Preface

In the early 1980s, Bernie Fields originated the idea of a virology reference textbook that combined the molecular aspects of viral replication with the medical features of viral infections. This broad view of virology reflected Bernie's own research, which applied molecular and genetic analyses to the study of viral pathogenesis, providing an important part of the foundation for the field of molecular pathogenesis. Bernie led the publication of the first three editions of *Virology*, but he unfortunately died soon after the third edition went into production. The third edition became *Fields Virology* in his memory, and it is fitting that the book continues to carry his name.

A number of changes and enhancements are being introduced with the seventh edition of *Fields Virology*. The publication format of *Fields Virology* has been changed from a once every 5 to 6 years, two volume book to an annual publication that comprises approximately one-fourth of the chapters organized by category. The annual publication will be both a physical book volume and importantly an eBook with an improved platform. Using an eBook format, our expectation is that individual chapters can be easily updated when major advances, outbreaks, etc., occur. The editorial board organized a four-volume series for the seventh edition consisting of volumes on Emerging Viruses, DNA Viruses, RNA Viruses, and Fundamental Virology, which will be published on an annual basis, with the expectation that the topics will then cycle every 4 years creating an annualized, up-to-date publication. Each volume will contain approximately 20 chapters.

The first volume of this seventh edition of *Fields Virology*, entitled *Emerging Viruses*, has been edited principally by Sean Whelan. There have been continued rapid advances in virology since the previous edition 6 years ago, and all of the chapters in the *Emerging Viruses* volume are either completely new or have been significantly updated to reflect these advances. In this seventh edition, we have chosen to highlight updated lists of references while maintaining older classics. The main emphasis continues to be on viruses of medical importance and interest, but other viruses are

described in specific cases where more is known about their mechanisms of replication or pathogenesis.

We wish to thank Patrick Waters of Harvard Medical School and all of the editorial staff members of Lippincott Williams & Wilkins for all their important contributions to the preparation of this book.

CHAPTER 1

Virus Evolution

Jemma L. Geoghegan • Edward C. Holmes

Introduction
The Origins of Viruses and Patterns of Virus Evolution
- The Origins of Viruses
- The Time Scale of Virus Evolution
- Codivergence and Cross-Species Transmission in Virus Evolution
- Metagenomics and Virus Evolution

Processes of Virus Evolution
- Mutation and Nucleotide Substitution in Viruses
- Natural Selection and Genetic Drift in Virus Evolution
- Intra- and Interhost Diversity and Transmission Bottlenecks
- Evolutionary Interactions: Epistasis, Defecting Interfering Particles, and Complementation
- The Evolution of Viral Recombination
- The RNA Virus Quasispecies

Patterns and Processes of Viral Genome Evolution
- The Evolution of Virus Genome Size
- The Evolution of Genome Organization
- Lateral Gene Transfer and Modular Evolution

INTRODUCTION

Although Charles Darwin preempted many of the great questions in evolutionary biology, he wrote little about viruses. Of course, viruses were

not formally identified until a full decade after Darwin's death and, aside from some brief discussion of the origins of yellow fever, his writings make scant reference to what we now know are diseases caused by viruses. This is a great historical shame because it seems certain that Darwin would have held viruses up as some of the best exemplars of evolution by natural selection, with the evolutionary process sometimes so rapid that it can be effectively followed in "real time" by observant researchers.[91,100,236]

Although evolutionary analysis arrived relatively late in the science of virology, the study of virus evolution has become one of the most rapidly growing and successful aspects of modern microbiology. The blossoming of evolutionary virology is largely due to two developments. First, viruses, and especially those that possess RNA genomes, have become remarkably powerful research tools for the study of evolutionary processes. The utility of RNA viruses in this respect is a function of the fact that they usually evolve extremely rapidly, they are easy to manipulate *in vitro* and *in vivo*, mutations in their genomes can have large and measurable effects on phenotype, and they possess such small genomes that the mutations associated with any phenotypic change can sometimes be determined relatively easily.[68,247] It is therefore no surprise that a growing number of evolutionary researchers are turning to viruses as model systems. For example, studies of viruses represent one of the few cases in which biologists have been able to achieve two of the great aims of modern evolutionary genetics: to measure the fitness effects of individual mutations,[3,227,248] and to determine the nature of the epistatic interactions between these mutations.[228] Second, the rapidity of virus evolution has acted as a direct stimulus for the development of phylogenetic methods that are able to incorporate information on the exact time of sampling of the sequences in question, allowing the spread of viruses through populations to be carefully tracked and in turn revolutionizing molecular epidemiology.[53,100,152] Similarly, many of the computer programs designed for the evolutionary analysis of genome sequence data were first applied to viruses, such that determining the origin and pathways of spread of specific viruses over epidemiologic time has become a relatively exact science with a myriad of potential applications. The advent of next-generation sequencing and metagenomics promises even more rapid advances in this area, potentially enabling the analysis of many thousands of sequences with detailed associated clinical and epidemiological metadata.[115] An important

spin-off from these studies has been new insights into the patterns and processes of virus evolution.[110] In sum, although their focus is very different, the combination of experimental analyses of model viruses as a means to understand the intricacies of the evolutionary process and studies of molecular epidemiology and phylogeography based on the comparative analysis of virus genome sequence data to document patterns of virus spread has told us a great deal about the nature of virus evolution (Fig. 1.1). Evolutionary virology has blossomed into a well-developed science.

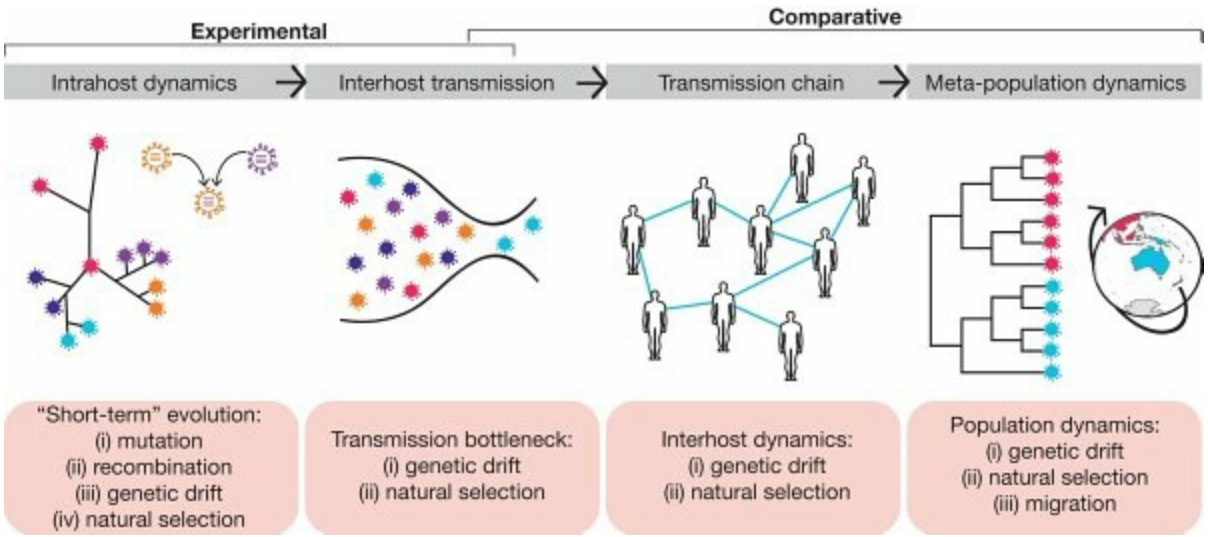

Figure 1.1 The different scales over which studies of virus evolution can be performed, using both experimental and comparative (i.e., largely phylogenetic) approaches, and the evolutionary processes that occur at each scale. These range from analyzing short-term intrahost evolution, through the interhost transmission bottleneck, to analyses of the initial host contact network within an infected population, and finally out to the meta-population scale, representing long-term virus evolution as often considered in the fields of molecular epidemiology and phylogeography.

Despite advances on multiple fronts, some fundamental aspects of viral evolution remain unknown, contentious, or both, which will be highlighted in

this chapter. There are still major debates over some of the key mechanisms of evolutionary change in viruses, particularly the exact roles and frequency of mutation, natural selection, genetic drift and recombination as forces of evolutionary change.[110] Similarly, although we know a great deal more about the origin of viruses than we did a generation ago, particularly through the analysis of highly conserved protein structures, exactly when and how viruses first evolved, whether this occurred before or after the appearance of the first cellular organisms, what a precellular world might have looked like, and even if viruses should be classified as living are sources of major debate.[81,141,162,184] In part, this debate highlights our profound ignorance of the total universe of viruses—the virosphere. For example, does the apparent absence of RNA viruses in *Archaea* (besides a single highly debatable case[23]) mean that they never existed in these organisms, that they have been selectively removed, or that they are too divergent in sequence to detect using the standard sequence-similarity searching methods like BLAST? We also remain ignorant of a number of key aspects of the patterns and processes of DNA virus evolution, particularly whether common principles can be applied to DNA viruses that differ so fundamentally in size and genome structure and which likely have different origins, and even how large the genome sizes of the largest DNA viruses can be. It is hoped that the rise of metagenomics will enable us to sample far more of the virosphere, and it has already led to the discovery of a multitude of diverse viruses and a changing view of the fundamental patterns and processes of virus evolution.[240,241] Finally, the time scale of evolutionary history in many viruses is unclear, with very different inferences drawn from the study of virus distributions among hosts and of endogenous viruses, which are usually indicative of ancient origins,[239] or the molecular clock analysis of recently sampled and often rapidly evolving viral genomes, which usually paint a picture of very recent origins.[95,111] Fortunately, metagenomics has already provided important insights into this area (see below).

Aside from their ability to inform on evolutionary processes, there are a variety of practical reasons why the study of virus evolution matters. It is likely that a better understanding of the exact processes of evolutionary change in viruses will assist in the development of improved strategies for their treatment and control and for understanding the origin and spread of newly emerged pathogens. For example, knowledge of the factors that impact

how viruses diffuse at the epidemiologic scale represents useful information for any emergent virus,[115] while knowing whether natural selection or genetic drift largely controls how mutations spread through a population is essential to understanding the likelihood and rate that a specific drug resistance mutation will become established.[150] Similarly, it is likely that a better understanding of the origin of viruses will be essential to obtaining a more precise picture of the earliest events in the early history of life on earth, including the genesis of both RNA and DNA, as it seems reasonable to suppose that some of the earliest replicators resemble what we now know as viruses.

The future of evolutionary virology is strong. The development and continued refinement of next-generation sequencing and metagenomic methods will doubtless provide unprecedented amounts of data for evolutionary study and stimulate the development of new analytical methods for use in all genetic systems. Innovations in experimental studies of virus evolution will continue, addressing ever more intricate questions, increasingly considering *in vivo* systems, and providing broad-scale evolutionary insights particularly when linked with comparative data. Metagenomic studies of the virosphere will give a powerful new perspective on virus biodiversity and evolution, providing important new information on virus ecology, origins, and cross-species transmission and emergence. It therefore seems easy to predict that our understanding of viral evolution a decade from now will be very different, and more complete, than it is today.

THE ORIGINS OF VIRUSES AND PATTERNS OF VIRUS EVOLUTION

The Origins of Viruses

Of all topics in the study of virus evolution, determining exactly how and when viruses first evolved is perhaps the most challenging. The main hindrance to progress in this area is that viruses likely originated so long ago, perhaps even before the first cellular species, that the signal of ancient evolutionary history that can be recovered through phylogenetic analysis has largely been eroded. This is particularly true for RNA viruses in which rapid

rates of evolutionary change ensure that phylogenetic signal is quickly lost. Accordingly, each individual amino acid and nucleotide site in a viral genome has accumulated so many substitutions since its origin that accurate phylogenetic inference, and hence establishing evolutionary links, becomes a highly challenging, if not impossible, task. For this reason, sequence-based phylogenies have proven to be blunt tools for the study of viral origins, although signs of common ancestry may still reside in aspects of protein structure.

Despite the inherent limitations to understanding viral origins, a number of important theories have been proposed for the genesis of both RNA and DNA viruses, which continue to be debated to this day. Two such theories currently dominate discussions in this area; first, that viruses have a precellular origin, such that they are billions of years old, and may have even contributed to some of the fundamental architecture of the first cells; second, that viruses evolved after the first cellular organisms as “escaped genes” that acquired capsid proteins and the ability to replicate autonomously[110] (Fig. 1.2). Although a third hypothesis—that viruses are regressed copies of cellular species that have shed those genes whose functions are provided by the host—has also been proposed, most notably in the case of the giant mimiviruses of amoeba,[13,144] this hypothesis does not appear to be of general applicability. For example, the gene contents of RNA viruses and cellular species have almost no overlap, whereas under the regressive theory, virus genes should have their ancestries in cellular genomes. In addition, although often discussed as such, these theories of viral origins are not mutually exclusive, and it is plausible that while some viruses predate the appearance of the first cells, others appeared more recently.

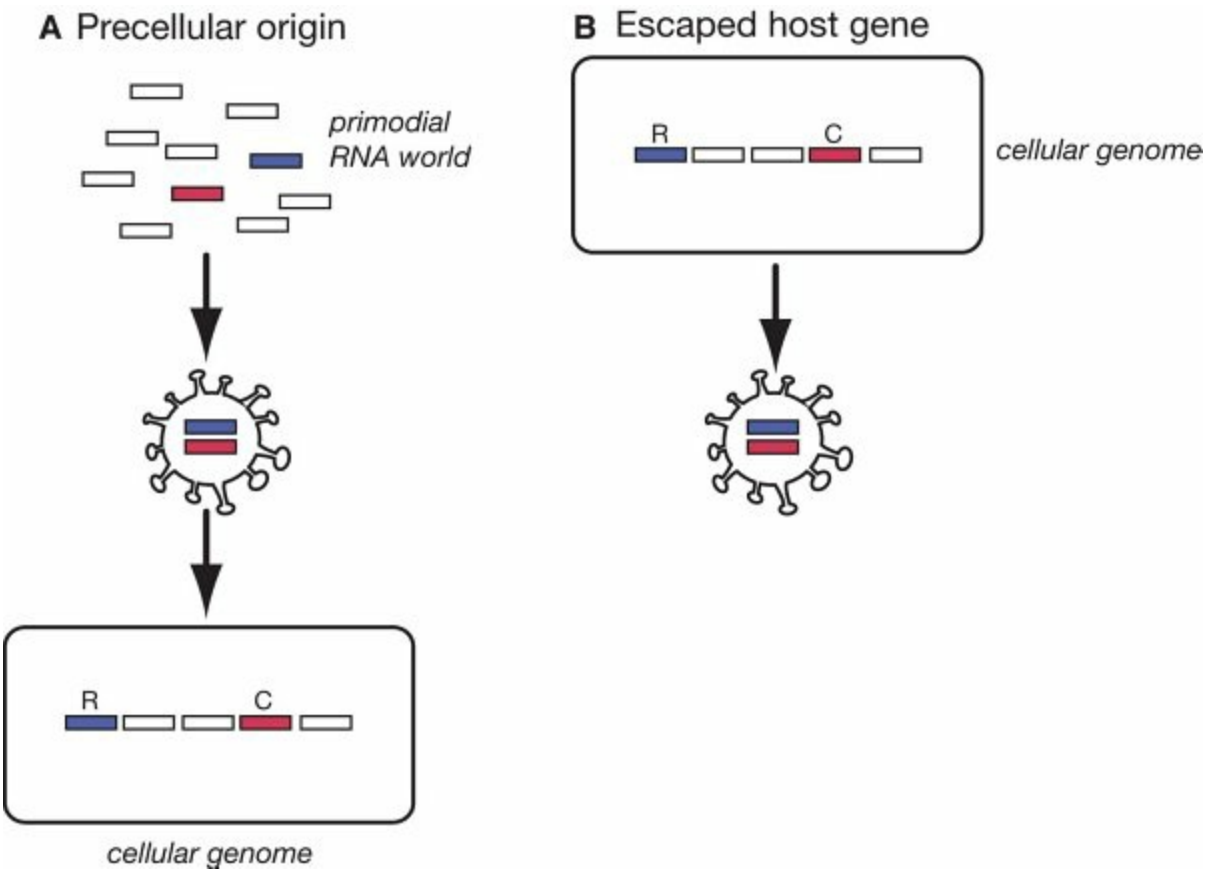

Figure 1.2 Schematic representation of two competing models for the origin of viruses. **A:** The precellular origin theory, in this case depicting the origin of RNA viruses. **B:** The escaped gene theory. Cellular genomes are represented by *rounded rectangles*, and the simplest model virus is shown here to comprise replicase (R) and capsid (C) genes only. (Adapted from Holmes EC. *The Evolution and Emergence of RNA Viruses*. Oxford: Oxford University Press, 2009, by permission of Oxford University Press.)

For many years, the escaped gene theory dominated discussions on virus origins.[110,162,185] Support for this theory was often based on the idea that as viruses are, by definition, obligate parasites of host cells now, they must have always been so, such that cells must have evolved before viruses. However, this idea is easy to refute. Because it is commonly thought that the first replicating molecules resided in an "RNA world" that existed before the evolution of DNA,[78] it is easy to believe that the lineages that gave rise to

modern RNA viruses originated from such ancient self-replicating RNA molecules and parasitized cells at a later date. Important evidence for the existence of an RNA world is that ribonucleotides can be synthesized *de novo* under conditions that might replicate those of early Earth.[210] In most cases, the escaped gene theory was also taken to mean that viruses could have escaped from host cells on multiple occasions. This is an attractive idea given the huge (and growing) phylogenetic and phenotypic diversity seen in viruses and that there is no one gene that characterizes all viruses. For example, an early idea was that eukaryotic viruses had escaped from eukaryotic cells, while bacteriophages had escaped from bacterial cells.[211] Similarly, it is possible that RNA, DNA, and perhaps retroviruses represent independent episodes of host gene escape, and it is clear that small ssDNA and large dsDNA viruses have little in common, strongly suggestive of independent origins.

However many different origins are postulated, the same general mechanisms are thought to have occurred: that a host gene that possessed or acquired the ability to self-replicate escaped from the cell, acquiring a protein coat on the way, eventually evolving into an autonomously replicating entity. For example, RNA viruses, particularly those with single-strand positive-sense RNA (ssRNA+) genomes, might be descended from escaped cellular messenger RNA (mRNA) molecules that either possessed or evolved RNA polymerase activity, while DNA viruses could be descended from DNA transposable elements or bacterial plasmids. It is also the case that all forms of the escaped gene theory make two important predictions: first, that most virus genes, including the capsid and replicase proteins, ultimately have their ancestries in cellular genomes, and second, because escape events could have occurred multiple times, viruses do not have a single (i.e., monophyletic) origin. In other words, there is no single phylogeny linking all types of virus, as is easily argued from the huge diversity of viruses described today. In theory, both of these predictions are testable, although in practice this is greatly inhibited by the enormous sequence divergence among viruses.

A number of pieces of data have been used to support the idea that viruses had multiple origins after the appearance of cells. At the level of primary amino acid sequence, there is currently no robust sequence-based phylogeny for either RNA or DNA viruses, nor any gene that contains statistically significant sequence similarity at such vast evolutionary

distances. Although there have been attempts to infer the evolutionary history of RNA viruses based on phylogenetic analyses of the RNA-dependent RNA polymerase (RdRp), the phylogenies in question are highly uncertain at the deepest branches, such as those linking the different orders of ssRNA+ and ssRNA− viruses, where there is often no more sequence similarity than expected by chance alone, greatly compromising these analyses including reliable sequence alignment.[113,272] Importantly, however, lack of phylogenetic resolution is not the same thing as an absence of common ancestry, and it is more likely that the inability to accurately infer the evolutionary history of all RNA viruses simply reflects extreme levels of sequence divergence. Indeed, it is striking that the RdRp sequences assigned to different RNA virus families still share a number of short, signature, amino acid motifs (such as a highly conserved GDD motif), some of which are also found in the RT protein used by retroviruses.[96,139] Such conservation, albeit fragmentary, suggests that these replicatory proteins are distantly related. Unfortunately, these motifs are too short to allow the inference of robust phylogenetic trees. Even more notable is that recent analyses of protein structures have revealed strong similarities between viruses that exhibit no primary sequence similarity,[71] including between RNA and DNA viruses, that again argues for their common ancestry (see later).

In the case of RNA viruses, early phylogenetic analyses of RdRp sequences combined with information on gene order and content were used to construct higher level classification schemes encompassing multiple viral families. For example, one such early study suggested that RNA viruses be classified into the alpha-like, carmo-like, corona-like, flavi-like, picorna-like, and sobemo-like “supergroups,” each of which is characterized by a conserved gene order, distinctive 5′ and 3′ genome structures, and clustered together in RdRp phylogenies.[96] Similarly, there is now considerable effort devoted to establishing orders and even higher level taxonomic ranks in viruses, although how these relate to each other is far less certain because of the huge genetic distances involved. Indeed, all-encompassing RdRp phylogenies are of debatable validity.[113,270] For example, the ssRNA viruses are now classed as a phylum (the *Negarnaviricota*), containing subphyla, classes, and multiple orders (such as the *Mononegavirales*). Unfortunately, it is also difficult to infer phylogenetic trees using aspects of genome composition like gene order and content because these characteristics differ

so dramatically among viral families and in the case of RNA viruses contain too few genes to be informative. Because of these inherent difficulties, deep interorder phylogenies of RNA viruses have in reality told us little about their origins.

In contrast, interfamily phylogenetic analyses of DNA viruses have generally proven more successful, in large part because the reliance on high-fidelity DNA polymerases for replication means that dsDNA viruses exhibit lower rates of nucleotide substitution and hence preserve the phylogenetic signal for longer time periods. For example, a number of families of large dsDNA viruses (i.e., those with genomes >100 kb) clearly possess common ancestry such that they can be classified as nucleocytoplasmic large DNA viruses (NCLDVs), currently comprising ascoviruses, asfarviruses, iridoviruses, marseilleviruses, mimiviruses, phycodnaviruses, and poxviruses, with newly identified viruses such as pandoraviruses, pithoviruses, and molliviruses, also likely to be classified as new families.[86,124] In other DNA viruses, elements of capsid protein structure have been used to link herpesviruses with tailed bacteriophages,[173] while there are clear evolutionary links between the *Papillomaviridae* and *Polyomaviridae* families of small dsDNA viruses.[268] However, there is no single phylogeny that encompasses both single- and double-stranded DNA viruses, which again reflects the great divergence between these very different types of virus that share no genes in common and differ massively in genome size. More starkly, it is even difficult to infer phylogenetic trees that link all the large dsDNA viruses that infect eukaryotes.[125]

The second component of the escaped gene theory—that most virus proteins ultimately have a host origin—is equally difficult to resolve. The two most important proteins in this respect, as they essentially define viruses, are the polymerase (a defining feature of all RNA viruses that carry an RdRp or RT) and those that make up the capsid (a defining feature of viruses). The case of the DNA polymerases used by DNA viruses is the easiest to discuss in this context as these enzymes are of the same form, and hence ancestry, as those used by cellular species (i.e., they are classified within the same polymerase families), and small DNA viruses utilize the host DNA polymerases for replication. However, while it is clear that these host and virus DNA polymerases are related,[72,123] the position of the root and therefore the direction of evolutionary change, in phylogenetic trees of DNA

polymerases is uncertain. Hence, it is difficult to determine whether DNA polymerases are ultimately of host or viral origin,[233] particularly as DNA polymerases may also have been involved in ancient lateral gene transfer (LGT) events.[73]

A similar discussion can be mounted in the case of RT. Proteins that function as RT are a common component of cellular genomes in the form of telomerase, the group II (self-replicating) introns observed in a variety of bacterial species, not to mention the abundant retroelements found in many cellular species, as well as a variety of other genetic elements. Importantly, there are recognizable sequence similarities between the RTs of viruses and those that reside in host genomes, such that it is possible to infer phylogenetic trees containing both.[34,62] These trees have revealed a number of interesting features, including a major division between the long terminal repeat (LTR) and non-LTR retrotransposons, with retroviruses most closely related to the LTR retrotransposons, and that hepadnaviruses and caulimoviruses (small dsDNA viruses that utilize RT) have independent origins and are probably from LTR retrotransposons. However, as with the case of the DNA polymerases, the lack of an outgroup makes the rooting of these phylogenies uncertain, so whether viral RT genes preceded those present in cells or vice versa is difficult to determine.[63]

The situation is far more complex when it comes to the origin of the RdRp used by RNA viruses. Although the cells of some eukaryotic species contain proteins that function as RdRps, particularly those involved in the production of microRNAs, these exhibit little similarity with the RdRps encoded by viruses, even at the structural level.[126] Similarly, cellular DNA polymerase (Pol) II, which catalyzes the synthesis of RNA from DNA, possesses RdRp activity[149] yet shares little similarity with the RdRp utilized by RNA viruses, such that their evolutionary origins are currently impossible to resolve. Clearly, determining the evolutionary relationships among these highly diverse polymerase proteins represents a major technical challenge.

Another challenge for the escaped gene theory is that there is little evidence of its defining process—host gene escape. A highly informative example concerns the HDV agent, the ribozyme of which shows sequence similarity to the CPEB3 ribozyme found in a human intron sequence.[223] That HDV was until recently only found in humans and thought to always require

hepatitis B virus (HBV) for replication suggested that its origins lay with the human genome.[223] However, it has now been shown that viruses other than HBV can act as helpers for HDV replication,[206] and close relatives of HDV have recently been discovered in both ducks and snakes with no evidence of HBV coinfection.[107,266] These results indicate that HDV has a far longer history as an exogenous replicating virus and hence poses a major challenge to the escape gene theory.

There has also been considerable debate over the significance of the giant DNA viruses for understanding viral origins, particularly those from the families *Mimiviridae* and *Pandoraviridae*. For example, although phylogenetic analysis has shown that a small proportion (<1%) of mimivirus genes are of host origin, which has been used as support for the idea that viruses are "gene pickpockets" that originated after cellular species,[183,184] at least 25% of the approximately 1,000 genes in mimivirus clearly link it to the NCLDV group of large DNA viruses,[125] while an even larger set of genes (~70% at the time of writing) have no known homologs in either viral or cellular genomes.[72] A similar proportion of family-unique genes have been reported in the *Pandoraviridae* which are proposed to have arisen through a process of *de novo* creation within these viruses.[148]

Finally, it is striking that, at the time of writing, there is no clear-cut evidence for the presence of RNA viruses in *Archaea* (although there is one disputed case[23]). This could mean that either RNA viruses arose as escaped genes after the divergence of *Archaea* from other cellular species or that temperature constraints have led to a major reduction in the frequency of RNA viruses in hyperthermophilic *Archaea*,[273] although this does not explain their absence in nonthermophiles. An alternative, and perhaps more likely, explanation is that RNA viruses do exist in *Archaea* but have simply not been detected as yet, perhaps in large part because they are so divergent in sequence as to be "invisible" in metagenomic studies that rely on simple sequence comparisons.

The competing theory for the origin of viruses, for which there is growing evidence and making it the most likely, is that viruses originated before the last universal cellular ancestor (LUCA) and represent the modern descendants of the earliest time in earth's history. Hence, modern RNA viruses would be descendants of replicating elements from the RNA world,

while DNA viruses would be remnants of the first DNA replicators, and retroviruses perhaps descendants of the first molecules that made the transition from RNA to DNA. For example, because they lack protein-coding regions, possess ribozyme activity, exhibit complex secondary structures, and mutate very rapidly, viroids have been suggested to be potential candidates for extant descendants of the RNA world.[67] However, although the earliest RNA replicators may share some features with contemporary viroids, because viroids are currently only seen in plants and likely replicate with the assistance of host cellular DNA Pol II makes it more likely that they represent escaped host genes or introns that never acquired protein coats. Whether metagenomic studies will identify viroid-like sequences in host organisms other than plants is obviously a key topic for the future.

There are a number of ideas for what the pre-LUCA world may have looked like, although all reasonably assume that this precellular stage of evolutionary history contained genetic elements less complex than the viruses we see today. One theory is that there was an *ancient virus world* of primordial replicators that existed before any cellular organisms and that both RNA (first) and DNA (later) viruses originated at this time.[141] These ancient "viruses" may even have provided some of the features that characterized the first cellular organisms. For example, it has been proposed that the eukaryotic cell nucleus is derived from a virus envelope (the so-called viral eukaryogenesis hypothesis).[15] An alternative theory for the pre-LUCA world is that RNA cells existed before the LUCA, that RNA viruses parasitized these hypothetical RNA cells, and that DNA evolved later as a way of escaping host cell responses.[80] Although fascinating, such theories are unfortunately extremely difficult to test.

As sequence-based phylogenetic trees cannot provide insights into the pre-LUCA world, the main evidence for the precellular theory of virus origins is the presence of conserved genes, and more notably protein structures, among divergent viruses. In fact, arguably one of the most important advances in viral evolution has been the discovery of protein structures that are conserved among diverse viruses that possess little, if any, primary sequence similarity.[14] For example, a conserved palm subdomain protein structure, consisting of a four-stranded antiparallel β-sheet and two α-helices, is found in both RNA-dependent and DNA-dependent polymerases.[99] A more important case in point concerns the jelly-roll capsid, a tightly

structured protein barrel that forms the major capsid subunit of virions with an icosahedral structure. Remarkably, the jelly-roll capsid is found in the virions of both RNA and DNA viruses, including such diverse groups as herpesviruses (dsDNA), picornaviruses (ssRNA+), and birnaviruses (dsRNA).[14,43] Such conservation is strongly suggestive of an ancient common ancestry. Other highly conserved capsid architectures that strongly argue for ancient origins include the PRD1-adenovirus lineage, which is characterized by a double *β*-barrel fold and found in dsDNA viruses as diverse as bacteriophage PRD1, human adenovirus, and a variety of archaean viruses; the BTV-like lineage, which is found in some dsRNA viruses including members of the *Reoviridae* and *Totiviridae*; and the HK97-like lineage, which encompasses tailed dsDNA viruses that infect archaea, bacteria, and eukaryotes.[19,20,142] Finally, a common virion architecture has been proposed for some viruses that do not possess an icosahedral capsid, including the archaean virus *Halorubrum* pleomorphic virus type 1 (HRPV-1).[209]

Although such structural conservation seems to provide a compelling argument for the antiquity of viruses, it has been suggested that any similarities in protein structure could have arisen more recently due to either strong convergent evolution or LGT.[184] While it is theoretically possible that convergent evolution may occur relatively frequently in viral capsid proteins that may be subject to strong selection to be small and perhaps of a specific shape, such large-scale convergence seems highly unlikely given that the similarity in capsid structure covers a huge range of viral taxa. As a consequence, multiple convergent events need to be invoked from very different starting points, and the more convergent evolution that is required, the less likely it becomes. Although metagenomic data have provided greater evidence that LGT occurs more frequently in viruses than previously thought (see below), it seems unlikely that such a fundamental trait as the viral capsid would move so freely horizontally, although this view may change with increased sample size. In conclusion, the presence of structural similarities among highly divergent viruses currently constitutes the strongest evidence that viruses have a precellular origin.

The Time Scale of Virus Evolution

While our understanding of viral origins is vague, rather more is known about

the antiquity of those families of viruses that circulate today. Although viruses lack a fossil record, a growing number of studies of the host distribution of viral families have provided important insights into how long they have been in existence, which in many cases means times of origin hundreds of millions of years ago.[242]

There are four ways in which the evolutionary history of viruses has been placed on a chronological scale. First, if there is a general correspondence between the phylogenetic tree of viruses and that of their hosts, such that they have *codiverged* through evolutionary history, then it is possible to use the divergence times of hosts to calibrate the time scale of virus evolution. Second, for viruses that evolve rapidly such that there is *measurable evolution* (i.e., mutations are fixed in viral populations during the time frame of human observation), which has been clearly demonstrated in both RNA viruses and ssDNA viruses, as well as some larger dsDNA viruses following complete genome sequencing,[53] it is possible to determine the number of nucleotide or amino acid substitutions that have occurred between viruses sampled at known times (i.e., "heterochronous" samples) and use this information to calibrate the time scale of virus evolution under the assumption of a molecular clock (i.e., that there is an approximately constant rate of nucleotide or amino acid fixation). Third, for viruses where endogenous genome copies are present in the host, it is possible to use the substitution rate of the host to determine when these genome integration events occurred, especially if the endogenous sequences also codiverge with their host species.[130] Finally, in a limited number of cases, including some poxviruses,[60] hepadnaviruses,[187,202] and parvoviruses[188] it is possible to use virus sequences obtained from archival samples (i.e., ancient DNA) to date virus evolution. All four approaches have limitations and can lead to wildly different interpretations of evolutionary time scales, such that all should be used with caution.

Dating the time scale of virus evolution through the use of host divergence times (i.e., codivergence) is perhaps the simplest and most robust approach to this form of molecular archaeology. This approach has been successful in the study of DNA virus evolution, and metagenomic studies of families of animal RNA viruses have suggested that these may be as old as the animals they infect, so that they likely have origins with the earliest metazoans.[242] Specific examples of its utility are the dating of herpesvirus

evolution through an examination of the phylogenetic relationships of their vertebrate hosts, in which virus–host codivergence may extend to some 400 million years[172,173]; of the animal iridoviruses[128]; of the baculoviruses of insects[106]; and of the papillomaviruses sampled from a number of vertebrates including humans.[22] Clearly, although each of these virus families can be considered "ancient," they are in no way of sufficient age to inform on the question of virus origins. In addition, in some other large DNA viruses, with the poxviruses a good example, frequent host jumping and limited sampling means that patterns of host–virus codivergence can be difficult to infer, so that the times of origin of key human pathogens like variola virus (VARV; the agent of smallpox) are still the source of considerable debate.[60,156,238] A compelling example of virus–host codivergence being used to date the origin of a number of RNA viruses and retroviruses concerns the retrovirus simian foamy virus (SFV). Here, a statistically significant match between the phylogenetic trees of host and virus may extend to at least 30 million years,[160,250] and the analysis of endogenous foamy viruses places their evolutionary history in mammals to over 100 million years,[132] with a likely origin early in vertebrate evolution.[102] More recently, metagenomic analyses have revealed a general correspondence between different classes of vertebrate and the RNA viruses they carry (although with frequent host jumping), which again points to ancestries dating back hundreds of millions of years.[90,239]

While *bona fide* examples of virus–host codivergence constitute a powerful way to date the age of specific viruses, it is also the case that the resemblance of between host and virus phylogeny could occur by chance alone or because related host species are more likely to share their pathogens.[37] Given that cross-species transmission is a very common mode of virus macroevolution,[90] it can be dangerous to construct a time scale of virus evolution without strong evidence for codivergence. Overall, there is a growing view that virus evolution represents a complex interplay between codivergence and cross-species transmission, with both processes commonly co-occurring in many virus families (see below).[90] Although these broad-scale patterns have provided important insights into the timescale of virus evolution, such complexity can make dating the ancestry of individual viruses very difficult.

Using heterochronous samples to calibrate the virus molecular clock is an extremely powerful and increasingly popular way to study the time scale of virus evolution in the recent past (i.e., on time scales no more than a few hundred years) and is commonly used with RNA viruses where measurable sequence evolution is a routine observation. Because large numbers of gene sequences where the precise date of sampling is known are now available, and because virus evolution is often relatively clock-like, it is a straightforward exercise to date the age of samples of genetic diversity if performed with care.[53] In some cases, divergence times estimated in this manner can be very accurate. For example, an analysis of heterochronous samples of human influenza A virus was able to accurately reconstruct the seasonal peaks and troughs in the population size of this virus.[214] However, while these molecular clock approaches can work well for recent virus evolution, they are prone to error at deeper divergence times, providing a picture of virus evolution that is too recent, particularly given the time-dependent nature of virus evolution in which rate estimates are elevated toward to present (see below).[56] An important example of this effect is provided by the case of the SIVs. While molecular clock studies of SIV evolution using heterochronous samples place this on a time scale of hundreds of years, a calibration based on the biogeographic separation of Bioko Island from the coast of West Africa gave dates of at least 32,000, and perhaps over 100,000 years.[269]

In a number of cases, the time scale of virus evolution can be inferred using the sequences of endogenous viral sequences that are a common component of eukaryotic genomes. Endogenous genomic copies of exogenous viruses that have entered the germ line are particularly commonplace in retroviruses, and it is estimated that approximately 5% to 8% of the human genome is composed of endogenous retrovirus, comprising many distinct families.[133] In addition, there is a growing list of endogenous RNA and small DNA viruses, also referred to as endogenous viral elements (EVEs), that usually comprise partial virus genome sequences and are commonly found following the sequencing of host genomes.[5,111,130] Endogenous viruses also represent a sort of “fossil record” of past viral infections: once integrated into host genomes, they cease to evolve like viruses and instead assume the low rates of nucleotide substitution that characterize their hosts, replicating using high-fidelity host DNA

polymerases and likely experiencing fewer replications per unit time (Fig. 1.3). Consequently, if the mutational differences between endogenous viruses are known to occur postintegration, such as those observed between the LTRs of a single endogenous retrovirus, between duplicated EVEs, or when there is clear evidence for codivergence, then divergence times can be estimated in a relatively straightforward manner using host substitution rates.

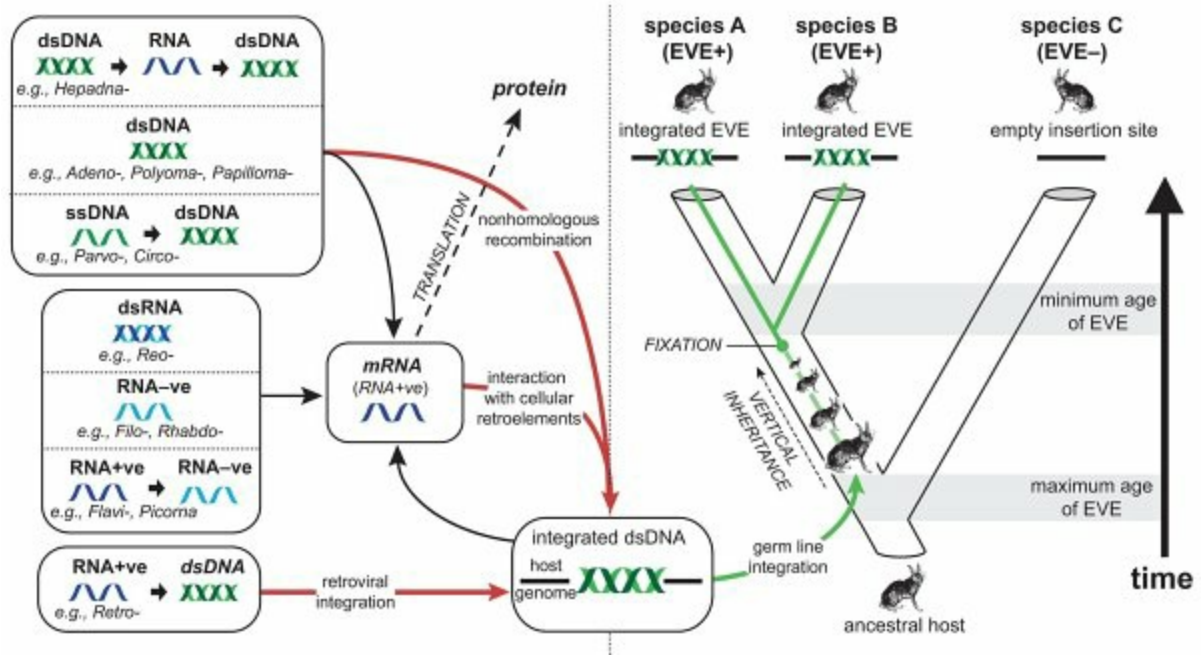

Figure 1.3 How endogenous virus elements (EVEs) are generated and can be used to estimate the age of viral families. Examples of different types of mammalian RNA and DNA viruses are shown. The presence of EVEs in related host species A and B and integrated into the same genomic position indicates that this integration event occurred prior to the divergence of these two species, such that its minimum age can be estimated if it is known when the host species diverged. (From Katzourakis A, Gifford RJ. Endogenous viral elements in animal genomes. *PLoS Genet* 2010;6:e1001191. Original figure kindly provided by Dr. Rob Gifford.)

Molecular clock dating using EVEs suggests that the exogenous ancestors of some human retroviruses may have diversified relatively early on in mammalian evolution.[133] Most dramatic are cases of when both exogenous and endogenous copies of the same virus exist: these have generally resulted in a radically different picture of the time scale of viral evolution than using clock estimates based on heterochronous samples. For example, estimates of the age of primate lentiviruses based on the use of heterochronous sequences generally result in time scales of thousands of years at most,[237] while the presence of endogenous lentiviruses in lemurs suggests that these viruses have circulated in primates for at least several million years.[131] The same is true of endogenous viruses that are not retroviruses. A compelling example is provided by the avian hepadnaviruses, in which the observation of EVEs integrated at the same genomic positions in bird species that diverged at least 19 million years ago strongly suggests that hepadnaviruses are at least of the same age,[95] and endogenous hepadnaviruses are now increasingly observed in the genomes of birds[46] and other vertebrates.[249] The same phenomenon has been proposed for a variety of other RNA viruses, including bornaviruses and filoviruses,[17,118,132] and help to calibrate the timescale of virus evolution when combined with comparative studies of exogenous viruses,[239] as well as ssDNA viruses of the families *Circoviridae* and *Parvoviridae*.[18,129,159] In each case, integrated copies of these viruses are observed in diverse host species, for example comprising both placental and marsupial mammals in the case of the filoviruses, and sometimes showing virus–host codivergence indicating that they are millions of years old.[130] As more host genomes are sequenced, it is certain that more EVEs will be discovered, which in turn will shed new light on the true time scale of virus evolution.

The final way in which a timescale has been placed on virus evolution has been through the use of so-called ancient DNA, in which evolutionary analyses are performed on viruses sampled from archival material. Because of its greater preservation, this approach has been more successful in the case of DNA than RNA viruses, with variola virus (VARV),[60] human papillomavirus,[38] HBV,[187,202] human T-cell lymphotropic virus,[157] and B19 parvovirus[188] constituting important examples. Although there have been a number of reports of ancient RNA viruses, including the compelling case of a plant virus recovered from a caribou feces frozen on permafrost dating to 700 years ago,[194] in many other instances it is difficult to exclude the issue of

contamination that plagues studies of ancient DNA, particularly as the ancient samples possess sequences that are closely related to modern variants.[207] In addition, in the case of human RNA viruses, there is currently little evidence for the preservation of viruses older than the influenza A virus associated with the global pandemic of 1918–1919.[251] However, with *bona fide* samples, the analysis of ancient DNA can provide important insights into virus evolution. For example, in the case of HBV the ancient samples showed not only that modern viral genotypes have been associated with human populations for at least 7,000 years but also that the ancient geographic distributions of genotypes are different to those observed today.[187] This has important implications for theories of HBV origin and spread, and shows that rates of evolutionary change in this virus are lower than those observed using heterochronous samples.[187] Similarly, the analysis of VARV samples dating to the 17th century has shown that the diversification of smallpox virus to generate the lineages present during the 20th century occurred more recently than previously imagined.[60] Importantly, however, while ancient DNA is an increasingly valuable tool to study virus evolution on the time scales of thousands of years at most, it will not be informative on the deep origins and evolution of viruses as a whole.

Codivergence and Cross-Species Transmission in Virus Evolution

Emerging infectious diseases are often characterized by “host switching” events, in which a pathogen jumps from its original host to infect a novel species. Indeed, the cross-species transmission of viruses is responsible for the majority of emerging infections and can profoundly affect human and animal health. More fundamentally, cross-species transmission is also one of the key processes of virus evolution.[90] Although most emerging diseases seemingly result from such a process of cross-species transmission, it is also the case that some viruses seem to rarely jump the species barrier and instead codiverge with their hosts over long stretches of evolutionary time. For example, long-term virus–host codivergence has been suggested to play a key role in the evolution of vertebrate herpesviruses over periods of approximately 400 million years[172] and insect baculoviruses over a timescale of approximately 310 million years.[253] In fact, a number of families of DNA

viruses have clearly codiverged with their hosts over long evolutionary timescales,[110,260] and do so more frequently than do RNA viruses.[90] This may, in part, be due to the fact that many RNA viruses are characterized by short durations of infection that will limit the opportunities for virus–host codivergence, although there is also growing evidence for host codivergence among families of RNA viruses.[240,241] Similarly, the high rates of evolutionary change that characterize RNA viruses should confer more rapid adaptation to new environments, which, coupled with the frequency of exposure to new hosts, will facilitate host switching.

Most attention has been directed to RNA viruses, and these often seem to evolve through a combination of codivergence and host switching. While phylogenetic trees for some RNA viruses, such as particular retroviruses, are similar with those from their hosts suggesting that there has been long-term codivergence,[127] for others, such as coronaviruses, flaviviruses, and picornaviruses, host jumping appears to be relatively frequent.[90,138] The situation appears to be even more complex in cases such as the hantaviruses, where the respective contributions of codivergence and host jumping can be difficult to determine.[116]

Although host jumping is commonplace, it is also the case that many emerging diseases are in reality transient “spill-over” infections, in which onward transmission between members of a new host species is limited and extinction of any novel virus occurs rapidly. This is to be expected as viruses must overcome a variety of evolutionary and ecological barriers to successfully establish themselves in new hosts.[92,93] Nevertheless, it is possible that an increased sampling of hosts and their viruses, particularly through novel virus discovery via metagenomics, will reveal even further instances of cross-species transmission. As a case in point, although there is strong evidence that hepadnaviruses have codiverged with their vertebrate hosts over hundreds of millions of years,[249] the recent identification of hepadnaviruses in fish and amphibians has revealed more instances of cross-species transmission, potentially including that from aquatic to terrestrial vertebrates[49,89] (Fig. 1.4).

