. Interstitial pneumonia has been observed in cases of BHF or Venezuelan hemorrhagic fever (VeHF). In cases of AHF, secondary bacterial lung infections (acute bronchitis and bronchopneumonia, myocardial and lung abscesses) have been observed.[61,98,150,346]

Patterns of clinical AHF illness are JUNV strain specific and can be “hemorrhagic” (Espindola strain), “neurologic” (Ledesma strain), “mixed” (P-3551 strain), and “common” (Romero strain).[146,259,260] In animal models of AHF, each isolate induces a disease syndrome that replicates the clinical variant of the disease in the human from whom the viral strain was obtained.

Animals infected with JUNV Espindola strain (“hemorrhagic”) demonstrate apronounced bleeding tendency with disseminated cutaneous and mucous membrane hemorrhage. In guinea pigs, the Espindola strain replicates predominantly in the spleen, lymph nodes, and bone marrow, the major sites of necroses, whereas lower virus loads are present in the blood and brain. In contrast, animals infected with JUNV Ledesma strain (“neurologic”) show little or no hemorrhagic manifestations but develop overt and generally progressive signs of neurologic dysfunction: limb paresis, ataxia, tremulousness, and hyperactive startle reflexes. The Ledesma strain is found predominantly in the brain, where moderate polioencephalitis is observed, and only low amounts of virus are recovered from the spleen and lymph nodes.

A single well-studied LCM encephalitis case showed mononuclear cell infiltrates in the meninges and around vessels and glial nodules in the deeper structures.[397] Fluorescent antibodies detected viral antigen in meninges and in cortical neurons. During the CNS disease, there is no viremia, but virus is still detectable in cerebrospinal fluid (CSF), and the pathogenesis is believed to be immunopathological. An animal model of congenital LCMV infection has demonstrated the very strong tropism of LCMV for neuroblasts and that infection disturbs neuron migration. These findings explain, respectively, the location of periventricular calcifications and the gyral malformations in children with congenital LCMV.[30] Studies with this model have also shown that the age of the developing host at the time of infection profoundly affects the patterns of infection and pathology within the brain.

Immune Responses

T-cell responses play a crucial role in the control of LASV infection in both *in vitro* and *in vivo* animal models. Severe or fatal LASV infection seems to be associated with defective T-cell responses (low and delayed T-cell activation), whereas the effective control of LF seems to be mediated by robust and efficient responses. In hospitalized patients and NHP models of LF, strong (IgG and IgM) antibody responses are not correlated with the outcome of disease; however, high viral loads are associated with a poor prognosis. Therefore, humoral responses are not effective in controlling LASV replication and the resulting pathology.[192,338] Unlike LF, humoral immunity plays an important role in controlling AHF. In both humans and

animal models, immune plasma treatment from previously exposed individuals is efficacious in treating AHF if administered early during infection. The efficacy of the treatment appears to be due to the ability of the antibodies to neutralize virus, as viral loads are reduced after transfusion with immune plasma.[242] A recent study suggests that the number of *N*-glycosylation sites on the arenaviral GPs is inversely correlated with the protective efficacy of neutralizing antibodies.[365]

Mammarenavirus infections cause immunosuppression in humans and other animals. The hallmark of LASV infection is generalized immunosuppression. In accordance, LASV-infected APCs do not mature or become activated; elevated levels of activation markers (CD80, CD86, CD40, CD54, and HLAs) or cytokines (tumor necrosis factor [TNF-α], interleukin [IL]-1β, IL-6, and IL-12) and increased phagocytic activity are not observed following infection.[263] Furthermore, in LF patients, fatal outcome correlates with absence or minimal levels of IL-8 and interferon-inducible protein 10 (IP-10) in serum.[240] In recent studies, however, human LF survival was correlated with low levels of IL-6, IL-8, IL-10, macrophage inflammatory protein (MIP1β), and CD40L.[35]

In AHF patients, immunosuppression is not generalized. Decreases in the number of T and B lymphocytes, lower ratio of CD4 to CD8 T cells, and diminished response to mitogens are reported in acute AHF patients. However, JUNV-infected patients have elevated proinflammatory cytokine (TNF-α, IFN-α, IL-6, and IL-10) levels. In fact, the severity of disease is consistently associated with elevated levels of TNF-α and IFN-α.[164,224,248]

In vitro studies suggest that macrophages are not responsible for the increased cytokine production as IFN-α, IFN-β, TNF-α, IL-10, IL-6, and IL-12 levels do not increase in these cells following inoculation with JUNV. In contrast to LASV, both JUNV and MACV can readily induce IFN production in cultured human primary DCs.[145,171,263] The exact role of cytokines in the pathogenesis of NW arenavirus disease is yet to be determined, but a common hypothesis is that cytokines may be important in controlling virus replication in the early stages of infection, whereas a delayed response could contribute to pathogenesis as seen in patients with severe disease and high levels of cytokines.

Congenital LCMV infection in animals triggers a robust inflammatory

response, driven by cytotoxic T lymphocytes. This finding explains the lymphocytic pleocytosis in patients with LCM and the inflammation-induced destructive cerebral lesions in children with congenital LCMV.[30]

Mammarenavirus RNA can activate the RIG-I/melanoma differentiation–associated protein 5 (MDA5)-mitochondrial antiviral signaling (MAVS)-dependent signaling pathway to induce the IFN-I response.[423] However, mammarenaviral NP is a potent inhibitor of IFN-I. Specifically, NP (with the exception of TCRV NP) expression blocks phosphorylation and prevents the nuclear translocation of interferon regulatory factor 3 (IRF3).[251,316] NP (with the exception of TCRV NP) also inhibits the nuclear translocation and transcriptional activity of the nuclear factor kappa B (NF-κB).[332] NP interacts with RIG-I and MDA5[423] and prevents potentiation of RIG-I function by the cellular protein PACT. The exo activity of NP is required for this function.[357] The C-terminus (exoribonuclease domain) of LCMV NP also binds the kinase domain of cellular protein kinase IKKε, thereby blocking its autocatalytic activity and its ability to phosphorylate IRF3.[316]

In addition to NP, mammarenaviral Z suppresses IFN-I response. According to one study, pathogenic mammarenavirus Z binds to the CARD domains of RIG-I–like receptors and disrupts their interactions with MAVS, thereby leading to down-regulation of the IFN-β response.[410] Another study reported similar finding with the exception that Z of NW, but not OW, mammarenaviruses was found to interact with RIG-I and interfere with the interaction between RIG-I and MAVS.[108]

EPIDEMIOLOGY

Arenaviruses are ecologically diverse and have been found in rodents, bats, and ticks (mammarenaviruses)[92,320,351] snakes (reptarenaviruses, hartmaniviruses),[168], [169], [170,366] and fish (antennaviruses).[359] Most mammarenaviruses infect muroid rodents of only one or a few species and, therefore, are geographically constrained (Fig. 18.5). However, LCMV, which infects the ubiquitous house mouse, is distributed globally.[62,347] Within these host ranges, the prevalence of each virus may be spatially or temporally patchy. One mammarenavirus, TCRV, was found in phyllostomid

bats and lone star ticks (*Amblyomma americanum* Linnaeus, 1758).[92,351] The natural distribution of reptilian and fish arenaviruses is unknown thus far.[168], [169], [170,366]