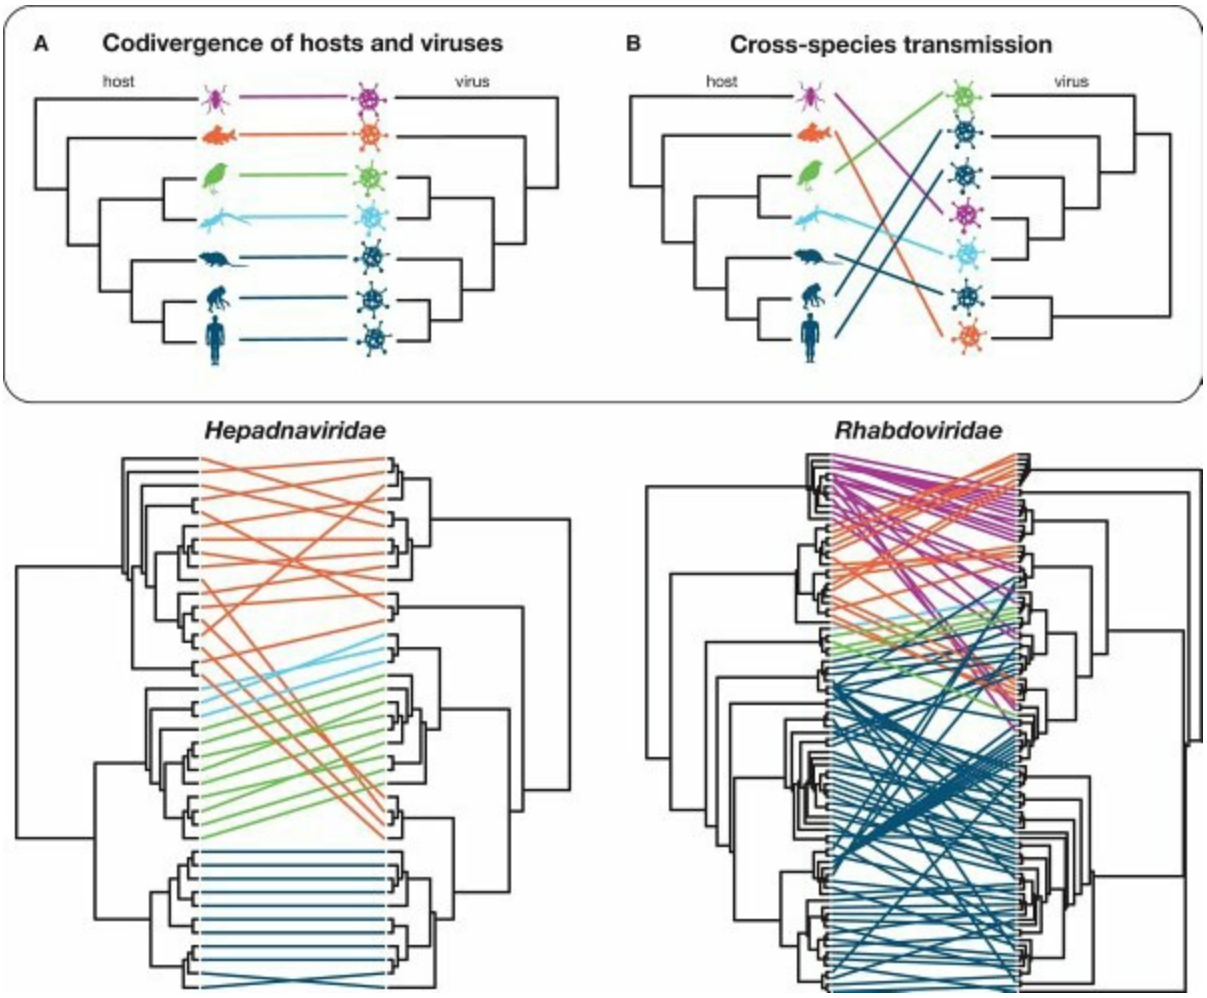

Figure 1.4 The contrasting processes of virus–host codivergence and virus cross-species transmission to novel hosts. **A:** When host populations diverge and speciate, often over periods of millions of years, viruses may evolve with them through codivergence and hence the phylogenies for viruses and hosts will have similar topologies (i.e., exhibit congruence). **B:** Conversely, if viruses evolve by jumping to new hosts, then the phylogenetic relationships among viruses and their hosts will mismatch (i.e., exhibit incongruence). Real data examples are shown in the bottom part of the figure, in which the match between the virus and host phylogenies are shown for the *Hepadnaviridae* and the *Rhabdoviridae*. Cross-species transmission is relatively common in both cases, especially the *Rhabdoviridae*.

To understand the basic mechanisms of virus evolution and disease emergence, it is obviously important to identify the relative frequencies of codivergence and cross-species transmission among viruses and their hosts. In particular, this information will help determine whether some virus families have a greater propensity to jump hosts than do others and, if so, even reveal what factors may govern this pattern. This can be achieved using a "co-phylogenetic" analysis that assesses the degree of phylogenetic congruence (i.e., similarity) between hosts and their parasites.[127] That is, a clear congruence between the host and virus phylogenies provides strong evidence for a history of codivergence, whereas phylogenetic incongruence (i.e., discord) is compatible with cross-species transmission (Fig. 1.4).

It is also likely that successful cross-species transmission occurs more frequently among phylogenetically related hosts, a process termed "preferential host switching."[37] This is because it is easier for a virus to infect and replicate in genetically similar hosts that share less divergent cell receptors.[201] In addition, related hosts may often inhabit the same geographic region, increasing the probability of cross-species transmission through more frequent exposure.[190] Hence, the closer the phylogenetic relationship between hosts, then, given appropriate exposure, the more likely that a pathogen will be able to jump between them.

Finally, it is important to note that cross-species transmission events revealed through such co-phylogenetic analyses have likely occurred over very long evolutionary timescales, and that many of the viral families that present frequent host switching have done so for many millions of years. Therefore, the observation that many viruses can frequently jump species boundaries over evolutionary timescales[198] provides no assistance in predicting what happens over shorter timescales that govern epidemiological processes relevant to epidemics.[91]

Metagenomics and Virus Evolution

Metagenomics is transforming studies of virus evolution, with a massive amount of new genetic diversity revealed in DNA bacteriophage[105] and RNA viruses.[240,241] Indeed, it is a safe bet that our view of the virosphere and the evolutionary processes that shape it will be very different in this edition of Field's virology and the next.

Before the advent of DNA sequencing, new viruses were discovered using a variety of approaches, including filtration, cell culture, electron microscopy, and serology. Many of these techniques remain important,[151] and the gold standard for virus discovery is still the propagation of viruses in cells, accompanied by the visualization of virus particles by electron microscopy and the successful replication of infection in animal models. However, the enormous time and effort required for work of this kind, and the sheer scale of the virosphere, means that this is often practically impossible. In addition, most viruses are not culturable, and there are not enough cell lines to meet the diversity of viruses.

A more modern approach to virus discovery, which is transforming our understanding of virus diversity and evolution, is through a coupling of metagenomics and high-throughput sequencing. Indeed, metagenomics has revolutionized virus discovery in terms of speed, accuracy, sensitivity, and the amount of information generated.[77] Among the various metagenomics approaches that are available, meta-transcriptomics, based on total RNA sequencing, has recently come to the fore in the case of RNA viruses. This approach involves gathering total transcriptome information from a host sample, often after depletion of ribosomal (r) RNA as this is the dominant component of host transcriptomes. Previous methodologies were often based on removing as much nucleic acid outside viral particles as possible by filtering, centrifugation, lysis, and nuclease treatment, although this seldom results in a complete depletion of host RNA and may bias against the detection of particular types of virus.[76,181] In contrast, in meta-transcriptomics total RNA is directly extracted from untreated homogenates and used for library preparation without filtering, capture, or enrichment, thereby providing an unbiased picture of host viromes, although what viruses are found strongly depends on the depth of sequencing coverage. Metagenomics based on shotgun DNA sequencing may still be the most profitable approach for the study of DNA viruses, although to date less effort has been devoted to describing new DNA viruses in animal hosts.

The most obvious evolutionary insight from metagenomics is that the number of undetected viruses is enormous such that we are still only scratching the surface of the virosphere, particularly when compared with the number and diversity of viruses that can be revealed through other approaches such as cell culture and consensus PCR (Fig. 1.5). This, in turn,

suggests that we still have a great deal to learn about virus diversity and evolution. As well as revealing an abundance of new virus taxa, and determining the evolutionary processes that have shaped this diversity, it is undoubtedly the case that viruses exist in hosts that have not yet been screened for viruses or that are so divergent in sequence that they cannot readily be detected by standard homology-based methods (such as Blast) or included in phylogenetic analyses.[242] If the nature of this "dark matter" can be resolved, it will doubtless shed new light on the ultimate origins of viruses as well as their deep phylogenetic relationships, and perhaps even on the origins and evolution of the first replicating systems. In particular, it is of critical importance to characterize the unknown biodiversity of viruses in prokaryotes (both archaea and bacteria) and basal eukaryotes that may possess highly divergent genome sequences that are currently difficult to identify. Unfortunately, this will also require the development of new computational methods to extract sequence information from highly divergent genome sequences.

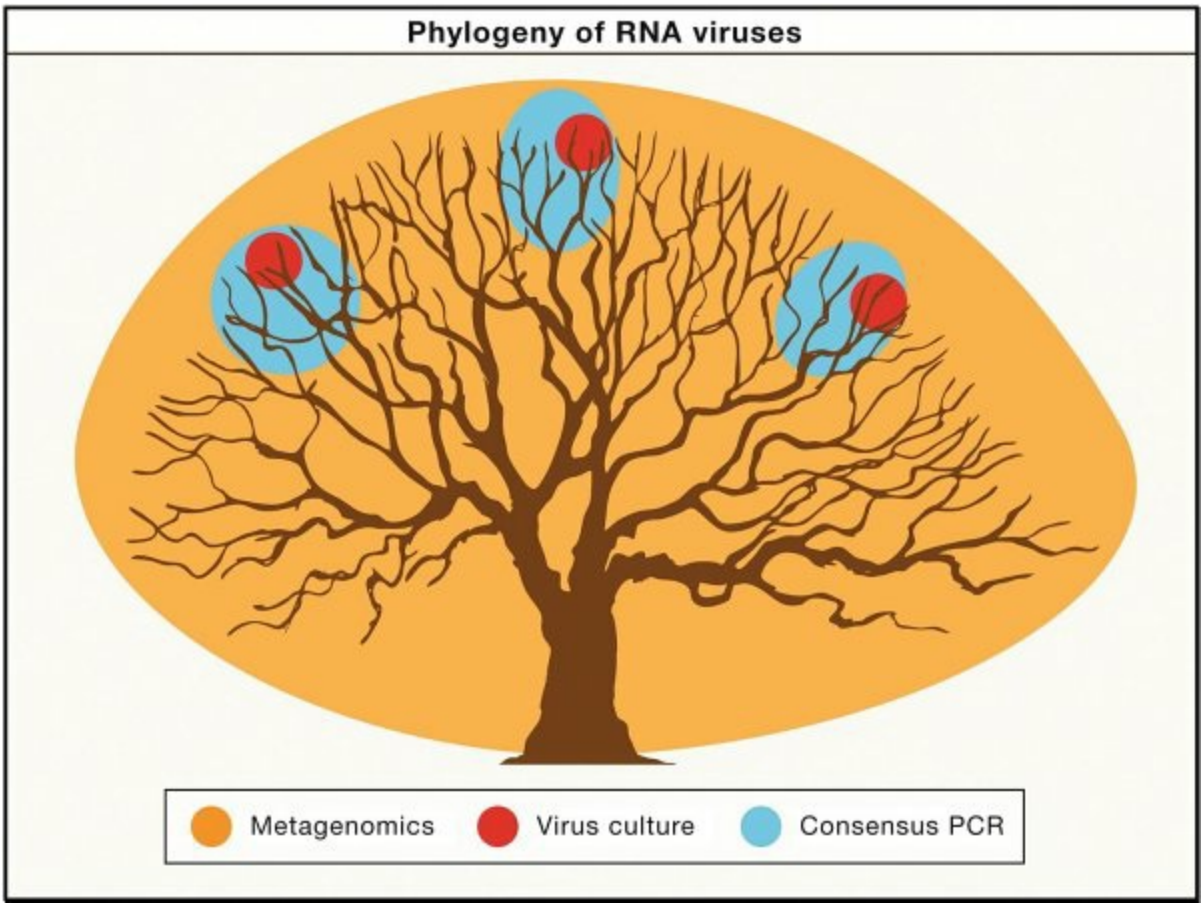

Figure 1.5 Different analytical techniques to explore the virosphere. A schematic tree is used to represent the total phylogenic diversity of RNA viruses (although the same scheme also applies to DNA viruses). The *colored circles* depict the extent of viral diversity that can be discovered using cell culture (*red*), consensus PCR (*blue*), and metagenomics, such as RNA sequencing (meta-transcriptomics, *orange*). (From Zhang YZ, Shi M, Holmes EC. Using metagenomics to characterize an expanding virosphere. *Cell* 2018;172:1168–1172, by permission of Cell Press.)

The rise of metagenomics has also made it clear that our knowledge of the evolutionary processes that have generated the diversity of the virosphere has been strongly skewed by a focus on those viruses that act as agents of disease in economically important animals and plants as well as those that can be easily cultured. In particular, recent work has shown that animals, and invertebrates in particular, harbor enormous uncharacterized viral diversity, only some of which has been associated with disease.[158,240] Key questions for future research that can be addressed with metagenomic data include (a) determining the processes that shape virus ecosystems, particularly the factors that assist or inhibit the flow of viruses between hosts; (b) revealing the mechanisms of long-term virus macroevolution, particularly the rates and causes of virus lineage birth and death, and (c) revealing the mechanisms and evolutionary processes that are responsible for the diverse array of virus genome structures, and how these genome structures are connected to each other in evolutionary space.[242] Finally, there is a growing realization that metagenomic data provide both important opportunities and challenges for virus classification,[244] and that a combination of metagenomics and phylogenetics will soon become the standard means to address issues of virus taxonomy.

PROCESSES OF VIRUS EVOLUTION

One of the strongest arguments that viruses are alive is that they are subject

to the same forces that shape the evolution seen in cellular species: mutation, natural selection, genetic drift, recombination (and reassortment), and migration. We will discuss the first four of these processes in this chapter. Migration, in the guise of viral epidemiology, is discussed elsewhere in this volume.

Mutation and Nucleotide Substitution in Viruses

The simplest way to examine the role of mutation in virus evolution is to measure the rate of its occurrence. Indeed, understanding the factors that shape the speed at which genetic variation is generated in viruses is central to understanding their evolution. For RNA viruses, mutation can in some ways be thought of as their defining evolutionary feature, as it occurs at a pace that greatly exceeds that observed in other organisms and determines much of their evolutionary "behavior."

Although mutation is the ultimate source of genetic variation, the pace of evolutionary change can be measured in two rather different ways. One method is to estimate, experimentally, the rate at which mutations are generated *de novo*. Such rates have usually been presented as the number of mutations per nucleotide or per genome, per replication. However, because of the inherent complexities and biases in making these estimates, it has been suggested that estimates of mutation rate per nucleotide, per cell infection may be more informative.[229] For example, one important complicating factor is that some viruses employ so-called stamping machine replication, in which a single virus acts as the template for all progeny genomes, so that mutations accumulate linearly, while others utilize "geometric" replication, in which some of the early progeny genomes are used as templates to produce further progeny, in turn increasing the rate of mutation accumulation.[59]

The importance of mutation rate estimates is that they reveal the intrinsic error dynamics of the RNA or DNA polymerases used in viral replication and in theory allow a count of each type of mutation—advantageous, neutral, or deleterious—before they have been shaped by natural selection, although it is always difficult to accurately count the number of lethal mutations that are rapidly removed by purifying selection. A detailed compilation of mutation rate estimates for 27 viruses, and accounting for many of the complexities inherent in analyses of this kind, revealed that these rates vary from averages

of 1.6×10^{-6} to 1.5×10^{-4} mutations/nucleotide/cell infection for RNA viruses, from 1.6×10^{-5} to 4.4×10^{-3} mutations/nucleotide/cell infection for retrotranscribing viruses, and 5.9×10^{-8} to 1.1×10^{-6} mutations/nucleotide/cell infection for DNA viruses (Fig. 1.6).[226,229] For RNA viruses that replicate with a RdRp, an enzyme that lacks a proofreading or repair function, this equates to mutation rates that are usually around one per genome, per replication.[51,52,57] Similarly, the lower mutation rates observed in large DNA viruses clearly reflect the higher fidelity of the DNA polymerases employed in their replication cycle. Of particular note is that mutation rate estimates in ssDNA viruses (a maximum of 1.1×10^{-6}, although only two estimates are available) are higher than those of large dsDNA viruses (which range from 5.9×10^{-8} to 5.4×10^{-7}),[226] even though ssDNA viruses have such small genomes that they use host DNA polymerases for replication. Although it remains to be determined, it is possible that the higher mutation rates in ssDNA viruses reflect less efficient proofreading and excision repair on ssDNA and/or frequent deamination.[58] The study of Sanjuán and Domingo-Calap[226] was also of note in that it revealed that retroviruses such as HIV have error rates that often higher than those of RdRp-utilizing viruses, even though earlier studies suggested that RT exhibits higher fidelity than does RdRp.[51,52,166]

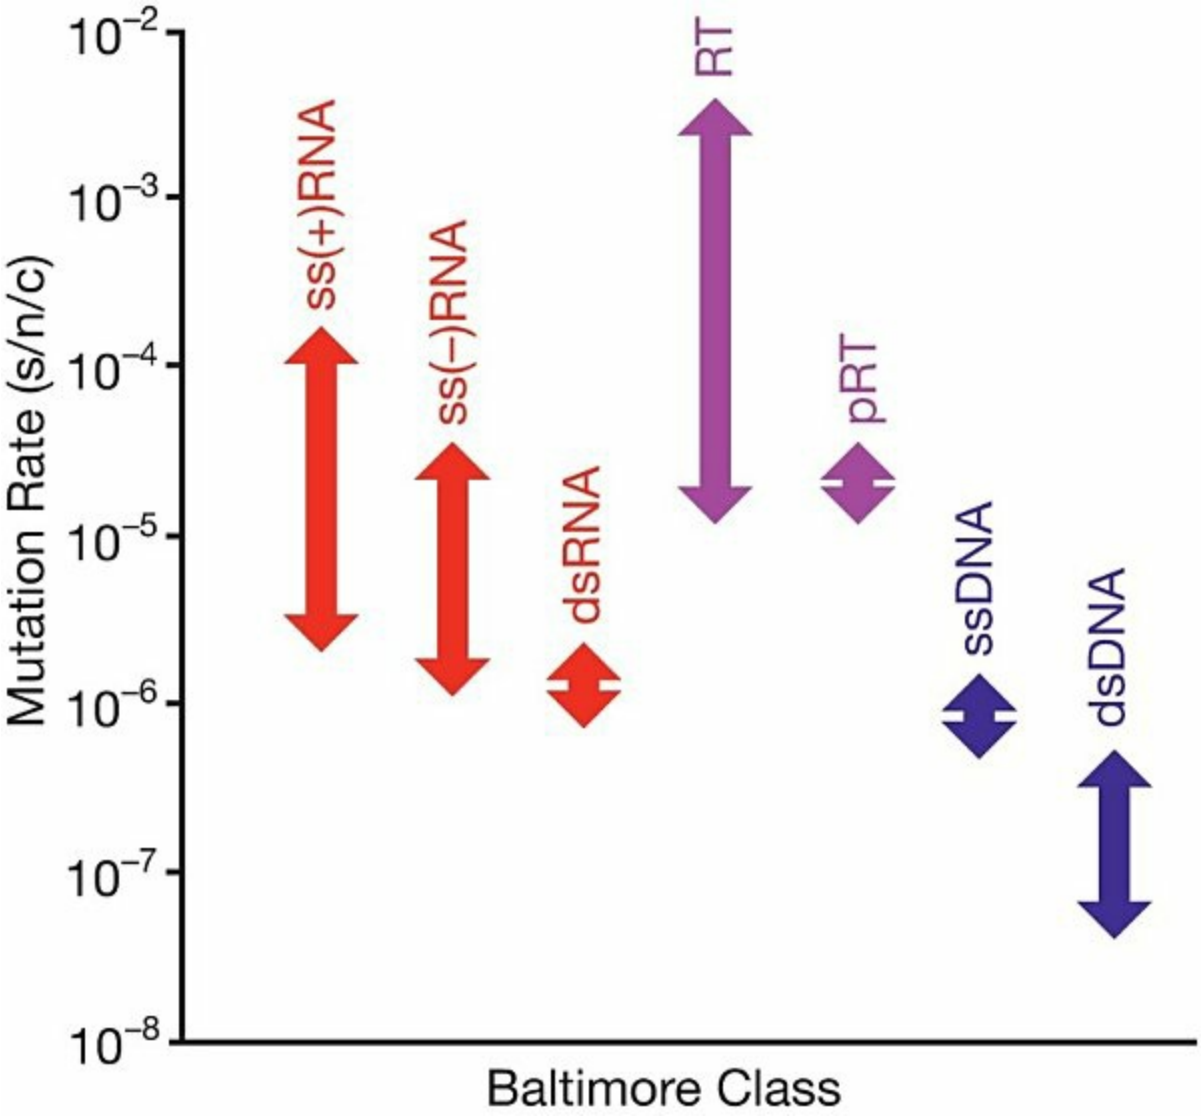

Figure 1.6 The large-scale variation in mutation rates among viruses. The range of variation in mutation rates is shown for the seven classes of viruses classified under the Baltimore scheme. ss, single-strand; ds, double-strand; +/− genome polarity; RT, retroviruses; pRT, para-retroviruses. (From Sanjuán R, Domingo-Calap P. Mechanisms of viral mutation. *Cell Mol Life Sci* 2016;7:4433–4448, by permission of Springer Nature.)

From a broader perspective, these estimates of mutation rate are compatible with the idea that there is a strongly inverse relationship between mutation

rate and genome size that applies to all living systems (Fig. 1.7).[85,112] It also seems likely that the systematic difference in mutation rate and genome size between RNA and DNA viruses is associated with many of the main evolutionary distinctions between these two types of infectious agents that are discussed throughout this chapter.[110]

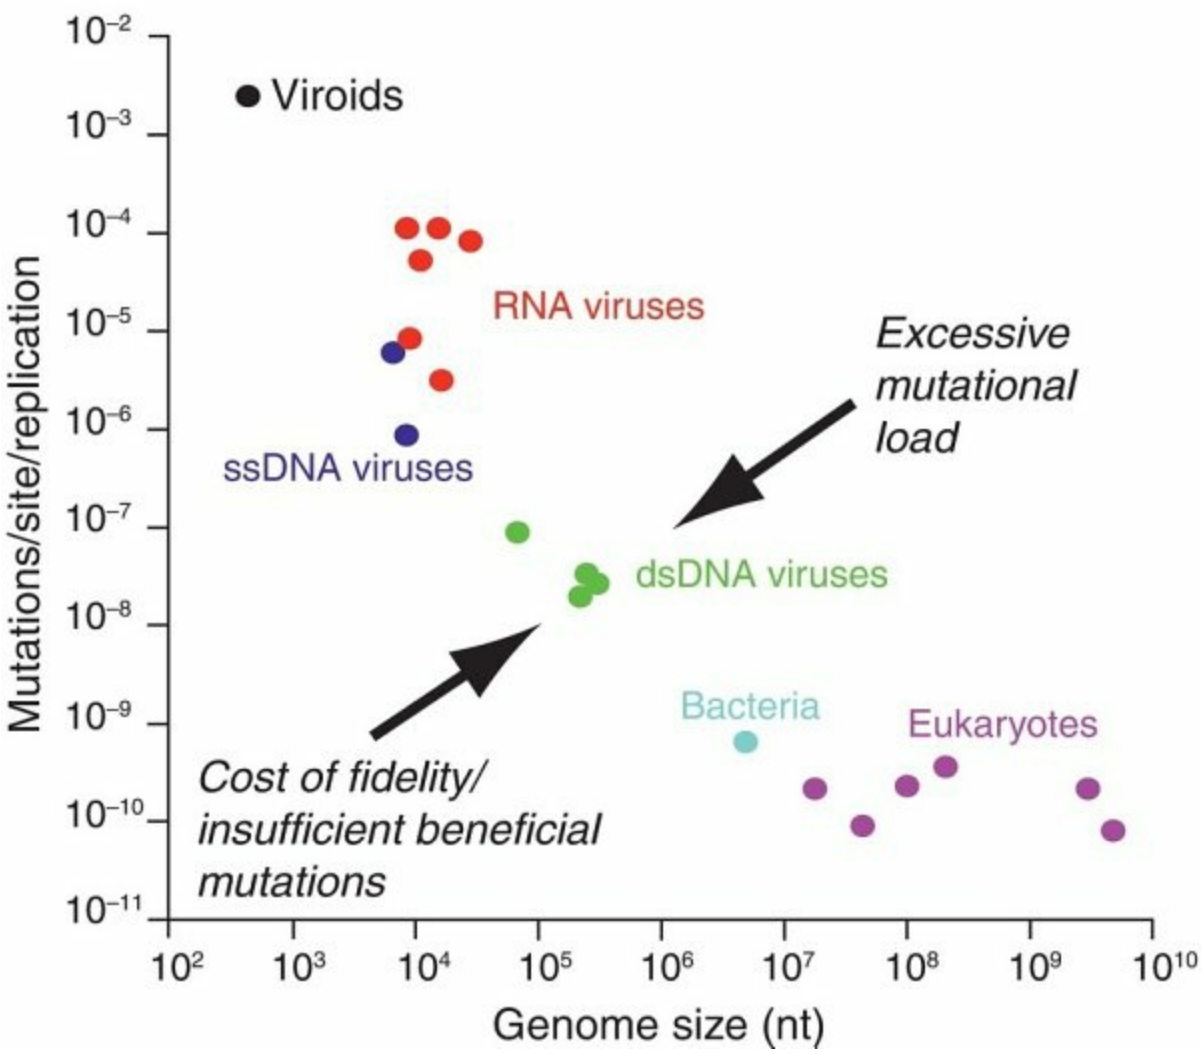

Figure 1.7 Relationship between mutation rate and genome size in diverse organisms including RNA and DNA viruses and viroids. The competing evolutionary forces that might be responsible for the limited range of observed mutation rates and genome sizes are shown. See also Figure 1.6. (From Holmes EC. What does virus evolution tell us about virus origins? *J Virol* 2011;85:5247–5251,

by permission of the American Society for Microbiology.)[108]

Although they utilize related DNA polymerases, mutation rates in large DNA viruses are higher than those of bacteria and eukaryotes, which may reflect an absence of the full set of repair enzymes and pathways. There are, however, two possible exceptions to this rule. First, there is currently no estimate of mutation rates in the giant DNA viruses, although these are expected to fall within the bacterial range (as the genome sizes of these viruses overlap with those of bacteria), and hence lower than that observed in any virus to date. Although a higher rate of nucleotide substitution was estimated in the case of the giant pandoraviruses,[154] which would imply a high background mutation rate, this was later shown to be questionable and it is clear that more data are required.[55] Second, we similarly lack an estimate of mutation rate in the small dsDNA viruses, such as the papillomaviruses. Although the relationship depicted in Figures 1.6 and 1.7 implies that these viruses will mutate rapidly, most estimates of substitution rate in papillomaviruses are in a similar range to those of large DNA viruses.[76,216] This implies that papillomaviruses similarly mutate relatively slowly, which would break the simple relationship between mutation rate and genome size. Whether any of the new viruses discovered by metagenomic surveys will similarly break the proposed association between mutation rate and genome size is a key research question.

The relationship between mutation rate and genome size is of twofold importance. First, because it incorporates genetic systems ranging from viroids to eukaryotes, it covers at least eight orders of magnitude of both genome size and mutation rate, and few things in biology encompass such diversity. Second, it implies that mutation rates that are either too high or too low are selected against.[112] With respect to the latter, a popular idea is that viral mutation rates, particularly the high mutation rates of RNA viruses, are the result of an evolutionary trade-off, either between replication rate and replication fidelity[84] or between the rates of deleterious and advantageous mutation.[59,247] Data can be cited in support of both relationships,[110,167,259] with a recent study showing that the evolution of mutation rates may reflect an evolutionary trade-off between replication speed and fidelity; that is, rapid replication is selectively advantageous for a virus but comes at the cost of

lower replication fidelity.[79] However, it is also likely that this evolutionary trade-off will vary depending on virus type and the duration of infection, differing, for example, between viruses associated with either acute or chronic infections.

It is also possible that there is trade-off between the rates of deleterious and advantageous mutation in viruses. On the one hand, as viruses will be commonly exposed to changing environments (i.e., different hosts, a variety of cell types, frequent immune pressure), the generation of some genetic variation via mutation is likely to be selectively advantageous. This idea also has experimental support: RNA polymerases with lower fidelity and that generate more diversity are sometimes selectively favored over those with higher fidelity.[110,167,259] On the other hand, there must be an upper limit on the mutation rates experienced by viruses (and all living systems), as excessive error will result in major fitness losses. Powerful evidence for this ceiling on mutation rates is provided by experiments invoking *lethal mutagenesis* (see later), in which artificially increasing error rates with mutagens such as 5-fluorouracil and ribavirin result in an excessive mutational load.[30] It is therefore likely that RNA viruses exist close to their maximum tolerable mutation rates, which in turn imposes an upper limit on genome size. However, it is also likely that RNA viruses are mechanistically unable to reduce their error rates to the levels associated with DNA polymerases. A higher-fidelity RNA polymerase would need to be more complex, and hence longer, than those that currently exist, yet this cannot evolve because by increasing genome length too many deleterious mutations will accumulate. This evolutionary conundrum is commonly referred to as *Eigen's paradox* and is a key element in theories for the early evolution of genomic complexity.[109]

The second measure of the pace of virus evolution is the rate of nucleotide substitution per nucleotide site, per year (subs/site/year). As this measure reflects the *population* success of any mutation, it by necessity incorporates the action of natural selection. Accordingly, deleterious mutations that have been removed by purifying selection will not be counted, while advantageous mutations will be fixed more rapidly than neutral ones. Because they only involve sequence comparisons, nucleotide substitution rates are usually far easier to estimate than mutation rates and so provide a simple and powerful means to compare patterns of virus evolution.

As with rates of mutation, rates of nucleotide substitution vary markedly among viruses. Across RNA and DNA viruses as a whole, nucleotide substitution rates vary by over five orders of magnitude, in large part reflecting the differences in background mutation rate described earlier.[57,114] Hence, most substitution rates in RNA viruses fall within an order of magnitude of a value of 1×10^{-3} subs/site/year,[110,114] while the rates in many dsDNA viruses are closer to 1×10^{-8} subs/site/year.[104,168,172,216] Undoubtedly, our understanding of viral substitution rates would be improved by reliable measures of evolutionary dynamics in the smallest (i.e., viroids) and largest (i.e., pandoravirus) viral systems.

Most of the variance in the substitution rates in both RNA and DNA viruses likely reflects virus-specific differences in rates of mutation, replication, or both. Mutation rates have been discussed earlier. Although few direct estimates of replication rate are available, they likewise clearly play a major role in shaping substitution rates. For example, although the retrovirus SFV likely has an RT-associated error rate that is similar to those of other retroviruses, its codivergence with primates for over 30 million years leads to estimates of the substitution rate of only 1.7×10^{-8} subs/site/year.[250] This most likely reflects a low rate of replication in the long term, although this merits further investigation. Similarly, replication rates appear to be low in papillomaviruses, in which virus replication occurs simultaneously with the division of host epithelial cells, at approximately 10 to 100 generations per year,[22] which likely contributes to the low substitution rates estimated in this virus. In contrast, that DNA viruses often replicate more rapidly than do their hosts may in part explain why virus substitution rates are higher than host substitution rates even though they utilize similar polymerases. For example, the Bo17 protein of bovine herpesvirus 4 represents a viral capture of the mammalian 2β-1,6-*N*-acetylglucosaminyltransferase-mucin protein.[168] As a phylogenetic analysis revealed that this gene was captured from the host after the split between cattle and African buffalo approximately 1.5 million years ago, it was possible to estimate that the viral gene had evolved 20 to 30 times faster than its cellular homolog.[168] Finally, for persistently infecting viruses, substitution rates may also differ between periods of intra- and interhost evolution. For example, HIV-1 substitution rates are higher within than among hosts.[165] This may be because intrahost HIV evolution is dominated by the positive selection of immune escape mutations or because some of the

mutations that occur within hosts are purged at interhost transmission, thereby reducing the substitution rate. As noted earlier, it is also the case that substitution rates in viruses are strongly time dependent, such that they are elevated in the recent past because of the presence of transient deleterious mutations that have yet to be purged by purifying (negative) selection.[56] When comparing substitution rates among viruses, it is therefore critical to base studies on those sampled over approximately the same time frame.

Although most estimates of substitution rates suggest a fundamental division in virus evolution in which RNA viruses evolve rapidly and DNA viruses evolve slowly, there are a number of important exceptions (although there is currently no convincing evidence for anomalously slowly evolving RNA viruses). Most notably, most ssDNA viruses seem to exhibit substitution rates—often in the realm of 10^{-5} to 10^{-6} subs/site/year—that are lower than those of RNA viruses but more rapid than those of large DNA viruses and likely reflect the specifics of their background rates of mutation and replication. Such rate estimates have now been provided for carnivore[235] and human[196,234] parvoviruses, including involving comparisons utilizing ancient sequences sampled many hundreds of years before the present,[188] in some circoviruses,[75] and in plant geminiviruses.[58,257]

Nucleotide substitution rates also exhibit marked variation within large DNA viruses with some, particularly poxviruses, exhibiting such relatively high rates that they can be readily measured over the timescale of human observation and which likely reflects high background rates of mutation and replication. A case in point is VARV, in which estimates of the substitution rate fall between 10^{-6} and 10^{-5} subs/site/year, and hence are far higher than those observed in other large DNA viruses (particularly the herpesviruses) where evolutionary rates have been inferred.[60,76,238] VARV evolution is also characterized by a strongly linear relationship between genetic distance and time of sampling (i.e., measurable evolution) that is indicative of both a relatively constant molecular clock and a high substitution rate.[60,76] A similar picture can be painted for myxoma virus (MYXV). Sampling over 50 years in both Australia and Europe has revealed usually highly clock-like evolution on both continents, with substitution rates again in the realm of 10^{-5} subs/site/year.[136]

Natural Selection and Genetic Drift in Virus Evolution

Despite long-standing and continuing debates over whether natural selection or genetic drift is the more important process of evolutionary change at the molecular level, there is little doubt that viruses provide some of the very best examples of natural selection in action. The available literature contains numerous examples of natural selection for such properties as immune evasion (of antibody, T-cell, or innate responses), antiviral resistance, and the adaptation to new cell types and host species. The strength of these selection pressures is readily apparent in the fact that the genomes of large DNA viruses such as poxviruses and herpesviruses contain many genes dedicated to immune evasion, and that host genes that provide the strongest evidence for adaptive evolution are those involved in antiviral responses.[176] The frequency with which positive (i.e., Darwinian) selection is identified should come as no surprise as virus and host are locked in an evolutionary arms race.[231]

As there are numerous examples of positive selection for both RNA and DNA viruses, and since they are generally not contentious, we will not discuss them here. A more pressing question is what proportion of all the mutations that arise and are fixed in viral genomes are entirely free of natural selection and hence evolve in a strictly neutral manner, compared to the proportion that are fixed because they are selectively advantageous. Simple population genetic theory predicts that natural selection should be a potent force in viral evolution because of their often very large population sizes. Specifically, natural selection dominates molecular evolution when $Nes >> 1$, where Ne is the effective population size, and s the selection coefficient (i.e., the fitness of the mutation in question). However, estimating these parameters is usually extremely difficult, such that the measures obtained are often only approximate. As a consequence, conclusively determining the role of natural selection versus genetic drift in viral evolution is inherently complex, although a number of important generalities can be made.

In the case of RNA viruses, and likely small DNA viruses, it is probable that few amino acid mutations are strictly neutral (i.e., $s = 0$), with most clearly deleterious. In particular, the small genomes of RNA viruses ensure there is extensive pleiotropy, epistasis, and multifunctionality such that there

is little evolutionary elbow room. For example, mutagenesis studies of vesicular stomatitis virus (VSV) revealed that nearly 40% of random mutations are lethal, another 29% deleterious, a further 27% neutral, and only 4% beneficial.[227] A similar preponderance of deleterious compared to beneficial mutations was observed in poliovirus (Fig. 1.8).[3] Importantly, however, these estimates only relate to fitness effects in a single cell and a far larger proportion of mutations are expected to be deleterious (or lethal) when considering the entirety of the virus life cycle. The same is also likely to be true of ssDNA viruses, which are also characterized by very small genome sizes. Accordingly, most estimates of the ratio of nonsynonymous (d_N) to synonymous (d_S) nucleotide substitutions per site (ratio d_N/d_S, a common measure of selection pressures, with $d_N/d_S = 1$ indicative of selective neutrality) in RNA and ssDNA viruses indicate that purifying selection is the most common evolutionary force (i.e., $d_N/d_S < 1$).[110,121] However, the case of large DNA viruses is far less clear, in large part because relatively few studies of their molecular evolution have been undertaken. One comparative study of d_N/d_S revealed weaker purifying selection in DNA than RNA viruses,[121] suggesting that the former may possess a class of neutrally evolving amino acid sites. Although the explanation for this effect is unclear, it may be a function of the large genome sizes in large dsDNA viruses, which allow more genetic redundancy through the presence of duplicated genes (see later). Alternatively, it may be indicative of greater levels of positive selection in DNA viruses, as also suggested by the high rates of nucleotide substitution documented in some cases.[76] Determining the exact nature of the selection pressures acting on large DNA viruses, including the fitness of individual mutations, is clearly an area where a combination of experimental study and evolutionary analysis will be of fundamental importance. Finally, in the same way that substitution rates are time dependent in viruses, so are inferences of selection pressures based on estimates of d_N/d_S.[56] In particular, the presence of transient deleterious mutations will tend to inflate estimates of d_N/d_S toward the present, such that sequence comparisons should again only utilize sequences sampled over the time spans.

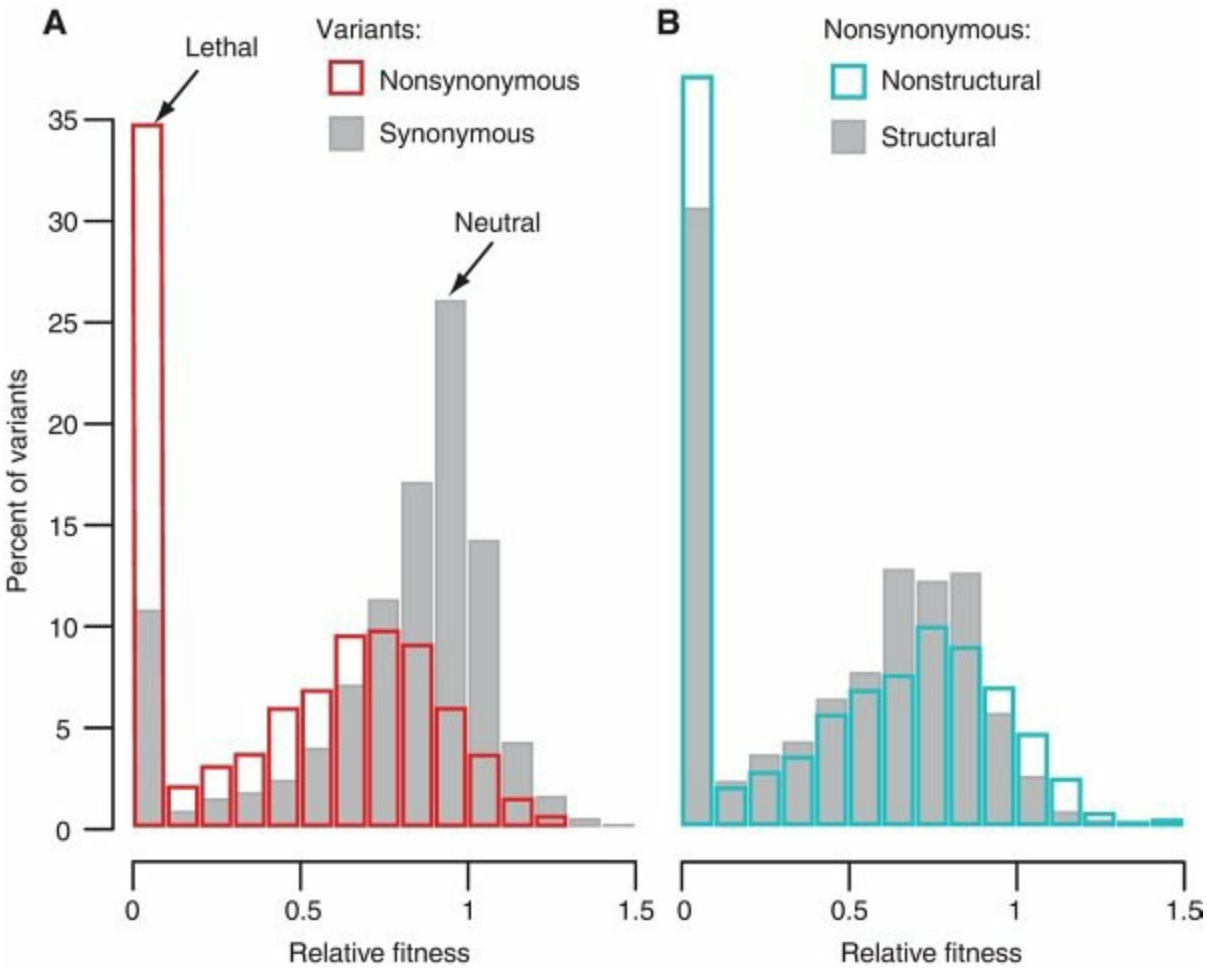

Figure 1.8 The distributions of fitness values among mutations in poliovirus revealed by a next-generation sequencing approach. **A:** The overall fitness of synonymous (*gray*) and nonsynonymous (*red*) mutations. **B:** The fitness of nonsynonymous mutations in structural (*gray*) and nonstructural (*blue*) genes. Note that the great majority of mutations fall into the deleterious class. (Adapted from Acevedo A, Brodsky L, Andino R. Mutational and fitness landscapes of an RNA virus revealed through population sequencing. *Nature* 2014;505:686–690, by permission of Springer Nature. Original figure kindly provided by Dr. Raul Andino.)

Obviously, the most likely class of neutral sites in viral genomes are those that do not code for proteins. For RNA viruses it is debatable how many

nucleotide sites fall into this category, particularly as these viruses contain very few, if any, clear-cut examples of “functionless” noncoding RNA, such as pseudogenes and introns, and where RNA secondary structure may also impose selective constraints (Fig. 1.9). A similar story can be told for small DNA viruses, either single or double stranded, which can be considered as exemplars of genomic efficiency. Indeed, many small DNA viruses, such as circoviruses, parvoviruses, and hepadnaviruses, contain extensive overlapping reading frames, suggesting that they are under strong selective pressure to maximize the phenotypic diversity they can produce from a restricted genomic space.[39] Importantly, the existence of overlapping reading frames changes the selective regime acting on many nucleotide sites. In particular, synonymous sites in one reading frame are likely to be nonsynonymous in another, such that they must be subject to some sort of purifying selection. Similarly, although some pseudogenes are present in the genomes of large DNA viruses,[87] there are relatively few gene overlaps, and it is unclear whether they contain stretches of purely nonfunctional DNA. For example, although the genomes of herpesviruses and poxviruses contain many regions that do not code for protein (~5%–15% of the genome in the case of poxviruses), these may still encode promoters, transcription termination signals, functional RNA molecules, or other functional elements. One candidate for truly nonfunctional sequences is the imperfect tandem repeat seen in the intergenic regions of some poxviruses and that exhibit various deletions and duplications. Understanding the potential functions, if any, of these noncoding regions is an important goal for the future.

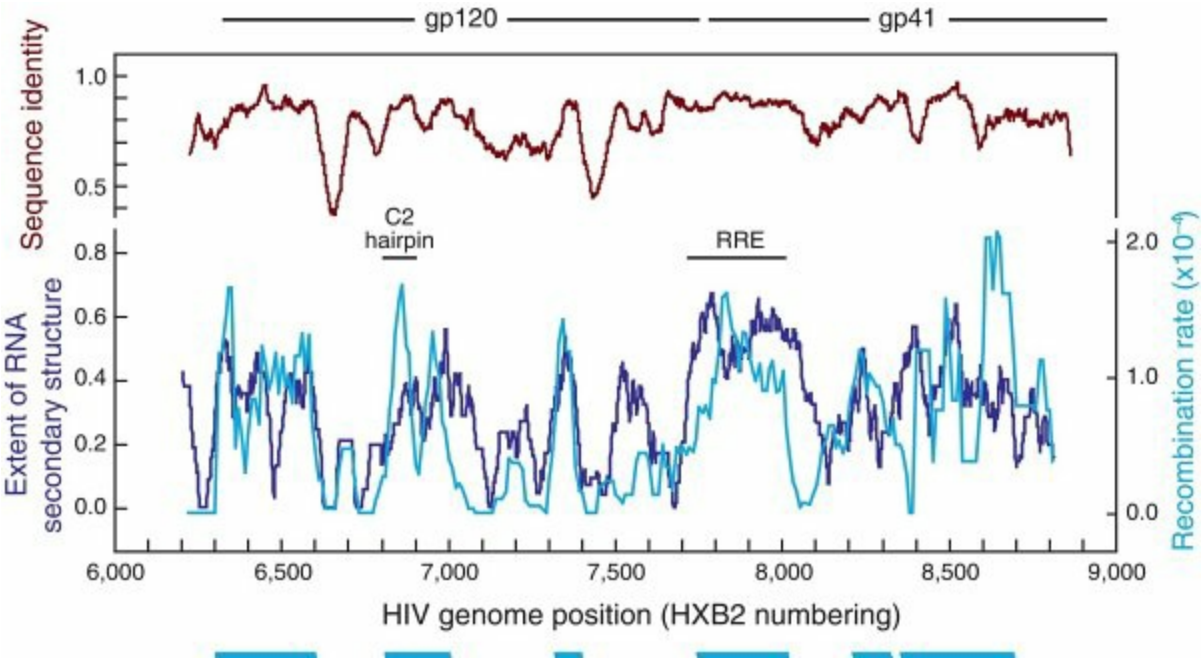

Figure 1.9 The relationship between recombination rate, sequence similarity, and RNA secondary structure in the *env* (envelope) gene of human immunodeficiency virus type 1 (HIV-1). Recombination rates are shown in *light blue*, conserved RNA structures in *dark blue*, and sequence similarity (identity) in *brown*. The location of recombination hotspots are marked by *light blue bars* at the bottom of the figure. (Adapted from Simon-Loriere E, Martin DP, Weeks KM, et al. RNA structures facilitate recombination-mediated gene swapping in HIV-1. *J Virol* 2010;84:12675–12682, which should be consulted for more details; by permission of the American Society for Microbiology. Figure kindly provided by Etienne Simon-Loriere.)

Intra- and Interhost Diversity and Transmission Bottlenecks

After the selective coefficient of mutations, the second factor that determines the respective roles of natural selection and genetic drift in virus evolution is the effective population size (*Ne*), which is usually far lower than the census

population size, *N*. Available data indicate that *Ne* fluctuates dramatically during the life cycle of most viruses. For all exogenous viruses, large values of *Ne* are most likely observed within an individual host following multiple rounds of replication and at the epidemiologic scale. Natural selection is expected to be an efficient force in these cases. For example, perhaps 10^{10} virions are produced by HIV-1 replication per day in every infected individual,[205] with some 10^7 human hosts HIV infected on a global scale. In addition, the burst sizes of many acute viruses will be large, such that within-host values of *Ne* are expected to be high for at least some parts of the virus life cycle. The exception to this rule may be latent viruses, in which effective population sizes are often likely to be relatively small, reflecting a lack of active replication.

Conversely, low values of *Ne*, reflecting the time when genetic drift is strongest and perhaps overriding the action of natural selection, will generally occur at interhost transmission. At this point in the virus life cycle, a major population bottleneck may be a common occurrence, although this is also likely to be at least in part determined by the mode of transmission and hence the infecting dose; for example, vertical transmission (wide bottleneck) might be expected to be associated with the transfer of more viruses between hosts than sexual transmission (narrow bottleneck).[155] In some cases, including HIV-1 and influenza virus, it is possible that the transmission bottleneck is so extensive that new infections are initiated by a single virus particle,[2,79] which would obviously result in a major stochastic effect on virus genetic diversity. Similarly, experimental studies of plant viruses have commonly revealed the existence of extensive population bottlenecks, both at interhost transmission and as the virus moves through an individual plant[6,221] and which may also be true of vector-borne viruses of animals.[246] In these cases, the stochastic effects of genetic drift are expected to be strong, even to the extent of allowing many slightly deleterious mutations to rise to appreciable frequencies, although there have been few experiments to address this issue. Interestingly, other sequencing studies have suggested that interhost transmission might be associated with relatively wide population bottlenecks. For example, multiple viral lineages passed among horses during experimental transmissions with equine influenza virus,[189] while the occurrence of mixed infections in viruses such as influenza[94] and dengue[1] also suggests that transmission bottlenecks might be relatively broad in some

cases. Overall, it is evident that a great deal more work is needed to fully understand the nature and scale of population bottlenecks in viruses, particularly those that accompany interhost transmission, and what this means for the relative frequencies of natural selection versus genetic drift, and for evolutionary processes like complementation (see below) that require the transmission of multiple virus particles (Fig. 1.10).

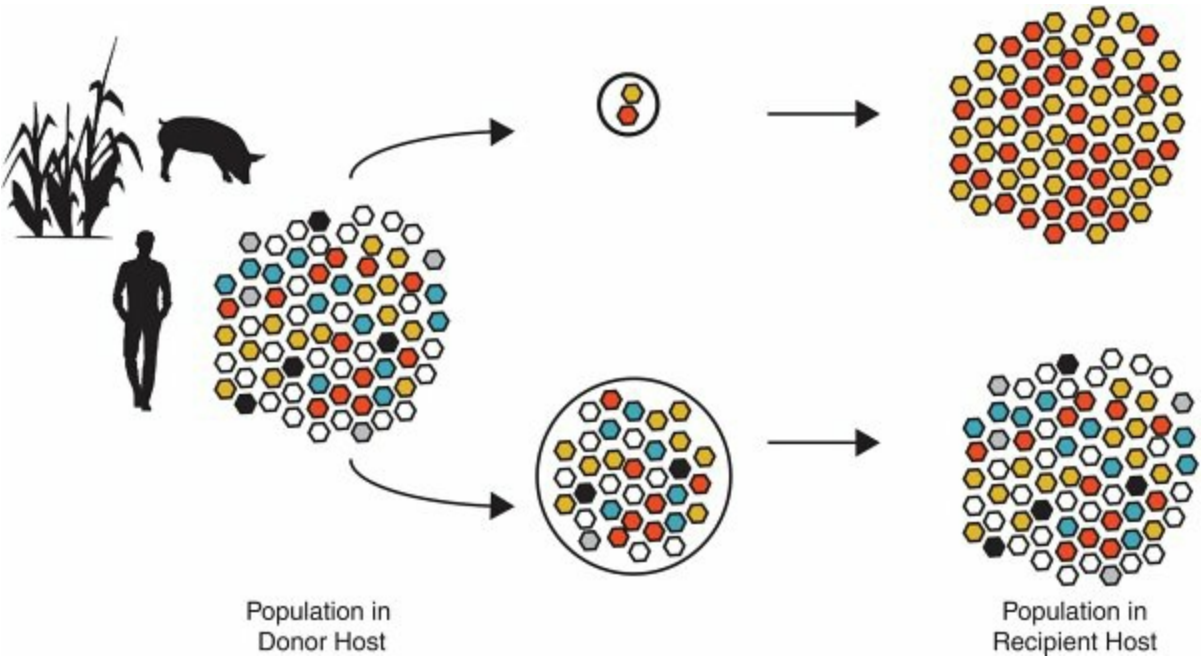

Figure 1.10 The effect of transmission bottlenecks on viral diversity. In a variety of hosts (with the examples of humans, pigs, plant shown here), severe population bottlenecks (*top*) limit the size and diversity of a virus population and hence greatly alter their composition. In contrast, the relatively large populations that pass through looser bottlenecks (*bottom*) allow for the transmission of rarer variants, thereby impacting onward virus evolution, and facilitate virus–virus interactions. (From McCrone JT, Lauring AS. Genetic bottlenecks in intraspecies virus transmission. *Curr Opin Virol* 2018;28:20–25, by permission of Elsevier.)

Evolutionary Interactions: Epistasis, Defecting

Interfering Particles, and Complementation

A common assumption in many evolutionary studies is that nucleotide sites evolve independently. However, this assumption is often highly simplistic as epistatic interactions among mutations are a regular occurrence in viral genomes. Not only might such epistasis be of great functional importance, such as that resulting from RNA or protein secondary structure (see Fig. 1.9), but it may also tell us a great deal about the basic mechanics of virus evolution.

Epistatic effects can be antagonistic (positive), in which case they reduce the effect of combined mutations on fitness, or synergistic (negative), in which case they increase this effect. Although determining the nature of epistasis represents a major technical challenge because it entails a precise measurement of the combined fitness effects of multiple mutations, there is strong evidence for epistasis in viruses, and particularly in RNA viruses where experimental studies are rather easier to perform. Importantly, most of the epistatic interactions determined to date in RNA viruses are antagonistic rather than synergistic,[24,143,228] which has major implications for understanding why recombination evolved in viruses (see later). Similar epistatic effects have been observed in small ssDNA viruses.[204]

It is useful to discuss the extent of epistasis in the context of mutational robustness, which is a way in which phenotypes can be "protected" against the adverse effects of deleterious mutation pressure. Robustness can be generated in a number of ways, including through genetic redundancies such as duplicated genes, through the creation of neutral spaces as might be contained in RNA or protein secondary structure, or by complementation.[48,182] There is a strong relationship between the level of genetic redundancy and epistasis, such that antagonistic epistasis is most common in genomes that are characterized by little redundancy and weak robustness, as is the case for RNA and ssDNA viruses (Fig. 1.11).[66,224] Hence, when mutations occur in viruses with small genomes, which contain many overlapping reading frames and functions, they will tend to repeatedly damage the same functions, leading to antagonistic epistasis.[264] Conversely, synergistic epistasis is more commonplace in larger DNA-based organisms that exhibit a greater level of genetic redundancy and robustness, of which duplicated genes are a good example, which allows them to tolerate a certain

number of deleterious mutations (Fig. 1.11). Where large DNA viruses fall on this spectrum is uncertain, as there have been no experimental measures of the rate and sign of epistasis in these organisms to date. However, that multigene families are a common occurrence in large DNA viruses, resulting in a level of genetic redundancy, suggests that most of the epistatic interactions that occur in these viruses will be synergistic.

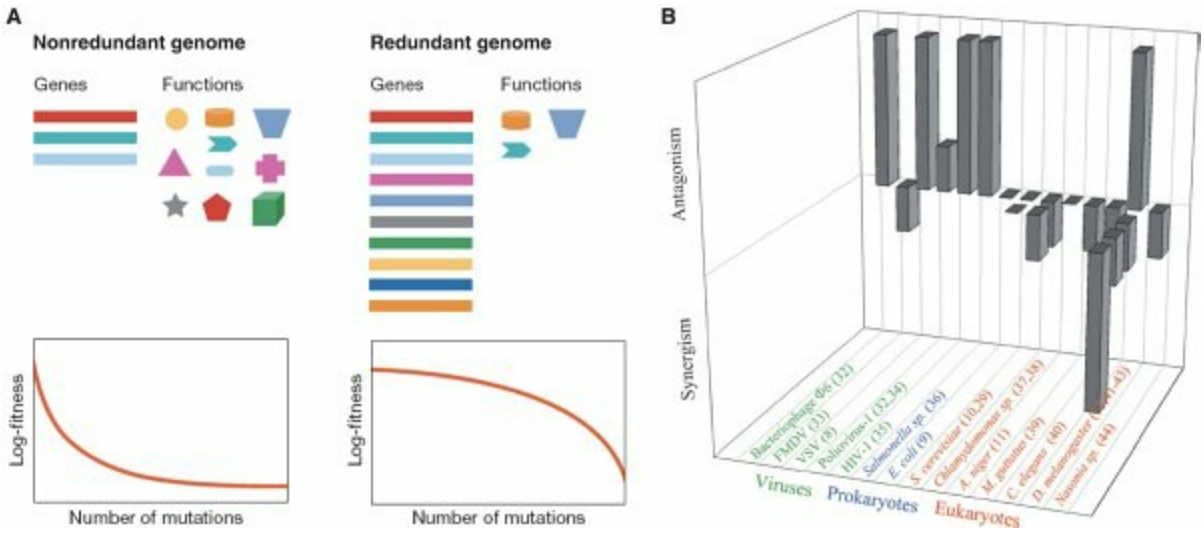

Figure 1.11 Redundancy and epistasis in viruses. **A:** Differing properties of robust (redundant) and nonrobust (nonredundant) genetic systems. In robust genetic systems that contain many genes, which may include large DNA viruses, the presence of genetic redundancy means that individual mutations have weak fitness effects and interact through synergistic epistasis. In contrast, in nonrobust systems such as RNA viruses and single-stranded DNA (ssDNA) viruses, there are few genes, and hence little genetic redundancy, so that single genes have multiple functions and single mutations have strong fitness effects. This results in antagonistic epistasis. (From Elena SF, Carrasco P, Daròs JA, et al. Mechanisms of genetic robustness in RNA viruses. *EMBO Rep* 2006;7:168–173, by permission of EMBO Press.) **B:** The type of epistasis seen in a variety of organisms: long bars, significant epistasis; short bars, nonsignificant epistasis; flat bars, no evidence for epistasis. For

details see reference[225]. (From Sanjuán R, Elena SF. Epistasis correlates to genomic complexity. *Proc Natl Acad Sci U S A* 2006;103:14402–14405, by permission of the US National Academy of Sciences.)

While individual mutations in viruses can interact through epistasis, whole virus genomes can interact through the presence of defective interfering (DI) particles and complementation.[256] DI particles are a common observation in many virus families[119] and have been implicated in a number of virological traits, including persistence.[219] DI particles often harbor large genomic deletions and compete with fully functional viruses during replication because they are able to replicate faster. DI particles have a number of interesting evolutionary consequences, although these will usually be short term. First, the high frequency of DI particles further illustrates the high rate at which deleterious mutations are produced in virus populations, including large-scale deletions. Second, as noted later, the polymerase error process that generates DI particles also has important implications for the evolution of recombination in viruses. Third, because they are able to replicate more rapidly than full-length viral genomes, DI particles may theoretically inhibit the spread of the advantageous mutations that are present on full-length viral genomes, if only transiently.

DI particles are likely to be maintained in virus populations through complementation, which is predicted to be a common occurrence at high multiplicity of infection (i.e., in the absence of large-scale transmission bottlenecks), and which has been relatively frequently documented in both RNA[88,256] and DNA viruses.[40,174,222] Perhaps the most interesting evolutionary consequence of complementation is that it allows deleterious mutations to persist for extended periods.[83] Traditionally, the evidence for complementation came from *in vitro* studies, such that DI particles were thought to survive for just a few generations and therefore had little long-term evolutionary consequence. However, it is now clear that complementation may be frequent in nature[82] and may extend over very long time periods.[1,134] As a consequence, complementation may play more of a role in virus evolution than is usually envisioned,[153] particularly in the

context of how deleterious and advantageous mutations interact with each other, although this will evidently require further study.

The Evolution of Viral Recombination

A combination of comparative genomics and experimental study has provided growing evidence for the importance of recombination, and its sister process reassortment, in viral genomes, although recombination rates vary substantially among viruses. At the sequence level recombination is commonly observed and displayed as incongruent phylogenetic trees, in which phylogenies inferred on either side of a recombination breakpoint differ significantly in topology, reflecting the contrasting evolutionary histories of these gene regions. Although such phylogenetic approaches can be biased in two ways—false positives caused by mixed infection or experimental error[25] and that tree-based methods only detect recombination when there is measurable sequence diversity—they represent a simple means to detect recombination in a wide range of viruses.

Mechanisms of recombination differ markedly between viruses, reflecting the very different types of replication strategy employed, although all require co-infection of a single cell by two or more viruses and it is likely that rates of cellular co-infection vary markedly among viruses. In the case of dsDNA viruses, recombination likely occurs in a manner analogous to that observed in other DNA-based organisms, although the precise mechanisms of recombination are not known in all cases. Hence, recombination will involve the occurrence and repair of double-stranded breaks and, in the case of large dsDNA viruses, the presence of multiple recombination enzymes.[125] Recombination appears to be particularly commonplace in poxviruses, an apparent outcome of the form of DNA strand invasion used in replication,[70,72] as well as in herpesviruses.[27] Recombination in large DNA viruses can be both homologous, in that it occurs at regions exhibiting strong sequence identity, and nonhomologous, involving divergent gene sequences (usually occurring as LGT) and can occur at the intra- and interspecific levels.[254] It therefore plays a major role in shaping genomic architecture.[175] For example, in poxviruses recombination may be more commonplace at the extremities of the genome, as these contain most of the species-specific genes, than in the central genomic regions that are conserved among viruses.[69,175] Less is known about the mechanics of recombination in ssDNA

viruses, although it is likely to occur as a consequence of the rolling circle replication employed by these viruses,[232] which may both determine the distribution of recombination breakpoints[258] and result in frequent genome rearrangements, as in the case of Torque teno (TT) virus.[153]

Evolutionary aspects of recombination are better studied in RNA viruses. Recombination in this case occurs by two rather different mechanisms. The first, sometimes called RNA recombination, occurs when two viruses co-infect a single host cell and a hybrid molecule is produced, most likely through a process of *copy-choice replication*,[146] although other mechanisms have been proposed. Under the copy-choice model, the viral polymerase is thought to jump templates during negative strand synthesis, generating a chimeric RNA molecule.[146] Although this process is usually homologous, template switching can also occur among genomic regions that do not share sequence similarity. In theory, RNA recombination can occur in any type of RNA virus, irrespective of their genome structure or orientation, although rates vary substantially among viruses (see later). The second process of recombination in RNA viruses is reassortment, which only occurs in RNA viruses that possess segmented genomes, such that a progeny virus packages segments with different ancestries. Rates of reassortment also vary markedly among RNA viruses, from very frequent in the case of influenza A virus,[161] in which it is likely to be a common occurrence during individual infections, while the process is far less so in the case of hantaviruses.[193]

Clearly, recombination can be of great evolutionary importance for viruses[245] and has been associated with such features as the evasion of host immunity,[164] the development of antiviral resistance,[195] the ability to infect new hosts,[117] escape from RNAi,[4] increases in virulence,[137] and even the creation of new viruses.[262] As a consequence, it is important to document cases of viral recombination and reveal the determinants of this process. However, the occasional occurrence of beneficial traits arising from recombination, including those documented in experimental studies focusing on single systems, does not necessarily mean that recombination evolved for this purpose, as recombination is as likely to break up beneficial genotypic configurations as create them. Indeed, explaining why recombination evolved in general is one of the outstanding questions in evolutionary biology.

For viruses, clues for the reasons underlying the evolution of

recombination are provided by the huge variation in recombination rates, from effectively clonal (i.e., asexual) as seen in some single-stranded ssRNA-viruses,[245] to cases in which the recombination rate per nucleotide exceeds that of mutation. This extensive rate variation is particularly true of RNA viruses. The most common theory for the evolution of recombination across living systems as a whole is that it functions as a form of sexual reproduction in viruses and as such has been selectively optimized to either create advantageous genetic configurations or remove deleterious mutations (Fig. 1.12). However, this seems unlikely as high rates of recombination are only seen in some viruses, with picornaviruses a good example, such that high recombination rates cannot be universally advantageous.[245] This rather patchy distribution sits in marked contrast to theories for the evolution of sex in eukaryotes, the aim of which is to explain common recombination and sporadic asexuality.[218] Similarly, the patchy distribution of recombination means that it is unlikely to universally have evolved as a form of repair.[178]

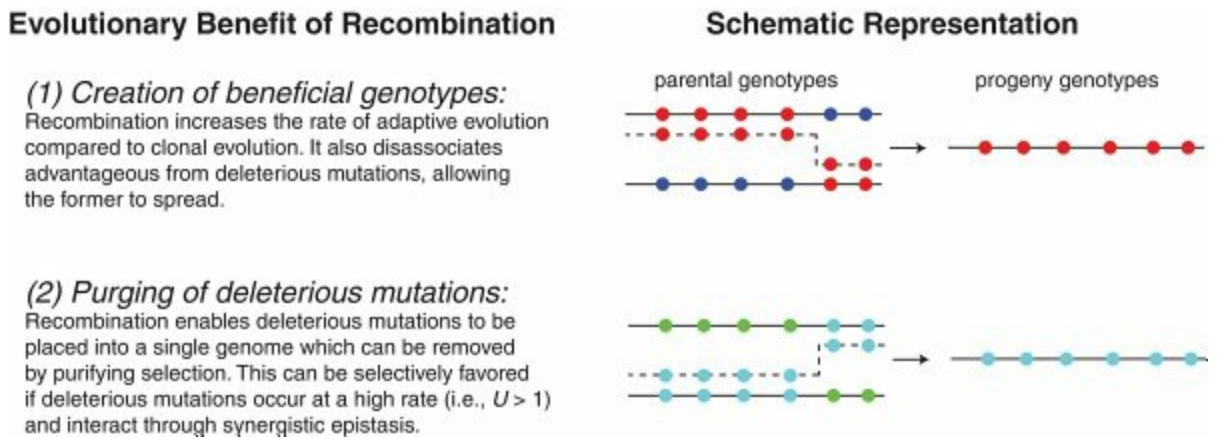

Figure 1.12 Potential evolutionary benefits of viral recombination (and reassortment) that might be favored by natural selection and that are commonly invoked in discussions of the evolution of sex. Accordingly, recombination can either (1) create advantageous genetic configurations (*red circles*), and also disassociate advantageous from deleterious mutations, or (2) purge deleterious mutations (*green circles*) by placing them in a single individual, which can be removed by purifying selection. In both cases, the *dashed line* denotes the recombination event. The rate of

deleterious mutations per genome replication is denoted *U*. (Adapted from Simon-Loriere E, Holmes EC. Why do RNA viruses recombine? *Nat Rev Microbiol* 2011;9:617–626, which should be consulted for more details, by permission of Springer Nature.)

It is obvious that recombination allows viruses to create potentially beneficial genetic configurations more rapidly than asexual populations, and there are many documented cases in viruses in which recombination has been associated with the generation of advantageous characteristics, such as drug-resistant genotypes. However, there are a number of viruses where rates of recombination are very low but where adaptive evolution is extremely common, with hepatitis C virus (HCV) a good case in point.[217] Hence, it may be that many RNA viruses are able to create a sufficient number of beneficial genotypes through mutation alone to offset the need for recombination.

As well as generating advantageous genotypes, recombination disassociates advantageous from linked deleterious mutations,[218] and prevents *clonal interference*. The latter describes a competition between beneficial mutations as they go to fixation in asexual populations, such that their rate of adaptation is retarded compared to that of sexual populations. Although both these processes are likely to occur in virus populations,[180] their overall importance is unclear.

The second advantage of recombination over purely clonal evolution is that it facilitates the efficient removal of deleterious mutations. This is often called the *mutational deterministic hypothesis* and is a much debated theory for the evolution of sex in a wide range of species.[135] The central idea is that rather than many individuals (or genomes) carrying deleterious mutations, which would have a major negative impact on fitness, recombination allows these injurious mutations to be placed in a single individual whose selective removal greatly reduces fitness costs. A related theory is that of Muller's ratchet, which describes a progressive decrease in fitness due to the gradual accumulation of deleterious mutations in asexual populations of finite size and where genetic drift accelerates the loss of mutation-free individuals. Muller's ratchet has been observed in laboratory populations of RNA

viruses[35,36,54] and may play some role when clonal viruses experience small population sizes, such as during transmission bottlenecks, although its effects are likely to be negated when viruses reach large population sizes. Importantly, sequence comparisons suggest that the burden of deleterious mutation is high for all RNA viruses studied, irrespective of background recombination rate.[212] Hence, it is not recombination that saves RNA viruses from an excessive mutational load as predicted under the deleterious mutation hypothesis, but their large population sizes that provide a form of *population robustness* that offsets the effects of deleterious mutation.[66]

An opposing theory for the evolutionary origin of viral recombination is that rather than being optimized by natural selection as a form of sexual reproduction, it is in fact a mechanistic by-product of differing types of genome architecture, replication strategy, and polymerase processivity.[245] Importantly, however, this does not exclude recombination rates then being selectively optimized in individual viruses to increase other aspects of viral fitness.[271] The main evidence for this theory is that there is an apparent association between recombination frequency and virus genome structure. Hence, recombination is relatively frequent in some retroviruses, and as reassortment in viruses with segmented genomes. Far more variable recombination rates are observed in ssRNA+ viruses; for example, frequently in coronaviruses and picornaviruses, sporadically in flaviviruses, and currently not documented in the *Leviviridae* and *Narnaviridae* (although this may simply be a function of sample size). Finally, recombination is far less common in ssRNA– viruses. An informative example of the disparity of recombination rates is provided by a comparison of HIV-1 and HCV. In the former, recombination rates have been estimated at between 1.38×10^{-4} and 1.4×10^{-5} recombination events per site, per generation,[192,243] while the equivalent estimates for HCV are only 4×10^{-8}.[217] Most DNA viruses studied to date seem to experience relatively high levels of recombination (including through LGT in the case of large DNA viruses), although there have been few attempts to estimate rates of recombination relative to those of mutation.[27]

In each case described previously, the frequency of recombination seems to reflect the genome structure of the virus in question.[245] Hence, the high recombination rates of retroviruses are likely a function of the fact that their virions carry two RNA molecules, such that *heterozygous* progeny will be

produced when viruses with different ancestries are packaged together. Copy-choice recombination, which is common in RNA viruses, may then produce genetically distinct progeny during reverse transcription. That heterozygous viral progeny cannot be produced when the genomic material is present as a single molecule obviously acts to reduce recombination rates in most RNA viruses. However, in some cases specific genome organizations can facilitate frequent recombination. Case in point are the coronaviruses, such as murine hepatitis virus (MHV), where up to 25% of the progeny of coinfected cells may be recombinant. Such a high recombination rate reflects the mechanisms controlling gene expression in coronaviruses, in which discontinuous transcription leads to the production of subgenomic RNAs through a copy-choice mechanism.[230] An even more dramatic example of how replication strategy and genome organization may shape recombination rate occurs in the ssRNA– viruses, in which recombination is relatively infrequent. In these viruses the genomic and antigenomic RNA molecules are quickly bound to multiple nucleoprotein subunits, as well as to other proteins, to form ribonucleoprotein (RNP) complexes from which viral replication and transcription can proceed. This tight complex of RNA and protein necessarily limits the probability of hybridization of complementary sequences between the nascent and acceptor nucleic acid molecules, and hence the probability of template switching.[245] This likely explains why phylogenetic studies undertaken to date have revealed relatively few cases of recombination in ssRNA– viruses.[10,267]

The RNA Virus Quasispecies

One of the most debated issues in the study of virus evolution is whether RNA viruses evolve according to a particular population genetic model known as the *quasispecies*.[110] In some respects, this merely reflects a semantic point about how best to describe the intrahost genetic variation commonly seen in RNA viruses. However, a far more important issue, and the true essence of the quasispecies debate, is how natural selection acts on virus genomes.

Quasispecies theory was originally developed by Manfred Eigen and colleagues as a model of the evolution of self-replicating RNA molecules that are strong candidates for the first replicators on earth.[64,65] The theory was first applied to RNA viruses after genetic variation was observed in a number

of experimental systems, beginning with the bacteriophage Qβ.[50] Since this time, the quasispecies has become a popular and common descriptor of intrahost RNA virus evolution, particularly because widespread gene sequencing has uncovered abundant genetic diversity. However, because the theory is based on high mutation rates (see later), it should not be applied to large DNA viruses where error frequencies are lower and hence there is no evidence for quasispecies evolution.

Although commonly used simply as a synonym for genetic variation, the quasispecies in fact describes a specific mutation–selection balance. Mutation–selection balances are commonly invoked in population genetics and describe an evolutionary equilibrium between the generation of new mutations and their removal by purifying selection.[91] The mutation–selection balance in quasispecies theory is based on the occurrence of an extremely high mutation rate, which ensures that the frequency of any variant in the virus population is a function of both its individual fitness *plus* the frequency at which it is produced by the erroneous replication of other variants in the population that are linked to it in mutational (i.e., sequence) space. This *mutational coupling* (which should be distinguished from complementation) means that viral genomes are not independent entities, such that natural selection favors the entire population as opposed to individual variants. In this manner the group, rather than the individual, becomes the unit of selection.[9,65]

The central tenet of quasispecies theory is thus that natural selection acts on the viral population as a whole, rather than on individual variants. As a consequence, the entire quasispecies evolves to maximize its average fitness, rather than that of individual variants as is the case in other population genetic models. The most interesting outcome of this particular evolutionary process is that low-fitness variants can sometimes outcompete those of higher individual fitness if the former are surrounded by beneficial mutational neighbors. This is sometimes referred to as the *quasispecies effect* or the *survival of the flattest,*[265] and describes a situation in which a population whose component mutants have a similar mean fitness can outcompete a population that has a lower average fitness even though it contains variants of higher individual fitness. Under classic *survival of the fittest* population genetic models, the individual high-fitness variants are selectively favored, whereas under *survival of the flattest* (i.e., quasispecies) models, the flatter

population is selectively superior as it possesses a higher mean fitness (Fig. 1.13). This can also be thought of as a form of mutational robustness.

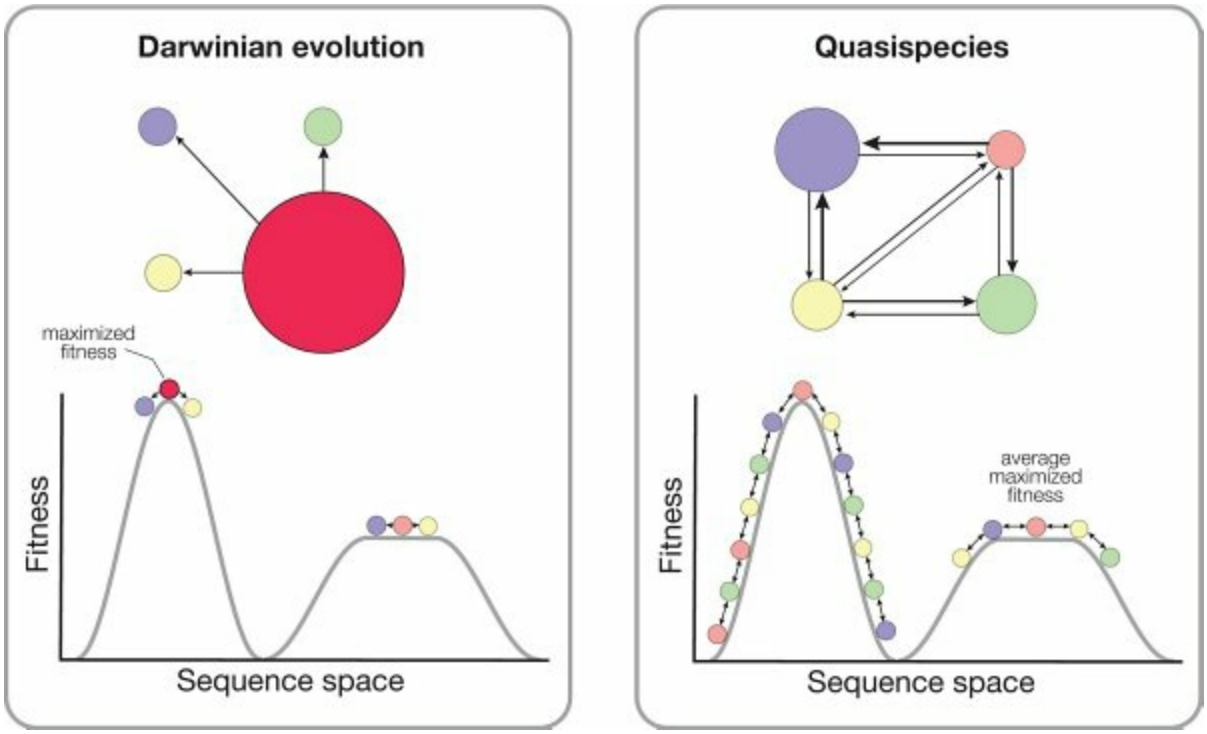

Figure 1.13 Comparing "Darwinian" and quasispecies models of RNA virus evolution. In the Darwinian virus population, natural selection favors the single variant with the highest individual fitness (*circle shown in red*). Genetic variants of lower fitness (*colored blue, green, and yellow*) are produced by mutation at a relatively low rate. In contrast, under the quasispecies model, very high mutation rates mean that individual variants (represented by different colors) experience a mutational coupling. This, in turn, means that the viral population will evolve as a single unit, with natural selection acting on the population as a whole (rather than on individual variants), maximizing mean fitness. Accordingly, the mutational landscape greatly impacts virus evolution. In the top part of the figure the circle sizes represent relative fitness values, whereas they are drawn to equivalent sizes in the bottom part of the figure. (From Geoghegan JL, Holmes EC. Evolutionary virology at

40. *Genetics* 2018;210(4):1151–1162. https://doi.org/10.1534/genetics.118.301556)

A key component of quasispecies theory is that intrahost populations of RNA viruses harbor abundant genetic diversity. There is no doubt that this specific aspect of quasispecies theory is correct, and even so for short-term acute infections, as intrahost genetic variation is commonly observed in RNA viruses.[110] In particular, deep sequencing studies of individual virus populations have revealed extensive genetic diversity, with HIV-1,[33] HCV,[177] foot-and-mouth disease virus (FMDV),[270] dengue virus,[199,200] and influenza virus[171] serving as good examples, although a multitude now exist. Importantly, however, although the observation of intrahost genetic variation is a necessary criterion for an RNA virus population to be thought of as a quasispecies, it is not sufficient in itself as intrahost genetic diversity is expected under any evolutionary model where mutation rates are high. Hence, the quasispecies is not simply another word for intrahost genetic variation.

Both *in silico* and *in vitro* studies have provided some evidence for the existence of quasispecies dynamics defined correctly. As an example of the former, computational studies using *digital organisms* revealed that the survival of the flattest could be induced at very high mutation rates.[42,265] However, as the mutation rates involved were always higher than one mutation per genome replication, it is uncertain whether such mutation rates could ever be attained for sustained periods in RNA viruses in nature. Similar results have been obtained from some experimental analyses of RNA virus evolution. Studies using both viroids of plants and VSV showed that viral populations with lower replication rates were able to outcompete those with higher replication rates, as expected under the quasispecies model, although this again requires the elevation of mutation rate (by either chemical mutagens or ultraviolet C light) to levels that may not commonly occur in RNA viruses in nature.[41,225] Additional experimental evidence for the existence of RNA virus quasispecies was the observation that high-fitness clones of bacteriophage ϕf6 evolved to a lower mean fitness because their mutational neighbors were of low fitness.[31] More controversial evidence was that strains of poliovirus that possessed higher fidelity than the wild type,

such that the virus population carried less genetic diversity, were unable to infect the full range of tissues that are associated with severe disease.[259] While this was suggested to mean that quasispecies dynamics might be a central determinant of viral pathogenesis,[259] it has also been suggested that this observation more likely reflects a trade-off between replication speed and fidelity.[79]

Another class of experimental studies that have been cited in support of the quasispecies model involves lethal mutagenesis. This entails treating virus populations with mutagens, such as 5-fluorouracil and ribavirin, that increase the error rate to the extent that so many deleterious mutations are produced that fit genotypes are never able to regenerate themselves. Although lethal mutagenesis can clearly result in virus extinction, especially if mutagens are used in combination with more standard antiviral inhibitors,[8] the basis of this effect is more complex. Quasispecies theory predicts that virus extinction in this instance occurs because of an *error catastrophe*, which is the point at which the fittest genotype suffers so many deleterious mutations that it cannot sustain itself in the population (i.e., it has breached an *error threshold*). However, another interpretation is that the virus has instead crossed an *extinction threshold*, the point at which deleterious mutations accumulate faster than they can be eliminated by natural selection, which will also lead to population extinction.[30] Importantly, error catastrophe requires a fundamental shift in viral genotype that is independent of population size, whereas extinction threshold entails a major decline in viral population size.

Studies of RNA virus evolution based on the comparative analysis of gene sequence data have provided less support for the existence of quasispecies. Indeed, there is currently no clear evidence from comparative genomics that selection acts on groups rather than individual variants in natural populations of RNA viruses, although this may reflect the fact that even with the most sophisticated tools of gene sequence analysis it is difficult to discern the effects of all but the most strongly favored and disfavored variants. For example, the deep sequencing of intra- and interhost diversity in dengue virus provided strong evidence for host adaptation, with the same virus mutations appearing independently across multiple patients.[200] Importantly, however, there was no evidence for the quasispecies expectation that fitness was impacted by mutational neighborhood and hence no evidence

for quasispecies dynamics. In other cases, such as influenza virus, the adaptive evolution required under quasispecies theory appears to be of limited importance within individual hosts, with random genetic drift and large-scale population bottlenecks playing a more important role.[170] Again, though, it is arguable that natural selection is so strong in these cases as to obscure any quasispecies effect, and that the latter model is a far better description of mutations subject to weaker positive selection as most natural selection will be in nature. This is clearly a major area for further study.

Given a sufficiently high mutation rate, quasispecies is a viable and interesting evolutionary model that has undoubtedly helped introduce evolutionary ideas into virology. However, it is less clear whether the quasispecies concept can be successfully applied to RNA viruses in nature, where to date there has been no convincing evidence for its occurrence. This does not necessarily mean that the quasispecies model is wrong, but rather that too few RNA viruses have been studied in sufficient detail through a combination of deep sequencing and precise fitness assays to determine whether they form quasispecies, exemplified by a process of natural selection acting on the virus population as a whole.

PATTERNS AND PROCESSES OF VIRAL GENOME EVOLUTION

The Evolution of Virus Genome Size

Viruses possess a remarkable range of genome sizes (Fig. 1.14). This is especially so in the case of DNA viruses in which genome sizes range from less than 2,000 nt in circoviruses (ssDNA) to a remarkable 2,473,870 nt (comprising 2,394 ORFs) in the case of *Pandoravirus salinus* (dsDNA),[148,208] hence covering over three orders of magnitude, although all ssDNA viruses have genomes less than 11,000 nt in length. A far narrower range of genome sizes is observed in RNA viruses. The smallest RNA virus currently known is HDV at only about 1,700 nt, while the largest RNA viruses are from the order *Nidovirales*, and can possess genome sizes over 40,000 nt,[220] and it is possible that ongoing metagenomic surveys will eventually uncover far larger viruses. Interestingly, there does not appear to

be a major difference in genome size between segmented and unsegmented RNA viruses,[110] with, for example, the unsegmented *Nidovirales* possessing larger genomes than all segmented RNA viruses, and metagenomic studies have shown that invertebrate viruses often possess longer genomes than do their vertebrate counterparts.[240,241] This strongly suggests that genome segmentation has not evolved as a way to increase virus genome sizes. Similarly, metagenomic studies have revealed that in the case of some RNA virus families such as the *Flaviviridae*, the genomes of viruses are longer and more complex than those of their vertebrate counterparts,[241] although the reasons why are again unclear.

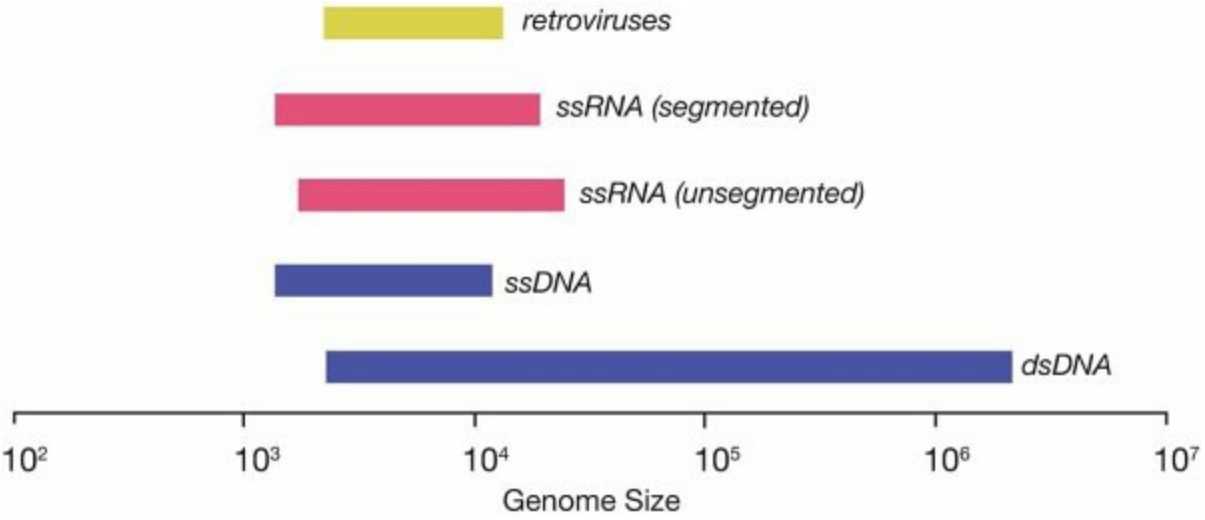

Figure 1.14 Currently known distribution of genome sizes (bp) in RNA and DNA viruses. Note the similarity in (small) genome sizes between RNA viruses, retroviruses, and single-stranded DNA (ssDNA) viruses.

A variety of theories have been proposed to explain the evolution of genome sizes in viruses. One theory is that virus genome sizes are constrained by the maximum size of the genetic material that can be contained within a single capsid protein,[274] and there does appear to be a strong allometric relationship between genome and virion sizes in viruses, although what drives what is difficult to resolve.[45] However, the huge range of genome sizes, especially in DNA viruses, argues against this. The genome content of large DNA viruses

in part reflects often frequent LGT and gene duplication (see later). In particular, the central part of the genome of many large DNA viruses is composed of a set of core genes that control basic biochemical functions, including replication, while the outer, flanking genes distinguish individual viruses and are often responsible for modulating immunity, host range, and virulence, and it is these that have often been captured from host genomes. This process of gene birth and depth has resulted in a great variation in genome sizes, with, for example, a massive increase in genome size from the ancestral NCLDV to those circulating today.[125] This evolutionary process, combined with the discovery of the giant viruses of algae and amoeba, suggests that there are unlikely to be strict constraints against genome sizes in large DNA viruses. Similarly, that bacteriophages are able to transiently carry large parts of bacterial genomes, which evidently plays a key role in LGT among bacterial species,[197] also argues against strict constraints on genome size.

However, it is also the case that certain structural features must constrain genome sizes to some extent. First, longer viral genomes are expected to cause an increase in replication times, which may be disadvantageous. Second, in the case of RNA viruses, it is possible that the difficulty in unwinding potentially long regions of dsRNA during replication inhibits the maximum genome size attainable.[215] For example, it has been argued that the unwinding of dsRNA in RNA viruses with genomes greater than 6,000 nt is controlled by the presence of a helicase (HEL) domain,[98] the evolution of which allowed RNA viruses to greatly increase their genome size.[97]

A more plausible explanation for the range of viral genome sizes is that they reflect background mutation rates. As noted previously, there is a fundamental relationship between mutation rate and genome size that seemingly applies to all living systems (Fig. 1.7). Accordingly, dsDNA viruses with relatively low mutation rates will be able to attain relatively large genome sizes, while the small genomes observed in RNA and ssDNA viruses reflect the higher error rates seen in these systems. Perhaps paradoxically, the idea that mutation rates set genome size can be extended to explain the very large (by RNA virus standards) genomes seen in the *Nidovirales*. The major part of the genomes of these families is composed of a large (>20,000 nt) replicase gene that contains an ExoN domain encoding a 3′ to 5′ exoribonuclease. As this ExoN domain is homologous to cellular

proteins of the DEDD superfamily of exonucleases that are involved in proofreading and repair,[179] it is possible that *Nidovirales* reduce their error rate through some sort of proofreading activity of the 3′ to 5′ exoribonucleases.[61] This, in turn, will reduce mutational load and allow larger genome sizes.

A final important difference between RNA and dsDNA viruses with respect to genome size is that the former (as well as ssDNA viruses) frequently utilize overlapping open reading frames, whereas these are less common in the latter (although, e.g., the M065R and M066R genes of the poxvirus myxoma virus overlap by ~100 bp). Belshaw et al.[16] noted 819 cases of gene overlap among 701 RNA virus genomes; 56% of the viruses examined possessed some degree of overlap, which nearly always involved a +1 or –1 frame shift. In addition, RNA viruses with longer genomes tend to show less gene overlap than do those with shorter genomes.[16] Although the exact evolutionary processes responsible for the evolution of overlapping reading frames are uncertain, they clearly allow an increase in the number of proteins and hence the amount of protein diversity encoded by a single nucleotide sequence.

The Evolution of Genome Organization

It is arguable that viruses contain a greater diversity of genome structures and organizations than any other group of organisms. As well as the obvious division into RNA viruses, DNA viruses, and retroviruses, distinct genome structures include viruses in positive and negative sense orientations, those with single or double strands of the nucleic acid, those with single or multiple segments (which are usually multicomponent in the case of ssRNA+ viruses from plants), those that utilize subgenomic RNAs, and those like the coronaviruses that utilize ribosomal frame shifting. A key challenge for evolutionary virologists is therefore to explain why such a diverse array of structures exists.

One of the most debated issues with respect to the evolution of genome structures in RNA viruses is why some are segmented and others not. As noted previously, one theory for the evolution of segmentation is that it evolved as a way of facilitating reassortment, although this seems unlikely.[245] Similarly, there is no good evidence that segmentation allows the evolution

of longer genomes. Another possibility is that genome segmentation, particularly in the case of multicomponent viruses, resulted from the intracellular selection for smaller RNAs that, because they are shorter, would have had a replication advantage over their full-length counterparts.[191] However, this theory cannot easily explain why multicomponent viruses are nearly all restricted to plants (although this may change with more extensive sampling).

A competing theory for the evolution of genome segmentation is that it allows greater control over gene expression. Clearly, all RNA viruses need to control the levels of each protein they produce. For many ssRNA+ viruses such control occurs at the level of translation as this is necessarily the first step in the virus life cycle. Additional constraints faced by viruses of this type are that eukaryotic ribosomes only recognize the 5′ regions of mRNA molecules, so that internal start codons are not utilized, and mRNAs are usually monocistronic.[110] Many ssRNA+ viruses therefore simply translate a single polyprotein that is proteolytically cleaved into individual protein products, which may represent the ancestral type of genome organization in ssRNA viruses. Although this genomic structure allows efficient replication, similar amounts of each protein product are produced, so that there is relatively little control over gene expression. As a consequence, other ssRNA+ viruses have evolved a variety of more complex ways to control gene expression, all of which can be envisioned as ways of dividing the viral genome into individual *transcriptional units*, within which transcription (and translation) can occur at different rates. Such a division can involve the creation of multiple genome segments, the utilization of subgenomic RNAs, and the use of a –1 ribosomal frameshift to produce multiple open reading frames as in the case of the *Nidovirales*[110] (Fig. 1.15).

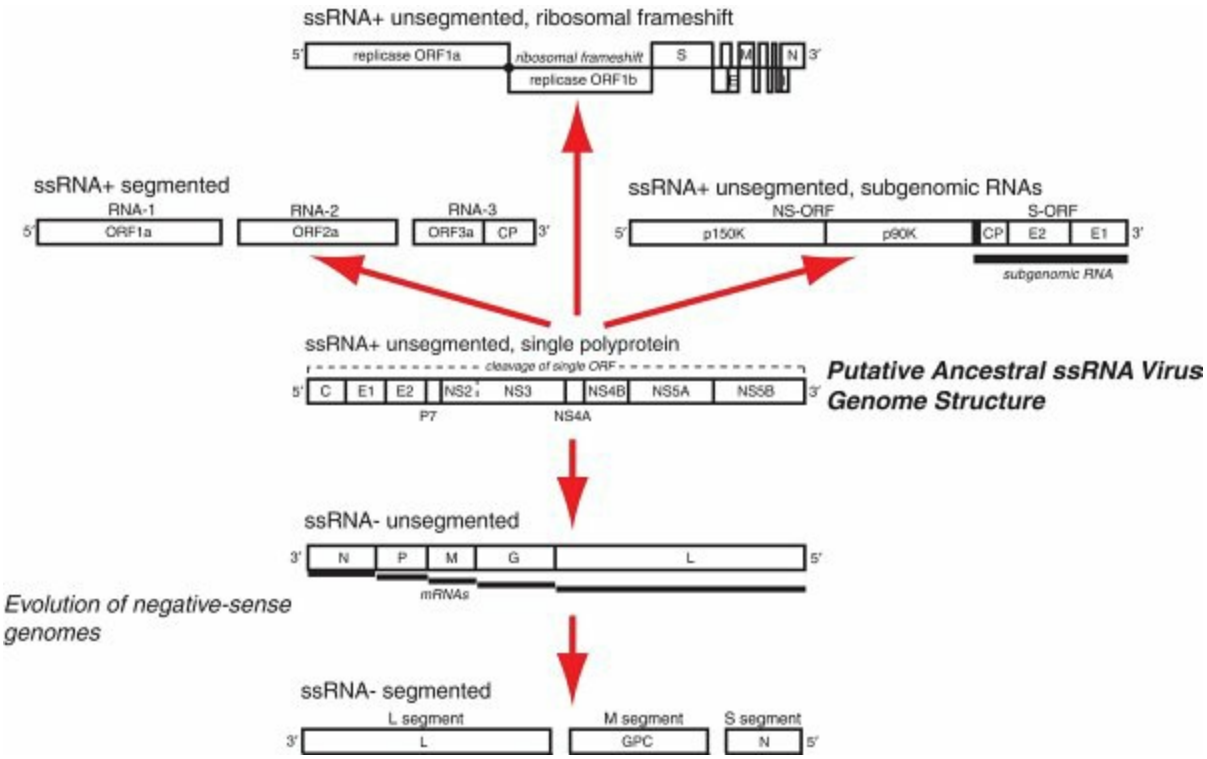

Figure 1.15 Schematic representation of the major types of genome organization and replication strategy in RNA viruses and a scenario for their evolutionary origin. Each of these organizations results in a different way to control gene expression, although they should not be considered as mutually exclusive. Unsegmented single-stranded RNA-positive (ssRNA+) viruses that produce a single polyprotein are considered here to be the ancestral type, although this is debatable. Gene and segment sizes are drawn approximately to scale within each of the six organizations, but not among them, and the 5' and 3' terminal sequences have been excluded for ease of presentation. (From Holmes EC. *The Evolution and Emergence of RNA Viruses*. Oxford: Oxford University Press, 2009, by permission of Oxford University Press.)