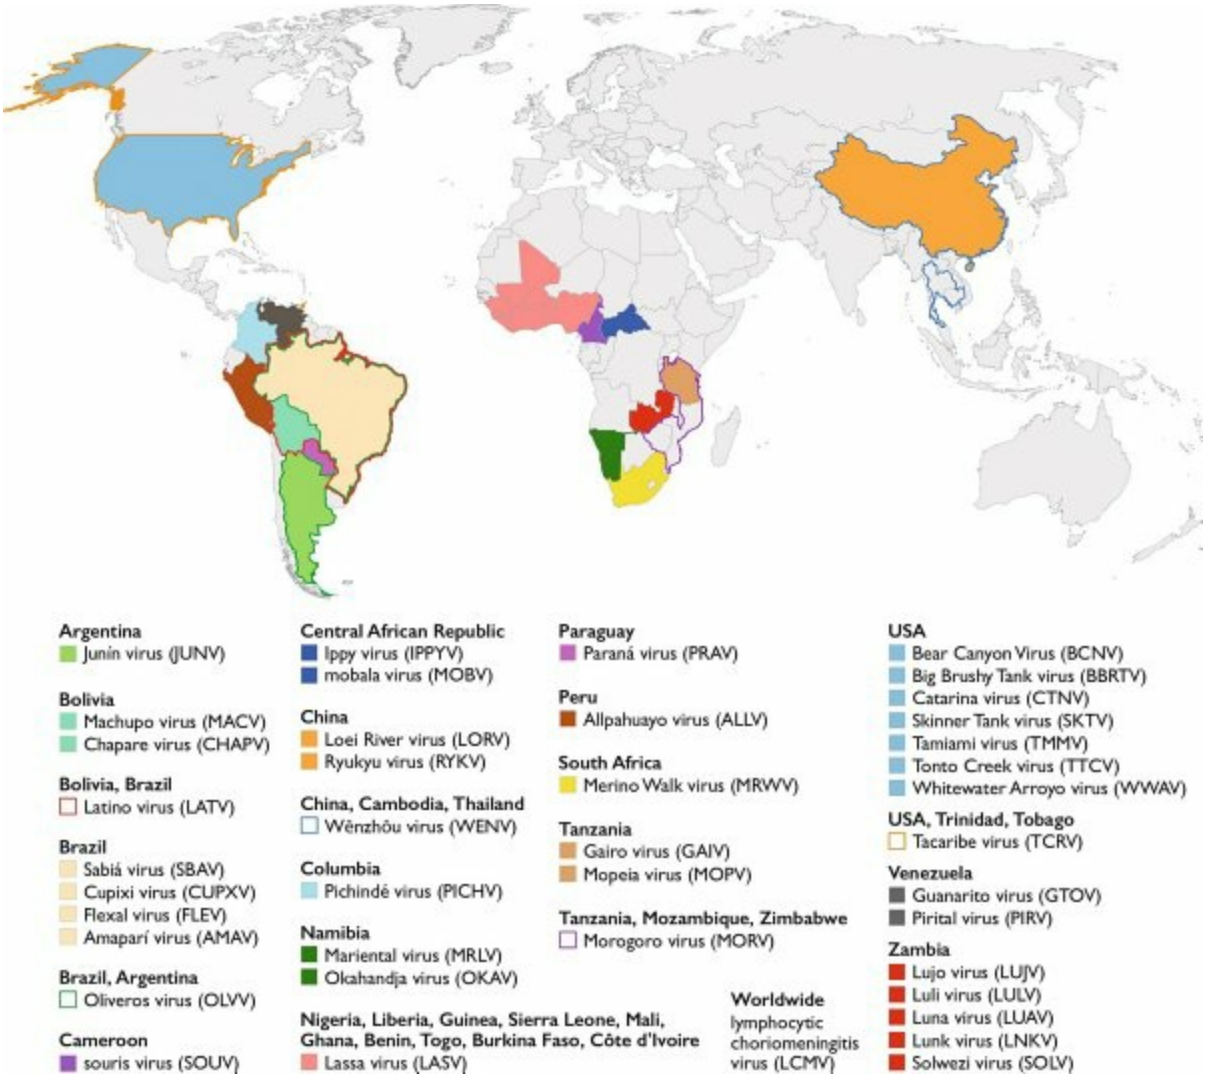

FIGURE 18.5 Global mammarenavirus distribution. Human arenavirus infections are indicated on a global map by colors. (Courtesy of Jiro Wada, IRF-Frederick, Fort Detrick, MD, USA.)

Typically, mammarenaviruses cause persistent, frequently asymptomatic infections in their reservoir hosts, which are characterized by virus multiplication in many different tissues and chronic viremia and viruria.

Chronic infections are suspected to be caused by suppressed host immunity. The chronic carrier state in rodents usually results from vertical transmission (exposure to infectious virus early in ontogeny) or horizontal transmission (exposure to virus later in life through aggressive or venereal behavior).[30,114,271,339,394,398]

Mammarenaviruses do not normally infect mammals other than their immediate reservoir hosts. However, some viruses are pathogenic and are often highly virulent for humans. Human infections occur via exposure to rodent fomites, ingestion of contaminated food, exposure to broken skin or mucous membranes, or inhalation of aerosolized virions from contaminated material.[25,73,104,253,276,375]

Lassa Fever

LF is endemic in areas of western sub-Saharan Africa: Nigeria, Liberia, Guinea, and Sierra Leone (Fig. 18.5). Recent data also indicate the presence of circulating strains in the surrounding countries of Mali,[342,345] Ghana,[94] Benin (http://www.who.int/csr/don/13-june-2016-lassa-fever-benin/en/), Togo,[299,404] Burkina Faso,[373] and Côte d'Ivoire.[364] Imported cases of LF have been reported in the United States, Canada, the United Kingdom, Japan, Germany, the Netherlands, and Israel.[147,236] The etiologic agent of LF is LASV.[125] The CFR of LF is about 1% to 2% in the endemic areas, with estimated 300,000 infections annually.[257] Most LASV infections in Africa are asymptomatic, mild, or subclinical, but the CFR in hospitalized confirmed cases of LF can be as high as 69%.[44,175,356] The CFR increases with age, and patients aged 50 years and older are more likely to die.[9,44,288] High CFR for children aged 9 years or younger and adolescents and adults less than 29 years of age has also been reported.[44,124,356] The disease is especially severe late in pregnancy with fetal death, miscarriage, or spontaneous abortion occurring in nearly all cases.[124,255,314,356] Most LF cases recorded during recent outbreaks were in the older age group of ≥20 years.[175,356]

The Natal mastomys (*Mastomys natalensis* Smith, 1834) is the main reservoir host of LASV.[215,279] Experimental LASV infection of adult and neonatal Natal mastomys and field studies support the notion that these rodents are not adversely affected by LASV infection. However, some infected adult rodents develop mild meningoencephalitis.[245,394] Maintenance

of LASV in Natal mastomys is thought to occur via vertical transmission (*in utero* or postnatal transmission).[394] However, recent studies suggest the existence of an additional horizontal transmission mechanism.[114] Other rodents might also serve as LASV hosts or have roles in LASV transmission.[114,257,290,409] Humans become infected with LASV through direct contact with infected rodent excreta, tissues, or blood or via inhalation of aerosolized virus.[192,276,375] Accordingly, poor sanitation and housing conditions correlate with greatest risk of infection.[29] In Western Africa, peridomestic rodents are also part of the diet in certain populations. Consequently, infected meat could be another route of virus transmission.[199] Person-to-person transmission of LASV can occur in nosocomial settings via direct contact with body fluids from symptomatically infected individuals or corpses and is estimated to occur in ≈20% of LF cases.[122,227,276] Human infections tend to be more common in the dry season, between November and April,[97,175,356] which may reflect a higher prevalence of Natal mastomys inside houses.[115]

LASV prevalence is focal and varies greatly between geographical regions. In Guinea, the reported seroprevalence varies from 4% to 55% (with the highest prevalence in forested Guinea).[20,233] In Sierra Leone, seroprevalence ranges from 8% to 52%[257] and in Nigeria from 13% to 37%.[379] Prevalence of LASV IgG antibodies is 26% in Côte d'Ivoire.[2] At least in Nigeria, the occurrence of LF seems to drift from rural to predominantly urban residential areas.[358]

A striking feature of LASV is the high level of genetic diversity between strains; nucleotide differences can reach up to 32% and 25% for the L and S segments, respectively.[7,33,97] The diversity among LASV strains correlates with geographic location rather than time, and no evidence of a “molecular clock” has been found. Six major LASV clades have been reported thus far based on sequencing data: I–III in Nigeria; IV covering the countries of Sierra Leone, Guinea, and Liberia; V covering southern Mali and Côte d'Ivoire, and the recently recognized clade VI from Togo.[7,244,404] The high diversity of LASV might explain the observed variability of LF's clinical presentation and possible regional differences.