The situation is rather different in the case of ssRNA– viruses. Because ssRNA– viruses by necessity transcribe their genomes before translating them, some control over gene expression can occur at the level of

transcription; multiple mRNAs can be produced and there will be a transcriptional gradient from the first (i.e., 3′) mRNA, of which most is produced, to the last (5′) mRNA, of which least is produced. It is therefore possible that the ability to better control gene expression, itself through the control of transcription, represents the reason that negative-sense genomes evolved in the first instance. In this respect, it is significant that the genomes of unsegmented ssRNA– viruses possess a highly conserved gene order, cluster together on polymerase phylogenies, and can easily be classified within the *Mononegavirales*. Moreover, this genome order seems to be a function of the amount of each protein product required, such that the 3′ gene encodes the nucleocapsid while the 5′ gene encodes the RNA polymerase, again suggesting that it is an adaptation to facilitate the control of gene expression.

It is also possible that some of the variation in the genome sizes of RNA viruses reflects the action of gene duplication. Indeed, gene duplication is one of the most important processes of genome evolution in eukaryotes and is a simple way to create new genes that, following subsequent mutation and adaptation, can exhibit different but related functions, which often appear as multigene families. However, it is striking how rarely this process has been observed in RNA viruses,[110] although more examples are being recovered from expansive metagenomic studies and highly divergent gene duplicates may be very difficult to detect. Only occasionally have gene duplication events been described that produce multiple complete (and sometimes tandemly repeated) genes,[28,261] although improvements in computational analysis are likely to reveal more. For example, phylogenetic analysis revealed that three proteins within the Flanders virus genome arose by gene duplication rather than simply being pseudogenes as previously reported.[7] The difficulties in analyzing highly divergent sequences notwithstanding, there are good reasons for the relative rareness of gene duplication in RNA (and ssDNA) viruses. In particular, given the size limit on virus genome discussed throughout this chapter, increasing genome size through gene duplication is likely to result in major fitness losses through an increase in the load of deleterious mutations.

The situation is very different in large dsDNA viruses, where cases of gene duplication, as well as gene loss, are a common observation and are evidently responsible for some of the size variations among viruses[120,233]

(Fig. 1.16). Gene duplication can occur in both the core and species-specific genes of large DNA viruses as signified by the presence of related gene pairs and multigene families.[173] For example, gene duplication has been commonplace in the E4 region of some adenoviruses[47] and in the terminal inverted repeats of the poxvirus myxoma virus,[145] although many other examples exist. The process of gene duplication may also be related to that of recombination. For example, in some poxviruses recombination seems to have resulted in the duplication, inversion, and transposition of genes to opposite ends of the genome.[186] Finally, the analysis of protein structure suggests that some of these gene duplication events may have occurred in the distant past and assisted in the production of very distinct proteins, such as the head–tail connector protein and tail tube protein of bacteriophage lambda.[32]

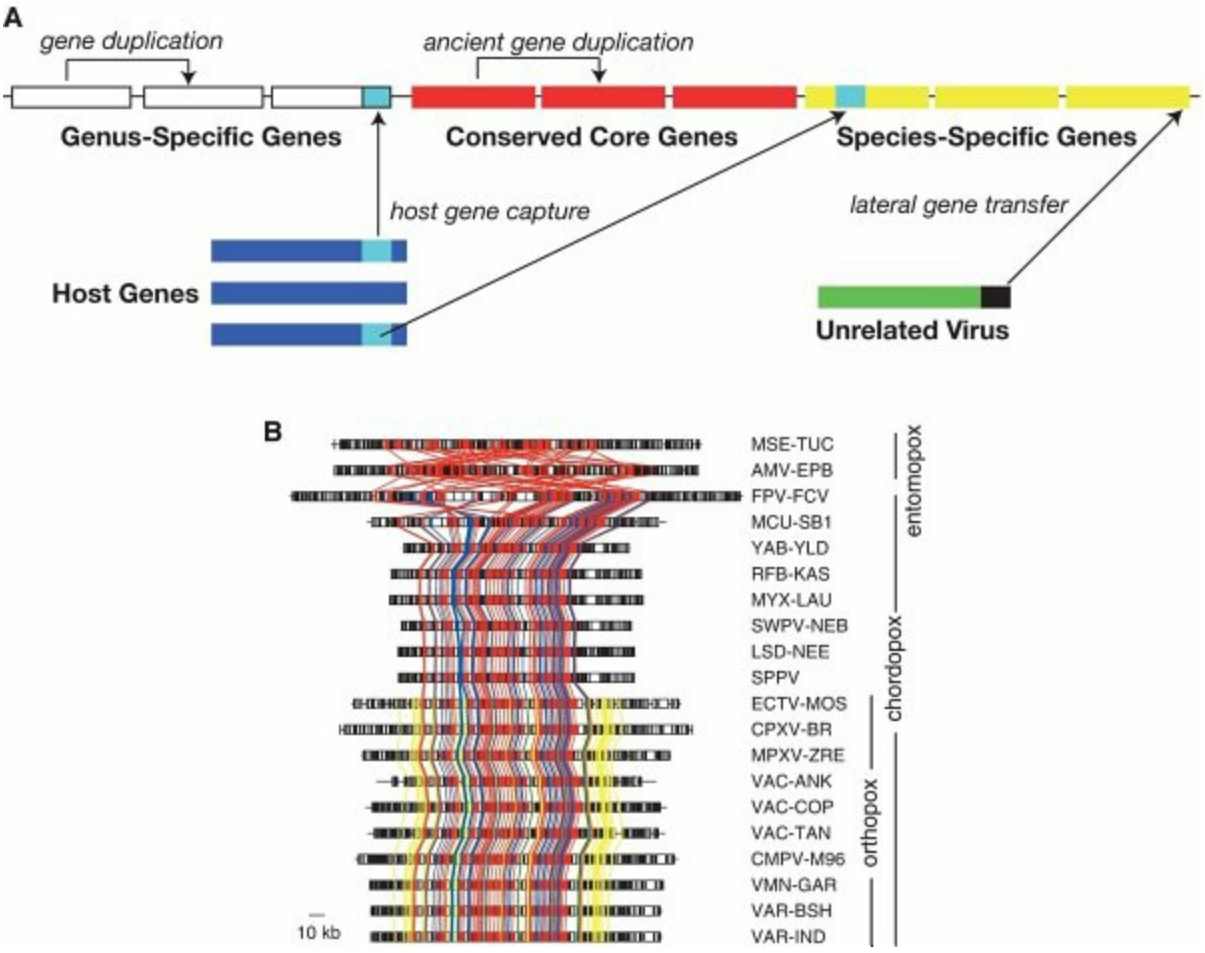

Figure 1.16 Genome evolution in DNA viruses. **A:** Processes of

lateral gene transfer, from both hosts and other viruses, and gene duplication in large double-stranded DNA (dsDNA) viruses. Core viral genes, which are conserved across divergent taxa, are shown in *red* and often located in the central part of the genome. Genus and species-specific genes are shown as *white* and *yellow*, respectively, and more often located at the terminal regions of the genome. (Adapted from Shackelton LA, Holmes EC. The evolution of large DNA viruses: combining genomic information of viruses and their hosts. *Trends Microbiol* 2004;12:458–465, by permission of Cell Press.) **B:** Specific example of the comparative genomics of poxviruses. The figure shows a comparison of 92 gene families from 20 different poxviruses. Genes present in all the poxviruses analyzed are shown in *red* and are located in the central genomic regions. Those genes present in chordopox viruses only are shown in *blue*, while those present in orthopoxviruses only are shown in *yellow*. Vertical lines link orthologous genes. Horizontal differences are drawn proportional to genetic distances. (From McLysaght A, Baldi PF, Gaut BS. Extensive gene gain associated with adaptive evolution of poxviruses. *Proc Natl Acad Sci U S A* 2003;100:14960–14965, by permission of the US National Academy of Sciences. Figure kindly provided by Dr. Aoife McLysaght.)

Lateral Gene Transfer and Modular Evolution

A major way for bacteria to create evolutionary novelty is through lateral (or horizontal) gene transfer (LGT), which can sometimes result in genes being transferred for large phylogenetic distances.[197] Both recombination and LGT are also important because they pose a major challenge to current phylogenetic protocols and may require a new computational tool kit.[122,140] As LGT will also result in an increase in virus genome size, unless the original gene is directly replaced by the invading gene (which is unlikely unless an exact excision is made, as faulty excision will result in deleterious

mutants), it might be expected that it should only occur sporadically in RNA viruses. Although this initially appeared to be the case,[110] more recent metagenomic studies have now revealed multiple examples of this process, including the capture of some host genes.[240] For example, LGT from the host genome was responsible for the appearance of two exoribonucleases in two RNA viruses found in the sea-slater, an invertebrate.[240] Another well-documented case of LGT in an RNA virus involves the acquisition by influenza C virus of the hemagglutinin-esterase (*HE*) gene of coronaviruses.[163] In reality, however, there are few reports of the stable integration of cellular sequences into the genomes of RNA viruses, although more are likely to be documented following more intensive metagenomic studies.

The capture of host genes is very well documented in the case of large DNA viruses, including those from both bacteria[203] and eukaryotes,[125] although the complex phylogenetic shadows cast by gene birth and gene loss means that it is sometimes difficult to determine from which host species and when these gene transfer events occurred. The poxviruses have been very well studied in this respect, with the interleukin-10 (*IL-10*) gene family and the vertebrate vascular endothelial growth factor (*VEGFA*) genes, which are distributed among both poxviruses and a range of vertebrates, as well as the DNA ligases, acting as good examples (and the IL-10 family is also observed in herpesviruses).[29,120,175] In fact, LGT is a common occurrence in all NCLDVs and covers an enormous taxonomic range of hosts.[74,125] For example, it has been suggested that mimivirus acquired some 10% of its total gene content from bacterial species, including a number of mobile genetic elements.[72] In poxviruses, gene content seems to change more rapidly than gene order, reflecting the fact that species-specific genes tend to get added to the extremities of genomes (Fig. 1.16). That the flanking genes of large DNA viruses are often the ones captured by the host in turn suggests that internal gene orders are optimized to the extent that disrupting them may result in major fitness losses. Similarly, human herpesviruses contain homologs to such important immune genes as those that encode cytokines, chemokines, and complement system proteins, as well as those of the immunoglobulin superfamily.[168,213] These genes may modulate the immune response of the host, often by interfering or mimicking their cellular homologs. However, it is not only host immune genes that are acquired by dsDNA viruses. As a case

in point, iridoviruses encode a number of cellular proteins that seem essential for virus replication.[255]

It is also the case that LGT has occurred among large DNA viruses and is particularly well documented in bacteriophage, where it appears to be a common mode of molecular evolution (see below)[101] (and phage-mediated LGT is of course a key process of bacteria evolution,[197] as well as in a number of eukaryotic viruses,[47] including the giant viruses from the *Mimiviridae* and *Pandoraviridae*.[148] As another example, the entomopoxvirus *Amsacta moorei* virus (AMV) contains a number of genes that have been acquired from baculoviruses.[125] However, as with the case of LGT among viruses and hosts, it is often hard to pinpoint the exact origin and direction of any gene transfer event.

Less clear is exactly how viruses capture host genes. Although such an event could obviously occur through direct recombination, this would require entry into the nucleus and would result in virus genes containing introns. An alternative possibility is that complementary DNA (cDNA) copies of spliced cellular mRNAs, which do not contain introns, have been inserted into virus genomes, perhaps utilizing the RTs present in cellular retroelements.[233] On the other hand, LGT that occurs among viruses, or between viruses and bacteria, most likely occurs during host co-infections.

One of the most interesting developments in studies of virus evolution in recent years has been the observation of segments of RNA virus genomes incorporated into host cellular genomes. For retroviruses that make dsDNA and enter the cell nucleus, as well as small ssDNA viruses that are so restricted in size that they do not carry their own polymerase genes and similarly must enter the cell nucleus, the presence of these integrated virus genes is perhaps not a surprise. Indeed, it has been known for many years that much of the eukaryotic genome was composed of endogenous retroviruses.[21,263] More surprising was the discovery that RNA viruses, which do not make a DNA genomic copy and often replicate in the cytoplasm, could also become integrated into host genomes (in the form of EVEs; see earlier). The first clear-cut case of virus-to-host LGT to be documented involved sequences closely related to those of insect flaviviruses and found to be integrated into the genomes of *Aedes* mosquitoes.[44] Since this time, a number of other examples have been discovered, including

bornavirus,[118] filoviruses,[252] and rhabdoviruses,[130] often comprising a very wide range of hosts.[110,240] Similarly, EVEs have also been documented in a number of small DNA viruses, including circoviruses, parvoviruses,[12,18,129,159] and hepadnaviruses.[95,249]

As noted at the start of this chapter, the presence of these endogenous virus elements has changed our perspective of the time scale of virus evolution, providing important evidence that some virus families are older than previously anticipated. However, these sequences raise other interesting questions, most notably by what mechanisms single-stranded RNA is converted into double-stranded DNA. The most plausible answer involves interaction with the cellular retroelements that are an abundant component of eukaryotic genomes, with the L1 long interspersed nucleotide elements a notable example[118] (Fig. 1.3). In addition, some EVEs appear to be more conserved than expected if they were evolving in a strictly neutral manner, free of all selective constraints.[130] As such, some of these endogenous virus copies may be of functional importance, perhaps because they confer resistance against related exogenous viruses.[11]

Finally, one process of genome evolution that is mechanistically similar to that of LGT, and that has been of great historical importance in studies of virus evolution, is that of *modular evolution.*[26] This theory posits that viral genomes can be thought of as comprising a series of functional modules, such as those containing the capsid and the polymerase, that can be exchanged through recombination, and in doing so sometimes create entirely new viruses. For example, it has been suggested that some RNA viruses were created through a process of modular evolution,[103] and evidence that this is the case has increased through metagenomic studies.[240] Indeed, interfamily phylogenetic trees based on RdRp sequences are often markedly different to those derived from viral capsids, indicative of relatively widespread recombination and LGT which would drive modular evolution. In addition, it has been proposed that extensive sharing among diverse taxa dominates the evolution of DNA viruses.[140] Finally, there is evidence that recombination may occasionally reflect aspects of genome modularity in some small DNA viruses,[147,169] as well as some RNA viruses, which is compatible with a form of modular evolution.

Perspectives

Viruses in the family *Picornaviridae* comprise nonenveloped particles with a single-stranded RNA (ssRNA) genome of positive polarity. Among the many members of this family are numerous important human and animal pathogens, such as poliovirus, hepatitis A virus, foot-and-mouth disease virus (FMDV), enteroviruses, coxsackieviruses, and rhinoviruses. The name of the virus family was intended to convey the small size of the viruses (pico, a small unit of measurement [10^{-12}]) and the type of nucleic acid that constitutes the viral genome (RNA).

Picornaviruses have played important roles in the development of modern virology. FMDV was the first animal virus to be discovered, by Loeffler and Frosch in 1898.[422] Poliovirus was isolated 10 years later,[393] a discovery spurred by the emergence of epidemic poliomyelitis at the turn of the 20th century. The discovery in 1949 that poliovirus could be propagated in cells in culture led to studies of viral replication.[183] The plaque assay, an essential method for quantification of viral infectivity, was developed using poliovirus.[176] The first RNA-dependent RNA polymerase identified was that of mengovirus,[38] a picornavirus, and the synthesis of a precursor polyprotein from which viral proteins are derived by proteolytic processing was first identified in poliovirus-infected cells.[668] The first infectious DNA clone of an animal RNA virus was that of poliovirus,[581] and the first three-dimensional structures of animal viruses determined by x-ray crystallography were those of poliovirus[303] and rhinovirus.[607] Poliovirus RNA was the first messenger RNA (mRNA) shown to lack a 5′ cap structure.[295,508] This observation was

subsequently explained by the finding that the genome RNA of poliovirus, and other picornaviruses, is translated by internal ribosome binding.[330,543] Because they cause serious diseases, poliovirus and FMDV have been the best-studied picornaviruses. Research on poliovirus has produced two effective vaccines, and it is likely that poliomyelitis will be eradicated from the globe in the near future. The World Health Organization (WHO) has established a future goal of cessation of vaccination, at which time all poliovirus stocks must be destroyed. When this historic event takes place, all research on this virus will cease, as has already been the case for type 2 poliovirus, which has been declared eradicated by the WHO.[229] Consequently, other picornaviruses have become the focus of research on fundamental mechanisms of reproduction.

CLASSIFICATION

The family *Picornaviridae* is part of the order *Picornavirales* and comprises 40 genera (Table 2.1), all of which contain viruses that infect vertebrates.[314] The number of new picornaviruses has seen a stunning increase in the past 5 years, mainly due to metagenomic analysis. In many cases, classification is based only on genome sequences, and no virus isolates are available. It is therefore unknown if replication occurs in the hosts from which these nucleic acids were isolated. Some of the best-studied picornaviruses are described below.

TABLE 2.1 Members of the family *Picornaviridae*

Genus	Species
Aalivirus *Ampivirus* *Aphthovirus*	*Aalivirus A* *Ampivirus A* *Foot-and-mouth disease virus* *Equine rhinitis A virus* *Bovine rhinitis A virus*
Aquamavirus *Avihepatovirus*	*Aquamavirus A* *Avihepatovirus A*
Avisivirus *Bopivirus* *Cardiovirus*	*Avisivirus A* *Bopivirus A* *Cardiovirus A* (encephalomyocarditis viruses 1–2, Theiler murine encephalomyelitis virus) *Cardiovirus B* (Vilyuisk human encephalomyelitis virus, Saffold viruses 1–11) *Cardiovirus C*
Cosavirus *Crohivirus* *Dicipivirus* *Enterovirus*	*Cosavirus A–F* *Crohivirus A, B* *Cadicivirus A* *Enterovirus A* (coxsackievirus, enterovirus) *Enterovirus B* (coxsackievirus, echovirus, enterovirus) *Enterovirus C* (poliovirus, coxsackievirus, enterovirus) *Enterovirus D* (enterovirus) *Enterovirus E* (group A bovine enteroviruses) *Enterovirus F* (group B bovine enteroviruses) *Enterovirus G* (porcine enteroviruses) *Enterovirus H* (simian enteroviruses) *Enterovirus I* (camel enterovirus) *Enterovirus J* (simian enteroviruses) *Enterovirus K* (rodent enterovirus) *Enterovirus L* (monkey enterovirus) *Rhinovirus A* *Rhinovirus B* *Rhinovirus C*
Erbovirus	*Erbovirus A*
Gallivirus *Harkavirus* *Hepatovirus*	*Gallivirus A* *Harkavirus A* *Hepatovirus A* (hepatitis A virus) *Hepatovirus B–I*
Hunnivirus *Kobuvirus*	*Hunnivirus A* *Aichivirus A–F*
Kunsagivirus *Limnipivirus* *Megrivirus* *Mischivirus* *Mosavirus* *Orivirus* *Oscivirus* *Parechovirus*	*Kunsagivirus A–C* *Limnipivirus A–C* *Megrivirus A–E* *Mischivirus A–C* *Mosavirus A* *Orivirus A* *Oscivirus A* *Parechovirus A–D*
Pasivirus *Passerivirus* *Potampivirus* *Rabovirus* *Rosavirus* *Sakubovirus* *Salivirus* *Sapelovirus*	*Pasivirus A* *Passerivirus A* *Potampivirus A* *Rabovirus A* *Rosavirus A* *Sakubovirus A* *Salivirus A* *Avian sapelovirus* *Sapelovirus A, B*
Senecavirus	*Senecavirus A*
Shanbavirus *Sicinivirus* *Teschovirus* *Torchivirus* *Tremovirus*	*Shanbavirus A* *Sicinivirus A* *Teschovirus A* *Torchivirus A* *Tremovirus A*

The genus *Aphthovirus* consists of four species: *foot-and-mouth disease virus*

(FMDV), *bovine rhinitis A* virus, *bovine rhinitis B virus*, and *equine rhinitis A virus*. FMDV infects cloven-footed animals (e.g., cattle, goats, pigs, and sheep), primarily via the upper respiratory tract, and has been isolated from at least 70 species of mammals. Seven serotypes of FMDV have been identified, and within each serotype, there are many subtypes. These viruses are highly labile and rapidly lose infectivity at pH values of less than 6.8.

There are three species within the genus *Cardiovirus*: *Cardiovirus A*, *Cardiovirus B, and Cardiovirus C.* Isolates of *Cardiovirus A* include encephalomyocarditis viruses (EMCV) 1 to 2 and Theiler murine encephalomyelitis virus. These are murine viruses, which can also infect many other hosts, including humans, monkeys, pigs, elephants, and squirrels. *Cardiovirus B* includes Vilyuisk human encephalomyelitis virus and Saffold viruses 1 to 11.

There are 15 species in the *Enterovirus* genus: *Enterovirus A* to *L and Rhinovirus A* to *C*. Common members of this genus include polioviruses (3 serotypes), coxsackieviruses (28 serotypes), echoviruses (28 serotypes), human enteroviruses (53 serotypes), and many nonhuman viruses. There are 78, 30, and 51 types of *Rhinoviruses A*, *B*, and *C*, respectively.[522] Enteroviruses such as poliovirus and some coxsackieviruses replicate in the alimentary tract and are resistant to low pH. The acid-labile rhinoviruses (so named because they replicate in the nasopharynx) are important agents of the common cold. Rhinoviruses may also replicate in the lower respiratory tract; human rhinovirus C have been associated with severe lower respiratory tract disease.[452] Enterovirus D68 is unusual in that it shares genetic and biochemical properties of poliovirus and rhinovirus. This acid-labile virus replicates in both the upper and lower respiratory tracts and may be associated with a polio-like acute flaccid paralysis.[32,250,360,394,437,462,464–466,552,658,659]

The genus *Hepatovirus* with nine species has one human pathogen, *Hepatovirus A*, hepatitis A virus. Other members of this genus infect bats, hedgehogs, and shrews. Hepatitis A virus particles are highly stable and resistant to acid pH and high temperatures (60°C for 10 minutes). The virus infects epithelial cells of the small intestine and hepatocytes. An unusual feature of hepatitis A virus is the acquisition of a lipid envelope during nonlytic release from cells.[187]

The *Parechovirus* genus contains four species, *Parechovirus A* to *D*. The 16 different types of *Parechovirus A* are etiologic agents of respiratory and gastrointestinal disease. Proteins of parechoviruses are substantially diverged from those of other picornaviruses, with no greater than 30% amino acid identity. Ljungan virus is a virus of rodents within *Parechovirus B*.

The *Erbovirus* genus consists of one species, *Erbovirus A*, with three types of equine rhinitis B virus. These viruses cause upper respiratory tract disease in horses that is associated with viremia and fecal shedding of virus particles. The *Kobuvirus* genus contains six species, *Aichivirus A* to *F*, which cause gastroenteritis in humans and possibly in other animals. The *Teschovirus* genus consists of *Teschovirus A* with 13 types of porcine teschovirus. Some isolates can cause polioencephalitis in pigs, also called Teschen/Talfan disease or teschovirus encephalomyelitis. There are three species in the *Sapelovirus* genus: *Avian sapelovirus* and *Sapelovirus A and B*. Porcine sapelovirus, classified in *Sapelovirus A*, is a ubiquitous virus of pigs first isolated in the 1950s. The sole species in the genus *Senecavirus* is *Senecavirus A* whose members are found in pigs throughout the United States, Brazil, and China. Virus infection causes blisters on the snout and hoofs,[12,188] though the prototype isolate, Seneca Valley virus 001, is nonpathogenic in both pigs and humans. This trait has been exploited for the clinical development of Seneca Valley virus as a safe and effective oncolytic agent for treating human tumors.[101,611]

The picornavirus family will continue to expand, as hundreds of genome sequences of these viruses have been determined but not yet assigned to either a species or genus.[377]

VIRION STRUCTURE

Physical Properties

Picornavirus particles are spherical with a diameter of about 30 nm and consist of a protein shell surrounding the naked RNA genome (Fig. 2.1A). Infectivity is insensitive to organic solvents as the particles lack a membrane. Cardioviruses, enteroviruses (except enterovirus D viruses), hepatoviruses, and parechoviruses are acid stable and retain infectivity at pH values of 3.0

and lower. In contrast, rhinoviruses and aphthoviruses are labile at pH values of less than 6.0. Differences in pH stability reflect the sites of replication of the virus. For example, rhinoviruses and aphthoviruses replicate in the respiratory tract and need not be acid stable. Because they are acid labile, they cannot replicate in the alimentary tract. Cardioviruses, enteroviruses, hepatoviruses, and parechoviruses pass through the stomach to gain access to the intestine and, therefore, must be resistant to low pH. The structural basis for the acid lability of FMDV and enterovirus D68 is partly understood (see *Entry into Cells*).

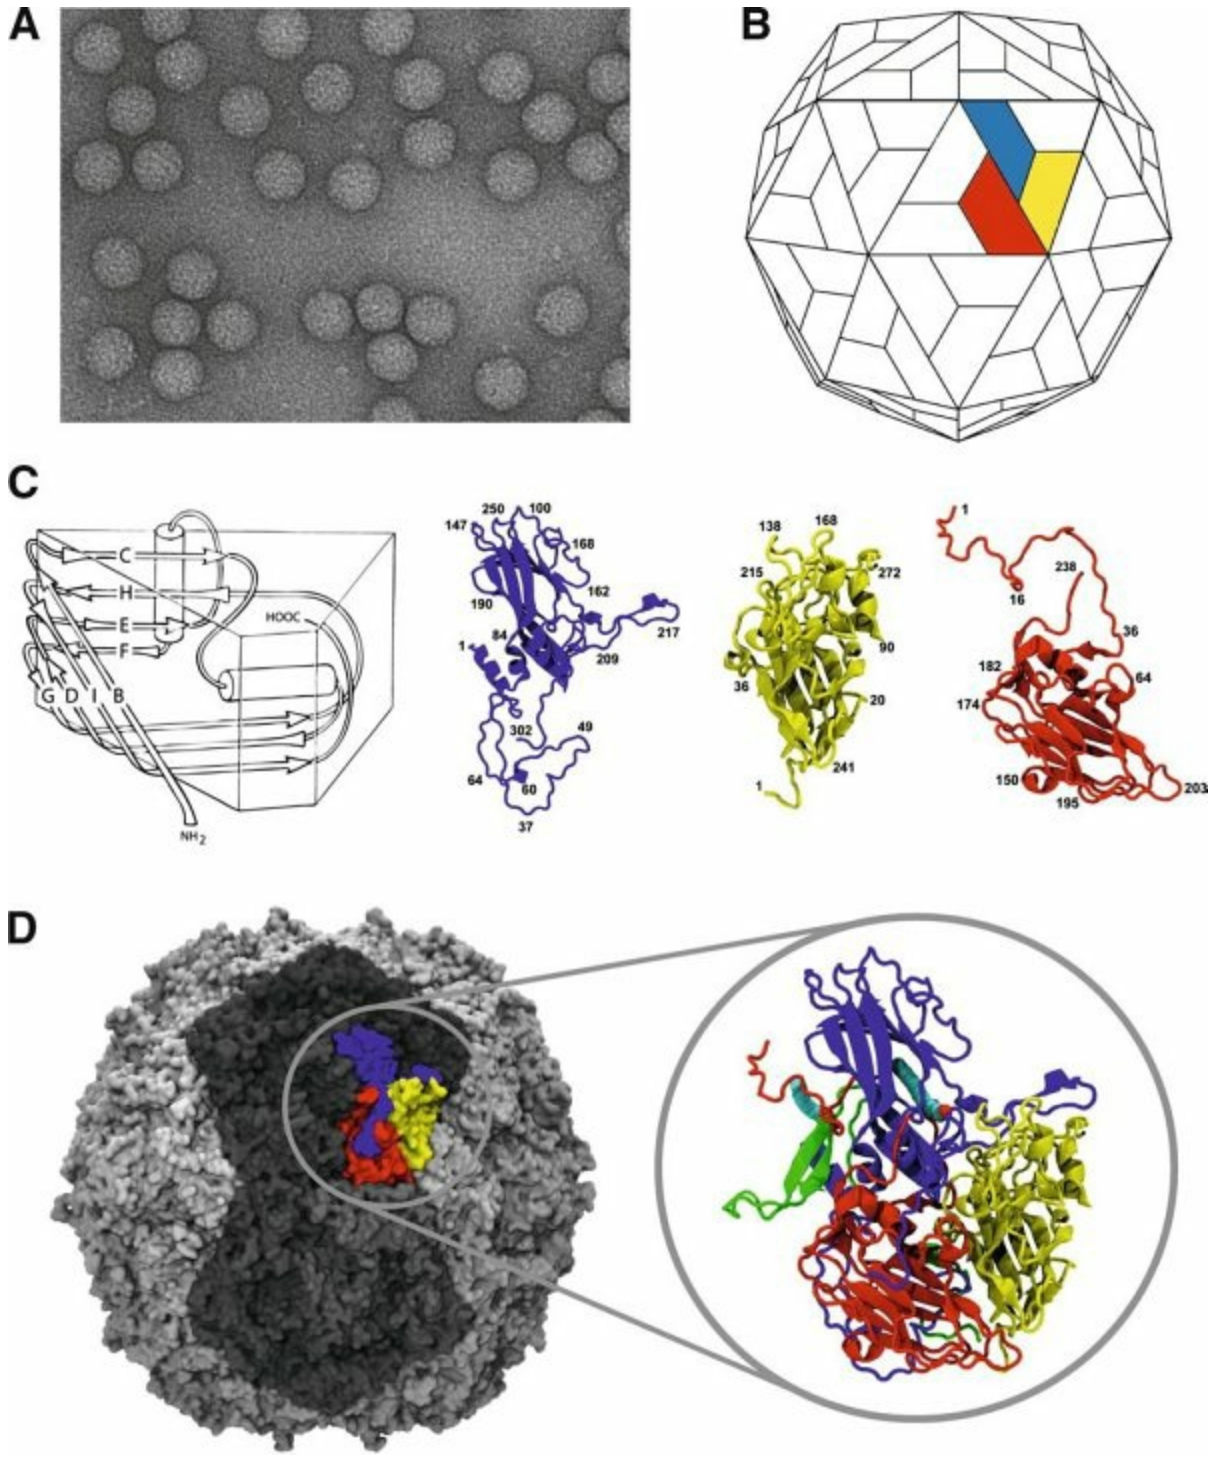

FIGURE 2.1 Structural features of picornaviruses. **A:** Electron micrograph of negatively stained poliovirus (×270,000 magnification). **B:** Schematic of the picornavirus capsid, showing the pseudoequivalent packing arrangement of VP1 (*blue*), VP2

(*yellow*), and VP3 (*red*). VP4 (*green*) is on the interior of the capsid. A single biologic protomer is colored. **C:** The topology of the polypeptide chain in *β*-barrel jelly roll, which composes the core of the three capsid proteins, VP1, VP2, and VP3. The *β*-strands, named by the letters B to I, form two antiparallel sheets juxtaposed in a wedge-shaped–like structure. The loops that connect *β*-strands are denoted by two letters reflecting those they connect. Individual capsid proteins VP1, VP2, VP3, and VP4 are shown as cartoon representations of the alpha carbon backbone. **D:** Model of poliovirus type 1, Mahoney, based on x-ray crystallographic structure determined at 2.9 Å. Two adjacent pentamers aligned at the twofold axis of symmetry are shaded *dark gray*. A single protomer is colored and also expanded at right as a cartoon of the alpha carbon backbone; capsid proteins are color coded according to **(B)**.

The buoyant densities of picornaviruses are quite different (Table 2.2). Cardioviruses and enteroviruses have a buoyant density of 1.34 g/mL, that of FMDV is 1.45 g/mL, and rhinoviruses have an intermediate value (1.40 g/mL). The reason for the difference lies in the permeability of the viral capsid to cesium. The capsid of poliovirus does not allow cesium to reach the RNA interior; hence, the virus sediments at an abnormally light buoyant density.[201] In contrast, *Aphthovirus* capsids contain pores that allow cesium to enter.[1] The rhinovirus capsid is permeable to cesium, but the presence of polyamines in the capsid interior limits the amount of cesium that can enter, which provides a possible explanation for the intermediate buoyant density value of these viruses.[201]

TABLE 2.2 Physical properties of some picornaviruses

Genus	pH Stability	Virion Buoyant Density	Sedimentation Coefficient
Aphthovirus	Labile, <6.8	1.43–1.45	142–146S
Cardiovirus	Stable, 3–9	1.33–1.34	160S
Enterovirus Enteroviruses Rhinoviruses	 Stable, 3–9 Labile, <6	 1.34 1.40	 160S 160S
Hepatovirus	Stable	1.32–1.34	160S
Parechovirus	Stable	1.36	160S
Kobuvirus	Stable, >4	1.25–1.30	140–165S
Teschovirus	Stable	1.35	

Ratio of Particles to Infectious Viruses

The ratio of particles to infectious virus is determined by dividing the number of virus particles in a sample (determined by electron microscopy or spectrophotometric measurements) by the plaque titer, yielding the particle–to–plaque-forming unit (pfu) ratio. This ratio is a measurement of the fraction of virus particles that can complete an infectious cycle. The particle-to-pfu ratio of poliovirus ranges from 30 to 1,000, and that of other picornaviruses is in the same range. The high particle-to-pfu ratio may be caused by the presence of lethal mutations in the viral genome. This explanation, however, probably does not apply to all picornaviruses; it has been shown that the infectivity of *Aphthovirus* RNA approaches one infectious unit per molecule.[69] An alternative explanation is that all viruses do not successfully complete an infectious cycle because they fail at one of several essential steps, including attachment, entry, replication, and assembly. For additional discussion of the role of mutation in the particle–to–plaque-forming unit ratio, see *Origins of Diversity*.

High-Resolution Structure of the Virus Particle

The capsids of picornaviruses are composed of three structural proteins: VP1, VP2, and VP3. All but hepatoviruses and kobuviruses have a fourth protein, VP4, in the capsid interior, which is the N-terminal cleavage product of the VP2 precursor, VP0. The results of x-ray diffraction studies, electron microscopic observations, and biochemical studies of virus particles and their dissociation products led to the hypothesis that the picornavirus capsid contains 60 structural units composed of three virus-specific proteins arranged into an icosahedral lattice.[612] Our understanding of the architecture

of picornaviruses was substantially advanced in 1985 when the atomic structures of poliovirus type 1[303] and human rhinovirus type 14[607] were determined by x-ray crystallography. Since then, the high-resolution structures of over 200 picornaviruses have been determined.

The smallest structural unit of the picornavirus capsid is the protomer, which is built with one copy of each capsid protein (Fig. 2.1B, C). Five protomers form the pentamer, and 60 pentamers form the characteristic icosahedral capsid of this family of viruses. The virus particles are described as a pseudo T = 3 structure because they are constructed with three different polypeptides.

VP1, VP2, and VP3, which compose the outside of the shell of the particle, have no sequence homology, yet all three proteins have the same topology: they form an eight-stranded, antiparallel *β*-barrel (also called a *β*-barrel jelly roll or a Swiss-roll *β*-barrel) (Fig. 2.1C). The picornavirus particle is therefore composed of 180 *β*-barrels: 60 *β*-barrels each of VP1, VP2, and VP3.

The *β*-barrel is a wedge-shaped structure made up of two antiparallel *β*-sheets (Fig. 2.1C). One *β*-sheet forms the wall of the wedge, and the second, which has a bend in the center, forms both a wall and the floor. The wedge shape facilitates the packing of structural units to form a dense, rigid protein shell. Packing of the *β*-barrel domains is strengthened by a network of protein–protein contacts on the interior of the capsid, particularly around the fivefold axes, generating a pentamer. This network, which is formed by the N-terminal extensions of VP1 to VP3 as well as VP4, is essential for the stability of the virus particle. The increased length of VP4 in kobuviruses leads to the “bow and arrow” shape of the protein, allowing more extensive interactions between VP4 and the other protomers of a pentamer and formation of an extensive network at the inner surface of the capsid. Despite these interactions, stability of kobuvirus particles is very similar to that of other enteroviruses. The lack of extensive interactions between pentamers in the *Aphthovirus* capsid renders these virions the least stable of all picornaviruses.

A different organization in the structure of hepatitis A virus is caused by a flip in the torsion angle of the peptide at VP2 residue 53, which sends the chain across the interpentamer boundary. The consequence is that neighboring protomers of one pentamer are linked together via the adjacent

pentamer. Such an arrangement is not seen in other picornaviruses but does occur in insect picorna-like viruses. Together with properties of the pocket (see below), these observations suggest that hepatitis A virus is a primordial picornavirus.

The antiparallel *β*-sheets of each capsid protein are connected to each other via the BC, HI, DE, FG, GH, and CD loops (Fig. 2.1C). These loops confer the main structural differences among VP1, VP2, and VP3: their amino acid sequences and length give each picornavirus its distinct morphology and antigenicity. The N- and C-terminal sequences of each protein extend from the *β*-barrel domain. The C-termini of the proteins are located on the surface of the virion, and the N-termini are in the interior, indicating that significant rearrangement of the P1 precursor occurs on proteolytic cleavage (see *Assembly of Virus Particles*).

Resolution of the structures of poliovirus and rhinovirus revealed that the *β*-barrel domains are strikingly similar in structure to those of plant viruses such as southern bean mosaic virus and tomato bushy stunt virus. The capsid proteins of these viruses bear no sequence homology with those of the picornaviruses. It has since become apparent that similar protein topology is found in the capsid proteins of many plant, insect, and vertebrate positive-strand RNA viruses as well as in the DNA-containing polyomaviruses and adenoviruses. These findings suggest that either the polypeptides evolved from a common ancestor or the *β*-barrel domain is one of the few ways to allow proteins to pack to form a sphere.

VP4 lies on the inner capsid surface and differs significantly from the other three proteins in that it has an extended conformation (Fig. 2.1D). This protein is similar in position and conformation to the NH_2-terminal sequences of VP1 and VP3 and functions as a detached NH_2-terminal extension of VP2 rather than an independent capsid protein. In some viruses, such as the kobuviruses and parechoviruses, VP0 remains uncleaved. In the Aichi virus capsid, the consequence is a unique extended “bow and arrow” structure described above. In kobuviruses, uncleaved VP4 is approximately 30 to 50 amino acids longer than in other picornaviruses,[781] while in hepatitis A virus VP4 is very small.

Surface of the Virus Particle

Resolution of the structures of poliovirus, rhinovirus, and mengovirus revealed that the surfaces of these viruses have a corrugated topography: a prominent, star-shaped plateau (mesa) and solvent-filled channel at the fivefold axis of symmetry, surrounded by a deep depression (canyon) and another protrusion (three-bladed propellers) at the threefold axis (Fig. 2.2). The spike-like protrusions on the external surface of the capsid reflect the length and amino acid composition of the loops. Despite VP1 being the most external and antigenic capsid protein of picornaviruses, the majority of residues that line the canyon are derived from the core of VP1, while the loops form the star-shaped mesa. The unstructured ends of VP1 are found at the fivefold axes. In contrast, the unstructured ends of VP2 and VP3 are found at the threefold axes, while the cores of these proteins are woven together to form the hubs of the propellers. The propeller blades are made up by the EF loop of VP2 and supported by the GH loop of VP1 and the C-terminus extensions of VP1 and VP2. The north wall of the canyon lies near the fivefold axis and is composed of two N-terminal loops of VP1, the BC and DE loops. The C-terminal GH loop of VP1 as well as parts of VP2 and VP3 form the south wall and floor of the canyon. The GH loop of VP1 also forms the entrance to and defines the VP1 hydrophobic pocket (Fig. 2.3). Additionally, the C-terminus of VP3 decorates the north side of the canyon. The GH loop of VP0/VP2 forms the antigenic "puff." The remaining loops of VP0/VP2 and VP3 are not long enough to deform the particle surface. However, the b β-sheet of VP3 is fractured, leaving a long hairpin loop, "the knob," to extend from the surface of the virion. The internalized N-termini of VP3, a parallel β-tube, together with a three-stranded β-sheet of the myristylated N-termini of VP4, compose the plug of the solvent channel.

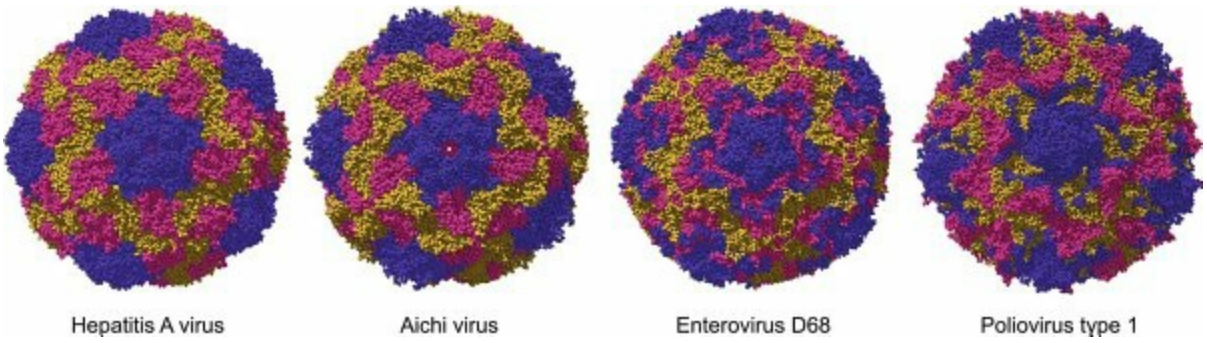

FIGURE 2.2 Structures of four different picornavirus virus

particles. In all panels, VP1 is *blue*, VP2 is *yellow*, and VP3 is *deep pink*. Surface view of the 3 Å structure of the hepatitis A virus particle, which lacks both a canyon and a VP1 hydrophobic pocket, determined by x-ray crystallography of purified virions [4QPI]. The smooth surface of the particle is due to woven interactions between pentamers that prevent formation of the canyon that surrounds the fivefold axes of symmetry. Surface view of the 3.7 Å structure of the Aichi virus virion, which lacks a VP1 hydrophobic pocket but deep pits are found at the fivefold axes, determined by cryo-EM reconstruction [5GKA]. Surface view of the 2 Å structure of the enterovirus D68 (Fermon) particle, has a shallow canyon and ill-formed VP1 hydrophobic pocket filled with a C12 cell lipid, determined by x-ray crystallography of purified virions [4WM8]. Surface view of the 2.2 Å structure of the poliovirus type 1 particle, possess both a deep canyon and VP 1 hydrophobic pocket occupied by a C16 cell lipid, determined by x-ray crystallography of purified virions [1HXS].

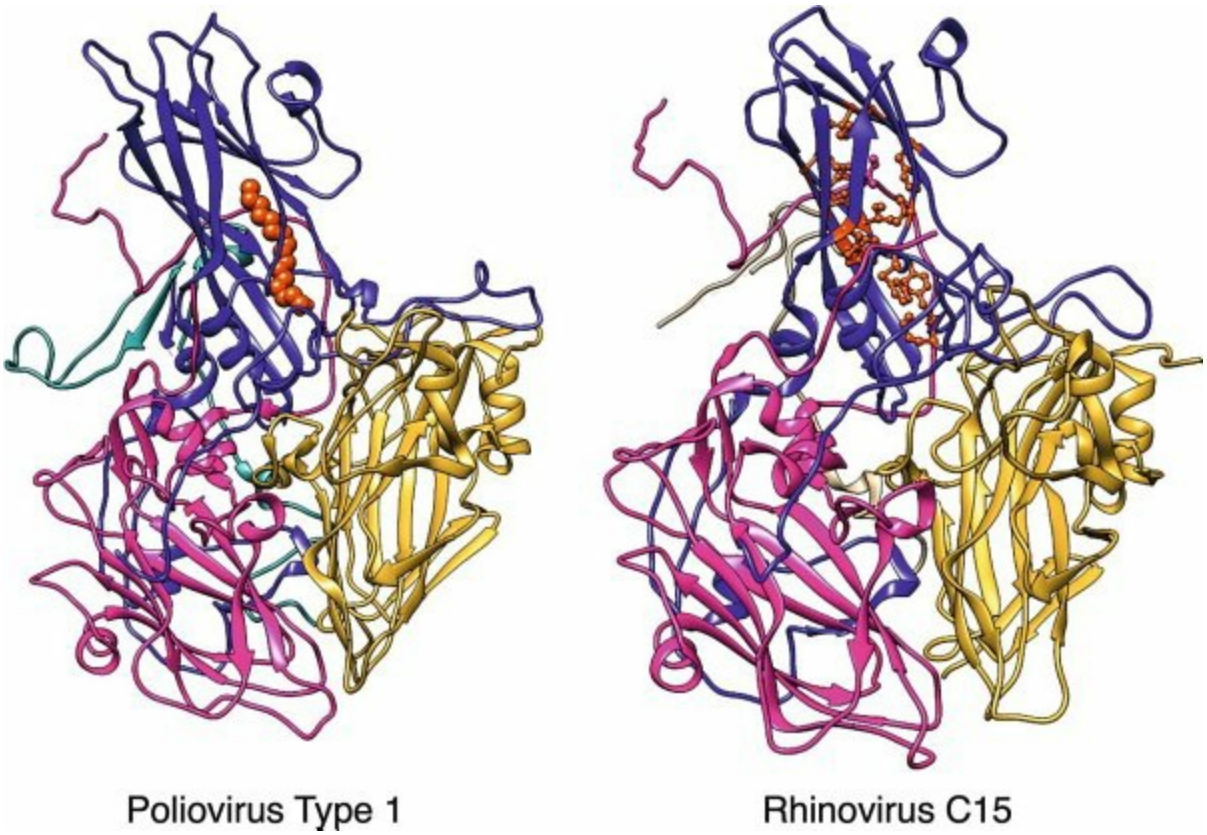

FIGURE 2.3 The hydrophobic pocket in the picornavirus capsid. VP1 is *blue*, VP2 is *yellow*, VP3 is *deep pink*, and VP4 is *green*. Cellular lipid bound in the hydrophobic pocket of poliovirus type 1. Top view of the poliovirus protomer, consisting of one copy each of VP1, VP2, VP3, and VP4. RNA is below, and the fivefold axis of symmetry is at the upper left. *Orange spheres* represent what is believed to be a molecule of sphingosine bound in the hydrophobic pocket. The lipid is just below the canyon floor [1HXS]. Top view of the rhinovirus C15 protomer, consisting of one copy each of VP1, VP2, and VP3. RNA is below, and the fivefold axis of symmetry is at the upper left. Capsid proteins are colored as in panel A. In *orange* are amino acids of VP1 GH loop (V1156, I1130, F1132, F1167, I1120, V118, I1169, M1116, W1080, F1096, M1180, Y1178, I1094) and one within VP3 (I3024) that occlude the hydrophobic pocket, inhibiting binding of the cellular lipid and activity of pocket-binding antiviral compounds [5KOU].

The presence of the canyon prompted the hypothesis that this depression is the receptor-binding site, which has been proved for a number of enteroviruses. Not all picornaviruses have canyons: the surface of cardioviruses and senecaviruses bears a series of depressions or "pits," which are involved in receptor binding, while the surface of FMDV, echoviruses, enterovirus D68, hepatitis A virus, and kobuviruses is much smoother (Fig. 2.2). The pits around the fivefold axes of cardioviruses are filled by the CD loop of VP1, and the VP2 "puff" is subdivided into two, puff A and puff B. The VP3 "knob" is the most prominent projection of the capsid and is composed of two β-strands. Also, within the CD loop of VP3, which is close to the knob, is a disulfide bond between cysteines that are separated by one amino acid. This disulfide bond introduces a sharp bend, which when disrupted results in a decrease of virus infectivity and increase in particle stability.[489] As will be discussed later, a flexible loop that projects from the capsid surface binds to the cellular receptor for FMDV and cardioviruses. Unlike the canyon of enteroviruses and other parechoviruses, the canyon of human parechovirus 3 is wide and shallow.[632]

Interior of the Virus Particle

A network formed by the N-termini on the interior of the capsid contributes significantly to the stability of the virion. For the majority of picornaviruses, the N-terminus of VP1 lines the interior of the virus particle along the fivefold axis, where the N-termini of five VP3 molecules form a cylindrically parallel β-sheet. This structure is surrounded by five three-stranded β-sheets formed by the N-termini of VP4 and VP1. The crystal structure of enterovirus A71, however, revealed an alternative organization of the interior of the capsid. Underneath the αA helices of VP2 and adjacent to the twofold axes and across the protomer lies the very N-terminus of VP1, while VP4 forms a loose spiral beneath VP1[739] (Fig. 2.4). For picornaviruses such as human parechoviruses, in which VP0 is not cleaved, the N-terminus does not surround the fivefold axis; instead, it straddles the adjacent threefold axes forming a loop, which stabilizes VP0 of the neighboring pentamer.[632] The myristate group attached to the N-terminus of VP4 mediates the interaction between the VP3 cylinder and the three-stranded β-sheet of VP4 and VP1.[125] Interactions among pentamers are stabilized by a seven-stranded β-sheet, composed of four β-strands of the VP3 β-barrel and one strand from the N-

terminus of VP1 that surround a two-stranded *β*-sheet made from the N-terminus of VP2 from a neighboring pentamer.[192]

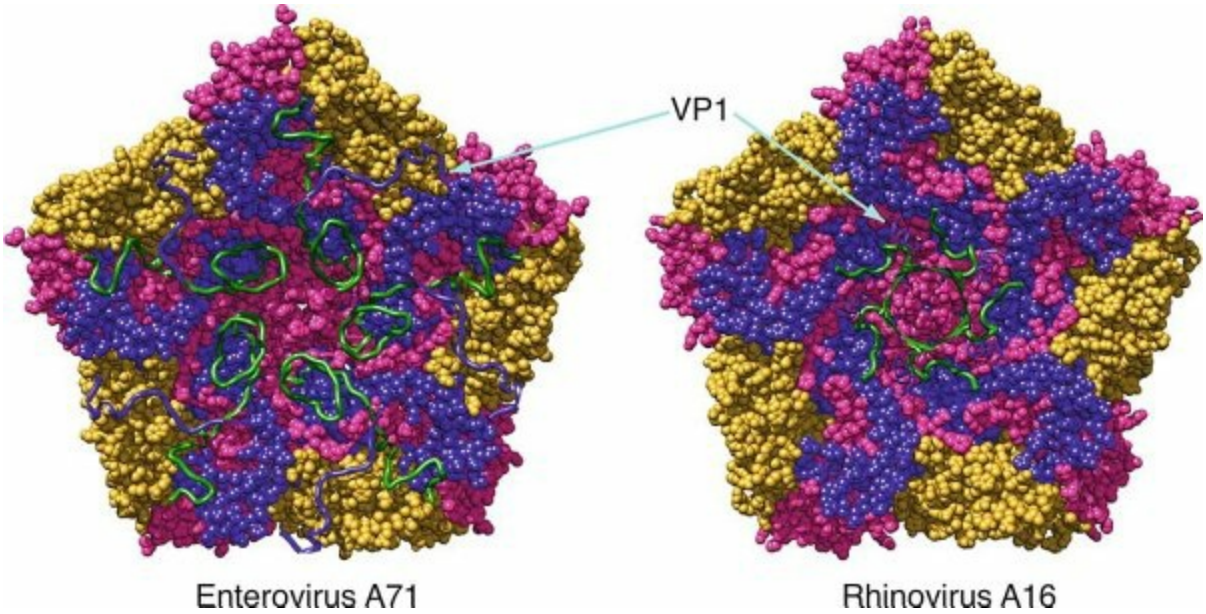

FIGURE 2.4 The unique inner organization of the enterovirus A71 particle. VP1 is *blue*, VP2 is *yellow*, VP3 is *deep pink*, and VP4 is *green*. *Turquoise arrows* point to N-terminus of VP1. Interior of the enterovirus A71 pentamer showing amino acids 1 to 26 of VP1 as a ribbon. This part of VP1 lays across the protomer underneath the *α*A helices of VP2 next to the twofold axes, while the loose spiral of VP4 (shown as a *ribbon*) is beneath VP1 [3VBS]. Interior of human rhinovirus 16 pentamer illustrates the more typical organization of amino acids of 1 to 28 of VP1 (shown as *ribbon*), which fold toward the fivefold axis and the five N-termini of VP4, which form five three-stranded *β*-sheets (shown as *ribbon*) [1AYN].

Poliovirus genomes containing an extra 1,250 nucleotides (17%) can be successfully packaged, indicating that the interior of the capsid is not fully occupied.[9] For some picornaviruses, it has been possible to visualize the RNA genome, which is highly condensed and may be evenly packed into the

particle at a concentration of 800 mg/mL.[173,388] The RNA is arranged in multiple layers approximately 18 Å apart, with a similar distance between the most external layer and inner capsid shell. For some picornaviruses such as Coxsackievirus A16, the RNA is more condensed and arranged so that a 15-Å gap exists between the genome and the capsid.[589] In cardioviruses, the inner and outer edges of the RNA genome are located 35 and 95 Å away from the center, respectively.[489]

It has been suggested that picornaviral capsids are stabilized by interactions with the RNA genome, based on findings with bean pod mottle virus, which is related to picornaviruses. In this virus, ordered RNA can be observed at the threefold axis, and packaging of viral RNA stabilizes subunit interactions.[119,409] Several nucleotides have been tentatively identified in a similar location in the structures of P3/Sabin and rhinovirus type 14.[29,192] In the atomic structure of poliovirus P2/Lansing, RNA bases have been observed stacking with conserved aromatic residues of VP4.[404] The structures of rhinovirus 2, Seneca Valley virus, and Coxsackievirus A10 also revealed the arrangement of the RNA within the capsid.[557,719,779] Much of the nucleic acid contacts the inner surface of the capsid, particularly near the twofold axes under VP2. The RNA forms a shell that contacts both VP2 and VP4 and which could serve as a scaffold for capsid assembly or might contribute to virion stability. A basic motif at the N-terminus of Ljungan virus VP3 around the fivefold axes interacts with 15 bases of ordered genomic RNA.[780] The basic amino acids constitute a positively charged environment that counters the negative charge of the RNA phosphate moieties. Approximately 900 bases, or 12% of the viral genome, are ordered within the capsid. The Coxsackievirus A10 virion is distinct in that the N-terminus of VP4 lies under the adjacent protomer and is of the opposite charge. The reversed orientation of the charge reveals a novel interaction between the inner capsid proteins and the tightly compacted RNA genome.[779] Additionally, amino acids of VP1 and VP3 that lie beneath the base of the canyon also interact with the RNA genome, suggesting that transmission of a signal is necessary for uncoating. Furthermore, the majority of the RNA within the particle does not exhibit icosahedral symmetry; instead, the RNA takes on a spherical shape with pseudo-fivefold symmetry. Analysis of the human parechovirus 3 structure determined that 25% of the genome is ordered and takes on a “finger-like” structure contacting the βIC terminus of

VP1 and the N-terminus of VP3 around the 60 vertices. Interaction between the N-terminus of VP3 and two RNA stem–loops was also observed.[632]

Hydrophobic Pocket

Lipids in the Virus Particle

Within the core of VP1, just beneath the canyon floor of many picornaviruses, is a hydrophobic tunnel or pocket (Fig. 2.3). Electron density observed in this area has been interpreted to be cell-derived lipids called "pocket factors" that regulate the conformational states of the virus during cell entry. Members of *Enteroviruses A*, *B*, and *C* have a well-formed pocket factor with a long aliphatic chain. In poliovirus types 1 and 3, the pocket factor is the C18 sphingosine[192] (Fig. 2.3). A C12 lipid occupies the pocket of human rhinoviruses types A16 and A2, a C16 lipid sits within the pocket of Coxsackievirus B3,[268,364,487] and Coxsackievirus A21 is believed to carry myristic acid.[759] A mixture of palmitic and myristic acid is present in the pocket of bovine enterovirus,[644] and a branched, elongated lipid is found in the pocket of Coxsackievirus A24 and swine vesicular disease virus.[721,782] In the enterovirus A71 virus particle, the C18 pocket factor is partly exposed on the floor of the canyon.[566] The pocket of some isolates of enterovirus D68, including the prototype Fermon, is shallow and ill-formed and contains a C10 lipid,[417] while in other isolates, the pocket is fully collapsed and unable to accommodate the lipid.[418] This trait, the absence of pocket factor, has also been recognized for rhinoviruses types B3 and B14, in which the pocket is empty and not well formed.[29] In rhinovirus C15, the pocket is collapsed but filled with bulky hydrophobic amino acids and cannot accommodate a lipid[416] (Fig. 2.3). The results of introducing amino acid changes in the pocket of rhinovirus 16 suggest that the hydrophobic pocket, and not the pocket factor, is important for maintaining capsid dynamics.[355] Additionally, kobuviruses, including Aichi virus, have a shallow and narrow depression, not a canyon around the fivefold axes; consequently, these virus particles lack a hydrophobic pocket and a pocket factor.[781] Viruses that lack canyons, such as hepatitis A virus and parechoviruses, do not have pockets or pocket factors[740] and may be a link between primitive and modern (e.g., with pocket factors) picornaviruses. Furthermore, the absence of a canyon suggests there

must be at least two mechanisms by which receptor binding, internalization, and uncoating occur.

Myristate

Myristic acid (*n*-tetradecanoic acid) is covalently linked to glycine at the amino terminus of VP4 of most picornaviruses.[125,536] This fatty acid is an integral part of the viral capsid. The N-termini of VP4 and VP3 cluster together at the fivefold axis of symmetry where they intertwine and form a twisted tube of parallel β-structure.[303] The five myristyl groups extend to cradle this twisted tube by interacting with amino acid side chains of VP4 and VP3.[125] The study of viruses with amino acid substitutions within VP4 has revealed a role for myristic acid modification in virus assembly and in the stability of the capsid.[20,439,440,481] However, inhibition of myristoylation modestly inhibits infectivity of enterovirus A71.[676] For most picornaviruses, particle *breathing* occurs at physiological temperatures, allowing for partial exit of VP4 including the N-terminal myristic acid. The presence of myristic acid facilitates membrane permeability by VP4 at high and low pH, both requirements for virus entry and uncoating.[526] These observations cast additional doubt that myristic acid is needed for virion stability.[406,410,652]

Myristic acid is added to VP0, the precursor to VP4+VP2, by cellular N-myristoyltransferases. Inhibitors of these enzymes suppress rhinovirus, poliovirus, Coxsackievirus B3 and FMDV replication by blocking particle assembly, RNA encapsidation, and inhibiting the cleavage between VP2 and VP4 that is necessary for particle maturation.[20,136,385] Infectivity of parechoviruses and Aichi viruses is resistant to myristoyltransferase inhibitors, likely because VP0 of these viruses does not undergo this maturation cleavage.[136] Myristoyltransferase inhibitors may be developed as antipicornavirus drugs against those viruses that require cleavage between VP2 and VP4 for mature particle formation.[136,486] (See *Assembly of Virus Particles*.)

Neutralizing Antigenic Sites

Viral serotype is determined by the connecting loops and C-termini of the capsid proteins that decorate the outer surface of the virus particle. These contain the major neutralization antigenic sites of the virus, the amino acid

sequences that are recognized by antibodies that block viral infectivity. The identification of mutations that confer resistance to neutralization with murine monoclonal antibodies directed against rhinovirus and poliovirus particles have defined four enterovirus neutralization antigenic sites.[468,469,636] Human sera contain antibodies directed against poliovirus antigenic sites identified in mice.[590] The major antigenic site for many picornaviruses is a linear stretch of 10 amino acids within the BC loop of VP1. Five neutralization antigenic sites have been identified in FMDV serotype O.[147,370] Eleven different neutralizing antibodies directed against porcine teschovirus 1 recognize three antigenic sites on the virus particle.[347] Neutralizing antibodies against hepatitis A virus protect against infection by acting as a receptor mimic, leading to destabilization of the particle in a fashion that is independent of virion expansion.[741] In contrast, two neutralizing antibodies generated against the empty capsid of enterovirus A71 are able to induce virion alteration and genome release.[565]

The capsids of rhinovirus, poliovirus, and other picornaviruses are dynamic, leading to transient display of the buried N-termini of VP1 on the particle surface.[336,354,410,576,602,621] Antibodies to this sequence of VP1 neutralize viral infectivity.

GENOME STRUCTURE AND ORGANIZATION

The genome of picornaviruses is a single positive-strand RNA molecule ranging in length from 6.7 to 10.1 kb (Fig. 2.5). The viral RNA is infectious because it is translated on entry into the cell to produce all the proteins required for viral reproduction. Picornavirus genomic RNA is unique because it is covalently linked at the 5′ end to a protein called *VPg* (virion protein, genome linked)[195,402] that is covalently joined to the 5′-uridylylate moiety of the viral RNA by an O4-(5′-uridylyl)-tyrosine linkage. The tyrosine that is linked to the viral RNA is always the third amino acid from the N-terminus. VPg of different picornaviruses varies in length from 22 to 24 amino acid residues and is present in one copy except in the genome of FMDV, which encodes three VPg proteins.[200] The absence of VPg differentiates poliovirus

mRNA from virion RNA. Furthermore, VPg is not required for infectivity of poliovirus RNA. If VPg is removed from viral RNA by treatment with proteinase, the specific infectivity of the viral RNA is not reduced. VPg is not found on poliovirus mRNA that is associated with cellular ribosomes and undergoing translation; these mRNAs contain only uridine 5′-phosphate (pU) at their 5′ ends.[507,547] It is not known whether removal of VPg is a prerequisite for association with ribosomes or is a result of that association, though its removal must occur as the genome is released into the cytoplasm.[13,725] Despite the fact that VPg-linked RNA can be translated in cell-free extracts, in the infected cell it is possible that VPg is rapidly cleaved from the RNA such that only RNAs lacking VPg are translated.[232,475,724] Furthermore, removal of VPg from CVB3 RNA is not necessary for translation or replication of the incoming genome, as determined by the introduction of a noncleavable bond between VPg and RNA.[395] VPg is present on nascent RNA chains of the replicative intermediate RNA and on negative-strand RNA, which has led to the suggestion that VPg is a primer for poliovirus RNA synthesis[506,547] (see *Viral RNA Synthesis*). These observations distinguish picornavirus VPg from that of calicivirus, in that it predominantly coordinates genome replication and does not participate in virus protein synthesis. The role of VPg in viral RNA synthesis is discussed in subsequent sections.

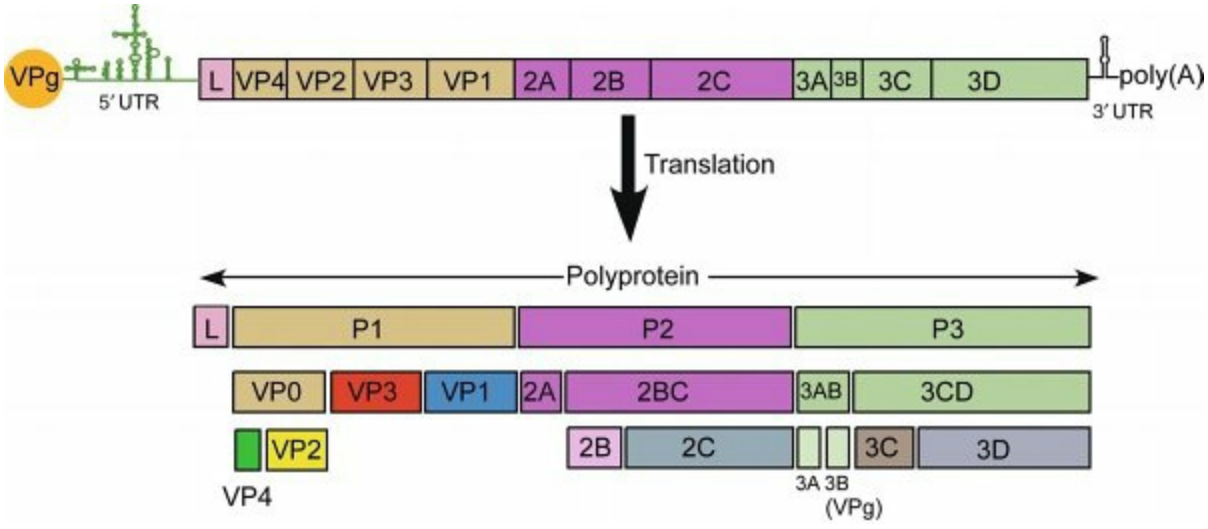

FIGURE 2.5 Organization of a picornavirus genome. **Top:**Schematic of the viral RNA genome, with the genome-linked

protein VPg at the 5′ end, the 5′-untranslated region containing the IRES, the protein-coding region, the 3′ untranslated region containing a pseudoknot, and the poly(A) tail. L is a leader protein encoded in the genomes of erboviruses, cardioviruses, and aphthoviruses but not in other picornaviruses. Coding regions for the viral proteins are indicated. **Bottom:**Processing pattern of picornavirus polyprotein. Some genomes encode multiple copies of protein-coding regions, for example, there are three VPgs in the FMDV genome, two 2A motifs in Ljungan virus and three 2A motifs in the duck hepatitis A virus genome.

VPg is removed from virion RNA by a host protein originally called *unlinking enzyme*[14] and subsequently identified as the DNA repair enzyme TDP2 (5′ tyrosyl-DNA phosphodiesterase 2).[725] This predominantly nuclear enzyme, which cleaves the 5′-tyrosine-phosphodiester bond of DNA linked to topoisomerase, is relocalized to the cytoplasm during picornaviral infection. However, the results of infecting cells lacking the gene encoding TDP2 reveal that the VPg unlinking activity is not essential for the replication of enteroviruses and cardioviruses. Its absence affects replication efficiency to different extents, depending on the virus.[434,435] Late in infection, TDP2 is sequestered away from sites of viral replication, possibly to avoid removal of VPg from newly synthesized genomes destined for packaging into new virus particles. Why removal of VPg is required earlier in infection for efficient replication is not known.

Nucleotide sequence analysis of many picornavirus genomes has revealed a common organizational pattern (Fig. 2.5). The 5′-noncoding regions of picornaviruses are long (192–1,500 bases) and highly structured. This region of the genome contains sequences that control genome replication and translation. Removal of several nucleotides from the 5′ end of the genome ablates the infectivity of the viral RNA of some picornaviruses such as hepatitis A virus, but for others, including poliovirus, the loss of two nucleotides from the 5′ end only reduces its infectivity.[281,290] Within the 5′-noncoding region is the internal ribosome entry site (IRES), which directs initiation of mRNA translation by internal ribosome binding. The 5′-

noncoding regions of aphthoviruses and cardioviruses contain a poly(C) tract that varies in length among different virus strains (80–250 nucleotides in cardioviruses, 40–400 nucleotides in aphthoviruses). Among cardioviruses, longer poly(C) length is associated with higher virulence in animals.[175,270]

A second characteristic of the 5′-noncoding region is the presence of multiple AUG codons, which vary in number among picornaviruses. Initially, these AUG codons were not thought to be physiologically relevant as deletion or alteration of these codons had no effect on picornavirus replication in HeLa cells, an assumption that is no longer correct. A small upstream open reading frame (uORF) encoding a polypeptide of approximately 56 to 76 amino acids with a predicted transmembrane domain has been identified within the 5′ end of type 1 poliovirus and enterovirus 7 that initiates from the sixth AUG.[428] The encoded polypeptide is thought to function during virus release from intestinal cells. A shorter ORF is present within the 5′-noncoding region of type 2 poliovirus; alteration of this AUG leads to a small plaque phenotype.[541] Bioinformatic analysis has identified uORFs initiating at the analogous AUG within the genome of viruses in the enterovirus A, B, C, E, F, and G species, as well as other picornavirus genera that infect the gut such as hunniviruses, lyssaviruses, rosaviruses B and C, sicinivirus, and cosaviruses.[428] No similar polypeptide was found to be encoded and initiating from this AUG within the 5′-noncoding region of rhinoviruses or enterovirus D viruses. Though no uORF has been identified within the 5′-noncoding region of cardioviruses, an alternative reading frame has been identified within the mRNA of Theiler murine encephalomyelitis virus (TMEV), which promotes the production of two different leader (L)* proteins, p18 and p15, in certain isolates such as DA.[709] Production of the smaller polypeptide begins at an AUG codon internal to and out of frame with the large polyprotein.[384,604] L* is thought to be produced during persistent infection by neurotropic isolates of TMEV.

The 3′-noncoding regions of picornaviruses vary in length from 14 to 795 nucleotides (Fig. 2.5). This region may also contain secondary structure, including a pseudoknot, that has been implicated in controlling viral RNA synthesis[328] and stem–loops. The 3′-noncoding regions of parechoviruses and pasiviruses are short and hypothesized to fold into one stem–loop, while that of FMDV and other picornaviruses are longer and may fold into multiple stem–loops[89] (reviewed in Ref.[375]). The entire 3′-noncoding region of

poliovirus and rhinovirus is not required, however, for infectivity.[97,685] Removal of part of the 3′-noncoding region, including sequence between the two stem–loops and the 5′ end of stem–loop 2 from the FMDV genome, renders the RNA noninfectious.[81] Additionally, bioinformatic analysis of the 3′-noncoding region of the megrivirus turkey hepatitis virus 1 and multiple chicken megriviruses suggest the presence of a short ORF.[90]

Both virion RNA and mRNA contain a 3′ stretch of poly(A).[769] This stretch of poly(A) varies in length, for example, from 50 to 125 nucleotides in poliovirus RNA,[5,657] and is required for genome replication. Viral RNA from which the poly(A) tract is removed is noninfectious.[651] Negative-strand RNA contains a 5′ stretch of poly(U), which is copied to form poly(A) of the positive strand.[768]

The results of early biochemical studies of poliovirus-infected cells had predicted the presence of a single, long ORF on the viral RNA that is processed to form individual viral proteins.[668] This hypothesis was supported by determination of the nucleotide sequence of the poliovirus genome, which revealed that the viral RNA encodes a single ORF.[369,582] The polyprotein is cleaved during translation, so that the full-length product is not observed. Processing is carried out by virus-encoded proteinases to yield 11 to 15 final cleavage products. Some of the uncleaved precursors also have functions during replication. A similar strategy for viral protein production occurs during the replication of all picornaviruses except those within the genus *Dicipivirus*. The genome of these viruses encodes two ORFs.

To unify the nomenclature of picornavirus proteins, the polyprotein has been divided into three regions: P1, P2, and P3 (Fig. 2.5). The genomes of some picornaviruses encode an L protein before the P1 region. It was once thought that many L proteins had protease and autocatalytic activities; however, L protein of kobuviruses possesses neither.[619] The P1 region encodes the viral capsid proteins, whereas the P2 and P3 regions encode proteins involved in protein processing (2A, $3C^{pro}$, $3CD^{pro}$) and genome replication (2B, 2C, 3AB, $3B^{VPg}$, $3CD^{pro}$, $3D^{pol}$). For many picornaviruses such as EMCV, FMDV, and kobuviruses, the 2A protein lacks protease activity; for others such as poliovirus, rhinovirus, and hepatitis A, 2A is a serine protease. The genome of Ljungan virus, a parechovirus, may encode two unrelated 2A proteins,[338] that of duck hepatitis A virus in the genus

Avihepatovirus encodes three 2A motifs, and the genome of *Aalivirus* may encode for up to six 2A proteins.[737]

Genetics

Infectious DNA Clones of Picornavirus Genomes

Recombinant DNA techniques allow the introduction of mutations anywhere within a gene or genome. Generation of an infectious DNA clone—a double-stranded DNA copy of a viral genome within a bacterial plasmid—or RNA transcripts derived by *in vitro* transcription of a DNA copy of the genome, can be introduced into cultured cells by transfection to recover infectious virus. The first infectious DNA clone of an animal RNA virus was that of poliovirus.[581] The infectivity of cloned poliovirus DNA (10^3 pfu/μg) is much lower than that of genomic RNA (10^6 pfu/μg). The development of plasmid vectors incorporating promoters for bacteriophage SP6, T7, or T3 RNA polymerase for the production of RNA transcripts *in vitro* enabled the production of infectious picornavirus RNA from cloned DNA.[706] Such RNA transcripts have an infectivity approaching that of genomic RNA. A similar approach has been adopted for the recovery of many other picornaviruses from cloned DNA copies of the viral genome.

Replicons

Development of infectious DNA clones of picornavirus genomes has facilitated studies to understand the mechanism of virus reproduction. One result of such studies has been the production of replicons and viral vectors. Picornaviral replicons can consist of defective genomes or genomes lacking specific proteins (subgenomic replicons), with the complementary or missing genes encoded within separate plasmids or transcripts. Introduction of mutant genomes together with plasmids encoding the unaltered gene can lead to the production of infectious virus lacking the mutation. The use of poliovirus subgenomic replicons demonstrated that the P1 region, which encodes the capsid proteins, is not necessary for translation or replication of the viral genome. However, these subgenomic replicons may interfere with production of infectious virus.[350] Furthermore, subgenomic replicons of picornaviruses allow for the production of exogenous proteins in cells.[544] Replicons have

been used to study genetic and protein requirements for the replication of multiple picornaviruses.

Gene Editing

The manipulation of DNA *in vitro* once solely depended upon restriction enzymes and other modifying enzymes such as DNA ligases. With the identification and elucidation of the mechanism of CRISPR/Cas9 (clustered regularly interspaced short palindromic repeats/CRISPR-associated nuclease 9) methodology, a DNA copy of the viral genome can be easily modified to encode desired mutations and also encode for exogenous genes.

STAGES OF REPLICATION

Replication of all picornaviruses occurs in the cell cytoplasm. The first step is attachment to a cell receptor (Fig. 2.6). The RNA genome is then uncoated, a process that involves structural changes in the particle. Once the positive-strand viral RNA enters the cytoplasm, it is translated to provide viral proteins essential for genome replication and the production of new virus particles. The viral proteins are synthesized from a polyprotein precursor, which is cleaved nascently. Cleavages are carried out mainly by two viral proteinases, $2A^{pro}$ and $3C^{pro}$ or $3CD^{pro}$. Among the proteins synthesized are the viral RNA–dependent RNA polymerase and accessory proteins required for genome replication and mRNA synthesis and the capsid precursor. The first step in genome replication is copying of the positive-strand RNA to form a negative-strand intermediate; this step is followed by the production of additional positive strands. These events occur on small membranous vesicles that are induced by several virus proteins. Once the pool of capsid proteins is sufficiently large, encapsidation begins. The precursor P1 is cleaved to produce an immature protomer, which then assembles into pentamers. Newly synthesized, positive-strand RNA associates with pentamers to form the infectious virus. Empty capsids that are found in infected cells are likely to be a storage form of pentamers.

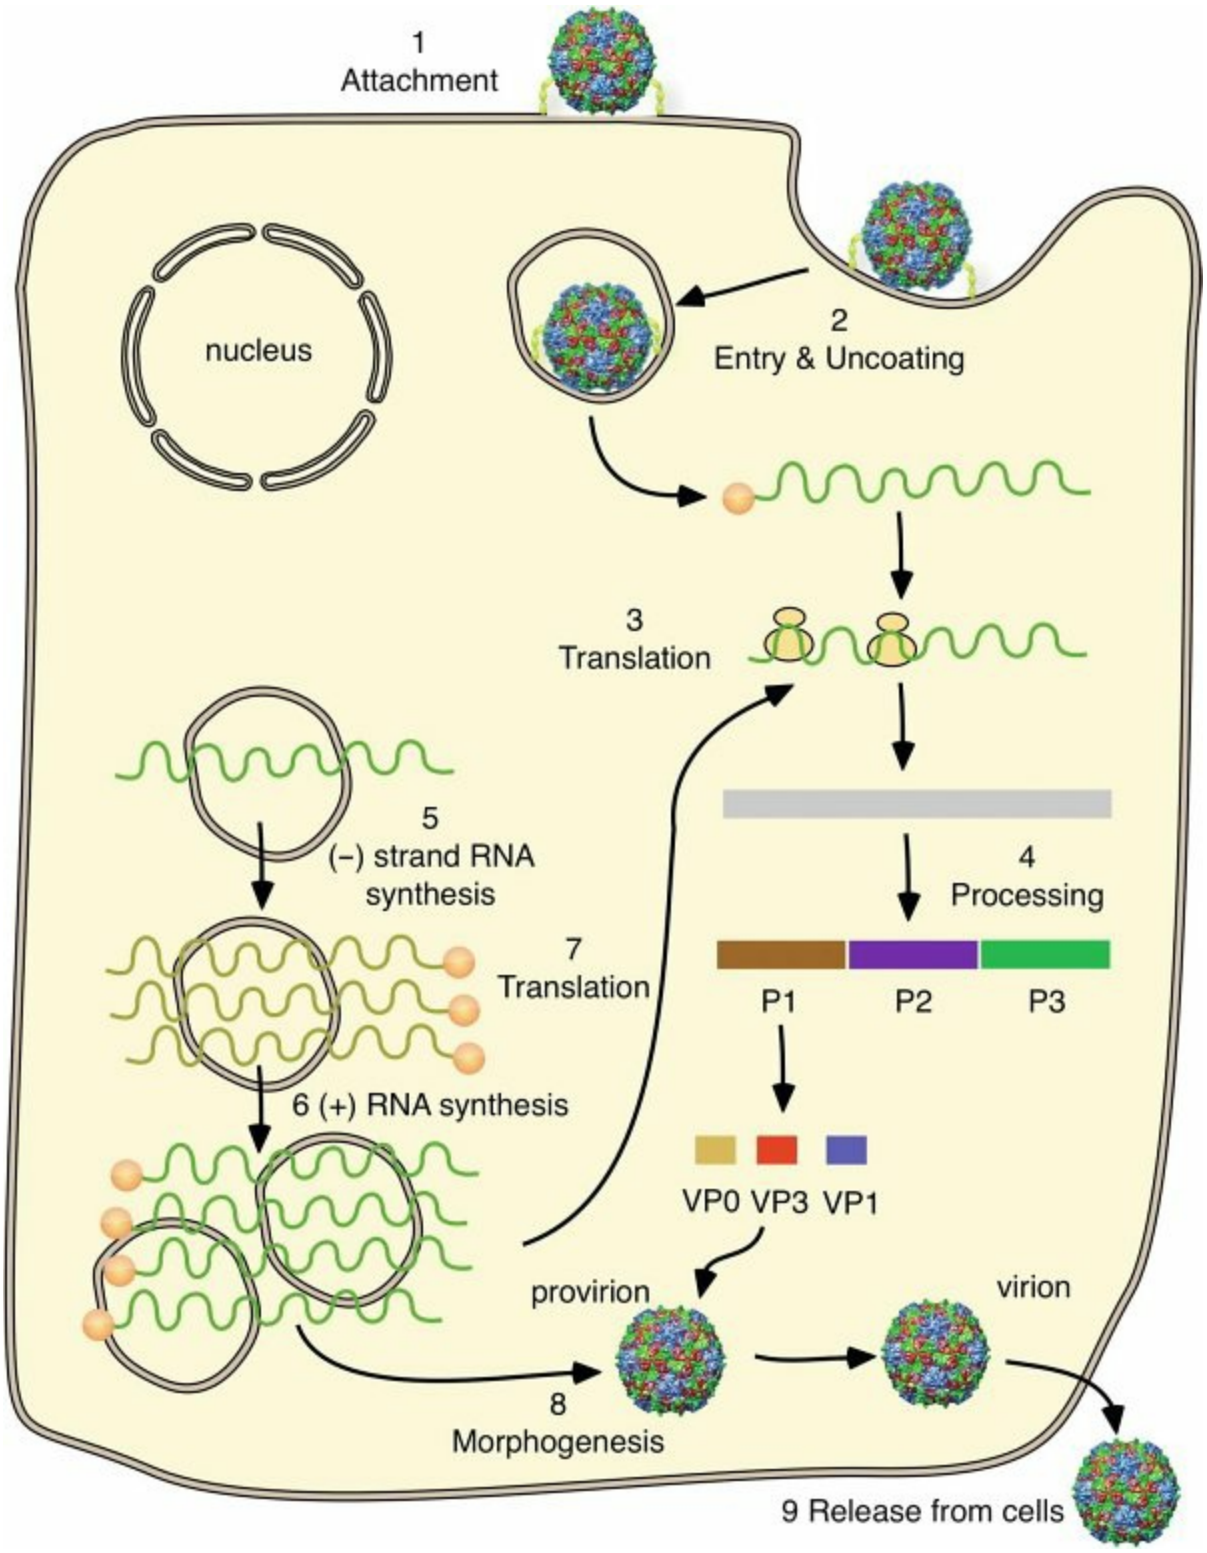

FIGURE 2.6 Overview of the picornavirus replication cycle. Virus binds to a cellular receptor (*1*) and the genome is uncoated (*2*). VPg (virion protein, genome linked) is removed from the viral RNA,

which is then translated (*3*). The polyprotein is cleaved nascently to produce individual viral proteins (*4*). RNA synthesis occurs on membrane vesicles induced by viral proteins (not drawn to scale). Viral (+) strand RNA is copied by the viral RNA polymerase to form full-length (–) strand RNAs (*5*), which are then copied to produce additional (+) strand RNA (*6*). Early in infection, newly synthesized (+) strand RNA is translated to produce additional viral proteins (*7*). Later in infection, the (+) strands enter the morphogenetic pathway (*8*). Newly synthesized virus particles are released from the cell by lysis (*9*).

The entire time required for a single replication cycle ranges from 5 to 10 hours, depending on many variables, including the particular virus, temperature, pH, host cell, and multiplicity of infection. Analysis of poliovirus replication in single cells reveals differences that are not apparent when infections are done in populations of cells.[262] For example, replication start times vary widely, and the production of infectious virus may begin later than predicted by population measurements. However, when multiple single-cell reproductive cycles are averaged, the result approximates the kinetics observed in populations of cells. Many picornaviruses are released as the cell loses its integrity and lyses. Other picornaviruses (e.g., hepatitis A virus) are released from cells in the absence of cytopathic effect within membranous vesicles.

Attachment

Cellular Receptors and Coreceptors

Like many viruses, picornaviruses initiate infection of cells by first attaching to a receptor on the host cell plasma membrane. The nature of picornavirus receptors remained obscure until 1989, when the receptors for poliovirus and the major group rhinoviruses were identified.[251,460,656] Receptors for many other members of this virus family have since been determined (Table 2.3). Different types of cell surface molecules serve as cellular receptors for

picornaviruses, and some are shared among picornaviruses and members of other virus families. For example, the cell surface protein CD55 is a receptor for certain Coxsackieviruses, echoviruses, and enterovirus 70, and the poliovirus receptor, CD155, is a receptor for alphaherpesviruses. For some picornaviruses (e.g., poliovirus and rhinovirus), a single type of receptor is sufficient for entry of viruses into cells. For other viruses, cell entry requires more than one molecule.

TABLE 2.3 Some cell receptors for picornaviruses

Genus/Virus	Virus Receptor	Type of Receptor	Second Receptor	References
Aphthovirus				
Foot-and-mouth disease virus (cell culture adapted)	Heparan sulfate	Glycosaminoglycan		323
Foot-and-mouth disease virus	$\alpha_v\beta_1$, $\alpha_v\beta_3$, $\alpha_v\beta_6$, $\alpha_v\beta_8$	Integrin		322,326,495
Equine rhinitis A virus	Sialic acid	Carbohydrate		660
Cardiovirus				
Encephalomyocarditis virus	Vcam-1	Ig-like		309
	Sialylated glycophorin A (for hemagglutination only) Sialic acid	Carbohydrate Carbohydrate		266
	ADAM9 (a disintegrin and metalloproteinase domain)	Metalloproteinase		60
Theiler murine encephalomyelitis virus				415
Low-neurovirulence strains	Sialic acid	Carbohydrate		
High-neurovirulence strains	Heparin sulfate	Proteoglycan		
Enterovirus				
Bovine enterovirus	Sialic acid	Carbohydrate		774
Coxsackievirus A9	$\alpha_v\beta_3$, $\alpha_v\beta_6$	Integrin	β_2-microglobulin, GRP78, MHC-1	601,694,696,754
Coxsackievirus A2–A6, A10, A12	KREMEN 1	Signaling receptor		653
Coxsackieviruses A13, A18, A21	Icam-1 (CD)	Ig-like		132
Coxsackievirus A16	P-selectin glycoprotein ligand-1 (PSGL-1), scavenger receptor class B (SCARB2)	Mucin-like	Heparan sulfate glycosaminoglycans	505,766
Coxsackievirus A21	Decay-accelerating factor (CD55)	SCR-like (complement cascade)	Icam-1	630
Coxsackievirus A24	Icam-1			36
Coxsackievirus A24 (variant)	Icam-1 α2,6-Sialic acid–containing, O-linked glycoconjugates	Carbohydrate		470,504
Coxsackieviruses B1–B6	Car (Coxsackievirus–adenovirus receptor)	Ig-like		71
Coxsackievirus B1, B3, B5	Decay-accelerating factor (CD55)	SCR-like (complement cascade)	$\alpha_v\beta_5$ integrin (CVB1) CAR (CVB3)	4,629,631
Echovirus 1, 8	$\alpha_2\beta_1$-Integrin (Vla-2)	Integrin	β_2-microglobulin	72,743
Echovirus 3, 6, 7, 11–13, 20, 21, 24, 29, 30, 33	Decay-accelerating factor (CD55)	SCR-like (complement cascade)	β_2-microglobulin, CD59 (E7)	70,238,574,608,743,743
Echovirus 5, 9, 11, 13, 25, 29, 30, 31, 32	FcRn		β_2-microglobulin	477,778
Echovirus 5	Heparan sulfate	Proteoglycan		320
Echovirus 9	$\alpha_v\beta_3$-Integrin	Integrin		496

Genus/Virus	Virus Receptor	Type of Receptor	Second Receptor	References
Enterovirus D68	α2,6-Sialic acid–containing, O-linked glycoconjugates ICAM-5	Carbohydrate Ig-like		318,746

Seneca Valley virus	Anthrax toxin receptor 1/ TEM 8	Signaling receptor		332

Ig, immunoglobulin; SCR, short consensus repeat.

One Type of Receptor Molecule for Virus Binding and Entry

Picornaviruses for which a single type of receptor molecule is sufficient for virus binding and entry include poliovirus (PVR/CD155) (Fig. 2.7), rhinoviruses (ICAM-1, low-density lipoprotein receptor [LDLR], LDLR-related protein, very-low-density lipoprotein receptor, CDHR3, cadherin-related family membrane 3), and Seneca Valley virus (TEM 8).

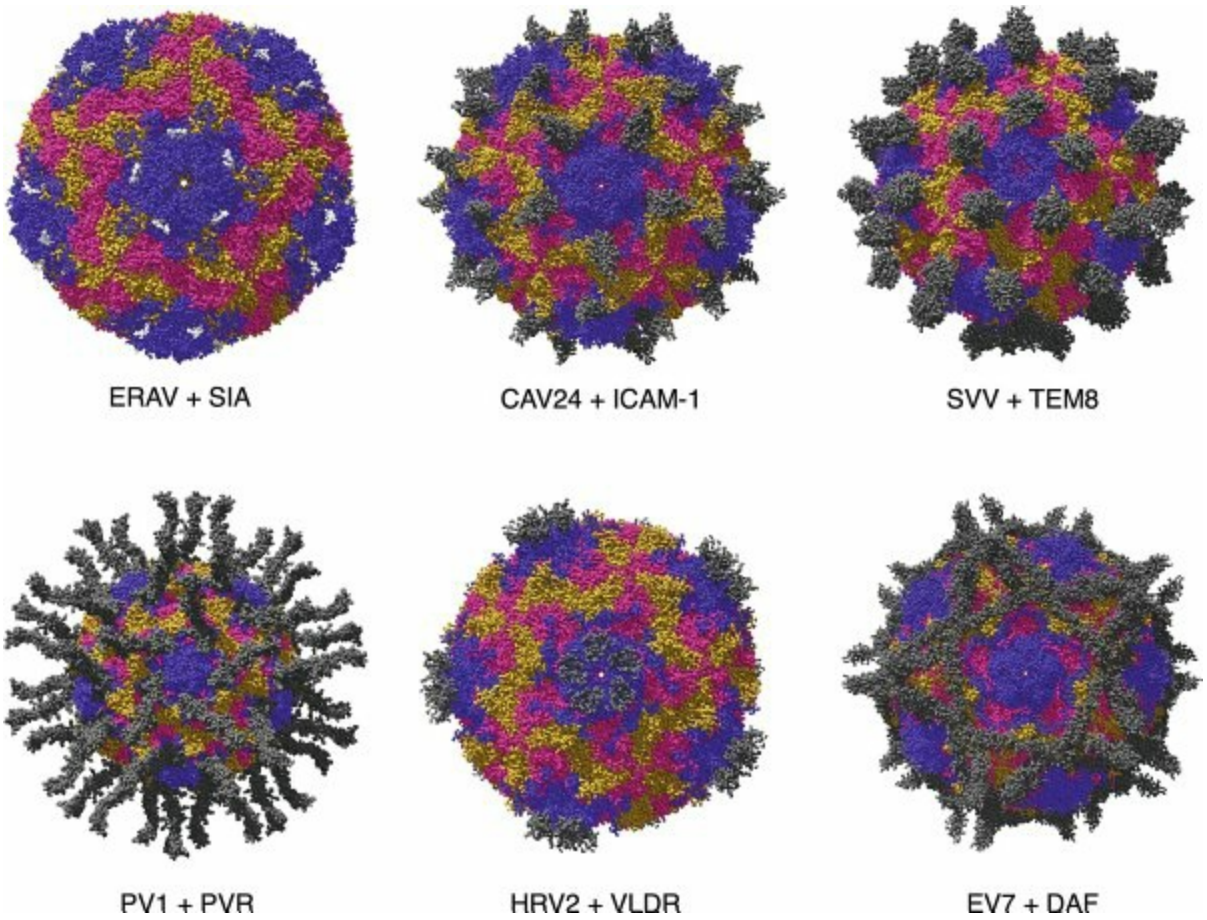

FIGURE 2.7 Interactions of six different picornaviruses with cellular receptors. VP1 is *blue*, VP2 is *yellow*, and VP3 is *deep pink*. Proteinaceous receptors are shown in *gray*. The 4 Å structure determined by x-ray crystallography of the cell receptor sialic acid bound to equine rhinitis A virus. The sugar moiety sialic acid (*white*) attaches to the rim of the capsid pit [2XBO]. The 3.9 Å structure determined by cryo-EM of domains 1 and 2 of the cell receptor ICAM-1 bound to Coxsackievirus A21. The immunoglobulin-like receptor binds at the pseudo threefold axes of the capsid [6EIT]. The 3.8 Å structure determined by cryo-EM of the cell receptor anthrax toxin receptor 1/TEM 8 bound to Seneca Valley virus (SVV). The single-chain transmembrane domain protein binds in a crown-like arrangement around the fivefold axis of the icosahedron [6CX1]. The 4.0 Å structure determined by

cryo-EM of the cell receptor PVR (CD155) bound to poliovirus type 1. The immunoglobulin-like protein binds within the canyon of the capsid [3J8F]. The 3.6 Å structure determined by x-ray crystallography of the cell receptor low-density lipoprotein receptor bound to rhinovirus 2. The single pass transmembrane protein binds on the plateau at the fivefold axis [2XBO]. The 7.2 Å structure determined by cryo-EM of the cell receptor DAF (CD55) bound to echovirus 7. The complement protein binds echovirus 7 near the twofold icosahedral axes [3IYP].