Lymphocytic Choriomeningitis

Mounting evidence indicates that LCMV is a neglected human pathogen. The disease burden in humans is unknown.[18] The primary host of LCMV is the house mouse, but other rodents, such as pet hamsters[26] and domesticated guinea pigs (*Cavia porcellus* Linnaeus, 1758), can become infected and transmit the virus to humans.[117] Infected rodents shed the virus in their urine, saliva, nasal secretions, and droppings throughout life.[30] LCMV is transferred vertically from one generation to the next via intrauterine infection within the mouse host. Offspring of rodents that acquire LCMV transplacentally are persistently infected and may have high viremia. However, these offspring often remain asymptomatic.[30]

Humans become infected with LCMV through close contact with infected rodents, through solid organ transplantation,[56,116] or by vertical transmission. Congenital LCMV infection occurs when a woman acquires a primary LCMV infection during pregnancy and the virus is passed to the fetus transplacentally or is acquired during the intrapartum period.[206] Human-to-human horizontal transmission of LCMV has not been documented (with the exception of transplantation).[26] Humans can acquire LCMV during any season, but most LCMV infections occur during the late autumn and early winter months, when house mice move into human dwellings during the cold season.[30] Human LCMV infections involve all age groups, and generally occur sporadically.[304] LCMV can also cause callitrichid hepatitis in New World primates. These primates develop hepatitis after contact with LCMV-infected house mice.[10,282,369]

The prevalence of LCMV within house mouse populations and in humans is highly variable, even within the same geographic region, resulting in the focal and uneven spatial distribution of the virus. For example, a study in Baltimore, MD, USA, found that the prevalence of LCMV antibody varied from 3.9% to 13.4% in house mice from inner-city locations. Study results provided evidence that infections were clustered within residential blocks and even within households.[63] In humans, LCMV prevalence in the USA and Argentina is estimated at ≈2% to 5%.[6,64,292,329,368] This prevalence suggests that the risk of infection has decreased since the 1940–1950s when the prevalence of LCMV infection was 8% to 11%.[1,270,326]

LCMV strains have been divided into four different lineages.[4] Most of the US strains, including the classic laboratory strains, WE and Armstrong,

and virus strains from France, Germany, and Slovakia, are located within lineage I. Lineage II appears to contain only viruses from Europe. An LCMV 1984 isolate from the state of Georgia (USA) is the sole member of lineage III. Lineage IV consists of viruses isolated in Spain from wild-caught long-tailed field mice (*Apodemus sylvaticus* Linnaeus, 1758).[216] LCMV exhibits high genetic diversity, comparable to that of LASV.[4] Up to 18% and 25% nucleotide divergence was observed within the S and L segment lineages, respectively. The high genetic diversity of LCMV and the lack of clear correlation of virus genetic lineages to particular geographic locations likely reflect the long and complex phylogeographic history of the common house mouse host.[4]

Argentinian Hemorrhagic Fever

JUNV, the etiologic agent of AHF, is estimated to have caused around 30,000 cases. In the absence of treatment, the CFR can reach 20% to 30%. Pregnant women have an increased CFR and many miscarry, especially during the third trimester.[38] The AHF-endemic region has expanded progressively into north central Argentina to the extent that currently 3 million people are considered to be at risk of infection (Fig. 18.5).[104] AHF is typically a seasonal disease, with a peak of frequency occurring during the corn-harvesting season (March–June). Infected cases are primarily rural male agricultural workers, aged 15 to 55 years.[73] The drylands laucha (*Calomys musculinus* Thomas, 1913) is the main reservoir of JUNV.[339,340] However, other animals can become infected.[271,272] The drylands laucha inhabits crop fields, pastures and adjacent roadsides, and fence lines. It is rarely captured in or around human dwellings. The patchy spatial distribution of this rodent has been suggested to account for the focal distribution of AHF. Furthermore, annual increase in the number of drylands laucha coincides with the corn-harvesting season providing opportunities for rodent-to-man transmission. Transmission to humans is believed to occur predominantly by inhaling aerosolized viral particles from contaminated soil and plant litter, which are disturbed during the mechanized harvesting process, or by exposure to primary aerosols of rodent urine or contact with contaminated nesting materials in border habitats.[73,104]

Results from field and laboratory studies suggest that horizontal

transmission via aggressive encounters among adult, male rodents is the primary mode of viral persistence in nature.[271,273] The high rate of JUNV production in salivary glands and virus isolation from saliva of drylands lauchas[271,300,339] make JUNV transmission following a bite highly likely. Vertical transmission has also been reported as possible maintenance mechanism of JUNV.[339] However, the virus cannot transgress the placenta,[391] and rodents infected at birth (during lactation) exhibit decreased survival, body growth, and fertility. In contrast, rodents infected as adults are usually asymptomatic.[388,389,391] Half of infected adult rodents develop persistent infection with virus isolated from the urine, saliva, blood, or brain, whereas the remainder develop serum antibodies and appear to clear the virus within 21 days.[391] Vertical transmission might contribute, to some extent, to the maintenance of infection, if not via transfer to the next generation, then via intragenerational infection by horizontal transmission when population numbers are reduced.[339,388,390]

Serological studies in Argentina found prevalence of JUNV-neutralizing antibodies to range from 4.7% to 12.3% in AHF-endemic areas.[82,400,401] In nonendemic areas, the prevalence is significantly lower (0.44%).[399] Clinically apparent disease occurs in nearly two-thirds of those infected. In rodents, prevalence of infection can be as high as 10.9% with highest prevalence observed in current epidemic areas and lowest (0.2%) in nonendemic areas.[271], [272], [273,399]

Nucleotide similarity between JUNV strains is high and can reach up to 94.5% and 95.4% for GP and NP, respectively.[135,141]

Bolivian Hemorrhagic Fever

MACV is the etiological agent of BHF.[193] The CFR of BHF is approximately 5% to 30% with the highest rates occurring among those under 5 and over 55 years of age. BHF cases are more common during the dry season, at the peak of agricultural activity, with males over 15 years of age more frequently affected.[238] The big laucha (*Calomys callosus* Rengger, 1830), a small pastoral and peridomestic rodent, is the reservoir host of MACV.[191] Suckling big lauchas infected with MACV develop viremia but are “immunotolerant.” In animals more than 9 days of age, a split response is observed following MACV infection (similarly to JUNV). “Immunocompetent” big lauchas

(about 50%) develop circulating neutralizing antibodies and clear viremia and have minimal or absent viruria, whereas “immunotolerant” mice develop persistent viremia, viruria, and little or no neutralizing antibodies. MACV antigen can be detected in most tissues of the latter animals, including the reproductive organs. Long-term effects of tolerant infection include mild runting, reduced survival rate, and almost total sterility among females, largely caused by virus infection of embryos.[195,398] Both horizontal and vertical transmissions have been shown as possible maintenance mechanism of the virus within its reservoir rodent. Infection of newborn mice can occur neonatally through the milk and of adult mice can occur via venereal encounters.[398]

Person-to-person transmission of MACV is not frequent but possible by direct contact with body fluids or excreta of infected patients. Transmission by intimate contact during convalescence is also feasible.[91,190] Such transmission is probably not the principal mode of disease dissemination. In fact, the frequency of MACV isolation from human blood or from throat and oral swabs of infected patients is low, and only small quantities of the virus have been detected in successful isolation attempts.[193]

Venezuelan Hemorrhagic Fever

GTOV emerged in 1989 as the cause of VeHF. This severe hemorrhagic illness has focal distribution in the southern and southwestern portions of Portuguesa state and in adjacent areas of Barinas state (Fig. 18.5). VeHF cases peak between November and January, during the period of agricultural activity in the regions. Similar to AHF, the majority of cases have involved male agricultural workers. The CFR is ≈30%.[83,129,346,376] The short-tailed zygodont (*Zygodontomys brevicauda* J. A. Allen and Chapman, 1893) is the main reservoir host of GTOV. The virus is also commonly found in Alston's cotton rats (*Sigmodon alstoni* Thomas, 1880). These rodents are most abundant in tall grass along roadsides and fence lines, on the edges of cultivated fields, and in the naturally occurring savanna that dominates the landscape of the VeHF-endemic regions.[377] These hosts have not been reported within houses or farm building. Therefore, similar to JUNV, GTOV infections are assumed to occur outdoors and in rural areas, and persons that have frequent contact with rodent-infested grassland habitats are at higher

risk.[83] Unlike, MACV and JUNV, newborn short-tailed zygodonts inoculated with GTOV develop chronic infection with no effect on growth and shed the virus in urine and saliva. Similarly to MACV and JUNV, GTOV infection of adult animals results in the typical split response: most animals produce chronic viremia characterized by persistent shedding of infectious virus in oral secretions and urine, whereas the rest develop neutralizing antibodies and clear viremia. Findings from experimentally GTOV-infected female zygodonts include a negative effect on reproductive fitness and evidence of vertical transmission to pups.[130]

CLINICAL FEATURES

Lassa Fever and Other Old World Mammarenaviral Diseases

The signs and symptoms of LF vary depending on the severity of the disease. The disease is mild or asymptomatic in about 80% of infected individuals, but 20% develop acute LF. The incubation period can range from 5 to 21 days but is typically 10 to 14 days. Disease onset is insidious with progressive fever, weakness, and general malaise (Fig. 18.6). Within 2 to 4 days, many patients experience an array of symptoms and signs including headache; myalgia; arthralgia; lower back, abdominal, and/or retrosternal chest pain; dizziness; nausea; tinnitus; or sore throat. Signs such as cough, vomiting, diarrhea, and/or constipation are also common. Lymphadenopathy (particularly cervical), oliguria, tachycardia, vertigo, splenomegaly, hepatomegaly, and jaundice have been reported occasionally. Pharyngitis, conjunctivitis, signs of respiratory distress (rales, wheezing, and rhonchi), pleural and pericardial effusions, or facial and neck edema can occur as the disease progresses.[20,75,123, 124, 125,198,205,255,267,277,281,288] The majority of patients begin to recover 8 to 10 days after disease onset, and virus is cleared from the blood 4 to 11 days later.[9,192,278] In severe cases, however, the illness worsens with respiratory distress and hemorrhagic and/or neurologic manifestations. Hemorrhagic manifestations can include skin and mucosal petechiae, mucosal bleeding (gums, vagina), epistaxis, hematuria, hemoptysis, bleeding from needle puncture sites, or conjunctival and GI

bleeding (melena, hematemesis). Neuroglial findings such as moderate-to-severe diffuse encephalopathy, confusion, tremors, coma, and/or convulsions are common just prior to shock and death.[20,75,123, 124, 125,198,205,255,267,277,281,288] In children, edema of the neck and face may progress to widespread edema, abdominal distension, and bleeding (termed “swollen baby syndrome”) that typically result in death.[280]

FIGURE 18.6 Lassa fever clinical presentation. **A:** Listed are typical symptoms and clinical signs of LASV-infected adults. **B:** Idealized progression of key clinical signs in Lassa fever. (Courtesy of Jiro Wada, IRF-Frederick, Fort Detrick, MD, USA.)

Common clinical findings include proteinuria, albuminuria, and elevated AST levels (at least mildly).[20,125,192,198,255,267,277,281,288] Moderate leukopenia, particularly in the initial phase of illness, has been reported in some, but not all, patients.[125,198,205,255,267,277,281] In some cases, hypotension has been described,[20,198,255,267] and even less frequently mild thrombocytopenia has been noted.[124,205,281]

Survivors of LASV infection often recover without sequelae. However, unilateral or bilateral sensorineural deafness, which may develop during disease, may persist permanently in ≈13% to 30% of survivors. The auditory patterns and clinical course resemble idiopathic sudden hearing loss.[77,226,289] In addition, pericarditis has been documented (particularly in males) as well as hair loss.[123,125,255]

LF presents with symptoms and signs indistinguishable from those of other febrile illnesses such as malaria, typhoid fever, gastroenteritis, pneumonia, and other severe viral infections. Therefore, LF is difficult to diagnose clinically but should be suspected in patients with fever (≥38°C) not responding to antimalarial and antibiotic drugs.[124,255,281] Past studies show that the most useful clinical predictors for diagnosis of LF are fever, pharyngitis, retrosternal pain, and proteinuria.[255] Fever, sore throat, vomiting, edema, and bleeding are the best predictors for negative outcome.[9,20,124,255,277] Disease outcome is also correlated to the degree of blood viremia; in fatal cases, viremia usually persists uncontrolled until death, and high LASV titers are found in visceral tissues at autopsy.[9,192] Recently, severe and nonsevere CNS signs, face and neck edema, jaundice, bleeding, hematuria, and proteinuria were shown to be more significantly associated with death.[288] Several laboratory-tested biomarkers had even greater association with increased CFR than did clinical features; these include raised concentrations of blood urea nitrogen and creatinine (biomarkers for kidney function), of serum AST (consistent with known liver

malfunction), and of the serum electrolyte potassium. These results highlight the role of liver and renal dysfunction and electrolyte disturbance in the severity of LF.[9,125,288]

Patients infected with LUJV initially present with symptoms and signs of nonspecific febrile illness such as severe headache, malaise, vomiting, fever, retrosternal pain, or myalgia. Disease manifestations increase in severity over 7 days with the development of diarrhea and pharyngitis. In some patients, morbilliform rash or facial edema is evident. Terminal features are acute respiratory distress syndrome, cerebral edema, neurologic signs, deteriorating renal function, or circulatory collapse. In some patients, no overt hemorrhage is observed besides gingival bleeding, petechial rash, or oozing from injection sites.[37] However, the clinical description of disease caused by LUJV infection is currently based on the observation of only five patients.