The poliovirus receptor is a type I transmembrane protein and a member of the immunoglobulin (Ig) superfamily of proteins, with three extracellular Ig-like domains: a membrane-distal V-type domain followed by two C2-type domains.[460] Domain 1 of PVR binds to the virus. Production of PVR in mice is sufficient to overcome the lack of susceptibility of this species to poliovirus infection.[380,586] Because *PVR* transgenic mice develop paralysis after inoculation with poliovirus by different routes, they have proved to be a valuable model for studying the pathogenesis of poliomyelitis.[580] *PVR* transgenic mice are not susceptible to infection by the oral route, the natural route of infection in humans, unless the gene encoding type I interferon receptors has been deleted.[516,776] PVR is synthesized in many tissues in transgenic mice, yet the main sites of poliovirus replication are the brain and spinal cord.[380,588] This restricted tropism is regulated by the interferon (IFN)-α/β response, which limits viral replication in extraneural organs.[315]

Production of PVR on cells in culture derived from different animal species leads to susceptibility to poliovirus infection. Therefore, it is likely that PVR is the only molecule required for poliovirus binding and entry. The observation that a monoclonal antibody directed against the lymphocyte homing receptor, CD44, blocks poliovirus binding to cells suggested that this protein might be a second receptor for poliovirus entry.[634,635] It was subsequently shown that CD44 is not a receptor for poliovirus and is not required for poliovirus infection of cells that produce PVR.[93,204] It seems likely that PVR and CD44 are associated in the cell membrane[205] and that anti-CD44 antibodies block poliovirus attachment by blocking the virus-

binding sites on PVR.

Orthologs of the *PVR* gene are present in the genomes of a number of mammals, including those not susceptible to poliovirus infection.[316] The amino acid sequence of domain 1 of PVR varies extensively among the nonsusceptible mammals, especially in the regions known to contact poliovirus. The absence of a poliovirus-binding site on these PVR molecules, therefore, explains why infection is restricted to simians.

PVR is an adhesion molecule that participates in the formation of adherens junctions through interaction with nectin-3, a related immunoglobulin-like protein.[488] It is also a recognition molecule for natural killer (NK) cells and interacts with CD226 and CD96 on NK cells to stimulate their cytotoxic activity.[92,209] PVR also interacts with T-cell Ig and ITIM domain membrane protein (TIGIT), a protein involved in regulating T-cell function.[426] The UL141 protein of cytomegalovirus (CMV) blocks display of PVR on the cell surface, leading to evasion of NK cell–mediated killing.[687]

The cell surface receptor for many human rhinoviruses (species A and B) was identified by using monoclonal antibodies directed against the cellular binding site to isolate the receptor protein from susceptible cells. Amino acid sequence analysis of the purified protein revealed that it is ICAM-1, a type I transmembrane protein with five immunoglobulin-like domains.[251,656,688] The normal cellular functions of ICAM-1 are to bind its ligand, lymphocyte function–associated antigen 1 (LFA-1), on the surface of lymphocytes and to promote a wide range of immunologic functions.[704] ICAM-1 is expressed on the surfaces of many tissues, including the nasal epithelium, which is the entry site for rhinoviruses.

Three members of the low-density lipoprotein receptor family are receptors for other species of A and B rhinoviruses (10 serotypes) (Fig. 2.7). These proteins consist of 7 LDLR, 8 VLDLR, or 31 LRP ligand-binding repeats, transmembrane, and cytoplasmic domains.

Bioinformatic comparison of susceptible and permissive cells with nonsusceptible but permissive cells leads to the identification of cadherin-related family member 3 (CDHR3) as a cellular receptor for rhinovirus C species.[85] These viruses are more likely to cause wheezing illnesses and asthma exacerbations than rhinoviruses A and B. It is hypothesized that a

single amino acid change, Y529 within CDHR3, a transmembrane protein of unknown biological function, but found on the surface of lung tissue and bronchial epithelial cells, and associated with asthma severity, also promotes rhinovirus C infection and may explain the association of virus infection with enhanced respiratory distress.[85] Most humans today have the nonrisk allele C529; however, Y529 is found in the genome of Neanderthals and Denisovans, indicating that it was initially present and then replaced with C529 by selection imposed by virus infection.[85] After an outbreak of lethal rhinovirus C infection in a chimpanzee population of Uganda, sequence analysis of the CDHR3 encoding locus revealed chimpanzees to be homozygous for Y529.[625] This observation suggests that rhinovirus C is only rarely transmitted from humans to chimpanzees; therefore, there has been little selection pressure for spread of the C529 amino acid change in apes.

Identification of virus receptors has been accelerated by the use of novel gene editing methodologies such as CRISPR/Cas9 and reagents including a collection of haploid human cells harboring retroviral gene insertions. Anthrax toxin receptor 1/TEM 8 and KREMEN 1 were determined to be the cellular receptors for Seneca Valley virus (Fig. 2.7) and Coxsackieviruses A2 to A6, A10, and A12, respectively, via these technologies.[467,653] These methodologies however do not distinguish between molecules necessary for cell surface attachment and those necessary for particle internalization and uncoating. Anthrax toxin receptor 1/TEM 8 is sufficient for Seneca Valley virus attachment to the cell surface but not for the conformational changes necessary for uncoating.[332]

Many picornaviruses bind integrins, which are dimeric cell adhesion receptors with α and β subunits. Integrin receptors recognize the tripeptide Arg-Gly-Asp (RGD) whose presence in the viral capsid suggests interaction with this type of receptor. A number of integrins can serve as entry receptors for FMDV (Table 2.3) although all may not be utilized during infection of animals. Although integrins are sufficient for FMDV infection, their interaction with the viral capsid does not lead to uncoating (see *Entry into Cells*). Enteroviruses that bind integrins typically require a coreceptor for cell entry. For CAV9, it has been suggested that β_2-microglobulin,[697] GRP78, and MHC-1[694] might fulfill this role.

The carbohydrate sialic acid is thought to function as the cellular receptor

for numerous picornaviruses including enterovirus D68, bovine enterovirus, equine rhinitis virus A (Fig. 2.7), and a variant of Coxsackievirus A24.[36,318,504,660,661] Sialic acid interacts with different picornavirus capsids at diverse sites. It binds within a shallow groove near the outer edge of the EF loop of VP1 of the adjacent protomer on the equine rhinitis virus A capsid.[208] Though the interactions between Coxsackievirus A24 (CAV24) and equine rhinitis virus with sialic acid are similar, it functions as an attachment molecule for CAV24, allowing for an increased concentration of virus on the cell surface. This binding facilitates the interaction between the entry receptor ICAM-1 and enhances infection and transmission.[36] Sialic acid binds within the VP1 pocket of enterovirus D68. Despite being able to evict the C10 lipid found in the pocket of enterovirus D68, binding of sialic acid does not lead to uncoating[417] indicating that another cell surface molecule is required for entry of this virus.

Two Receptors Required for Infection

Many enteroviruses bind to decay-accelerating factor (DAF, or CD55), a member of the complement cascade (Table 2.3); it is composed of four extracellular short consensus repeat modules (SCR1–SCR4) and is attached to the plasma membrane by a glycosylphosphatidylinositol (GPI) anchor (Fig. 2.7). Its ability to function as the receptor of viruses such as echovirus 6, 7, 11, 12, 13, 20, 21, 29, and 33 was defined not only by the use of antibodies generated against DAF that inhibit virus infection but also by conferring susceptibility to virus infection of nonsusceptible cells by production of the protein from a plasmid.[70,742] However, for most of these viruses, interaction with DAF is not sufficient for infection. Binding to DAF does not cause conformational changes and internalization; therefore, interaction between DAF and the virion does not lead to uncoating. Instead, DAF is an attachment receptor, facilitating virus adsorption, and a second receptor is necessary for conformational changes, internalization of the particle, and uncoating.[564,574] For example, Coxsackievirus A21 binds to DAF, but infection does not occur unless ICAM-1 is also bound.[630] In this case, ICAM-1 inserts into the canyon where it triggers capsid uncoating.[758] Coxsackievirus B3 also binds DAF, but virion uncoating does not occur unless CAR (coxsackievirus–adenovirus receptor; see below) binds in the canyon.[287] Despite being able to bind mouse CAR, production of human

DAF within the alimentary tract of mice, either immunocompetent or deficient in the IFN-α/β receptor, still does not allow for enteral infection by Coxsackievirus B3.[524] However, for other echoviruses, the absence of Fc receptors, antibodies against β2-microglobulin, or class I human leukocyte antigen (HLA) inhibited productive infection despite virus attachment to the cell surface being unaffected.[121,477,573] The requirement for binding to DAF for echoviruses to attach to the cell surface appears not only to be isolate specific but to be controlled by the cells in which the virus is passaged. The D'Amori-derived strain of echovirus 6, serially passaged in human rhabdomyosarcoma cells, weakly interacts with DAF, while the same isolate cultured in HeLa cells may attach to the cell surface in a DAF-independent manner.[573] Enzymatic removal of heparin sulfate impaired infection by both isolates suggesting a role for this extracellular matrix component in cell surface attachment of echoviruses.[239] Taken together, these observations suggest that a large protein complex that includes DAF, HLA, FcR, and β2-microglobulin may mediate echovirus cell surface attachment, internalization, and uncoating.

How two receptors collaborate in virus entry is illustrated by Coxsackievirus B3 infections of polarized epithelial cells.[139] The coxsackievirus and adenovirus receptor, CAR, mediates cell entry of all Coxsackie B viruses.[71] CAR is not present on the apical surface of epithelial cells that line the intestinal and respiratory tracts but is a component of the tight junction and is inaccessible to virus entry. Coxsackie B viruses first bind an attachment receptor, DAF, which is present on the apical surface of epithelial cells. Virus binding to DAF activates Abl kinase, which in turn triggers Rac-dependent actin rearrangements leading to virus movement to the tight junction where it can bind CAR and enter cells.[139]

Alternative Receptors

Some viruses bind to different cell surface receptors, depending on the virus isolate or the cell line (Table 2.3). Clinical isolates of FMDV bind to integrin receptors, but passage in cell culture can select for viruses that bind to heparin sulfate, a sulfated glycan.[323,445,614] Cell culture passage may also produce a virus that infects cells independent of heparin sulfate and integrins.[43]

How Picornaviruses Attach to Cell Receptors

Among the picornavirus members, the four capsid proteins are arranged similarly, but the surface architecture varies. These differences account for both the diverse serotypes and the varied modes of interaction with cell receptors. For example, the capsids of enteroviruses have a groove, or canyon, surrounding each fivefold axis of symmetry. In contrast, cardioviruses, aphthoviruses, and senecaviruses have a sharp pit.

The canyons of multiple enteroviruses are the sites of interaction with Ig-like cell receptors. The results of genetic and structural experiments demonstrate that the first Ig-like domain contains the site that binds poliovirus. Cells producing the first Ig-like domain of PVR, either alone or as a hybrid with other Ig-like proteins, are susceptible to infection with poliovirus.[379,479,627,628] Amino acid changes in the first Ig-like domain of PVR interfere with poliovirus binding.[21,74,478] Mutagenesis of ICAM-1 DNA has revealed that the binding site for rhinovirus is located in the first Ig-like domain.[450,585,655] Models of the interaction of poliovirus, rhinovirus, and Coxsackieviruses A and B with their cellular receptors have been produced from cryoelectron microscopy and x-ray crystallographic data (Fig. 2.7).[36,63,64, 109,110,286,381,518,520,763] These models reveal that only domain 1 of PVR or ICAM-1 penetrates the canyon of the respective virus and the alteration induced, pivoting of VP1 away from the fivefold axes, leads to the expulsion of pocket factor, which facilitates particle expansion, and destabilization.[662] Alterations that affect receptor binding map to the virion–receptor interface as determined by these structural studies. Change of amino acids that line the canyons of poliovirus and rhinovirus can alter the affinity of binding to receptors.[133–135,279,411] Despite also binding in the canyon and having the similar footprint to that of PVR and ICAM-1 on their respective viruses, CAR does not interact with the south canyon rim nor the floor of the canyon of the Coxsackievirus B3 virion.[520]

Although the capsids of some rhinoviruses possess a canyon around the fivefold axes, it is not the binding site for their cell receptor, members of the low-density lipoprotein receptor family (Fig. 2.7). Rather, the LDL receptor binds close to the fivefold axis, on the star-shaped mesa that is surrounded by the canyon.[294,579,583,720] In this way, multiple low-affinity interactions are combined to yield a high avidity virus–receptor complex.

Domain 1 of cadherin-related family member 3 (CDHR3), the cell receptor for members of *Rhinovirus C*, is sufficient to bind virus particles. Peptides that encompass this domain block attachment of virus to cells.[745] Molecular modeling suggests that the linear tandem repeat extracellular domains of CDHR3 occur as rod-like molecules that lie across the twofold axis of adjacent protomers, with domain 1 interacting just outside of the fivefold axis of symmetry.[85]

Sequence and structural comparisons have revealed how rhinoviruses bind either ICAM-1 or LDL. A lysine at position 224 of VP1, which is conserved in all minor group rhinoviruses, is the key amino acid that interacts with a negatively charged cluster of LDLR.[720] The electrostatic attraction between Lys1224 and the acidic cluster in LDLR might initiate contact between virus and receptor. Neighboring hydrophobic and basic residues in VP1 could then lead to tight binding between virus and receptor. The conserved lysine is not present in VP1 of rhinoviruses that bind ICAM-1, providing an explanation for failure of these viruses to bind LDLR. An exception is rhinovirus 85 that has the conserved lysine; presumably, it does not bind LDLR because of other amino acid differences in neighboring hydrophobic and basic VP1 residues.

It was originally hypothesized that the picornavirus canyons were too deep and narrow to allow penetration by antibody molecules, which contain adjacent immunoglobulin domains.[606] This physical barrier was thought to hide amino acids crucial for receptor binding from the immune system. Structural studies of a rhinovirus–antibody complex, however, revealed that antibody does penetrate deep into the canyon, as does ICAM-1.[641] The shape of the picornavirus canyon, therefore, is not likely to play a role in concealing virus from the immune system.

In contrast to the Ig-like receptors that bind the canyons of enteroviruses, the binding sites for DAF on the virion are diverse. For example, five amino acids of DAF interact with the VP2 puff region of Coxsackievirus B3 in an area that lies between the icosahedral threefold, twofold, and fivefold axes and away from the twofold axis.[564] In contrast, the binding sites of DAF on echovirus 7 (Fig. 2.7) and 12 are completely different, far from the canyon, at the edge of the depression at the twofold icosahedral axis.[548,564] There is no overlap between surfaces on echoviruses 7 and 12 and Coxsackievirus B3

that interact with DAF.

Integrin-binding picornaviruses attach to cell receptors through surface loops. In FMDV, an Arg-Gly-Asp sequence in the flexible, exposed βG–βH loop of the capsid protein VP1 is recognized by integrin receptors on cells.[162,203,423] Arg-Gly-Asp–containing peptides block attachment of FMDV,[55] and alteration of this sequence interferes with virus binding.[448] In Coxsackievirus A9, the Arg-Gly-Asp sequence is present in a 17–amino acid extension of the C-terminus of VP1 and is also the site of attachment to cell receptors.[114,601] Alteration of this sequence does not abolish binding to some cell lines but blocks infectivity in A549 cells (human lung carcinoma), suggesting that the virus can bind to another cell surface receptor.[310] In susceptible cells, β2M and HSPA5 (heat shock 70-kDa protein 5, also known as BiP or glucose-regulated protein 78 kDa, GRP78) are sufficient for infection by Coxsackievirus A9 with an altered Arg-Gly-Asp sequence.[288] Echovirus 1 is unusual in that it binds the RGD-independent integrin $\alpha_2\beta_1$ in the canyon.[762]

As discussed, FMDV binds alternative receptors, either integrin or heparan sulfate, depending on the virus isolate. The binding site for heparan sulfate on cell culture–adapted FMDV is a shallow depression on the virion surface, where the three major capsid proteins, VP1, VP2, and VP3, are located.[207] Binding specificity is controlled by two preformed sulfate-binding sites on the capsid. Residue 56 of VP3 is a critical regulator of receptor recognition. In field isolates of the virus, this amino acid is histidine. Adaptation to cell culture selects for viruses with an arginine at this position, which forms the high-affinity, heparan sulfate–binding site.

While the Seneca Valley virus particle is similar to that of cardioviruses lacking a canyon, structure of the virus bound to anthrax toxin receptor 1/TEM 8, a type I transmembrane protein, revealed that the protein binds the virion in a crown-like arrangement around the fivefold axis of the icosahedron (Fig. 2.7). TEM 8 is composed of an N-terminal integrin–like fold, an Ig-like domain followed by the transmembrane domain and cytoplasmic tail. The high-affinity interaction between TEM 8 and Seneca Valley virus occurs between helices α4 and α3 of the integrin-like fold and loops α2–α3 and β2–β3 of the Ig-like domain and the BC loop and loop II of VP1, the puff of VP2, and the knob of VP3 of the virus.[332]

Kinetics and Affinity of the Virus–Receptor Interaction

The affinity and kinetics of picornaviruses binding to soluble forms of their receptors (sPVR, sICAM, sCAR) and antibodies have been studied by surface plasmon resonance. Two classes of receptor-binding sites, with distinct binding affinities, exist on the capsids of poliovirus and rhinovirus.[110,451,763] The association rates for the two binding classes are 25 and 13 times higher for the poliovirus–sPVR interaction than for the rhinovirus 3 or 16–sICAM interaction at 20°C; though the first association rate of rhinoviruses 3 and 16–sICAM was highly similar, the second association rate for rhinovirus 16 is slower.[763] The greater association rate of poliovirus and sPVR may be caused, in part, by differences in the extent of contact between virus and receptor. However, the association rate for receptor binding to the virion is slower than that for antibody binding. This observation supports the hypothesis that a conformational change in the virus particle is required for receptor function.[110] In contrast, whereas two dissociation rate constants exist for the poliovirus–sPVR and coxsackievirus–sCAR interactions, only one has been reported for the rhinovirus 3–sICAM interaction.[108,110,451] The dissociation rates for the poliovirus–sPVR interaction are 1.5 and 2.0 times faster than for the rhinovirus–sICAM interaction, indicating greater instability of the former complex. The affinity constants for the poliovirus–sPVR interaction are 19 and 6 times greater than those reported for the rhinovirus–sICAM-1 complex. Despite lacking interaction with the south wall and floor of the canyon, the binding affinity for the monomeric sCAR–Coxsackievirus B3 interaction is similar to that for the poliovirus–sPVR and rhinovirus–sICAM interactions even though the dissociation rate for the sCAR–Coxsackievirus B3 is much lower than for poliovirus–sPVR.[237,520]

In contrast to the observations with poliovirus and rhinovirus, a single class of binding site was found on echovirus 11 for a soluble form of its receptor, CD55.[400] The affinity of this interaction is at least fourfold lower than either of the binding sites on poliovirus for sPVR. The association rate for the interaction between echovirus 11 and sCD55 is faster than that of poliovirus–sPVR and rhinovirus–sICAM-1. One explanation for these findings is that the contact between echovirus 11 and sCD55 is more

extensive than that of the other two virus–receptor complexes. The binding site for CD55 on echovirus 11 may also be more accessible than those of PVR and ICAM-1. The dissociation rate for the echovirus–sCD55 interaction is at least 97 times faster than that of either the poliovirus–sPVR or the rhinovirus–sICAM-1 interaction. These findings are consistent with a more accessible binding site for CD55 on echovirus 11, compared with the receptor-binding sites on poliovirus and rhinovirus. Atomic interactions between CD55 and echovirus 11 may be weaker than between the other two viruses and their receptors. The faster dissociation rate of the echovirus 11–sCD55 complex may be related to the finding that the interaction does not lead to structural changes of the virus particle,[574] as occurs with poliovirus and rhinovirus. In general, there is a higher affinity for virions of receptors that can uncoat particles ("unzippers"—poliovirus/PVR, HRV/ICAM-1, CVB3/CAR) compared with attachment receptors (E6, E7, E11, E12, CVB3 with DAF). This difference may reflect the energy necessary to release the viral RNA.

Why do poliovirus, rhinovirus, and Coxsackievirus B have two classes of receptor-binding sites? For poliovirus and rhinovirus, the receptors for both viruses make contacts at two major sites on the virus surface, one in a cleft on the south rim of the canyon and a second on the side of the mesa on the north rim. These two contact sites may correspond to the two classes of binding sites. Two classes of binding sites may also be a consequence of the structural flexibility exhibited by both viruses, which may cause exposure of different binding sites. Normally, internal parts of the capsid proteins of many picornaviruses including poliovirus, swine vesicular disease virus, and rhinovirus have been shown to be transiently displayed on the virion surface, a process called *breathing*.[336,406,410,577,621] As discussed later, the interaction of poliovirus and rhinovirus with their cellular receptors leads to irreversible and more extensive structural changes of the particle. In contrast to the findings with poliovirus and rhinovirus, binding of echovirus 11 with CD55 can be described by a simple 1:1 binding model. Such behavior, which would be expected for the interaction of two preformed binding sites, is consistent with the fact that CD55 is an attachment molecule and the echovirus–CD55 interaction does not result in detectable structural changes in the capsid.[574,666] Instead, secondary factors may contribute to internalization and uncoating the virus.

Entry into Cells

Once picornaviruses have attached to their cellular receptor, the viral capsid is brought into the cell by an endocytic pathway, followed by genome release into the cytoplasm, the site of picornavirus replication. For some picornaviruses, interaction with a cell receptor serves only to concentrate virus on the cell surface; release of the genome is a consequence of low pH or perhaps the activity of a second receptor. For other picornaviruses, the cell receptor is also an unzipper and initiates conformational changes in the virus that lead to release of the genome. In some cases, only one cell surface molecule functions as the cellular receptor, and the requirements for entry are determined by the cell type infected; the identity of the receptor may change according to how the virus is passaged, thereby changing the entry route.

Entry by Clathrin-Mediated Endocytosis

Several lines of evidence indicate that clinical isolates of FMDV, which bind multiple $\alpha_v\beta$ integrins to attach to the cell surface, enter cells by clathrin-mediated endocytosis.[322] Infection is inhibited by sucrose, which eliminates clathrin-coated pits and induces clathrin to polymerize into empty cages, by synthesis of a dominant negative form of the clathrin coat assembly protein AP180 that is needed for assembly of clathrin cages, or by chlorpromazine treatment of cells prior to infection; all treatments decreased FMDV internalization and replication.[75,276] Confocal microscopy also revealed that FMDV enters cells via a clathrin-dependent mechanism through colocalization of FMDV with the early endosome protein EEA1.[514] There is also some evidence that entry is dependent upon cholesterol in the plasma membrane, a requirement generally observed for lipid rafts.[442] While cholesterol may be required for clathrin-induced membrane curving and budding of the plasma membrane, it is also required for macropinocytosis.[252,596] Another *Aphthovirus*, equine rhinitis A virus, binds sialic acid–containing receptors but also enters into cells via clathrin-mediated endocytosis.[254] However, the cellular receptor for serially passaged isolates of FMDV is heparin sulfate; these viruses are thought to enter the cell via macropinocytosis, a pathway taken by echovirus 1, Coxsackievirus B, and Coxsackievirus A9.

LDLR family members that are receptors for some HRVs possess C-

terminal cytoplasmic domains with tyrosine- and di-leucine–based internalization signals that lead to clustering of the receptors in clathrin-coated pits.[540] Evidence for HRV entry via this pathway includes the inhibition of infection in cells producing dominant negative inhibitors of the clathrin pathway.[57,645] Cholesterol depletion also significantly impairs entry of LDLR binding rhinoviruses.[645] Despite ceramide-mediated inhibition of entry of LDLR–rhinovirus 2 complexes, lipid rafts do not directly participate in rhinovirus entry. It is thought that ceramide inhibits receptor clustering instead.[248] There is little genetic or biochemical evidence that ICAM-1–binding rhinoviruses enter cells via clathrin-mediated endocytosis despite transmission electron microscopy, which shows virions in clathrin-coated pits and vesicles 5 minutes after infection.[257] Entry of ICAM-1–binding rhinoviruses is not inhibited by sucrose, chlorpromazine, nystatin, cholesterol depletion or dominant negative forms of AP180, or the endosome adaptor Eps15.[490] Additionally, the internalized rhinovirus vesicles take on a unique morphology including alignment as “beads on a string.” Though a dominant negative dynamin inhibits infection,[159] dynamin also participates in non–clathrin-mediated entry. HRV infection also activates signaling pathways with links to the endocytic machinery. The cytoplasmic domain of ICAM-1 binds the adaptor protein ezrin, which links the receptor to Syk, a tyrosine kinase.[736] When HRV binds ICAM-1, Syk is recruited from the cytoplasm to the plasma membrane together with clathrin. Functional Syk is required for HRV entry via ICAM-1.[397]

When virions enter cells by clathrin-dependent endocytosis, they encounter low pH, which triggers release of the viral RNA from the capsid. A role for low pH in infection can be demonstrated by determining the effect on entry of compounds that block acidification, such as weak bases (ammonium chloride, chloroquine, methylamine), ionophores (monensin, nigericin, X537A), or inhibitors of the vacuolar proton ATPase (concanamycin A, bafilomycin A). The pH of early endosomes is 6.5; as these vesicles mature to late endosomes, the pH drops to 5.5. Endosomal maturation is dependent not only upon vacuolar ATPases but also upon microtubules and membrane GTPases of the Rab family. Early to late endosome maturation can be inhibited by drugs that depolymerize microtubules (nocodazole), dominant negative Rabs, or inhibitors of PI3K signaling (wortmannin). In this way, it is possible to determine if viral entry occurs from early or late endosomes.

Uncoating by FMDV clearly requires low pH because concanamycin A, monensin, and ammonium chloride all inhibit infection.[54,75,514,730] Entry occurs from the early endosome as determined by experiments with dominant negative Rab proteins.[339] FMDV that bind heparan sulfate enter cells via a caveolae-dependent route, but low pH is still required for infection.[513] Consistent with this mechanism of uncoating, FMDV that has been coated with antibody can bind to, and infect, cells that produce Fc receptors, in contrast to poliovirus, which cannot productively infect cells via this pathway.[446] Cell receptors for FMDV are, therefore, *hooks*: they do not induce uncoating-related changes in the virus particle but rather serve only to tether the virus to the cell and bring it into the endocytic pathway.

The range of pH at which rhinoviruses uncoat depends on the serotype and receptor bound by the virus. For LDLR interacting rhinoviruses such rhinovirus 2, the receptor is thought to only be required for trafficking the virus to the late endosome; downstream events are acid induced. Upon acidification of the virus-containing vesicle, LDLR dissociates from the virion, simultaneously pocket factor is released, and a hinge movement around the VP1 pocket facilitates a shift of VP2 and VP3, leading to particle expansion and formation of pores at the base of the canyon and twofold axes. VP4 is released and the amphipathic N-terminus of VP1 is relocalized to the surface of the virion.[58,79,214,383,497,512,575] Similar alterations have been observed between the native and empty capsids of enterovirus A71.[739] Infection by LDLR interacting rhinoviruses is inhibited by monensin, bafilomycin A1, nocodazole, and wortmannin.[73,95,497] Uncoating of ICAM-1–binding rhinoviruses, such as rhinovirus 14, is also sensitive to bafilomycin and monensin, but at too low a pH, the particle dissociates, suggesting that higher pH of the early endosome is sufficient for uncoating.[58] Although the receptor for enterovirus D68 is not known, low pH has been shown to lead to uncoating of multiple viral isolates. Analysis of cryo-EM reconstructions of acid-treated particles unveiled the structure of the expanded particle (E1), a transition intermediate between native and altered (Fig. 2.8). This newly described E1 particle retains the ordered structure of the N-terminal amino acids of VP1 and the ordered structure of VP4 despite expansion of the particle. Furthermore, pentameric interactions are weakened by disruption of the interpentamer β-sheets, and the capsid shell is thinner possibly allowing the influx of protons into the interior of the capsid needed to disrupt the

stability of the N-terminus of VP1 within the E1 particle.[418]

Hepatitis A virus (HAV) native [4QPI] and empty [4QPG] capsids, equine rhinitis A virus (ERAV) native [4CTF] and acid-induced expanded capsids [4CTG], enterovirus D68 (EV-D68) native [4WM8] and acid-induced expanded capsids [6CS5], and rhinovirus 2 (HRV2) native [1FPN] and empty B capsids [3TN9].

Echovirus 7, which binds DAF, enters cells by clathrin-mediated endocytosis, and trafficking into late endosomes is required.[362] However, infection does not appear to require low pH, and therefore the trigger for uncoating and its intracellular location remains in question.

Entry by Caveolin-Mediated Endocytosis

As discussed above, CVB3 binds DAF, a GPI-linked protein localized within lipid rafts on the apical surface of polarized cells. The virus–DAF complex then moves to tight junctions (TJ) where it engages CAR. The virus is then internalized along with the TJ protein occludin by caveolin-1–dependent endocytosis.[142] The role of occludin is not known but it could provide a scaffold for recruiting other molecules. Within 60 minutes, the virus is within caveolin-1–containing vesicles (caveolae and caveosomes). Phosphorylation of caveolin-1 by tyrosine kinases is required for CVB3 entry, but the role of this modification is not known. Dynamin is not required for uptake of this virus, suggesting that other routes of entry are involved. Inhibitors of micropinocytosis (rottlerin and dominant negative Rab34) block infection, indicating a role for this type of uptake.

Echovirus 1, which binds the integrin $\alpha_2\beta1$, is taken into the cell by the caveolin-mediated endocytic pathway. The receptor is present in raft-like membrane domains that do not contain caveolin. Internalization of the virus does not depend on dynamin, but components of the macropinocytosis pathway, such as PKC, Pak1, and Rac1, are involved. By 30 minutes after infection, the virus appears in vesicular structures that may be caveolae.[441] These vesicles fuse with caveosomes, delivering the virus and its receptor to

the perinuclear region.[558] The resulting compartment may be a novel type of multivesicular body; virus transport to them appears to depend upon ESCRT proteins.[352]

Caveolin- and Clathrin-Independent Endocytosis

In HeLa cells, poliovirus is taken up into cells by an endocytic pathway that is dependent on actin, ATP, and a tyrosine kinase but independent of clathrin, caveolin, flotillin, microtubules, and pinocytosis.[96] Only after the conversion from the native to altered particle is poliovirus internalized.[96] These virus-containing endocytic vesicles lack signature characteristics of either the early or late endosome. Within the endosome, transition to the altered particle occurs. This alteration significantly reduces the affinity of PVR for the virion, suggesting that infectivity is independent of the receptor.[149] Subsequent work showed that within the endosomal vesicle, the altered particle is released from PVR but remains tethered to the membrane via insertion of the N-terminus of VP1.[253] RNA released from the particle into the lumen of the vesicle occurs rapidly and within 100 to 200 nm of the cell surface. Entry was different in a highly polarized human brain microvascular endothelial cell line.[142] Poliovirus enters these cells very slowly via dynamin-dependent caveolar endocytosis. Virus binding to PVR induces tyrosine phosphorylation of the receptor cytoplasmic domain, which in turn recruits and activates SHP-2, which is required for infection. These observations emphasize that virus entry pathways are likely to differ substantially according to cell type.

Uncoating

The interaction of enteroviruses and ICAM-1–binding rhinoviruses with susceptible cells leads to the conversion of virions to a more slowly sedimenting form (135S vs. 160S for native particles) (Fig. 2.7).[146,341] The resulting particles, called *altered*, or *A*, *particles*, contain the viral RNA but have lost the internal capsid protein VP4. In addition, the N-terminus of VP1, which is normally on the interior of the capsid, is on the surface of the A particle, externalized via a pore found at the pseudo threefold axes at the base of the canyon, binding the rearranged GH loop of VP3 and the top surface of VP2.[103,294,405,413,418] Conversion from the native particle to the altered particle typically includes a 4% increase in the diameter of the virion and

creation of pores within protomers by movement of the *β*-barrel cores of VP1, VP2, and VP3 at the twofold axes[64,293,294,418] (Fig. 2.9). Physiological temperatures can spontaneously induce the reversible conversion between native and altered particles at a slow rate; however, upon receptor binding or the presence of low pH for poliovirus and rhinovirus, respectively, the conversion is irreversible.[406,410] This tectonic rearrangement of the physical particle ends with formation of an amphipathic helix composed of VP4 and the N-terminus of VP1 inserted into the membrane of the endosome through which the viral RNA can travel to the cytoplasm (Fig. 2.9).[152,206,293,294,525,526,664,689,701] A variant of poliovirus containing an amino acid change at position 28 of VP4 can bind to cells and be converted to A particles, but these are blocked at a subsequent step in virus entry.[482] Additional genetic studies demonstrated that VP4 variants at position 28 lost the ability to form ion channels *in vitro* and delayed genome release.[152] Ectopic production of myristoylated rhinovirus VP4 can lead to the formation of membrane multimeric pores, which are similar in size to those necessary for RNA translocation.[154,526] Receptor binding (poliovirus) or low pH (rhinoviruses, cardioviruses, aphthoviruses, enterovirus D) are therefore the catalysts that lower the energy barrier for the irreversible conversion to the A particle necessary for uncoating and genome delivery to the cell.[418,575]

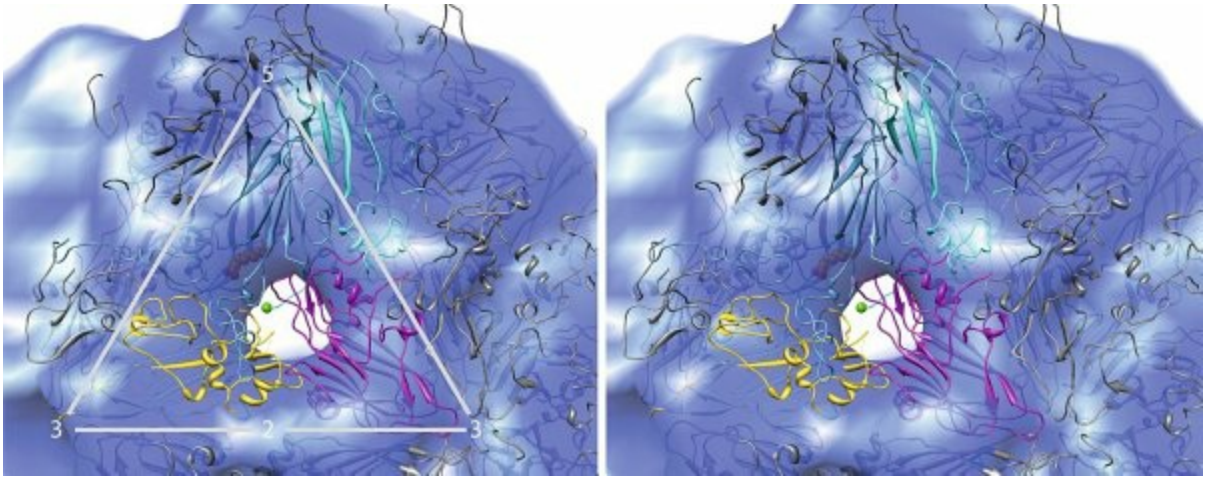

FIGURE 2.9 Hypothetical site for translocation of poliovirus RNA out of the capsid. Stereo views of the 80S pseudoatomic model superimposed on a map produced from 206 135S particles made by

incubation of native virus particles with receptor-decorated liposomes.[664] These particles have a pore in the capsid that is thought to be the exit channel for RNA. The pore lies above Gln-68 in the N-terminal extension of VP1 from the adjacent protomer (*green ball*). VP1 is *blue*, VP2 is *yellow*, and VP3 is *magenta*. Exposed N-terminus of VP1 is colored *cyan*. (Courtesy of Michael Strauss, McGill University, and James M. Hogle, Harvard Medical School.)

The initial model describing picornavirus uncoating and release of the RNA genome into the cytoplasm implied formation of a wide channel at the fivefold axes, displacing the solvent channel plug, and VP4, the N-termini of VP1 and RNA all exiting at this axis from a symmetric particle.[226,381] The initial cryo-EM reconstructions of the poliovirus 135S and 80S particles or those of the rhinovirus 2 80S particle do not support this model. This work did not reveal openings at the fivefold axes, which could allow for release of the viral genome, nor was removal of the solvent channel plug observed. Instead, this work leads to the suggestion that VP4 and the amino terminus of VP1 are externalized from the base of the canyon; the amphipathic helix bridges the canyon, binding to the EF loop of VP2 at the tip of the propeller near the threefold axes and at the twofold axes; and the RNA genome exits from the threefold axes[64,99,192,294,405,413,418,761] (Fig. 2.9). This hypothesis is further supported and refined by the finding that VP4 of rhinoviruses forms oligomers upon extrusion and exits near the twofold axis, based on the observation that insertion of a cysteine in the N-terminus of VP4 leads to disulfide linking upon breathing.[354] Cryo-EM reconstruction of the E1 and A particles of enterovirus D68 as well as the cryo-EM reconstruction of the poliovirus 135S and the rhinovirus 2 80S particle further support this model; hinge-like movement of the VP1 β-barrel flattening the top and temporarily moving through pores at the twofold axes is generated by the internalization of the C-termini of VP2 and expelling VP4. The GH loops of VP1 are rearranged to form a radially oriented hairpin. Together with VP2, a hole at a quasi-threefold axis is formed, and the tips of the propeller blades disappear (Fig. 2.9). By disordering the loops of VP1 and VP2, externalization of the

N-terminus of VP1 through the two-loop gates that separate holes at the twofold and pseudo threefold axes at the base of the canyon occurs. Once through the pore at the pseudo threefold axes, the N-terminus of VP1 is locked into place by interacting with the rearranged and exposed GH loops of VP3 and VP1 and binding the tips of the VP2 propellers.[103,294,418] The result of these structural alterations is tethering of an asymmetric particle to the vesicular membrane, the formation of an asymmetric channel, an umbilicus at the pseudo threefold axes necessary for RNA translocation into the cytosol on only the surface near where VP4 has inserted into the vesicular membrane in order to tether the virion.[103,403,664] However, the structural rearrangement of capsid proteins upon ICAM-1 binding of rhinovirus 14 is different. Analysis of the rhinovirus 14 80S particles revealed that the N-termini of VP1 exit through pores between neighboring VP1 molecules on the north rim of the canyon, not at the pseudo threefold axes, due to rearrangement of the N-termini of VP3 induced by ICAM-1 binding.[293]

Cryo-EM reconstructions of 80S particles of HRV2,[294] HRV14,[293] and poliovirus[405] also revealed a minimum of two classes of particles: those with partial or no electron density and particles surrounded by electron density, inside and out (presumably RNA). Analysis of these particles indicates that portions of VP1, which are not critical for the core structure of the virion, are no longer icosahedrally constrained, while the mesa found at the fivefold axes remains intact. The large pores between pentamers at the twofold axes also form during “breathing.” Moreover, the cryo-EM reconstructions divulged the presence of a highly structured RNA genome inside the virion; poliovirus genomic RNA is knobby and highly branched, while that of rhinovirus 2 is a well-ordered layer condensed into a rod under the protein shell oriented toward the twofold axes.[91,96,285,413,626] Analysis of the crystal structure of the enterovirus A71 73S particle, the empty capsid, unveiled a 5-degree counterclockwise rotation of the promoter around VP3 at the threefold axes, which pulls VP0 away from and leads to formation of pores at the twofold axes, as well as collapse of the external walls of the VP1 pocket including that formed by the GH loop of VP1.[739] Moreover, x-ray crystallography and cryo-EM reconstruction of the rhinovirus 2 native and altered particles highlighted specific changes in contacts between the RNA and the interior of the capsid that are thought to help maintain the protein network between promoters. In particular, the VP2 contact with the genome

is maintained during alteration, but expulsion of the N-terminus of VP1 breaks the RNA–VP1 interface promoting formation of a new interaction between the N-terminal β-tubes of VP3 and the RNA at the fivefold axes.[557] Consequently, exit of the RNA genome cannot occur at the fivefold axes; instead, the viral RNA gradually exits via a ratchet-like mechanism from an asymmetric site at the base of the canyon near the twofold axes as a single strand lacking any secondary structures. The interior of the capsid may function as rails that conduct the RNA toward the pore.[91,96,214] Annealing of complementary fluorescently labeled oligonucleotides to the ends of the rhinovirus 2 genome revealed that egress of the RNA begins with the poly(A) tail–3′ end in a tightly coordinated process to avoid tangling and steric hindrance of the capsid.[285]

Despite not knowing the cell molecule that functions as the receptor for Saffold virus, the energy required to facilitate A particle formation can be mimicked by heating the virus. Heating to 42 degrees and cooling induce particle alteration as well as dissociation into 14S pentamers. Similar observations have been made during mengovirus uncoating.[272] Cryo-EM reconstruction of the heat-induced A particle revealed that transition from the native to altered particle of cardioviruses follows a path similar to that described for enteroviruses: particle expansion of 4% and formation of large pores at the fivefold and threefold axes. Unlike enteroviruses, ordered residues of VP4 begin near the fivefold axes and end near the threefold axes of the same promoter, and no pore is observed at the twofold axes.[489] Further analysis of the A particle found that the RNA density was uniformly distributed at the center of the particle independent of any contact with the capsid.[489]

While enterovirus capsids are stable at low pH and maintain icosahedral symmetry during uncoating due to the presence of extra β-sheet interactions in VP1, the acid-labile aphthoviruses dissociate into pentamers at low pH, as the viral RNA is released.[75,107,192,376,436,442–444,716] A mechanism by which low pH causes disassembly of the FMDV capsid has been illuminated by structural and genetic studies. Examination of the atomic structure of the virus revealed a high density of histidine residues lining the pentamer interfaces, which are stabilized by β-sheet interactions.[1] These residues confer stability to the capsid; because the pK_a of histidine is 6.8, close to the pH at which the virus dissociates, protonation of the side chains of the

histidines might cause electrostatic repulsion, leading to disassembly.[148] To test this hypothesis, a histidine residue at position 142 of VP3 was changed to aspartic acid or phenylalanine. The resulting capsids were more stable at low pH than wild-type capsids,[181] supporting the proposed role of the histidine residue in acid-catalyzed disassembly. A single amino acid change of an alanine to valine in VP3 near the interpentameric interface enhances acid lability of the virus, while alterations of asparagine 17 in VP1 and histidine 145 in VP2 enhance acid stability of the capsid. These observations suggest that acid sensitivity is mediated by not only the pentameric interface of VP3 but also the N-terminus of VP1.[107,443,718] These data imply that the initial model may have oversimplified the mechanism of acid-induced RNA and VP4 release during *Aphthovirus* infection. Accounting for function of nonhistidine residues and cryo-EM reconstruction of the native and acid-treated virions, it has been proposed that protonation of two histidine residues within the interpentameric face of VP3 introduces an electrostatic repulsion with the dipole of the α-helix of the neighboring pentamer, which initiates uncoating, while the N-terminus of VP1 modulates the pH threshold necessary for uncoating and dissociating into pentamer subunits.[107] Uncoating of these viruses ends with the pentamers in an "inside-out" conformation as interactions at the midpoint between the two- and threefold axes remain intact.[436] How FMDV breaches the endosome membrane is not known; it does not have a hydrophobic VP1 N-terminus, and A particles are not produced. Despite the acid lability of equine rhinitis A virus and the absence of a hydrophobic N-terminus of VP1, this particle still undergoes acid-induced structural arrangement, VP4 expulsion, and gross expansion[37,702] (Fig. 2.8). Changes among all adjacent pentamers as well as disruption of the electrostatic interactions occur at low pH. The interface between pentamers is significantly smaller, hydrophobic, and built upon a ring stacking interaction between two VP2 proteins across the twofold axes, leading to formation of pores at the threefold axes of no less than 45 Å in diameter.[37]

Considering the various mechanisms for uncoating, the central problem is the same, how does the intact RNA genome transverse the protein shell and the vesicular membrane and enter the cytoplasm when its surrounding environment contains RNases and ions known to damage long molecules of RNA. Using fluorescent dyes, which only bind ssRNA, *in vitro* experiments

of heated receptor-decorated liposomes bound with poliovirus further supported the hypothesis that the RNA genome traverses the lipid membrane into the lumen of the vesicle as a linear molecule. A similar amount of intraluminal fluorescence was observed when the same receptor-decorated liposome–virus complexes were heated in the presence of RNase A. This observation suggests that the RNA genome is protected from degradation during uncoating and release.[253] Immunofluorescence assays of HeLa cells infected with poliovirus in the presence of RNase A confirmed the observation that the RNA genome is protected from degradation even though the RNase is taken up with the virion. Using this same assay, it was found that infection of equine rhinitis A virus was also refractory to the presence of RNase A and the genome remained protected from degradation.[253]

Regulation of Uncoating by Cellular Molecules

The majority of studies examining picornavirus attachment, entry, internalization, and uncoating were based upon the assumption that all that was necessary for these processes was the cellular receptor, formation of an endosome, and acidification of the endosome. Viral proteins perforated the membrane, formed the pore, and protected the genome as it was released as a single unstructured strand via a ratcheting motion. However, a perforated endocytic vesicle is generally marked and targeted for autophagic degradation. Consequently, cell proteins may participate in the later steps of picornavirus uncoating in order to circumvent premature degradation of the virus-containing vesicle and allow for genome release. The recent identification of the host lipid–modifying protein PLA2G16 as a modulator of enterovirus infection supports the need for cell proteins during virus entry.[654] PLA2G16 is a phospholipase, catalyzing the conversion of phospholipids to fatty acids. When PLA2G16 is absent from the cell, both poliovirus and rhinovirus replications are impaired. Specifically, it is thought that the recruitment of PLA2G16 to the surface of the virus-containing endosome may block autophagic degradation of these vesicles by preventing their detection by the glycan-binding LGALS8, a protein known to participate in the clearance of damaged vesicles.[182,654] Several picornavirus 2A proteins lack enzymatic activity, including those of kobuviruses, parechoviruses, and tremoviruses, but are homologs of PLA2G16.[654] It remains unknown if these proteins participate in viral uncoating as they are

not found within the incoming virion.

Beneath the canyon floor is a hydrophobic pocket that opens at the base of the canyon and extends toward the fivefold axis of symmetry. For many picornaviruses, this pocket is filled with a lipid of varied length. The icosahedral symmetry of the capsid therefore would allow each virion to contain up to 60 lipid molecules. It was originally thought that the presence of lipids in the hydrophobic pocket contributed to the stability of the native virus particle by locking the capsid and preventing conformational changes. This hypothesis comes from the study of antiviral drugs, such as the WIN compounds (first identified by Sterling-Winthrop, Inc.) and others including 3-(4-pyridyl)-2-imidazolidinone (GPP3), which displace the lipid and bind tightly in the hydrophobic pocket (Fig. 2.10).[156,643] These antiviral compounds block breathing of the picornavirus capsid.[406] For instance, binding of WIN compounds to rhinoviruses 14 and 16 causes conformational changes in the canyon that prevent attachment to cells.[550] Inhibition of virus attachment to the cell surface by these compounds is probably not a consequence of altering the receptor-binding site but rather the result of preventing conformational changes required for receptor binding. In contrast, drug binding to rhinoviruses 1A, 3, and 16, poliovirus, enterovirus A71, and Coxsackievirus A16 can cause small or negligible structural changes in the capsid.[155,156,247,267,298] Polioviruses containing bound WIN compounds can bind to cells, but the interaction with PVR does not result in the production of A particles.[202,455,775] WIN compounds appear to inhibit poliovirus infectivity by preventing PVR-mediated conformational alterations that are required for uncoating. Additional support for the role of lipids in uncoating comes from the analysis of poliovirus mutants that cannot replicate unless WIN compounds are present.[485] Such WIN-dependent mutants spontaneously convert to altered particles at 37°C, without the cell receptor, probably because of the absence of lipid in the hydrophobic pocket. Moreover, drug-dependent mutants of poliovirus are thermolabile and spontaneously lose infectivity in the absence of drug at 37°C, probably because they do not contain stabilizing lipid in the pocket.[485] Domain 1 of PVR penetrates the canyon of poliovirus and induces several dramatic structural arrangements, the pivoting of VP1 away from the fivefold axes, expulsion of pocket factor, and expansion of the particle.[662] Presence of the lipid in the hydrophobic pocket may therefore be a critical regulator of the receptor-induced structural

transitions of enteroviruses. Removal of the lipid is therefore necessary to provide the capsid with sufficient flexibility to undergo the changes that permit the RNA to leave the shell. The results of computational modeling and kinetic studies suggest that stabilization of virus particles by drugs that replace the lipid is a consequence of increased compressibility rather than increased rigidity.[555,652,698] In some picornaviruses (e.g., rhinovirus types 3 and 14, rhinovirus C), however, the pockets appear to be empty, and these viruses are not inhibited by pocket-binding drugs.[29,777]

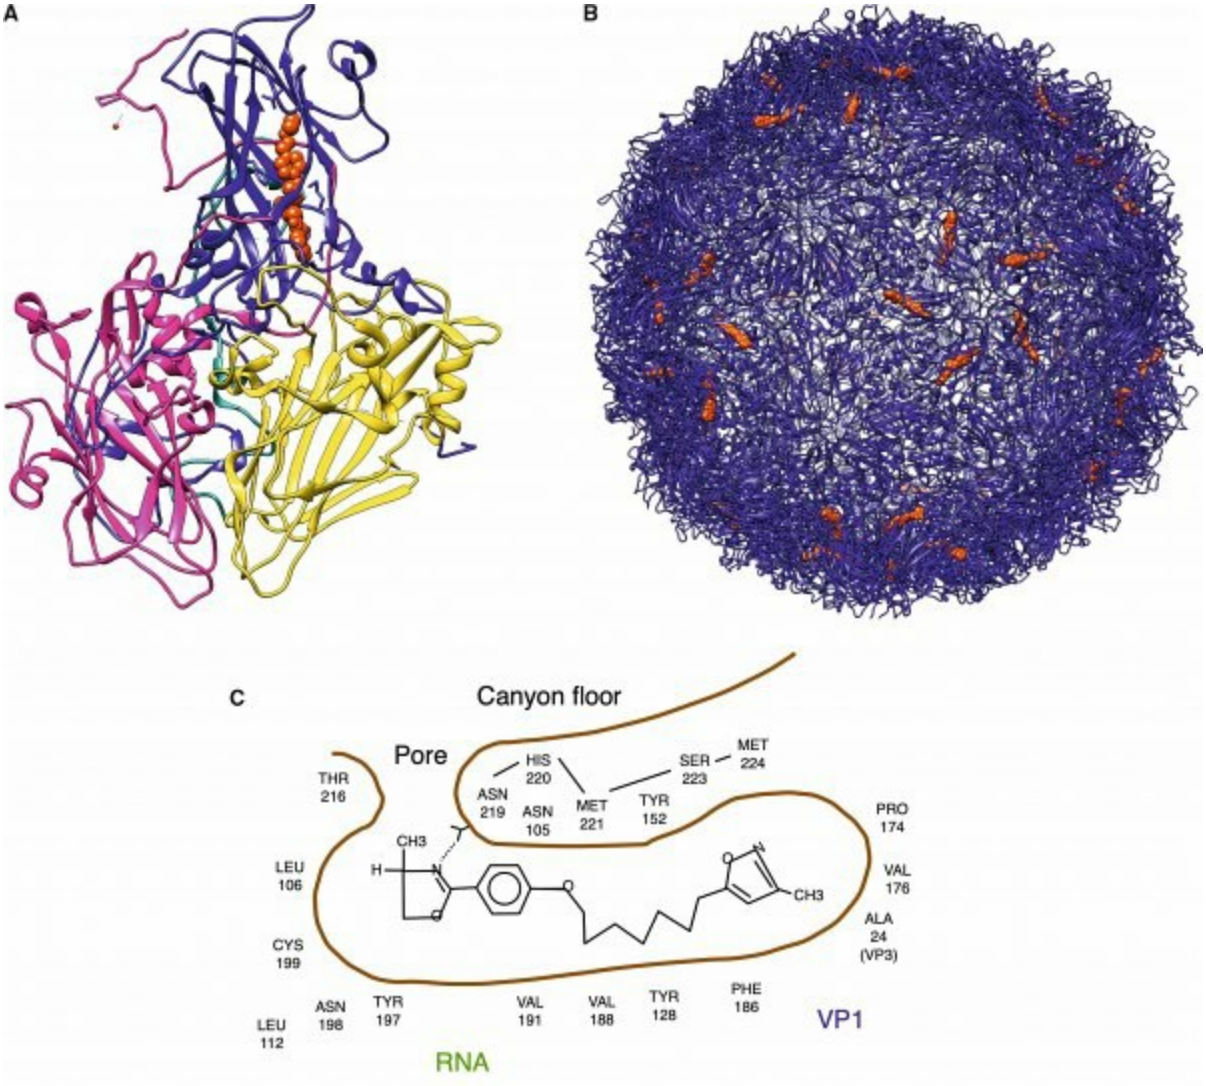

FIGURE 2.10 Mechanism of antiviral activity of compounds that bind within the hydrophobic VP1 pocket. **A:** Top view of a protomer, consisting of one copy of VP1 (*blue*), VP2 (*yellow*), VP3

(*deep pink*), and VP4 (*green*). *Orange spheres* represent one molecule of the pocket-binding compound 3-(4-pyridyl)-2-imidazolidinone (GPP3) bound in the hydrophobic VP1 pocket. **B:** GPP3 bound in the Coxsackievirus A16 capsid. The drug is the *small orange* molecule at the base of the canyon. **C:** WIN52084 bound in the hydrophobic pocket. These drugs displace the lipid from the pocket, thereby blocking infectivity. Amino acids of VP1 that line the pocket are indicated.

Several of these pocket-binding drugs have been evaluated in clinical trials, such as pleconaril for treatment of common colds caused by rhinoviruses[551] and for enteroviral sepsis syndrome.[501] Such drugs are ineffective against picornaviruses for which the VP1 is collapsed or are filled such as rhinovirus C (Fig. 2.3) and human parechovirus 3.[53,632]

Translation of the Viral RNA

Internal Ribosome Binding: The Internal Ribosome Entry Site

Once the picornavirus positive-strand genomic RNA is released into the cell cytoplasm, it must be translated because it cannot be copied by any cellular RNA polymerase and no viral enzymes are brought into the cell within the viral capsid. Several experimental findings led to the hypothesis that translation of the picornavirus genome was accomplished by an unusual mechanism. The positive-strand RNA genomes lack 5′-terminal cap structures; although virion RNA is linked to the viral protein VPg, this protein is removed by the cellular *unlinking* enzyme TDP2[13,725] on entry of the RNA into the cell. Furthermore, picornavirus genomes are efficiently translated in infected cells despite inhibition of cellular mRNA translation. Determination of the nucleotide sequence of poliovirus positive-strand RNA revealed a 741-nucleotide 5′-noncoding region that contains seven AUG codons.[369,582] Similar 5′-noncoding regions were subsequently found in other picornaviruses and shown to contain highly ordered RNA structures.[594,640]

Removal of an internal sequence of 300 nucleotides from the poliovirus 5′-noncoding region abrogates viral protein production,[542] while an internal sequence from the 5′-noncoding region of EMCV promoted translation initiation.[330] These findings led to the suggestion that ribosomes do not scan through picornaviral 5′-noncoding regions but rather bind to an internal sequence. The 5′-noncoding region of poliovirus positive-strand RNA was subsequently shown to contain a sequence that promotes internal binding of the 40S ribosomal subunit, and it was called the *internal ribosome entry site* (IRES) (Fig. 2.11).

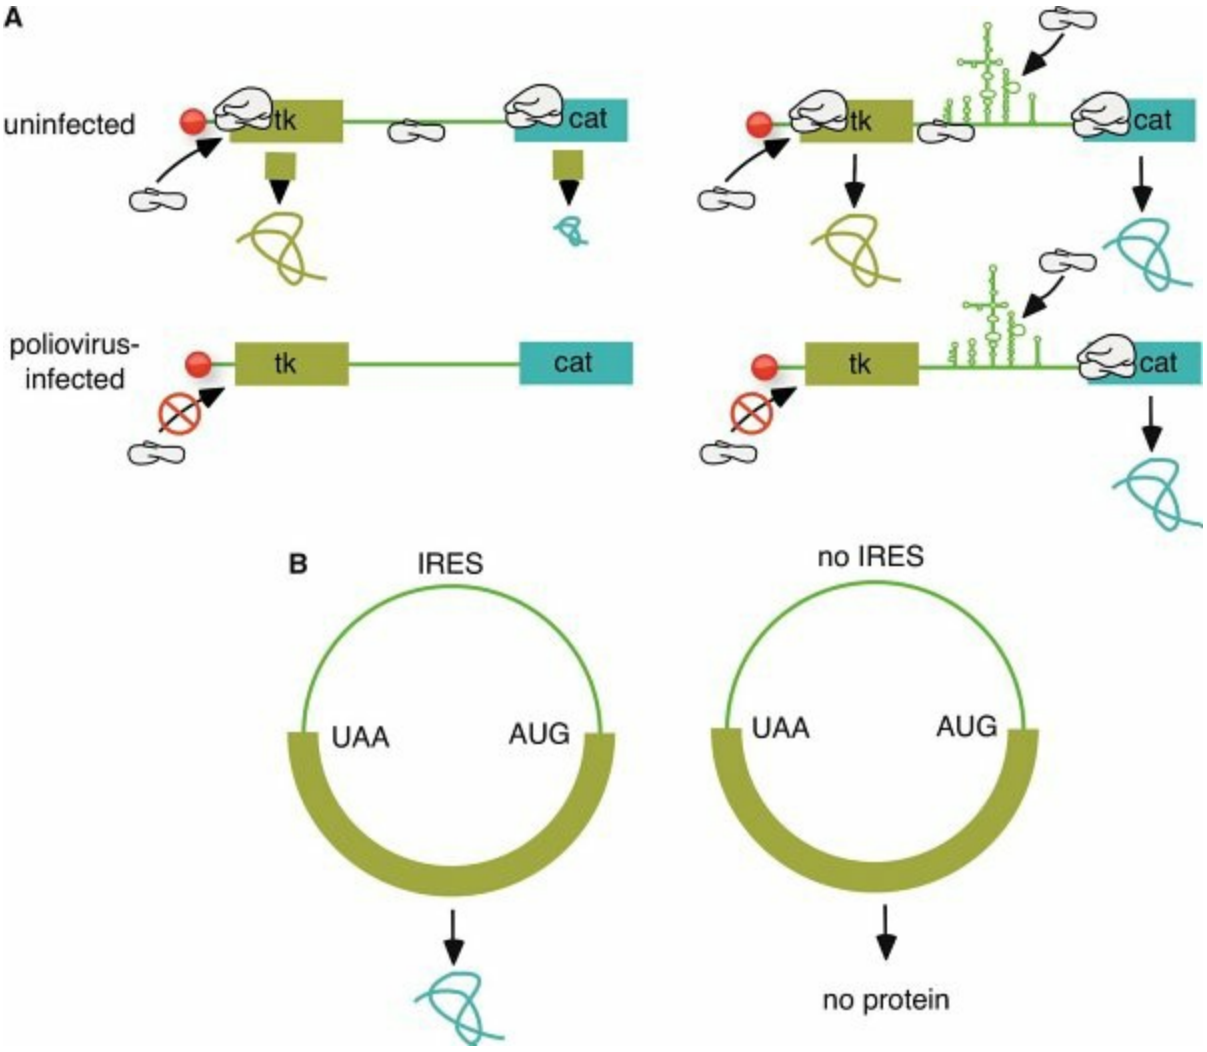

FIGURE 2.11 Discovery of the internal ribosome entry site (IRES). **A:** Bicistronic messenger RNA (mRNA) assay used to discover the IRES. Plasmids were constructed that encode two

reporter molecules, thymidine kinase (tk) and chloramphenicol acetyl transferase (cat), separated by an IRES or a spacer. After introduction into mammalian cells, the plasmids give rise to mRNA of the structure shown in the figure. In uninfected cells (*top line*), both reporter molecules can be detected, although cat synthesis is inefficient without an IRES and is probably caused by reinitiation. In poliovirus-infected cells, 5′-end–dependent initiation is inhibited, and no proteins are detected without an IRES, demonstrating internal ribosome binding. **B:** Circular mRNA assay for an IRES. Circular mRNAs were constructed and translated *in vitro* in cell extracts. In the absence of an IRES, no protein is observed because 5′-end initiation requires a free 5′ end. Inclusion of an IRES allows protein translation from the circular mRNA, demonstrating internal ribosome binding.

All picornavirus RNAs contain an IRES, as do other viral mRNAs.[432] Viral IRESs have been placed in eight groups, based on a variety of criteria, including primary sequence, secondary structure, location of the initiation codon, and activity in different cell types.[389] In the type I IRES (found in the genomes of enteroviruses and rhinoviruses) and the type III IRES (hepatitis A virus), the initiation codon is located 50 to 100 nucleotides beyond the 3′ end of the IRES, whereas it is located at the 3′ end of a type II IRES (cardioviruses and aphthoviruses) (Fig. 2.12). Avihepatoviruses, teschoviruses, tremoviruses, and members of the *Kobuvirus* genus harbor a type V IRES.

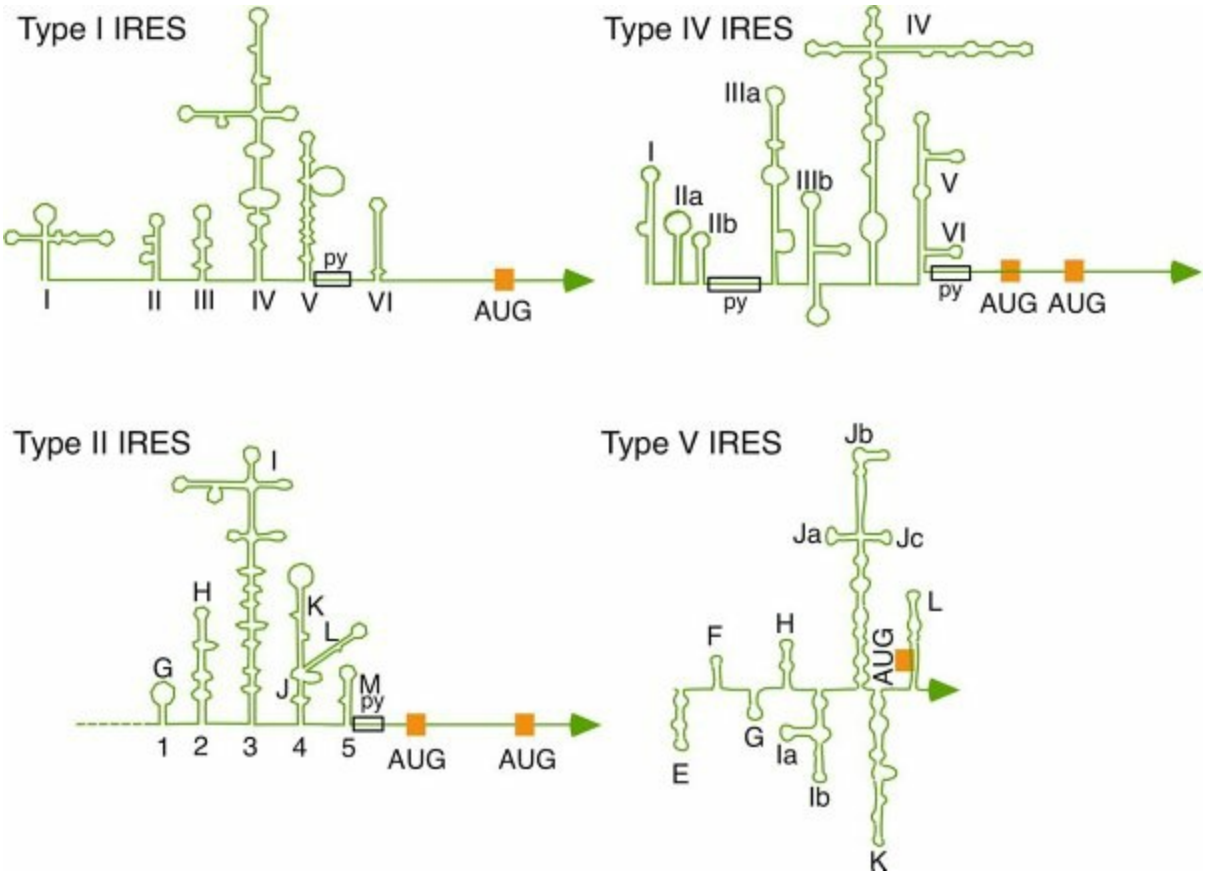

FIGURE 2.12 Four major types of picornaviral internal ribosome entry sites (IRES). The type I IRES is found in the genomes of enteroviruses. The genomes of cardioviruses and aphthoviruses contain a type II IRES. The IRES of hepatitis A virus is type IV, and the type V IRES is represented by porcine teschovirus 1 and kobuvirus.

There is little nucleotide sequence conservation among different IRES elements. The picornavirus IRES contains extensive regions of RNA secondary structure (Fig. 2.12) that are not strictly conserved but are crucial for ribosome binding. One sequence motif that is conserved among picornavirus IRESs is a GNRA sequence (G, guanine; N, any nucleotide; R, purine; A, adenine) in stem–loop IV of the type I IRES and in stem–loop I of the type II IRES. Another conserved element is an Yn-Xm-AUG motif, in which Yn is a pyrimidine-rich region and Xm is a 15- to 25-nucleotide spacer followed by an AUG codon. Translation initiation mediated by a type I IRES

involves binding of the 40S ribosomal subunit to the RNA and scanning of the subunit to the AUG initiation codon. The 40S subunit probably binds at the AUG initiation codon of a type II IRES.

The type III IRES has little homology with type I and type II IRES except for the Yn-Xm-AUG motif. It is structurally distinct, consisting of two major domains, and in addition requires intact eIF4F complex[10] (Fig. 2.12). The type V IRES functions in a prokaryotic-like manner. The secondary structures of these RNA elements facilitate direct interaction with the small 40S ribosome.[196,197,329,650] These interactions place a portion of the RNA within the P-site of the 40S ribosomal subunit as observed by *in vitro* toeprinting and structural analyses of RNA–protein complexes. Initiation of translation mediated by the type V IRES is therefore independent of all canonical translation initiation proteins including the ternary complex of eIF2α-GTP-met-tRNA$_i$. The only initiation protein required is DHX29, necessary to unwind secondary structure surrounding the initiation codon.[563,773] No Met-tRNA$_i$ is required as the first amino acid of this polyprotein is glycine.[329] Translation initiation mediated by the type V IRES may be also independent of all canonical translation initiation proteins as under stress conditions, the Met-tRNA$_i$ may bind directly to the ribosome.

The IRES of kobuviruses is distinct from the type I, II, and III IRES.[773] Domain I is not related to elements found in any other IRES. Domain J consists of a long interrupted basal helix and an apical four-way helical junction, similar to but smaller than domain IV in the type I IRES. Its apical subdomain (Jb) also includes a GNRA tetraloop, which is essential for the function of the type I and type II IRES. The apex of domain K contains an element identical to an apical motif in domain J of the type II IRES that is essential for specific interaction with eIF4G.[52,128] These domains are otherwise unrelated. An equivalent domain K of the type II IRES is also absent. Finally, the initiation codon is preceded by a Yn motif as in the type I/II IRES, but in contrast, it is sequestered in a long, stable hairpin, explaining why this IRES requires the DExH-box protein DHX29.

Mechanism of Internal Ribosome Binding

Different sets of translation initiation proteins are needed for internal initiation. Internal ribosome binding via the type IV IRES requires all of the

initiation proteins, including eIF4E. A subset of translation initiation proteins is required for the activity of most picornavirus IRES.

Translation initiation via a type I IRES involves binding of the 40S ribosomal subunit to the IRES, followed by scanning of the subunit to the initiation codon. In cells infected with enteroviruses, eIF4G, the large scaffold protein, which binds eIF4E, eIF4A, eIF3, and poly(A)–binding protein (Pabp), is cleaved, inactivating the translation of most cellular mRNA (Fig. 2.13). This observation led to the hypothesis that full-length eIF4G is not required for function of the IRES of poliovirus and other type I IRESs and that mRNA translation initiates when the 40S ribosomal subunit is recruited to the IRES through interaction with eIF3 bound to the C-terminal domain of eIF4G, which binds directly to the RNA. Addition of the C-terminal fragment of eIF4G to *in vitro* translation reactions stimulates activity of the poliovirus and other type I IRESs (Fig. 2.13).[100,517] These data are explained by the observation that the C-terminal fragment of eIF4G stimulates the helicase activity of eIF4A, which is necessary for initiation dependent upon the type I IRES, as the 40S ribosomal subunit is loaded on the RNA upstream of the initiating codon and must scan to the AUG.[31] It also explains why type I IRES activity is enhanced in cells in which the poliovirus protease $2A^{pro}$ is produced.[31,274] Protease $2A^{pro}$ is the picornaviral proteinase responsible for cleavage of eIF4G. Although the IRES of many picornaviruses functions with cleaved eIF4G, the type II and IV IRESs require intact eIF4G.[88] While the 40S ribosomal subunit binds at or near the AUG initiation codon of the type II IRES and no scanning occurs, eIF4G is required to induce conformational changes around the initiating codon necessary for recruitment of the 40S subunit and placement of the initiation codon in the ribosomal A site.[382] Independent of the IRES type, the efficiency of translation initiation is also dependent upon the interaction between eIF4G and Pabp. This interaction is thought to form a closed loop of mRNA, which is necessary for the efficient return of translating ribosomes to the 5′ end.

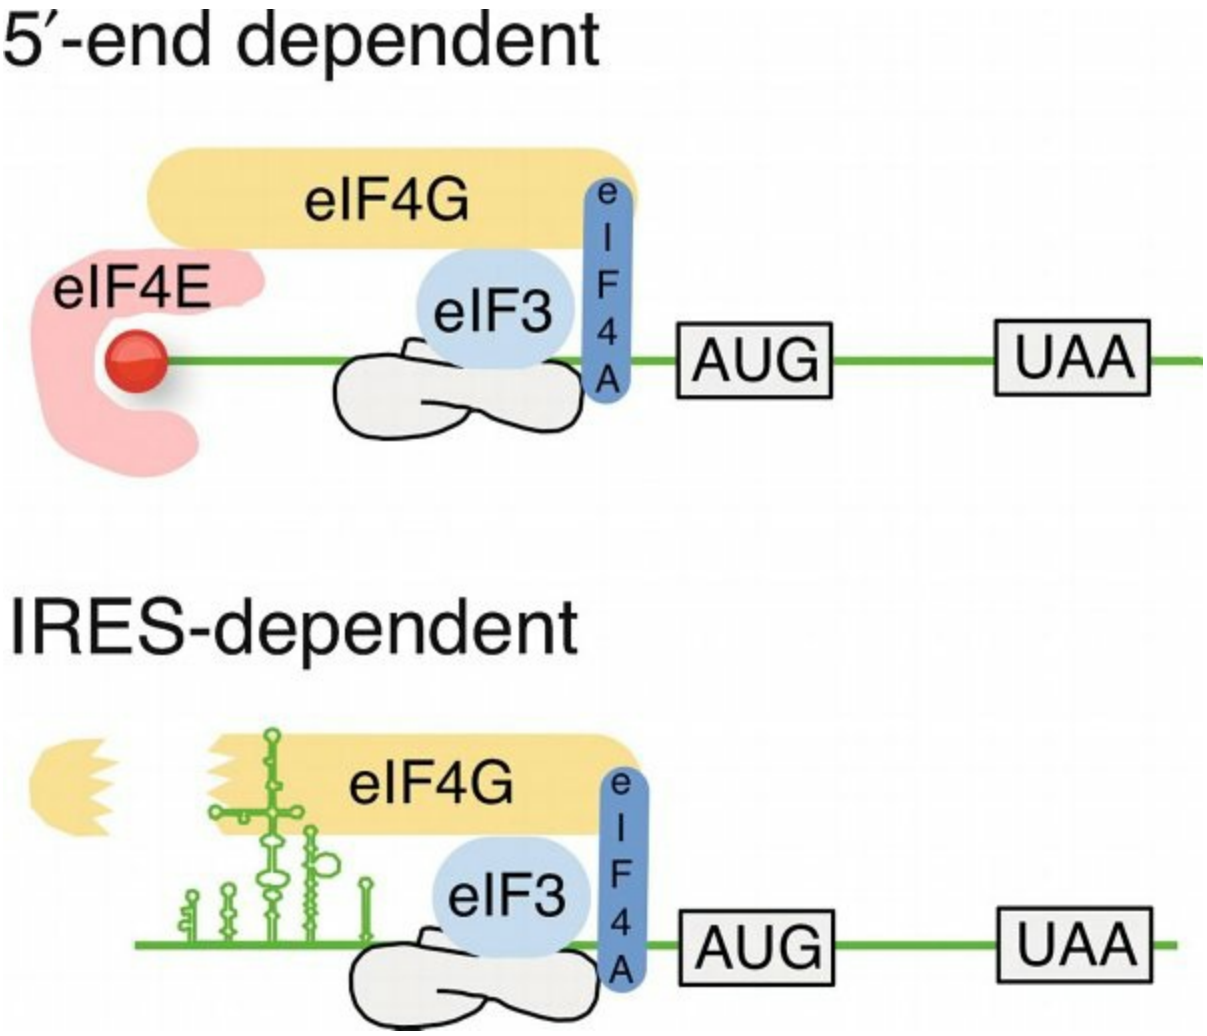

FIGURE 2.13 Models for translation initiation complex formation. In 5′ end–dependent initiation, the 40S subunit is recruited to the messenger RNA (mRNA) through its interaction with eIF3, which binds eIF4G. The latter initiation factor is part of eIF4F, which also contains eIF4A, a helicase to unwind RNA secondary structure, and eIF4E, the cap-binding protein. Binding of eIF4E to the cap thus positions eIF4E at the 5′ end and positions the 40S subunit on the mRNA. In IRES-dependent translation, a 5′ end is not required. The eIF3–40S complex is believed to be recruited to the RNA by the interaction of eIF4G with the IRES.

The poliovirus IRES functions poorly in reticulocyte lysates, in which capped

mRNA can be translated efficiently. Addition of a cytoplasmic extract to reticulocyte lysates restores efficient translation from this IRES. These observations led to the suggestion that ribosome binding to the IRES requires cell proteins other than the canonical initiation proteins. Such proteins have been identified by their ability to bind the IRES and restore internal initiation in reticulocyte lysates (reviewed in[193]). One host protein identified by this approach is the La protein, which binds to the 3′ end of the poliovirus IRES.[456] This protein is associated with the 3′-termini of newly synthesized small RNAs, including transcripts made by cellular RNA polymerase III. La protein is present in low amounts in reticulocyte lysates; addition of the protein to such lysates stimulates the activity of the poliovirus IRES.[456] La is a nuclear protein that is relocalized to the cytoplasm in poliovirus-infected cells.[638] La protein is also required for efficient function of the EMCV IRES.[363]

Polypyrimidine tract–binding (PTB) protein is composed of four RNA-binding domains and functions as a regulator of pre–mRNA splicing. It binds the poliovirus IRES[289] and is required by the type I, II, IV, and V IRES.[312] Removal of this protein from a cell extract with an RNA affinity column inhibits the function of the FMDV IRES[503,559] and that of EMCV, but does not affect translation by 5′-end–dependent initiation.[348] The deficiency in the function of these IRESs is restored by adding the purified protein back to the lysate. The depleted lysate, however, still supports the function of the IRES from Theiler murine encephalomyocarditis virus. It was subsequently shown that the requirement for PTB by the EMCV IRES depends on the nature of the reporter and the size of an A-rich bulge in the IRES.[349] It is thought that PTB facilitates initiation via the type I IRES by modulating binding of eIF4G to the viral RNA, through the interaction between the RNA-binding motifs 1 and 2 of PTB, the bottom of domain V, and the RNA-binding motifs 3 and 4 within the single-stranded region of the viral RNA surrounding domain V of the IRES.[346] Unlike the type I IRES, multiple copies of PTB are required to bind the FMDV, EMCV, and other type II IRES. RNA-binding domains 1 and 2 of one PTB molecule bind domain F of the IRES, and RNA-binding domains 3 and 4 bind domains D and E of the IRES. RNA-binding domains 1 and 2 of a second molecule of PTB bind domain K of the IRES, and RNA-binding domains 3 and 4 interact with IRES domains H, I, and L, all with lower affinity.[345]

HeLa cell extracts also contain unr, an RNA-binding protein with five cold-shock domains that is required for IRES function.[311] Recombinant unr stimulates the function of the rhinovirus IRES in the reticulocyte lysate and acts synergistically with recombinant PTB protein to stimulate translation mediated by the rhinovirus IRES *in vitro*. However, the poliovirus IRES inefficiently mediates translation initiation in *unr*$^{-/-}$ cells even though PTB is present.[94]

Ribosome-associated poly r(C)–binding proteins bind at multiple sites within the poliovirus IRES.[83,211] One binding site for these proteins has been identified within stem–loop IV of the poliovirus IRES.[83] Mutations in this region that abolish binding of poly r(C)–binding proteins cause decreased translation *in vitro*. Furthermore, depletion of poly r(C)–binding proteins from HeLa cell translation extracts results in inhibition of poliovirus IRES function.[84] When this assay was used to survey a wide range of picornaviral IRES elements, it was found that poly r(C)–binding proteins are required for function of the type I, but not the type II, IRES.[731] A second binding site for poly r(C)–binding proteins has been identified within a cloverleaf RNA structure that forms within the first 108 nucleotides of the positive-strand poliovirus RNA genome.[211,529] The interaction of poly r(C)–binding proteins with this part of the RNA has been proposed to regulate whether a positive-strand RNA molecule is translated or replicated.

The nucleocytoplasmic protein SRp20 functions with poly r(C)–binding protein 2 to promote initiation on poliovirus mRNA.[62] SRp20 binds to the KH3 domain of poly r(C)–binding protein 2. Depletion of SRp20 from cellular lysates by monoclonal antibodies or from cells by short interfering RNAs reduced IRES-mediated translation by 50%. Polysome analysis of infected cells by sucrose gradient fractionation demonstrated that both SRp20 and poly r(C)–binding protein 2 are at least partly associated with translation initiation complexes bound to stem–loop V of the poliovirus 5′-UTR.[194]

Murine proliferation–associated protein 1 (Mpp-1) is required for the function of the FMDV IRES. This protein binds to a central domain of the viral IRES and acts synergistically with PTB to increase the binding of eIF4F. It has been suggested that Mpp-1 may determine the tissues in which the IRES functions. To test this hypothesis, a recombinant virus was constructed by replacing the IRES of Theiler virus with that of FMDV.

Theiler virus replicates in the mouse brain, but the recombinant virus cannot, possibly because of the absence of Mpp-1 in this organ.[559]

The DExH-box helicase DHX29 is necessary for the activity of the type V IRES.[773] Initially, this protein was identified because it enabled efficient 48S preinitiation complex formation on cellular mRNAs possessing highly structured 5′-noncoding regions.[563] It is believed to be required for proper placement of the ribosome on RNAs possessing prokaryotic-like IRES elements, such as those of the flavivirus classical swine fever virus and the intergenic IRES of cricket paralysis virus, member of the *Dicistroviridae*.[563]

Two proteins that function during vesicular trafficking between the endoplasmic reticulum and Golgi apparatus, Rab1b and ARF5, modulate the activity of the FMDV IRES. By interacting with the RNA, Rab1b may facilitate RNA localization to the rough endoplasmic reticulum and promote protein synthesis, while ARF5 binding to the RNA on the surface of the trans-Golgi may prevent mRNA translation from occurring in the wrong cellular compartment.[189]

Several cell proteins have been identified that inhibit virus protein production, including double-stranded RNA-binding protein 76 (DRBP76), K homology–type RNA splicing regulatory protein (KHSRP), and AU-rich element degradation factor 1 (AUF1). These proteins were identified as binding the 5′-noncoding regions of different picornaviruses, and many inhibit mRNA translation[703] (reviewed in Ref.[401]).

No single cellular protein has been identified that is essential for the function of all viral IRESs. It has been suggested that the small ribosomal protein RPS25 may be an exception, as it appears to be required for translation from the IRES of poliovirus and the type IV IRES of the flavivirus hepatitis C virus, but not for 5′ end–dependent translation.[292] How RPS25 functions during internal ribosome entry has not been determined. A common property of some cellular proteins needed for IRES activity is that they are RNA-binding proteins that can form multimers with the potential to contact the IRES at multiple points. This observation has led to the hypothesis that such proteins may act as RNA chaperones, maintaining the IRES in a structure that permits it to bind directly to the translational machinery.[325] IRESs that do not require such chaperones may fold properly without the need for cellular proteins.

Processing of the Viral Polyprotein

Cleavage Cascades

Picornavirus proteins are synthesized by the translation of a single, long ORF encoded by the viral positive-strand RNA genome, followed by cleavage of the polyprotein by virus-encoded proteinases (Figs. 2.5 and 2.14). This strategy allows the synthesis of multiple protein products from a single RNA genome. The polyprotein is not observed in infected cells because it is processed as soon as the protease-coding sequences have been translated. The polyprotein precursor is processed cotranslationally by intramolecular reactions (in *cis*) in what are called *primary cleavages*, followed by secondary processing in *cis* or in *trans* (intermolecular). All picornavirus genomes encode at least one proteinase, $3C^{pro}$/$3CD^{pro}$, and some encode two others: L^{pro} and $2A^{pro}$.

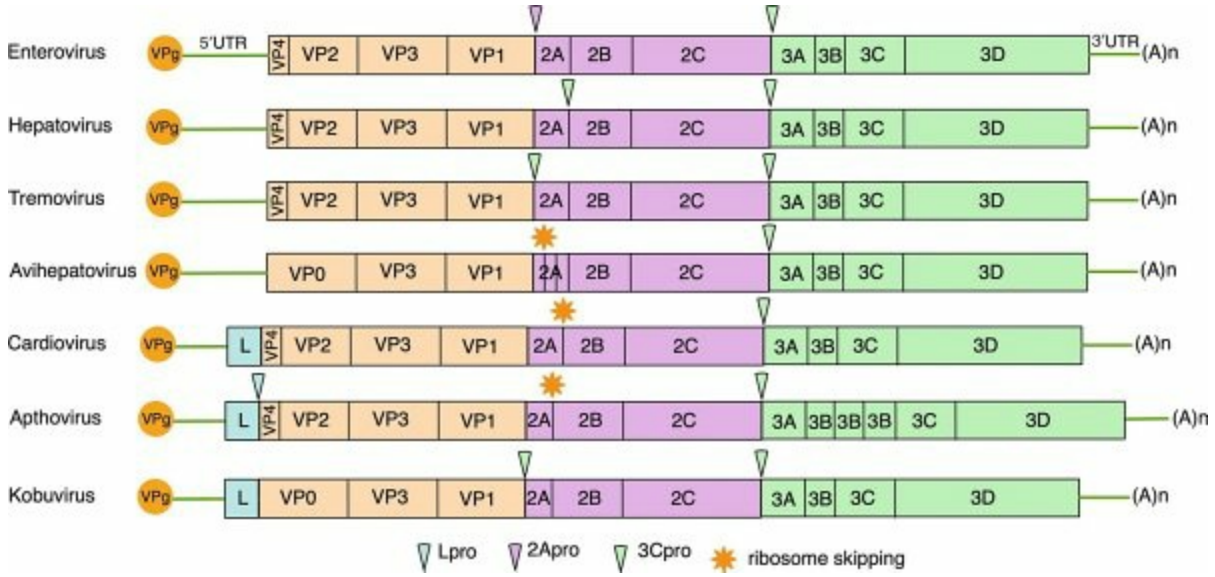

FIGURE 2.14 Primary cleavages of picornavirus polyprotein. In all viruses shown, the P2–P3 cleavage is carried out by $3C^{pro}$ (*green triangle*). In some picornaviruses, the P1–P2 cleavage is carried out by $2A^{pro}$ (*magenta triangle*) or $3C^{pro}$; in others, the 2A/2B bond is separated by ribosome skipping (*orange asterisk*). The L^{pro} proteinase (*blue triangle*) of aphthoviruses catalyzes its

release from VP4.

L Proteinase

The first protein encoded in the genome of aphthoviruses, cardioviruses, erboviruses, and sapeloviruses is the L protein (Figs. 2.14 and 2.15). The L protein of aphthoviruses and erboviruses (and possibly that of avian sapelovirus) is a proteinase that releases itself from the polyprotein by cleaving between its C-terminus and the N-terminus of VP4.[297,665] Based on sequence analysis, it was suggested that FMDV L^{pro} is related to thiol proteases.[243] This prediction was supported by the results of site-directed mutagenesis, which showed that Cys-51 and His-148 are the active site amino acids.[556,595] The atomic structure of L^{pro} reveals that it consists of two domains, with a topology related to that of papain, a thiol proteinase[260] (Fig. 2.15). The active site His is located at the top of the central α-helix, and substrate binds in the groove between the two domains. Besides releasing itself from the polyprotein, L^{pro} also cleaves the translation initiation protein eIF4G, causing inhibition of cellular translation, and G3BP1 and G3BP2, preventing stress granule formation.[160,726] Independent of its protease activity, L^{pro} may have deubiquitinase and deISGylase activities.[673,733] L^{pro} also is an antagonist of the innate immune response. By cleaving eIF4G, L^{pro} prevents synthesis of many IFN-stimulated gene products, but it also cleaves the Rig-I–like receptor laboratory of genetics and physiology 2 (LGP2) by impairing the positive feedback loop regulating interferon production.[599]

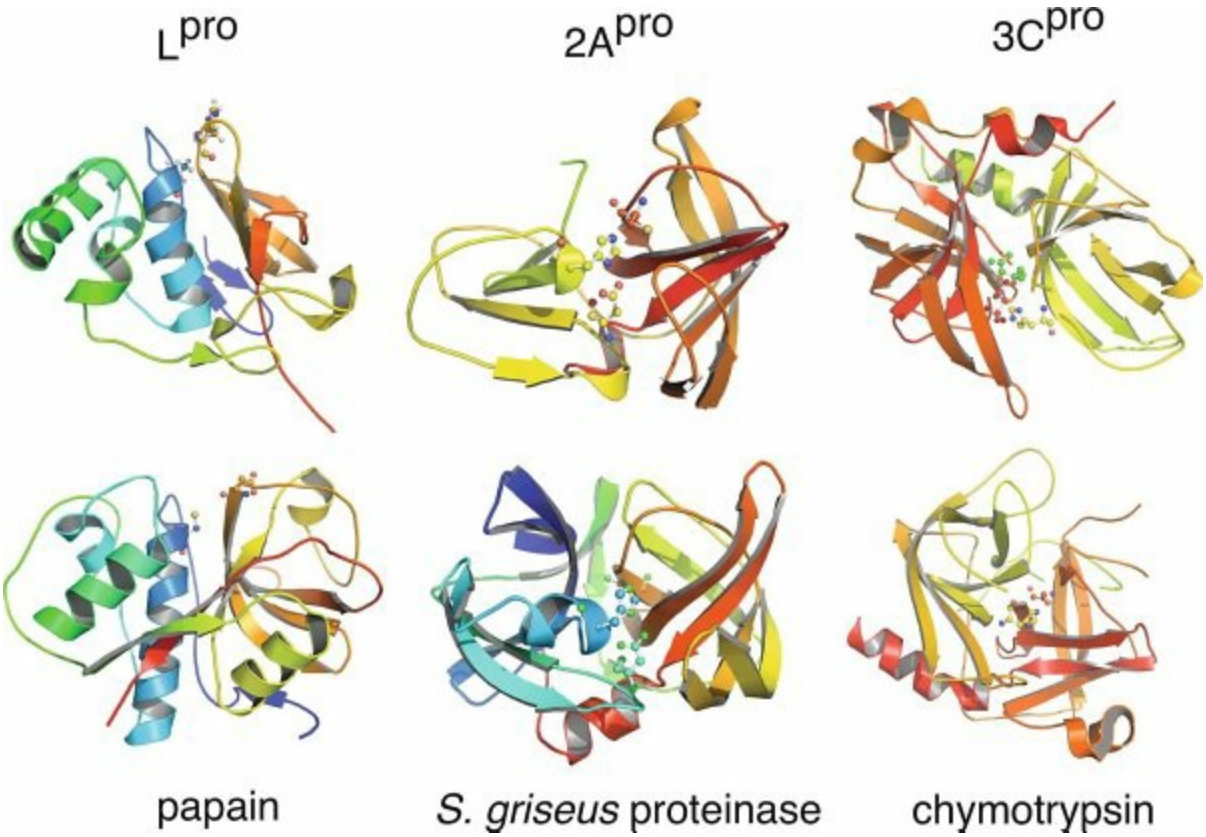

FIGURE 2.15 Three-dimensional structures of L^{pro} of foot-and-mouth disease virus, rhinovirus $2A^{pro}$, and hepatitis A virus $3C^{pro}$. Below each is the cellular proteinase that is structurally similar to each viral enzyme. Catalytic residues are drawn as *balls* and *sticks*. Images drawn with MacPymol using the following pdb files: [2SGA, 2HRV, 2JQG, 1PIP, 1HAV, 5CHA].

The cardiovirus and senecavirus L proteins, which do not have proteolytic activity, are released from the P1 precursor by $3C^{pro}$[523] (Fig. 2.14). They are small polypeptides with an N-terminal CHCC zinc-finger motif and interact with the cellular GTPase Ran, inhibiting many cellular processes dependent upon GTP/GDP cycling.[549,570] L protein is necessary for assembly of the virion and stimulates translation of the viral mRNA.[35,177] Although the proteins lack enzymatic activity, L proteins are potent antagonists of the innate immune response by inhibiting transcription of cytokine-encoding genes and iron/ferritin–mediated activation of the transcription protein NF-κB

as well as modulating nucleocytoplasmic trafficking.[570,708,715,783] The range of cell processes affected by L protein may allow for persistent infections by cardioviruses.

2A Protease

In cells infected with enteroviruses (and possibly sapeloviruses), the primary cleavage between P1 and P2 is mediated by $2A^{pro}$ (Fig. 2.14). Cellular proteins are also cleaved by $2A^{pro}$, including eIF4GI, eIF4GII, Pabp, heart muscle dystrophin, and nucleoporins.[34,112,245,246,264,265,337,359,387,527] In the protein precursor of rhinovirus, poliovirus, and some other enteroviruses, the cleavage site for $2A^{pro}$ is between tyrosine and glycine. Other sites cleaved by $2A^{pro}$ include threonine–glycine and phenylalanine–glycine in certain coxsackieviruses and echoviruses.

The relative resistance of poliovirus to IFN has been ascribed to $2A^{pro}$, as a single amino acid change from Y to L at amino acid 88 renders the virus sensitive to inhibition by this cytokine.[480] Additional support for the role of $2A^{pro}$ in countering IFN comes from experiments in which the proteinase-coding sequence was added to the genome of the IFN-sensitive EMCV. The production of $2A^{pro}$ during EMCV infection confers IFN resistance to the recombinant virus.[480]

Based on sequence alignments, it was suggested that the structure of $2A^{pro}$ would resemble that of small bacterial chymotrypsin-like proteinases (e.g., *Streptomyces griseus* proteinase A) and would possess a catalytic triad consisting of His-20, Asp-38, and an active site nucleophile of Cys-109 rather than serine.[59] The results of site-directed mutagenesis and the resolution of the atomic structure of rhinovirus and Coxsackievirus B4 $2A^{pro}$ confirm that these residues comprise the active site and that the fold of $2A^{pro}$ is very similar to that of *Streptomyces griseus* proteinase A[56,546,647,772] (Fig. 2.15). However, $2A^{pro}$ differs from all known chymotrypsin-like proteinases in that the N-terminal domain is not a β-barrel but rather a four-stranded antiparallel β-sheet. The larger C-terminal domain contains a six-stranded antiparallel β-barrel. The active site catalytic triad is located in a cleft between the two domains. Another unusual feature of $2A^{pro}$ is a tightly bound zinc ion located at the beginning of the C-terminal domain. Biochemical and structural studies

indicate that zinc is essential for the structure of the enzyme.[546,646,729]

The 2A/2B junction of aphthoviruses, avihepatoviruses, cardioviruses, erboviruses, senecaviruses, teschoviruses, Ljungan virus, and duck hepatitis virus is cleaved not by proteolysis but by an unusual mechanism called ribosomal skipping[167] (Fig. 2.14). Changes within the conserved amino acid sequence Asp-(Val/Ile)-Glu-X-Asn-Pro-Gly-Pro, which contains the cleavage site Gly-Pro, disrupt cleavage.[523] The cleavage reaction occurs within the ribosomal peptidyl transferase (P-) site. Despite the Pro-encoding codon at the end of the 2A-coding sequence being within the aminoacyl (A-) site, the translating ribosome pauses. This "stop," together with the conformational constraint of the added proline and the α-helix formed by upstream amino acids occluding the exit tunnel of the translating ribosome, impairs peptide bond formation between the Gly and Pro. These events lead the eukaryotic release factor 1 to enter the A-site, followed by release of the synthesized peptide chain. Mutation of the Pro codon inhibits ribosomal skipping, confirming that insertion of proline is essential for the stop and release of the synthesized polypeptide, not the codon sequence.[171,371,372] Consequently, the first amino acid of 2B is always a proline. Impairment of ribosomal skipping negatively impacts cleavage at the L-P1-2A boundaries by $3C^{pro}$.[271] The ability of the 2A sequence to yield two proteins from a single open reading frame, without proteinase activity, has led to its use in many research and biomedical applications.[609]

Because only enteroviruses and possibly sapeloviruses have proteolytically active $2A^{pro}$, in cells infected with other picornaviruses, the VP1-2A cleavage is either carried out by $3C^{pro}$[333,523,623,624] or in Ljungan virus–infected cells by a NPG/P sequence following the VP1 protein[338] (Fig. 2.14).