Lymphocytic Choriomeningitis

Postnatal infections in persons with an intact immune system are often asymptomatic/subclinical or result in a mild febrile illness. Following 1 to 2 weeks of incubation, infected individuals develop flu-like illness with malaise and weakness, fever, myalgia, headache, and/or photophobia. Gastrointestinal (GI) symptoms and signs such as anorexia, nausea, and vomiting are also common, and in some cases, diarrhea has been reported. Sore throat, cough, pharyngitis, and other symptoms of respiratory tract involvement are less common. Lymphadenopathy, dysesthesia, conjunctivitis, arthralgia, arthritis, rash, testicular or parotid pain, and abdominal, back, and chest pain have been reported but occur infrequently. Typically, the disease lasts 5 to 15 days, and virus can be isolated from the blood. Clinical findings may include leukopenia, moderate thrombocytopenia, mild elevations of AST levels, and infiltrates on chest radiographs. However, these findings are not present in all patients.

CNS viral invasion is seen only in a minority of patients either after an initial prodromal febrile illness (as described above), defervescence, or, less commonly, without any early symptoms. During this neurologic phase, most patients experience symptoms/signs of classic aseptic meningitis that include fever, severe headache, vomiting, nuchal rigidity, and/or photophobia. In some cases, encephalitis, encephalomyelitis, meningoencephalitis, acute hydrocephalus, ascending or bulbar paralysis, or transverse myelitis may

develop. The hallmark laboratory abnormality during this CNS phase of illness is a CSF pleocytosis. CSF leukocyte cell counts often exceed 1,000/ μL. Hypoglycorrhachia and mild elevations of CSF protein have also been reported. Virus can be isolated from the spinal fluid.[1,19,25,40,93,109,213,270,378,386,397] Infections are rarely fatal, and most patients survive without sequelae. However, some might experience asthenia, headaches, confusion, and difficulty in concentration. Alopecia, arthralgia, arthritis, orchitis, dysesthesias, and vertigo have also been reported infrequently.[1,19,386]

Infection during pregnancy increases the risk for miscarriage (especially during the first trimester of pregnancy), *in utero* fetal death, fetopathy, and severe neurologic sequelae. Congenital LCMV can result in severe CNS or ocular malformations (Fig. 18.7), including chorioretinopathy, congenital hydrocephalus, macrocephaly, or microcephaly, and can mimic the signs/symptoms of classic TORCH (toxoplasmosis/*Toxoplasma gondii*, other infections, rubella, cytomegalovirus, herpes simplex virus) syndrome. Neurologic sequelae include spastic quadriparesis, mental retardation, seizures, and visual impairment.[17,407]

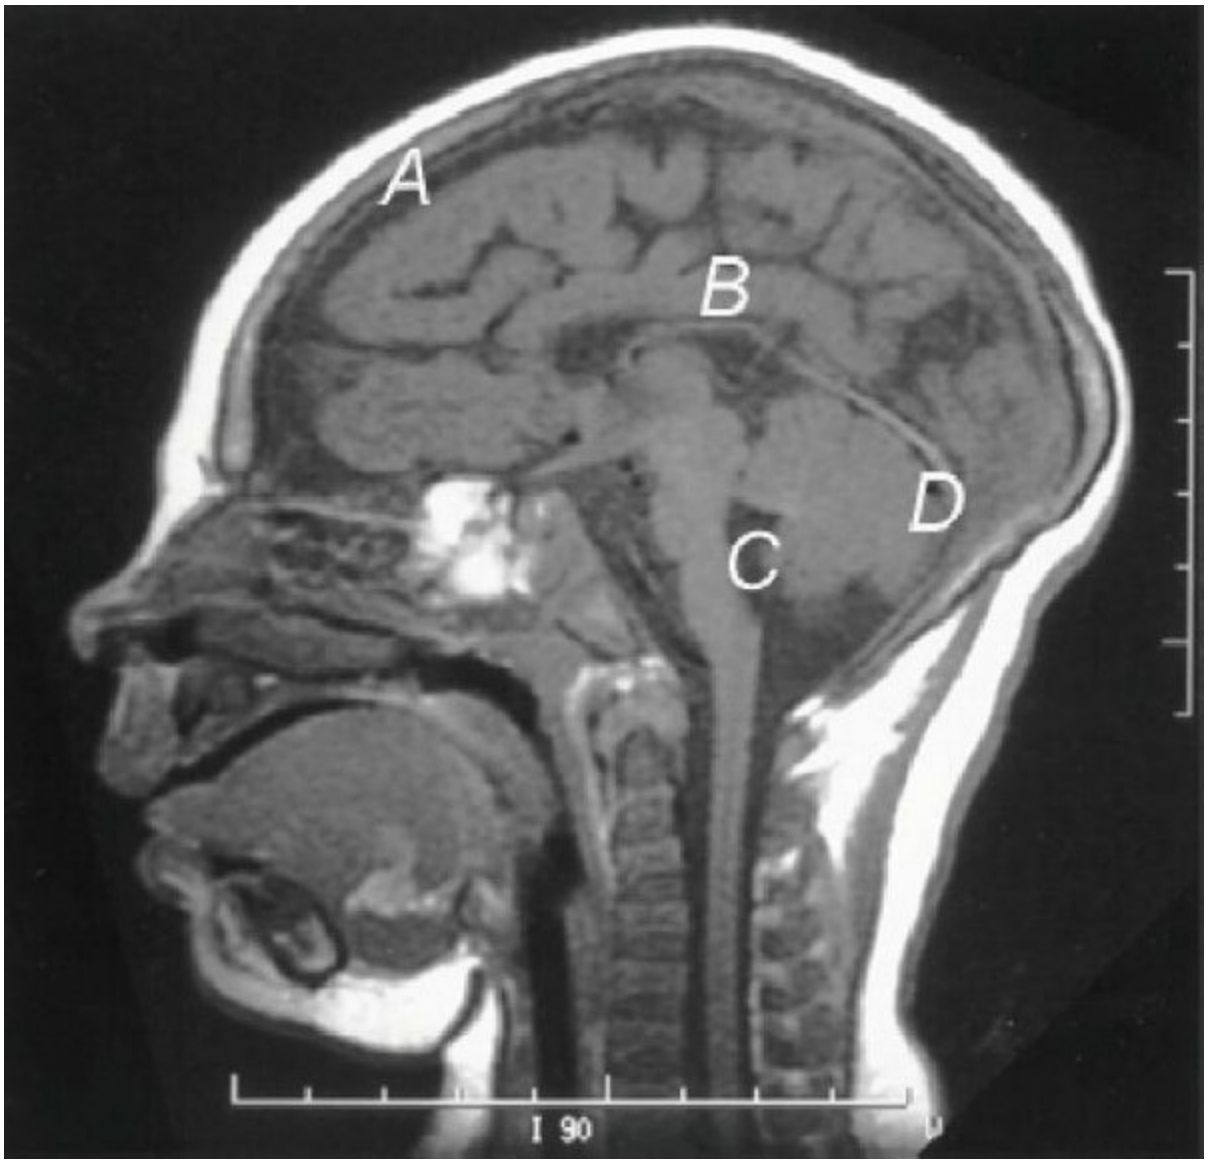

FIGURE 18.7 T1-weighted magnetic resonance imaging (MRI) scan of the brain of a 10-month-old child with congenital LCMV infection. The child had severe developmental delays, spastic quadriparesis, and medically intractable epilepsy. The MRI scan reveals microcephaly, a lissencephalic frontal lobe (*A*), and hypoplasia of the corpus callosum (*B*), the brainstem (*C*), and the cerebellum (*D*). (Courtesy of D. Bonthius, University of Iowa.)

In immunosuppressed organ recipients, LCMV infection can be fatal.[56,57,116,239] Of 17 recipients described to date, 13 died of multisystem

organ failure with LCMV-associated hepatitis as a prominent feature. Two surviving patients were treated with ribavirin. Initial illness in immunosuppressed patients is similar to the disease observed in immunocompetent patients (as described above): fatigue, headache, and GI-associated signs/symptoms (abdominal pain, anorexia, nausea, vomiting, diarrhea). However, in most immunosuppressed patients, the disease progresses to include CNS manifestations (meningoencephalitis, encephalopathy, encephalitis, confusion, seizures with myoclonus), hepatitis, and multisystem organ failure. Hypoxia and respiratory distress with pulmonary infiltrates have been reported in some cases as well as atrial fibrillation. Clinical findings include elevated transaminase (AST and ALT) levels, leukopenia, and/or thrombocytopenia. Elevated creatinine levels and hypotension are seen in some patients. Similarly to immunocompetent patients with CNS invasion with LCMV, CSF of immunosuppressed cases contains elevated protein levels, low glucose levels, and increased leukocyte numbers.

New World Mammarenaviral Hemorrhagic Fevers

Disease begins insidiously after an incubation period of 1 to 2 weeks. Initial symptoms/signs often include fever and malaise, headache, myalgia, epigastric pain, and anorexia. After 2 to 4 days, signs become increasingly severe with multisystem involvement: prostration and GI disturbances such as abdominal pain, nausea and vomiting, constipation, or mild diarrhea. In some cases, dizziness, photophobia, retro-orbital pain, or disorientation may also occur, and the earliest signs of vascular damage, such as conjunctival injection, skin petechiae, mild (postural) hypotension, or flushing over the head and upper torso, may appear. During the 2nd week of illness, about 20% to 30% of patients develop more severe hemorrhagic and/or prominent neurologic manifestations or secondary bacterial infections. Neurologic manifestations include seizures, convulsions, tremor of the hands and tongue, and, less frequently, delirium, coma, encephalitis, and meningoencephalitis. Typical hemorrhagic manifestations are bleeding from mucous membranes (gums, nose, vagina/uterus, GI tract) and ecchymoses at needle puncture sites. However, blood loss is minor overall. Following shock, death usually occurs 7 to 12 days after disease onset.

Typical clinical laboratory findings are leukopenia and

thrombocytopenia. AST and ALT levels are usually normal or slightly elevated. The electrocardiogram may be nonspecifically abnormal, and chest radiography is usually normal in the absence of secondary infections.[8,82,151,275,311,337,353]

Patients who survive begin to improve during the 2nd week of disease onset as the appearance of neutralizing antibodies signals the beginning of the immune response.[81] Convalescence often lasts several weeks with polyuria, fatigue, alopecia, and dizziness.

NW mammarenaviral HF caused by CHAPV, GTOV, MACV, or SBAV is clinically similar to AHF.[69,83,86,238,370] In BHF patients (particularly severe cases), proteinuria and elevated hematocrit are typical during the peak of hemorrhagic manifestations. During convalescence, beau lines in digital nails are common.[238,370] In VeHF cases, pharyngitis is more prominent, and hearing loss in convalescence has been reported.[83,305,385] CNS manifestations, including encephalitis and convulsions, are associated with poor VeHF prognosis.[83] Furthermore, VeHF initially presents with symptoms and signs that are indistinguishable from dengue fever, also common in Venezuela, especially in urban areas.[83]

Only a single naturally acquired infection with SBAV has been identified, and the disease resembles other NW mammarenaviral HF except for extensive liver necrosis.[69]

DIAGNOSIS

Lassa Fever

LASV is readily isolated from blood during the febrile phase of LF disease up to 14 or more days after onset of disease. LASV can be detected in necropsy tissues or Vero cells infected with tissue homogenates.[126,192] LASV antigen can be detected by enzyme-linked immunosorbent assay (ELISA) capture in serum, and serum samples may become antigen negative with the appearance of IgM antibodies.[21] Detection of LASV antigen by ELISA is robust, is reliable, and can be completed in short time. LASV-specific antibodies can be detected by indirect immunofluorescence assay (IFA) using

LASV-infected Vero cells, but the test is prone to discrepancies between laboratories. IFA IgG "seroreversion" has been reported and is thought to represent loss of antibody by previously seropositive individuals.[21,182,255] LASV-specific IgG and IgM can be detected by ELISA.[287] IgG ELISA antibody persists for long periods, whereas IFA antibody appears to wane below detectable limits within several years. ELISA IgM titers appear earlier and persist longer than IFA IgM titers.

Reverse transcriptase-PCR (RT-PCR) can detect virus RNA in blood with high sensitivity.[87,380] A recently available, recombinant Lassa virus (ReLASV) rapid diagnostic test (RDT)[27] is based on a lateral flow immunoassay using paired monoclonal antibodies to the Josiah strain of LASV (lineage IV). This test performed better than currently available RT-PCR detection assays, supporting the important role that recombinant antigen–based LASV immunoassays can play in the diagnosis of LASV infection.

Nanopore sequencing using the MinION device has been successfully used for genetic analysis of pathogens in field studies in regions with very limited resources[185] and was implemented to genetically characterize LASV isolates during the 2018 upsurge of LF cases in Nigeria.[196] The ability of this portable sequencing technology to genetically characterize *in situ* RNA viral samples will identify in real-time cases of LASV infection associated with disease symptoms. This approach, applicable to other arenaviruses, will represent a major breakthrough in the diagnosis of arenaviral HF.

Lymphocytic Choriomeningitis

During the acute febrile phase, LCMV can be isolated from blood. Viremia may also be detectable during meningitis symptoms, but CSF contains higher viral load.[109] Polymerase chain reaction (PCR) tests applied to CSF samples have been successfully used.[293] LCMV-specific IgM antibodies can be usually detected by ELISA and IFA in serum or CSF, or both, during acute cases.[84,85,113,220,225] As neutralizing antibodies appear late after onset of disease and are technically demanding to demonstrate, their value as a diagnostic tool is lessened.[220]

New World Mammarenaviral Hemorrhagic Fevers

Virus can be isolated from blood by inoculation of newborn hamsters or laboratory mice during the acute febrile phase up until 10 to 12 days after onset of symptoms.[34] Cocultivation of peripheral blood mononuclear cells with Vero cells seems to be more sensitive than suckling laboratory mouse or Vero cell inoculation for isolation of JUNV from AHF patients.[5] Virus can also be isolated from necropsy tissues, except from the brain. In rodent studies, virus is readily isolated from blood, urine, throat swabs, and autopsy tissue samples.[193,194] Antigen-capture ELISA detects viral antigen in blood and tissues from patients with JUNV, MACV, SBAV, or GOTV infection. Antigen detection is also possible in rodent urine, blood, and throat swabs during ecologic surveys.[271] Serologic diagnosis of AHF and BHF is usually made by complement fixation (CF)[237,405] and IFA,[249,307] but the limited specificity and sensitivity of these tests pose problems. The plaque neutralization test can distinguish between antibodies to JUNV and MACV and has been used for evaluation of convalescent plasma units intended for therapeutic use in AHF.[103] The ELISA test is the most useful and practical for rapid detection of IgM and IgG antibodies in a clinical setting and sero-epidemiologic surveys.[134,176] Antibodies detected by ELISA can persist for ≥30 years in some cases.

PREVENTION AND CONTROL

Medical Management

Supportive therapy is important in the management of patients with arenaviral HF.[306] Avoidance of travel and general trauma, gentle sedation and pain relief with conservative doses of opiates, the usual precautions for patients with bleeding diatheses (e.g., avoiding intramuscular injections and acetylsalicylic acid), and careful maintenance of hydration are indicated. Bleeding can be managed by platelet transfusions and factor replacement as indicated by clinical judgment and laboratory studies. Management of patients that undergo shock is difficult. Hematocrit readouts suggest a generalized vascular permeability problem but of modest magnitude. Infusion of crystalloids should be carefully considered as it carries a high risk of pulmonary edema. The low cardiac output observed in animal models of

AHF and clinical observations with human cases of AHF support the use of Swan-Ganz catheterization. The late neurological syndrome seen after immune plasma treatment of AHF is generally self-limited, and patient full recovery is accomplished with supportive therapy. LCMV ependymal infection and inflammation may cause acute hydrocephalus and a need for surgical shunting.[213] Steroids have not been evaluated in this condition.

Patients with arenaviral HF are considered to pose a minimal risk of contagion in the early stages of disease. Disease progression is associated with more extensive viral infection of target organs and increased viremia, which facilitate opportunities for dissemination. Nosocomial outbreaks and infection of multiple contacts have occurred when the index case corresponded to a severely ill patient, but they are uncommon.[52] The most dangerous exposure is parenteral and must be avoided through staff training. Protection to caregivers and other patients should be enhanced by implementing respiratory protection against small particle aerosols.[15] Special precautions are indicated when blood and other body fluids are handled in the clinical laboratory.

Close personal contacts should be monitored for fever for a period of 3 weeks. Patients may excrete virus in urine or semen for weeks after recovery from disease. Body fluids should be monitored for infectivity before the patient is released. In addition, counseling should be provided emphasizing protection of sexual partners and the use of disinfectant prior to use of toilets.

Antiviral Drugs

The prophylactic and therapeutic value of the nucleoside analog ribavirin (Rib) against several arenaviruses is well supported by results from both cell culture and all arenaviral HF animal models in which Rib has been studied.[79,181,200,203,352,363] Importantly, Rib has reduced both morbidity and lethality in human cases of LF. However, the need of intravenous administration for optimal efficacy, poor penetration into the CSF, and side effects, including anemia and congenital disorders, pose some limitations to the use of Rib. The mechanisms by which Rib exerts its antiarenaviral action are not fully understood but are likely to involve different steps of the virus life cycle.[294] Rib is efficacious against LF and remains the therapeutic agent of choice to treat cases of LF with a poor prognosis. Some evidence indicates

that Rib is also efficacious against AHF,[105] and treatment with Rib of human MACV and SBAV infections has shown clinical benefits.[16,203]

Prophylaxis with Rib for 7 to 10 days delayed the onset of acute disease in guinea pigs experimentally infected with PICHV or LASV, whereas increasing Rib prophylactic treatment to 14 days prevented disease.[229,363,367] Rib prophylaxis for 14 to 21 days prevented acute disease in JUNV-infected domesticated guinea pigs, but it did not prevent JUNV entering the CNS and causing fatal encephalitis.[200] Thus, high-risk exposures to arenaviruses are probably best managed by implementing treatment at the first sign of fever, rather than dealing with the uncertainties of prophylaxis and its potential risks.

Besides Rib, several compounds have been reported to have antiarenaviral activity in cultured cells, but their safety and efficacy *in vivo* remain to be determined.[271] Recent high-throughput screening (HTS) identified a potent small molecule inhibitor of TCRV and several other NW arenaviruses.[28] Likewise, such cell-based screening using pseudotyped virion particles bearing the GP of highly virulent arenaviruses identified several small molecule inhibitors of virus cell entry mediated by LASV GP.[218] The broad-spectrum RdRp inhibitor favipiravir[144,264,344] and the GP-mediated fusion inhibitor ST-193[214] have shown promising results providing protection of domesticated guinea pigs from otherwise lethal LASV infection. Nevertheless, the identification and characterization of additional safe and effective antiviral drugs against human pathogenic arenaviruses can facilitate the implementation of combination therapy to combat human pathogenic arenaviruses. This approach is known to counteract the emergence of drug-resistant variants often observed with monotherapy strategies.[90]

Using arenavirus molecular genetics, investigators are developing screens to identify drugs targeting specific steps of the arenavirus life cycle. These drugs include direct-acting antivirals that target specific viral gene products and functions and drugs that target host cell factors required for the completion of virus replication cycle. Direct-acting antivirals are likely to be well tolerated by the infected host cell, but the rapid emergence of drug-resistant variants can compromise their use.[90] Combination therapy has proven effective to reduce and delay the selection of escape mutants, but does not entirely solve this problem, as illustrated by the selection of hepatitis C

virus-resistant variants in patients who experienced virologic failure with asunaprevir and daclatasvir.[197] In contrast, intrahost virus evolution is unlikely to result in viral variants able to escape from host-targeting antivirals (HTAs). Moreover, related viruses are likely to rely on the same host machinery, thus providing an opportunity for the development of broad-spectrum antiviral therapeutics. HTAs can be associated with side effects that might be manageable during acute HF caused by arenaviruses, as the duration of the treatment would be rather short. An attractive host cell target for the development of broad-spectrum antiarenaviral drugs is SKI-1/S1P responsible for processing of arenavirus GPC into GP1 and GP2.[211,298,333,334,384] Several peptide-and non–peptide-based S1P inhibitors have been documented, but their lack of cell permeability would pose severe limitations to their use as antiviral drugs. The small molecule PF-429242 is reported to be a potent S1P inhibitor both *in vitro* and in cell-based assays,[161,162] and PF-429242 efficiently inhibits S1P-mediated processing of arenavirus GPC, which correlated with the drug's ability to interfere with propagation of both LCMV and LASV in cultured cells.[384]

Advances in arenavirus molecular genetics have also enabled the generation of recombinant arenaviruses expressing a variety of reporter genes that can be used in high-throughput screens to rapidly identify drugs that inhibit arenavirus multiplication, including LASV and JUNV.[48,99,101,274,402] These cell-based infection screens can be used for drug repurposing approaches[186,266] with the appeal that significantly less time and resources are required to advance a candidate drug to the clinic.

Antibody Therapy

Treatment of JUNV infections with convalescent plasma has been studied in humans and experimental animals and is quite effective, with reduction of mortality from 15% to 30% to 1% to 2% if initiated within the first 8 days of illness.[103,242] About 10% of patients treated with convalescent plasma may later (3–6 weeks) exhibit neurologic signs including fever, headache, cerebellar tremor, and cranial nerve palsies. This late neurological syndrome is usually self-limited. These patients exhibit higher and later peaks of serum antibody titers, and increased serum/CSF antibody ratios, compared to treated patients who do not develop neurologic symptoms, suggesting the prior

invasion of the CNS by virus.

Studies in animals suggest that passive antibody therapy would probably be useful to treat MACV and GOTV infections.[96,201] Early studies in animal models of LF required higher titers of virus-specific antibodies than MACV and GTOV infections, and treatment feasibility was contingent on availability of highly active preparations.[183,184] Experimental studies of passive protection by monoclonal antibodies have been successful in LCMV infection models.[13,14,406] Importantly, LASV GPC-specific recombinant human monoclonal antibodies derived from survivors of LF with strong neutralization profiles in cell-based assays exhibited robust therapeutic efficacy in a domesticated guinea pig model of LASV infection. These data support the feasibility of antibody-based therapy against LF.[74] Interestingly, the characterization of these antibodies revealed that most of them target quaternary epitopes that are displayed only in the context of the prefusion GPC trimer.[331] In contrast, in NW mammarenavirus infections, the GP1 subunit alone is the main target of neutralizing antibodies that act by blocking GP1 binding to TfR1.[241,420,421] Immune plasma therapy of LF is known to be complicated by a high prevalence of HIV-1 and *Plasmodium* spp. in the Western African population.[89]

Vaccines

The JUNV live attenuated Candid #1 strain was generated by serial passages of the JUNV XJ strain in laboratory mouse brains. The safety, immunogenicity, and protective efficacy of Candid #1 were demonstrated in preclinical studies in both domesticated guinea pigs and rhesus monkeys (*Macaca mulatta* Zimmermann, 1780).[261,262] Vaccination campaigns targeting agricultural workers in the JUNV-endemic area have shown Candid #1 to be an effective and safe vaccine in humans,[243,258] and it was licensed in 2006 for use exclusively in Argentina. Some concerns about the Candid #1 vaccine are the limited information about the viral determinants and mechanisms of Candid#1 attenuation and its potential genetic instability illustrated by a 1,000-fold range of virulence among Candid #1 clone isolates from blood of vaccinated rhesus monkeys.[102]

Among known mammarenaviruses, LASV poses the most concern to human health due to morbidity and lethality associated with LF together with

the vast LASV-endemic regions and size of the population at risk in Western Africa. Accordingly, LF has been included on the revised list of priority diseases of the WHO R&D Blueprint, and therefore, accelerated research and development for LASV vaccine is encouraged.[22,356] The target product profile from WHO seeks a preventive LASV vaccine for healthy adults and children that would protect against strains from major lineages I to IV of LASV.[33] In addition, the vaccine should meet WHO prequalification criteria, including low cost, high efficacy, and thermostability, and be environmentally and user-friendly.

Studies involving LF survivors and animals experimentally infected with LASV indicate that early and robust virus-specific $CD4^+$ and $CD8^+$ T-cell responses,[12,118,148] rather than the presence of neutralizing antibodies, which appear late after infection and at low titers,[338] are the best correlates of recovery and protection. Accordingly, in experimentally vaccinated and exposed crab-eating macaques (*Macaca fascicularis* Raffles, 1821), depletion of $CD8^+$ T cells abolished protection of vaccinated monkeys, whereas $CD4^+$ T-cell depletion resulted in partial protection.[112] LASV-specific antibodies can be detected in individuals shortly after recovery from LF, but become undetectable after several months,[119] whereas these LF survivors retain robust LASV-specific $CD4^+$ T-cell responses.[148] Although antibodies do not appear to contribute to viral control and recovery during acute LASV infection, neutralizing monoclonal antibodies genetically engineered from B cells of LF survivors can be successfully used for immunotherapy.[74,331] These data suggest that an ideal LASV vaccine should trigger both long-term robust cell-mediated immunity (CMI) and humoral responses following a single immunization. These responses are often induced by live attenuated vaccines (LAV); LAV, therefore, represent a highly promising approach to control LF.

LASV LAV candidates based on vaccinia virus,[11,66,118] vesicular stomatitis Indiana virus (VSIV),[133,138] Mopeia virus (MOPV),[53,202] ML29,[230,235] and yellow fever virus 17D[36,188] vectors and alphavirus replicons[315,396] have been tested in NHPs.[107,231,232] The Coalition for Epidemic Preparedness Innovations (CEPI) (http://cepi.net) was created as a nonprofit organization to accelerate vaccine development against emerging epidemic infections when the commercial market is insufficient to justify

private investment.[312] One of the LASV vaccine candidates supported by CEPI is based on a measles virus vector that has shown promising results in human clinical trials providing antibody-based protection.[325] Whether this platform would be effective for development of a vaccine against LASV with predominant T cell–mediated mechanism of protection remains to be determined. Another CEPI-supported platform is DNA-based immunization, an approach that is efficacious in the crab-eating macaque model of LF.[55] However, it may take years for the advances in plasmid formulations and subsequent delivery required for licensure of the first DNA vaccine against LF.

Two additional CEPI-supported platforms are recombinant VSIV (rVSIV)-based LASV vaccines. The first one, "rVSVΔG/LASV-GPC," uses the same concept behind the design of the "rVSVΔG/ZEBOV-GP" vaccine that showed promise in a ring vaccination trial against Ebola virus disease in Guinea. The vaccine's detailed efficacy profile remains to be determined.[165,166,268] A single injection of "rVSV/LASV-GPC" experimental vaccine, in which VSIV G was replaced with LASV-GPC, fully protected guinea pigs and NHPs against LASV strains from the same clade.[138,343] The "rVSVΔG/LASV-GPC" immunization did not induce detectable T-cell responses before virus exposure, and low IgG humoral responses detected by ELISA were found in three of four vaccinated animals. After LASV exposure, neutralizing antibodies were detected in all four macaques. Despite these promising results, there are still some safety concerns because of reported side effects in individuals vaccinated with "rVSVΔG/ZEBOV-GP." These side effects included postvaccination arthritis, vector RNAemia, and detection of infectious vaccine virus in the skin of vaccinated individuals.[173] The other rVSIV-based LASV vaccine candidate is based on the VesiculoVax platform licensed by Profectus BioSciences. This platform was developed to further improve safety of rVSIV vector by N gene translocation and truncation of the VSIV G cytoplasmic tail (CT1). The attenuated rVSV-N4CT1 vector is immunogenic in NHPs and induces only mild inflammatory response after intrathalamic inoculation.[65]

A number of other LASV vaccine platforms are in preclinical development. The reassortant ML29, an LAV vaccine, carries the L segment from nonpathogenic MOPV and the S segment from LASV strain Josiah. This vaccine induces, after single immunization in domesticated guinea pigs,

a robust cross-reacting and protective, sterilizing cell-mediated immune response against strains from distantly related LASV lineages.[54,235] In addition, ML29 is highly stable and safe in animal models of LF, including immunocompromised NHPs.[418,419] This finding is relevant because the LASV vaccine target population will likely include individuals with some degree of undiagnosed immunosuppression due to the high prevalence of malaria and HIV-1 infections in Western Africa. The use of a trisegmented (r3) mammarenavirus platform[99] would allow the incorporation into attenuated forms of ML29 of additional antigens from distantly related LASV strains to expand the cross-protection range. Progress in arenavirus molecular genetics can also facilitate the incorporation of additional safety measures into LASV LAVs, including the use of codon deoptimization[60] and reorganization of the coding[59] and noncoding IGRs.[177] These strategies result in the generation of highly attenuated and stable versions of LCMV that are able to induce protective immunity against otherwise lethal exposure with wild-type LCMV.

PERSPECTIVE

Since the fortuitous discovery of LCMV more than 70 years ago, arenaviruses have served as important model systems for the study of host–virus interactions. These studies illuminate a wide range of principles, including persistent infection, virus-induced immunopathological disease, cytotoxic T-cell recognition, and immunologic memory. Despite this wealth of knowledge, arenavirus infections of humans remain a significant public health risk in much of the world. Prospects for control of these diseases remain remote due to poor diagnostic protocols and sparse resource allocation for vaccine development and other control measures. Recent laboratory developments have advanced our understanding of arenavirus structure and biology. New vistas have been opened into arenavirus prevalence and distribution as a result of the application of deep-sequencing protocols applied to this interesting group of viruses. As the application of new approaches to antivirals and vaccines targeting arenaviruses continues, the lessons learned may provide a useful model for other geographically localized viral diseases where the knowledge exists, but where the financial resources for control or eradication are limited.