The polyprotein of Aichi virus, a member of the *Kobuvirus* genus, is unusual because the L and 2A proteins are not proteinases and there is no NPG/P motif at the 2A/2B junction. The only active proteinase encoded in the genome of this virus is $3C^{pro}$ and $3CD^{pro}$, which can process all cleavage sites in the polyprotein, including the VP1/2A site[618] (Fig. 2.14). Efficient cleavage of the VP1/2A site requires tight binding of $3CD^{pro}$ to the 2A region of the substrate.

3C Protease

All picornaviruses encode $3C^{pro}$, which carries out a primary cleavage between 2C and 3A (Fig. 2.14). Unlike the other picornavirus proteinases, $3C^{pro}$ may also carry out secondary cleavages of the P1 and P2 precursors. Poliovirus $3C^{pro}$ cleaves only at the Gln-Gly dipeptide; however, $3C^{pro}$ of other picornaviruses has less strict cleavage specificities and cleaves at other sites, including Gln-Ser, Gln-Ile, Gln-Asn, Gln-Ala, Gln-Thr, and Gln-Val. Clearly, other determinants of cleavage exist because not all such dipeptides in picornavirus polyproteins are cleaved by $3C^{pro}$. Additional determinants include accessibility of the cleavage site to the enzyme, recognition of secondary and tertiary structures in the substrate by the enzyme, and amino acid sequences surrounding the cleavage site. For example, efficient cleavage of poliovirus Gln-Gly pairs requires an Ala at the P4 position (Gln is residue P1, numbering is toward the N-terminus).[82]

Sequence comparisons with cellular proteinases led to the prediction that $3C^{pro}$ folds similarly to the chymotrypsin-like serine proteinases, in particular *Staphylococcus aureus* proteinase.[59,240–242] The putative catalytic triad was believed to consist of His-40, Asp-71 (aphthoviruses and cardioviruses) or Glu-71 (enteroviruses and rhinoviruses), and Cys-147 as the nucleophilic residue, in contrast to serine in cellular serine proteinases. These predictions have been confirmed by site-directed mutagenesis and by resolution of the atomic structures of rhinovirus, hepatitis A virus, poliovirus, FMDV, and enterovirus 71 $3C^{pro}$.[116,255,275,356,449,483,546,732] The viral enzyme folds into two equivalent β-barrels like chymotrypsin (Fig. 2.15) but differs in some of the connecting loops, in the orientation of the catalytic residues, and in areas needed for transition-state stabilization. The acidic member of the catalytic triad, Glu or Asp, points away from the active site His and, therefore, is not believed to assist in catalysis. However, $3C^{pro}$ also binds viral RNA (see discussion of genome replication and mRNA synthesis), and this binding site is distal from the active site of the enzyme. Despite the distance between the enzymatic active site and the RNA-binding motif, protease activity of $3C^{pro}$ is regulated by RNA binding, and the ability to bind RNA is modulated by protease activity.[113] The presence of this RNA-binding site imposes evolutionary constraints on $3C^{pro}$ that are not found in other proteinases.

Both $3C^{pro}$ and $2A^{pro}$ are active in the nascent polypeptide and release themselves from the polyprotein by self-cleavage. After the proteinases have been released, they cleave the polyprotein in *trans*. The cascade of processing events varies for different picornaviruses (Fig. 2.14). In cells infected with rhinovirus and enteroviruses, the initial event in the processing cascade is the release of the P1 precursor from the nascent P2–P3 protein by $2A^{pro}$. The activity of $2A^{pro}$ does not depend on whether it is cleaved from the precursor,[275] but further processing of P1 by $3CD^{pro}$ does not occur unless $2A^{pro}$ is released from P1.[502,771] Next, $3CD^{pro}$ is released from the P3 precursor by autocatalytic cleavage. This proteinase, which contains the entire sequence of the viral RNA polymerase, carries out secondary cleavage of glutamine–glycine dipeptides in poliovirus P1 far more efficiently than $3C^{pro}$.[342,770] Both $3C^{pro}$ and $3CD^{pro}$ process proteins of the P2 and P3 regions with similar efficiency. The $3D^{pol}$ sequence within $3CD^{pro}$ may be required to recognize structural motifs in properly folded P1, allowing efficient processing by the $3C^{pro}$ part of the enzyme. The presence of multiple activities in a single protein is not found among eukaryotic proteinases and is an example of how the coding capacity of small viral genomes can be maximized. Not all picornaviruses require $3CD^{pro}$ to process P1; aphthoviruses, cardioviruses, and hepatoviruses produce $3C^{pro}$ that can cleave P1 without additional viral protein sequence.

An advantage of the polyprotein strategy is that expression can be controlled by the rate and extent of proteolytic processing. Alternative use of cleavage sites can also produce proteins with different activities. For example, because $3CD^{pro}$ is required for processing of the poliovirus capsid protein precursor P1, the extent of capsid protein processing can be controlled by regulating the amount of $3CD^{pro}$ that is produced. Because $3CD^{pro}$ does not possess RNA polymerase activity, some of it must be cleaved to allow RNA replication. Cleavage of $3CD^{pro}$ releasing $3D^{pol}$ is regulated by cholesterol.[317]

A final processing step occurs during maturation, when VP0 is cleaved to form VP4 and VP2. This event is discussed later.

Viral RNA Synthesis

In the 1950s, it was believed that the genome of RNA viruses was replicated by the cellular DNA-dependent RNA polymerase, through an intermediate DNA strand. The replication of RNA viruses, therefore, was thought to occur entirely in the cell nucleus. In the early 1960s, studies of mengovirus showed that virus infection results in the induction of a cytoplasmic enzyme that can synthesize viral RNA in the presence of actinomycin D.[39] This observation suggested that viral genome replication occurred through a virus-specific RNA-dependent RNA polymerase because cellular RNA synthesis is DNA dependent; it occurs in the nucleus and is sensitive to actinomycin D. A similar cytoplasmic, actinomycin D–resistant genome replication system was discovered in poliovirus-infected cells.[39]

In poliovirus-infected cells, the positive-strand genome is amplified to about 50,000 copies per cell through a negative-strand intermediate. Three forms of viral RNA have been identified in the cell: ssRNA, replicative intermediate (RI), and replicative form (RF). ssRNA, the most abundant form, is exclusively positive-strand; free negative strands have never been detected in infected cells. RI is a full-length RNA from which six to eight nascent strands are attached. RI is largely of positive polarity with nascent negative strands, although the opposite configuration has been detected. RF is a double-stranded structure, consisting of one full-length copy of the positive and negative strands. Viral RNA synthesis is asymmetric; the synthesis of positive strands is 30 to 70 times greater than the synthesis of negative strands.[223,509]

Viral RNA–dependent RNA Polymerase, 3D^{pol}

The first evidence for a viral RNA–dependent RNA polymerase activity came from experiments in which lysates from cells infected with mengovirus or poliovirus were assayed for viral RNA polymerase activity by the incorporation of a radioactive nucleotide into viral RNA.[38] Initial experiments demonstrated that the viral RNA polymerase is associated with a cellular membrane fraction, subsequently shown to be comprised of smooth membranes, which was called the RNA replication complex.[227] A major component of the replication complex was a viral protein that migrated at 63 kD on polyacrylamide gels (therefore, called p63), which was suggested to be the viral RNA–dependent RNA polymerase. Other viral and host proteins,

including 2BC, 2C, 3AB, and $3C^{pro}$, however, were detected in the RNA replication complexes.

A limitation of this early work was that replication complexes only copied viral RNA already present in the complex and did not respond to added RNA. Attempts were made, therefore, to purify a template-dependent enzyme from membrane fractions of infected cells, using a poly(A) template and an oligo(U) primer. A poly(U) polymerase activity was purified from poliovirus-infected cells, which could also copy poliovirus RNA in the presence of an oligo(U) primer. Highly purified preparations contained only p63, the major viral protein found in membranous replication complexes.[195,707] This protein is the poliovirus RNA polymerase, now known as $3D^{pol}$. In the absence of an oligo(U) primer, $3D^{pol}$ cannot copy poliovirus RNA. Recombinant $3D^{pol}$ purified from bacteria or insect cells also requires the presence of an oligo(U) primer to copy poliovirus RNA.[498,568] $3D^{pol}$, therefore, is a template- and primer-dependent enzyme that can copy poliovirus RNA. Its molecular weight predicted from the amino acid sequence is 53 kD.

The structures of all four types of polymerases, DNA-dependent DNA polymerase, DNA-dependent RNA polymerase, RNA-dependent DNA polymerase (reverse transcriptase), and RNA-dependent RNA polymerase, are characterized by analogy with a right hand, consisting of a palm, fingers, and thumb. The palm domain contains the active site of the enzyme. The picornavirus RNA polymerase $3D^{pol}$ is produced by cleavage of a precursor protein, $3CD^{pro}$, which is highly active as a proteinase, and binds *cre* (see below). The precursor $3CD^{pro}$ has no polymerase activity, nor does it take on the hand-like structure of a polymerase.[283] The hand-like structure of a viral RNA–dependent RNA polymerase was first observed when that of poliovirus $3D^{pol}$ was determined at 2.6 Å resolution by x-ray crystallography.[277] Additional structures of $3D^{pol}$ from poliovirus, three rhinovirus serotypes, FMDV, EMCV, and Coxsackievirus B3, provide resolution of virtually all amino acids in the protein, offering a complete picture of this monomeric enzyme.[22,105,191,234,424,683] While the picornavirus polymerase has the same overall shape as other polymerases, the fingers and thumb differ (Fig. 2.16). The palm domain contains four conserved amino acid motifs (B, C, D, E) that are found in other RNA-dependent polymerases. Amino acids 1 to 68 of the

index finger rise from the palm domain before forming a loop that contacts the thumb domain by reaching across the palm. This loop traps the ring finger underneath it, leading it to form the top of the channel through which nucleotide triphosphates enter. The channel includes conserved motif F that is important for interacting with the triphosphates. This interaction also forms a large pore between the thumb and pinky through which the template–product RNA duplex exits, with the thumb domain stuck in the RNA major groove. The template and product are of reverse complementarity and anneal together such that no strand separation can be physically observed. Yet, mutations in the thumb domain can alter the length of the poly(A) tail, implying that slippage between the stands in the absence of detectable strand separation occurs in order to generate a tail of varied length, which is not fully templated.[357] *In vitro* RNA transcription by picornavirus polymerases occurs via a duplex template suggesting that $3D^{pol}$ must have an inherent strand separation function.[122] Together with data from structures of the elongating polymerase–RNA complex, the footprint of $3D^{pol}$ bound to the RNA duplex has been determined to include eight nucleotides of the elongating RNA and three base pairs downstream on the template.[233]

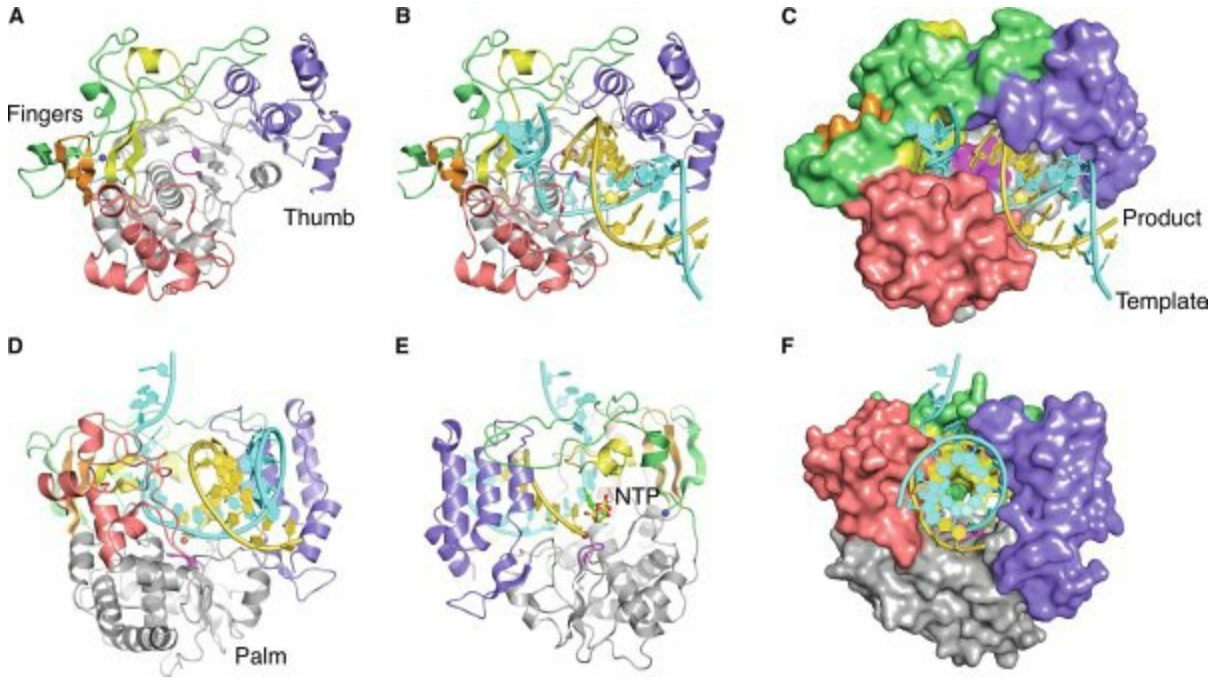

FIGURE 2.16 Three-dimensional structure of poliovirus $3D^{pol}$.

Structure of poliovirus $3D^{pol}$ polymerase and its elongation complex with primer-template RNA. The polymerase structure can be described by analogy to a cupped right hand, consisting of palm (*gray*) and thumb (*blue*) domains and finger domains with four discrete structural elements known as the index (*green*), middle (*orange*), ring (*yellow*), and pinky (*red*) fingers. The structure of the elongation complex shows the path of the RNA as the template strand (*cyan*) enters the polymerase from the top and of the template–product (*gold*) duplex as it exits the polymerase between the pinky finger and thumb structures.[300] **A–C:**Views from the top of the polymerase looking down into the active site (*magenta*) of $3D^{pol}$ in the absence of RNA **(A)**, the $3D^{pol}$ elongation complex with bound RNA **(B)**, and the elongation complex with a surface representation of the polymerase to show how the product RNA duplex is clamped in place between the pinky finger and thumb structures **(C)**. **D:** Front view of the elongation complex showing the path template and product RNA strands. **E:** Back view of the elongation complex showing the NTP entry channel with the priming 3′ OH (*red sphere*) positioned above the active site and a bound di-deoxy-CTP (*green ball-and-stick* with phosphate groups in *red* and *yellow*). **F:** Surface representation of the elongation complex looking down the axis of the exiting RNA duplex. $3D^{pol}$ from poliovirus and closely related picornaviruses is activated upon cleavage from the viral polyprotein, resulting in a newly created N-terminus that becomes buried in a pocket at the base of the finger domain that is ≈15 Å away from the active site itself (*blue sphere* in **A** and **E**). (Courtesy of Olve Peersen, Colorado State University.)

It was suggested that processing of 3CD affected the location of the N-terminal glycine of $3D^{pol}$, which is buried in a pocket at the base of the

fingers domain, in order to position Asp238 slightly away from the active site of the polymerase. On proteolysis, the N-terminal Gly was believed to push Asp-238 a distance of 1.4 Å into the catalytic site. This slight shift in position would allow for hydrogen bonding between the Asp and both the 2′- and 3′-ribose hydroxyl groups of the incoming NTP, a reaction critical for discriminating between rNTPs and dNTPs[230,234,308] and active site closure. Furthermore, it correctly coordinates Asp233 and two magnesium ions, which are necessary for polymerization.[234] Resolution of the structure of the Coxsackievirus B3 $3D^{pol}$ reveals an unusual conformation for residue 5, which is located at a distortion within a β-strand near the exit of the RNA channel and is conserved in all known $3D^{pol}$ structures.[105] Substitution of more hydrophobic residues, such as tryptophan at this position, results in higher enzymatic activity. Alterations at this position primarily change the temporal stability of the postinitiation elongation complex but may also affect the processivity of the enzyme and virus replication.[300]

The catalytic cycle is composed of six structural states beginning with paused polymerase bound to the template stacked upon the RNA duplex and poised for the incoming NTP and an unstructured active site. Nucleotides enter the catalytic site via a large opening on the backside of $3D^{pol}$. Upon selection, the nucleotide is positioned by the lysine and arginine residues that line the entrance. Base pairing between the template base and the incoming nucleotide triggers movement of the palm, facilitating rearrangement between the motif A-motif C- and the 2′OH of the triphosphate such that when the active site is closed, the triphosphate is correctly placed with the required magnesium ions coordinated to promote bond formation. Addition of the new base to the growing strand opens the active site, independent of movement of the fingers domain. Translocation of the RNA duplex one nucleotide occurs by “Brownian motion” and places the next templating base within the active site. The lack of movement in the fingers domain during polymerization is another unique feature of $3D^{pol}$.

What sets apart the picornavirus RNA polymerase from all others is that the templating nucleotide is prepositioned right above the active site stacked with the first base pair of the elongating strand and is ready for catalysis even in the absence of a bound nucleotide.[234] Consequently, there is negligible RNA movement during phosphodiester bond formation. Moreover, there are little to no changes when compared with the protein structure in the absence

of RNA. The simplicity of this nucleotide selection mechanism greatly influences polymerase fidelity.

The first poliovirus $3D^{pol}$ structure also revealed that the polymerase molecules interacted in a head-to-tail manner and formed fibers; subsequently, the protein was shown to form a lattice.[429] The implication was that RNA would be replicated as it moved along the lattice, rather than the polymerase moving on the template. The head-to-tail fibers were formed by interface I, which involves more than 23 amino acid side chains between the thumb of one polymerase and the back of the palm of another. Amino acid changes in the back of the thumb that disrupt this interface impaired replication.[161,301] Repetition of this interaction in a head-to-tail fashion results in long fibers of polymerase molecules 50 Å in diameter. A similar interface was observed in crystals of $3D^{pol}$ of rhinovirus 14 but not rhinoviruses 16 or 1b.[424] Interface II is formed by N-terminal polypeptide segments, which may lead to a network of polymerase fibers in combination with interactions at interface I. These N-terminal polypeptide segments may originate from different polymerase molecules.

The N-terminus of $3D^{pol}$ is required for enzyme activity, which would support the idea that interface II interactions are of functional consequence. Furthermore, intermolecular cross-linking has been observed between cysteines engineered at Ala-29 and Ile-441 of poliovirus $3D^{pol}$,[301] and disruption of these interactions leads to lethality.[680] Polymerase-containing oligomeric structures resembling those seen with purified $3D^{pol}$ were observed on the surface of vesicles isolated from poliovirus-infected cells.[429] Because picornavirus RNA synthesis occurs on membranous vesicles, the concept of a flat, catalytic lattice is mechanistically attractive.

Viral Accessory Proteins

The poliovirus capsid proteins are not required for viral RNA synthesis; the region of the viral genome that encodes these proteins can be deleted without affecting the ability of viral RNA to replicate in cells.[350] The capsid-coding regions of rhinovirus, Theiler virus, and mengovirus, however, contain a cis-acting RNA sequence required for genome replication.[421,453,454] A cis-acting RNA sequence required for RNA replication has also been identified in the poliovirus protein 2C–coding region.[236] Genetic and biochemical studies

implicate most proteins of the P2 and P3 regions of the genome in RNA synthesis.

2A Protein

As discussed above, $2A^{pro}$ protein is necessary for proteolytic cleavage of the polyprotein. The protein also appears to have a role in RNA replication. A deletion within the $2A^{pro}$-coding sequence severely inhibits replication of subgenomic replicons, which lack the capsid region and are not dependent on proteolytic activity of $2A^{pro}$ to release the P1 region.[131] In another approach, a second IRES element was placed in the poliovirus genome before the $2A^{pro}$-coding region, effectively alleviating the need for the processing activity of the enzyme. Such viruses are viable.[474] Deletion of part of the coding region for $2A^{pro}$ is lethal, however. By using a cell-free replication system, it was possible to determine the effect of $2A^{pro}$ on each step of the replication cycle.[343] The results show that $2A^{pro}$ stimulates the initiation of negative-strand synthesis, but has no effect on positive-strand synthesis. How $2A^{pro}$ achieves this affect is not known, but it has been suggested that the proteinase might modify a cellular protein required for negative-strand RNA synthesis.[343]

2B Protein

The 2B protein is a small, membrane-associated protein that is involved at an early step of viral RNA synthesis. Protein 2B has been called a viroporin, a protein that oligomerizes and inserts into membranes to create channels.[2,235] Alterations of the 2B protein of poliovirus and coxsackievirus lead to viruses with defects in RNA synthesis.[340,710] Adaptation of rhinoviruses to mouse cells is mediated in part by amino acid changes in 2B, which allow viral RNA synthesis in this host cell.[282] The structure and mechanisms by which 2B is membrane-associated varies among picornaviruses. Enterovirus 2B proteins, which are 97 to 99 amino acids long, are predicted to possess two small hydrophobic domains, the first is a cationic amphiphilic α-helix, while the second is a fully hydrophobic helix,[530,713] while that of hepatitis A virus is 274 amino acids. Membrane pores induced by 2B proteins of enteroviruses are thought to result from protein oligomerization and assembly of tetrameric bundles that insert into the membrane. While the 2B protein of hepatitis A

virus associates with membranes and induces the formation of tube-shaped vesicles, it does not oligomerize nor does it form a transmembrane pore. The structure of the soluble region of hepatitis A virus 2B protein including the C-terminus as determined by x-ray crystallography reiterated these differences. This region of the hepatitis A virus 2B protein is a curved five-stranded antiparallel β-sheet of striking similarity to the β-barrel domain of $2A^{pro}$ followed by a helical bundle.[727] The crystal structure also unveiled that 2B self-associates into a fiber- and amyloid-like structure that can act as platform for the recruitment of cellular and viral proteins necessary for replication.

The role of protein 2B in RNA synthesis, however, is not known. Synthesis of the protein leads to an inhibition of protein secretion from the Golgi apparatus[45,165] and permeabilization of membranes,[2,6,616,711,712] which may play a role in release of virus from cells. Protein 2B is also partly responsible for the proliferation of membranous vesicles in infected cells, which are the sites of viral RNA replication. Because protein 3A has the same effect, it is not clear whether altered membrane proliferation is responsible for the RNA-defective phenotype in 2B mutants.

2C Protein

Protein 2C is a highly conserved protein with membrane-, RNA-, and NTP-binding regions.[178,597,598,711,712] The structure of 2C suggests that it contains three domains, with amphipathic α-helices at both the N- and C-termini that mediate peripheral association with membranes[386,681] and a central region with NTP-binding domains. Mutations responsible for resistance of poliovirus and echovirus to guanidine hydrochloride, which blocks viral RNA replication, are located in the 2C protein.[373,560,561] This compound has been shown to inhibit specifically the initiation of negative-stranded RNA synthesis and has no effect on initiation of positive-strand RNA synthesis or on elongation on either strand.[50] The nucleoside triphosphatase (NTPase) activity of protein 2C is inhibited by guanidine.[554] Protein 2C shares amino acid homology with known RNA helicases, proteins encoded by most positive-strand RNA viruses with large genomes. These enzymes are believed to be necessary to unwind double-stranded RNA structures that form during RNA replication. Purified protein 2C, however, does not have RNA helicase activity.[597] Alteration of conserved amino acids within the NTPase

domain of 2C results in loss of viral infectivity; the protein may therefore have two functions during viral RNA synthesis: as an NTPase and directing replication complexes to cell membranes. Synthesis of 2C causes disassembly of the Golgi apparatus and endoplasmic reticulum, and formation of vesicular structures similar, but not identical to, those that constitute the replication complex.[7,123]

2BC Protein

Much of protein 2BC, the precursor to 2B and 2C, remains uncleaved during infection, and its presence is critical to viral replication.[123] Synthesis of 2BC causes membrane permeabilization to a greater degree than 2B synthesis alone[6] and leads to the formation of vesicles that are more similar to those formed during viral infection than does protein 2C.[7,123] The C-terminus of 2B and the N-terminus of 2C may interact intramolecularly in 2BC, and protein cleavage may cause a conformational change that alters the properties of 2B and 2C individually.[45,713] Larger 2BC-containing precursors are also required for certain steps of replication,[344] although an intact 2C–3A junction is not strictly required.[533]

3AB, 3A, and 3B Proteins

A strongly hydrophobic region in the C-terminus of 3A mediates the association of 3A and its precursor, 3AB, with membranes,[164,663,691] thereby orienting the protein such that the majority of it is on the cytosolic side of the vesicle.[124] Amino acid changes in the hydrophobic region of 3A yield replication-defective viruses.[221,390] Changes in viral host range have been mapped to 3A protein.[61,282,390,511] The efficiency of cleavage 3ABCD into 3ABC, 3AB, 3CD, 3A, 3B, 3C, and $3D^{pol}$ varies among picornaviruses. This series of cleavages occurs more efficiently during poliovirus infection than during Aichi or hepatitis A virus.[284,492,624] The solution structure of 3A demonstrates that it is a homodimer, with the dimer interface located in the central region of the protein.[663] The requirement for 3A dimerization during infection has not been explored. Protein 3B, also known as VPg, plays an indispensable role in viral replication by acting as a protein primer for viral RNA synthesis (see below). Protein 3AB is believed to anchor VPg in membranes for the priming step of RNA synthesis. The purified protein

greatly stimulates $3D^{pol}$ activity *in vitro*[532,567,591] as well as the proteolytic activity of $3CD^{pro}$.[473] 3AB interacts with $3D^{pol}$ and $3CD^{pro}$ in infected cells and with $3D^{pol}$ in the yeast two-hybrid system.[306] Amino acid changes in $3D^{pol}$ that disrupt its interaction with 3AB result in viruses with defects in protein processing and viral RNA synthesis.[221,222] A complex of 3AB and $3CD^{pro}$ also binds the cloverleaf at the 5′ end of the genome forming a RNA–protein complex that interacts with the poly(A) tail via interaction with Pabp.[284,757] Aichi virus replication, particularly negative-strand synthesis, may be dependent upon formation of a closed loop.[492] A complex of 3AB and $3CD^{pro}$ also binds 3′-terminal sequences of poliovirus RNA.

Cellular Accessory Proteins

Early studies of poliovirus replication using purified components suggested that a host cell protein is required for copying the viral RNA by $3D^{pol}$ in the absence of an oligo(U) primer.[153] Although this protein was never identified, the concept of a host factor required for poliovirus replication endured, largely because an ample precedent was seen for the participation of host cell components in a viral RNA polymerase. The best-studied example is the RNA polymerase of the bacteriophage Q*β*, which is a multisubunit enzyme consisting of a 65-kD virus-encoded protein and three host proteins: ribosomal protein S1 and translation factors EF-Tu and EF-Ts.[278] The 65-kD viral protein has no RNA polymerase activity in the absence of the host proteins but has sequence similarity with known RNA-dependent RNA polymerases. A subunit of the translation initiation protein eIF3 is part of the polymerase from brome mosaic virus.[578] Two different experimental systems have been used to provide additional evidence that poliovirus RNA synthesis requires host cell components.

When purified poliovirus RNA is incubated *in vitro* with a cytoplasmic extract prepared from cultured, permissive cells, the viral RNA is translated, the resulting protein is proteolytically processed, and the genome is replicated and assembled into new infectious virus particles.[475] If guanidine, an inhibitor of poliovirus RNA synthesis, is included in the reaction, complexes are formed, but elongation cannot occur.[48] The preinitiation complexes can be isolated free of guanidine, and, when added to new cytoplasmic extracts, RNA synthesis occurs. In the absence of cytoplasmic extract, preinitiation

complexes do not synthesize viral RNA.[47] These results indicate that one or more soluble cellular components are required for the initiation of viral RNA replication. A similar conclusion comes from studies in which poliovirus RNA is injected into oocytes derived from the African clawed toad, *Xenopus laevis*. Poliovirus RNA cannot replicate in *Xenopus* oocytes unless it is coinjected with a cytoplasmic extract from human cells.[210]

Cellular poly r(C)–binding proteins are required for poliovirus RNA synthesis. These proteins bind to a cloverleaf secondary structure, also called stem–loop I, that forms in the first 108 nucleotides of positive-strand RNA (Fig. 2.17). Binding of poly r(C)–binding protein to the cloverleaf is necessary for the efficient binding of viral protein $3CD^{pro}$ to the opposite side of the same cloverleaf.[17,19,211,529] Formation of a ribonucleoprotein complex composed of the 5′ cloverleaf, $3CD^{pro}$, and a cellular protein is essential for the initiation of viral RNA synthesis.[17] The human cell protein required for replication of poliovirus RNA in *Xenopus* oocytes has also been identified as poly r(C)–binding protein.[211] A model of how these interactions lead to viral RNA synthesis is shown in Figure 2.17. The ternary complex with stem–loop I may also function during positive-strand RNA synthesis.[728]

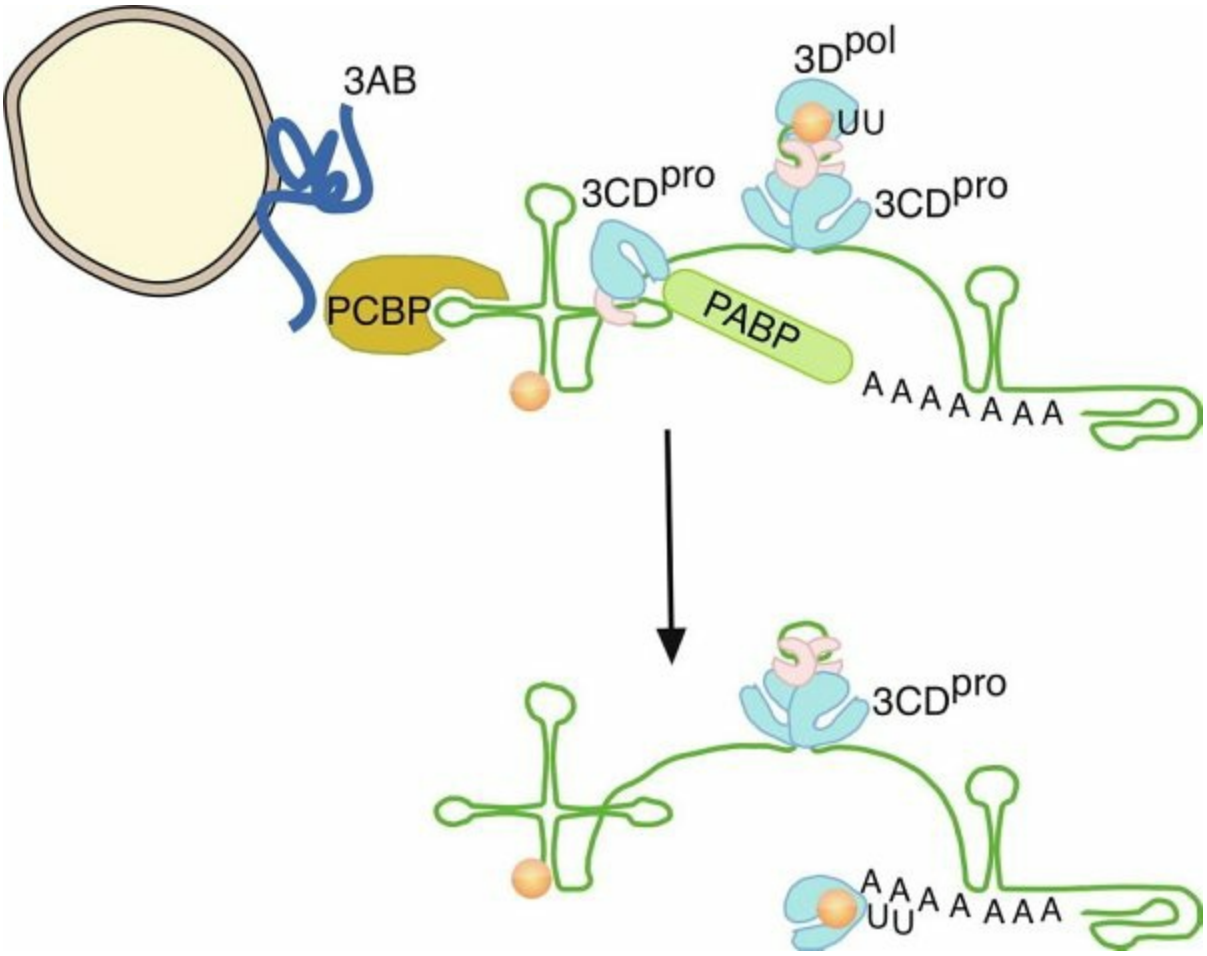

FIGURE 2.17 Model for the synthesis of poliovirus (–) strand RNA. The (+) strand template is shown in *green* with the 5′-cloverleaf structure, the internal *cre* sequence, and the 3′ pseudoknot. A ribonucleoprotein complex is formed when poly r(C)–binding protein (PCBP) and $3CD^{pro}$ bind the cloverleaf structure. The ribonucleoprotein complex interacts with Pabp1, which is bound to the 3′-poly(A) sequence, producing a circular template. Protease $3CD^{pro}$ cleaves membrane-bound 3AB to produce VPg and 3A. The cre sequence binds $3D^{pol}$, $3CD^{pro}$, and VPg. VPg-pUpU is synthesized by $3D^{pol}$ using the sequence AAACA of *cre* as template. The complex is transferred to the 3′ end of the genome, and $3D^{pol}$ uses VPg-pUpU to prime RNA synthesis.

Another candidate for a host protein that is essential for poliovirus RNA synthesis is poly(A)–binding protein 1. This protein interacts with poly r(C)–binding protein, $3CD^{pro}$, and the 3′-poly(A) tail of poliovirus RNA, circularizing the genome[50,291] (Fig. 2.17). The mechanism for negative-strand RNA synthesis is hypothesized to include formation of a circular ribonucleoprotein complex.

Even though infectious poliovirus and other picornaviruses can be produced from viruses that lack the 3′-noncoding region, replication is inefficient.[98,615,684,714] Binding of heterogeneous nuclear ribonucleoprotein C is necessary to bring both the 5′ and 3′ ends of the negative-strand RNA together forming a closed loop of RNA, necessary to stabilize interactions between the two ends to promote 3C/3CD binding to the replicative intermediate. The absence of the 3′-noncoding region abolishes the closed loop needed. Consequently, initiation of positive-strand synthesis is compromised.[184]

Protein-primed RNA Synthesis

As discussed, poliovirus $3D^{pol}$ is a primer-dependent enzyme that will not copy poliovirus RNA *in vitro* without an oligo(U) primer. The discovery of VPg linked to poliovirus genome RNA, as well as to the 5′ end of newly synthesized positive- and negative-strand RNA, suggested that VPg might be involved in the initiation of RNA synthesis. This hypothesis was supported by the finding that both VPg and a uridylylated form of the protein, VPg-pUpU, can be found in infected cells.[143] Furthermore, VPg-pUpU can be synthesized *in vitro* in a membrane fraction from poliovirus-infected cells.[675] Additional evidence that VPg can serve as a primer for poliovirus RNA synthesis comes from experiments in which synthetic VPg is first uridylylated *in vitro* and then added to an *in vitro* polymerase reaction containing a poly(A) template and $3D^{pol}$.[537] The labeled, uridylylated VPg is extended to form poly(U). This evidence shows that poliovirus RNA replication is primed by a genome-linked protein, a mechanism also involved in adenovirus DNA replication. A model for VPg priming of poliovirus RNA synthesis is shown in Figure 2.16.

The unprocessed P3 precursors 3BC and 3BCD, though minor products of P3 processing, can be uridylylated *in vitro* and bind the RNA stem–loop

where RNA replication is initiated with greater affinity than VPg. Moreover, the presence of 3BC facilitates recruitment and retention of $3D^{pol}$ for VPg and RNA.[531] Although no protein larger than VPg has been detected linked to nascent RNA strands during virus infection, the use of a subgenomic replicon with an uncleavable bond between 3B and 3C (Gly-Gly instead of Gln-Gly) demonstrated that processing of 3BC is not necessary for genome replication as 3BC could be linked to the nascent RNA strand. In fact, 3BC has a higher affinity for RNA than 3B.

The template for uridylylation of VPg is an RNA hairpin, the cis-acting replication element, *cre*, located in the coding region of many picornaviruses[535,593,767] (Fig. 2.17). The cre for FMDV replication is located within the 5′-noncoding region.[447] The *cre* functions independent of position in the genome, and its location differs among viruses. Within all *cre* elements is a conserved sequence, GXXXAAAXXXXXXA, of which only ^{5}AAA^{7} is essential for the reaction. VPg and two molecules of $3D^{pol}$ bind the RNA hairpin, placing ^{5}A within the palm domain of one molecule of polymerase. Uridylylation occurs within the active site of the second molecule of $3D^{pol}$.[669] The addition of two uracils to Tyr3 of VPg is templated by the ^{5}A, suggesting that uridylylation occurs via a “slide-back” mechanism.[538]

Results of genetic analysis suggested that the interaction of VPg with $3D^{pol}$ occurs on the surface of the enzyme near conserved motif E, on the back side of the palm near the base of the thumb, which is distant from the catalytic site, and are not consistent with structural data or the observation that alterations within the proposed 3AB binding site impair the reaction.[22,190,256,430,669] Instead, the crystal structures of the VPg-$3D^{pol}$ of FMDV, rhinovirus, enterovirus 71, and Coxsackievirus B3 suggest that the VPg contact sites on $3D^{pol}$ may vary among picornaviruses; VPg binds motif F and the thumb on FMDV $3D^{pol}$ placing VPg within the catalytic site and facilitating the *cis* mechanism of uridylylation, while VPg binds the end of the palm of Coxsackievirus B virus $3D^{pol}$, and the addition of UMP to tyrosine 3 occurs in *trans*.[22,190,256,680]

Cellular Site of RNA Synthesis

Remodeling of Cell Membranes

Picornaviral RNA synthesis, like that of most RNA viruses, occurs in the cytoplasm of the cell. Virus infection leads to the proliferation and rearrangement of intracellular membranes in infected cells, first described by electron microscopy studies done in the 1960s.[151] The single- and double-membraned vesicles, replication organelles (RO), are primarily derived from the ER, Golgi apparatus, and lysosomes, and *de novo* synthesized lipids eventually fill the cytoplasm.[307,484] Two distinct types of ROs have been identified, as vesicles with numerous separate invaginations at the boundary between the RO and host organelle with RNA synthesis taking place inside the folds or as a membrane protrusion from the cell organelle creating a tubular and/or vesicular structure and genome replication occurring on their surfaces. Both structures serve as platforms for viral replication by increasing the local concentration of proteins necessary for virus reproduction as well as hiding intermediates and preventing sensing by the innate immune response. Consequently, networks of single-membrane vesicles are the site of virus replication.

Rearrangement of the secretory pathway components ER, Golgi apparatus, and lysosomes begins early during picornavirus infection.[307] At 2 hours postinfection, dramatic alterations of cytoplasm can be seen, comprising an increased number of ribosomes along the ER and nuclear membrane and formation of single-membrane tubules with interior density.[78,180] Furthermore, trafficking of secretory cargo is also impaired. Electron tomography experiments revealed that poliovirus 3A–associated RO originates from the GM130-positive cis-Golgi apparatus as an intertwining network of clusters of single-membrane branched tubular structures in a porous sponge-like arrangement.[67,77,215,458,476,622] These observations support earlier data in which the RNA RF of the Coxsackievirus B3 genome in combination with the 3A and $3D^{pol}$ proteins and the Golgi-specific proteins Arf1, a small Ras-family GTPase, and GBF1, a guanine nucleotide exchange factor, were found to colocalize on the surface of the Golgi apparatus.[307] However, no component of the RO of cardioviruses colocalizes with Golgi-specific markers; instead, these structures are thought to be derived from the ER.[168] For those picornaviruses whose RO originates from the Golgi apparatus, the ER is a source of phosphatidylinositol-4-phosphate (PI4P)-rich

membranes.

Membrane contact sites are critical regulators of lipid homeostasis in both the infected and uninfected cell. They facilitate the nonvesicular exchange of lipids, cholesterol, and phosphatidylinositol-4-phosphate (PI4P) between organelles and are particularly crucial for movement of the molecules between the ER and Golgi apparatus. Proteins found within membrane contact sites include oxysterol-binding protein (OSBP) 1 and 2, a sterol-binding protein, which responds to levels of free intracellular cholesterol and PI4k*α*/*β*, phosphatidylinositol-4-kinase III*α*/*β*, which catalyzes production of PI4P in addition to regulating membrane fluidity. OSBP facilitates the trafficking of cholesterol from the ER to the Golgi and PI4P from the Golgi to ER,[461] ensuring a continuous flux of cholesterol toward the Golgi. During picornavirus infection, the membrane-bound 3A protein recruits both OSBP and PI4KIII*β* to the RO, creating contact points between the RO and either the Golgi (for enteroviruses and kobuviruses) or ER (for cardioviruses). Via activity of OSBP and PI4K, the lipid composition of the RO is unique, enriched for both PI4P and cholesterol.[493] 3A protein also interacts with ACBD3, acyl–coenzyme A–binding domain–containing 3 protein, aiding in the recruitment of PI4KIII*β* to the RO and to the surface of the Golgi apparatus. However, the need for ACBD3 to recruit PI4KIII*β* to the surface of the RO may be virus specific.[26,27,158,169,170,249,319,617,705] Furthermore, RO formation during hepatitis A virus and *Aphthovirus* infection is independent of PI4K and OSBP.[65,66,68,145,215,249,396,667] While modulation of the lipid composition of the RO may be necessary to ensure proper processing of the viral polypeptide,[24,25,199,459] the mechanisms by which the RO forms and how its lipid composition is achieved may reflect an evolutionary relationship among picornaviruses.

Although the ER is rearranged during picornavirus infection and vesicular trafficking proteins COPII and COPI, which mediate traffic between the ER and Golgi apparatus, associate with the replication structures of some picornaviruses such as echovirus and poliovirus and replication of these viruses is sensitive to BFA, a compound that inhibits GBF1 activity, the ER does not seem to be a source of membranes for enterovirus or kobuvirus RO generation as once thought.[120,215,307,613,693] The ER protein calnexin does not colocalize with 3A or other viral proteins needed for replication, COPII vesicle formation increases only early during infection, and the presence of

inactive Sar1, an ER-resident GTPase known to function during ER to Golgi trafficking, has little effect on Coxsackievirus B3 replication. Moreover, neither poliovirus nor Coxsackievirus B3 replication was rescued by the production of catalytically inactive GBF1 in the presence of BFA, and production of poliovirus 3A and 2C led to membrane arrangement indistinguishable from that observed during infection in the presence of BFA. Replication of a poliovirus variant with amino acid changes in 2C and 3A was not altered in the presence BFA despite the requirement for GBF1. Furthermore, Aichi virus replication is BFA insensitive and neither protein is necessary for cardiovirus replication. Moreover, reorganization of the membrane network and vesicle formation during virus infection does not rely on the vesicle budding machinery.[65,412] These data further support the notion that the requirement for proteins of the secretory and lipid-modulating pathways is virus specific. GBF1 and Arf1 instead may be needed for PI4KIIIβ and/or OSBP recruitment or functions of the RO during RNA synthesis.

Membranes for picornavirus ROs may also come from the ER–Golgi intermediate compartment (ERGIC). These membranes are enriched for PI4P, phosphatidylcholine, and phosphatidylinositol-4,5-bisphosphate (PIP2). Generation of RO from this membrane source is dependent upon 3CD instead of 3A. The results of numerous biochemical experiments describing replication of several picornaviruses, including poliovirus and coxsackievirus, indicate dependence upon GBF1. In this model, 3CD recruits GBF1 as well as Arf1 and GTP to the surface of the RO. The complex may in part be anchored by 3AB. Formation of a complex consisting of 3CD-GBF1-Arf1 promotes PI4Kβ recruitment, activation, and *de novo* synthesis of PI4P in the absence of Golgi destruction. The 3CD-anchored complex allows 3AB to inhibit GBF1 or PI4Kβ such that PI4P is removed from the Golgi membrane, and all PI4P biosynthesis would depend upon 3CD. Variants of poliovirus resistant to the PIK93, a compound that inhibits PI4P biosynthesis, were found to have amino acid changes within the 3AB protein. The increase in PIP2 concentration may aid in transiting the single-membrane RO to double-membraned and the autophagosome by recruiting ATG14, lipidated LC3, and proteins of the early autophagy pathway.[41]

Independent of the source of the membranes used to construct the RO, there is a continuous need for new membranes and lipids including

cholesterol and PI4P lipids.[249,307,317,617] Picornavirus infection stimulates *de novo* phospholipid synthesis, enhances uptake of long-chain fatty acids, and increases activity of acyl–CoA synthetase, elevating levels of intracellular free cholesterol and the rerouting of triglycerides to phosphatidylcholine synthesis.[261,317,494,723] Synthesis of 2BC protein stimulates clathrin-mediated endocytosis of cholesterol early during infection, while $2A^{pro}$, independent of its catalytic activity, is required for the import of long-chain fatty acids.[494] In addition, picornavirus infection triggers the relocalization of many enzymes, including those that participate in *de novo* lipid synthesis such as CCTα, from the nucleus to the RO, and the hydrolysis of neutral fatty acids.[723]

In enterovirus-infected cells, membrane contacts with lipid droplets are also essential for the formation of the RO.[398] The viral proteins 2C and 2BC on the surface of lipid droplets and the RO interact, tethering the two together. Furthermore, 2C interacts with the host lipolysis machinery to provide lipids needed for RO formation. Disruption of the membrane contacts or inhibition of lipolysis blocks RO biogenesis and interferes with viral replication.

Despite being morphologically distinct from the double-membraned vesicles, which fill the cytosol late during virus infection, the early single-membrane vesicles, sites of the exponential phase of RNA replication, are the precursors for these later vesicles.[67] The transition from single- to double-membraned vesicles may reflect the production of sites of encapsidation and particle maturation.

Vesicular maturation occurs via a bending mechanism, during which the single-membrane structures increase in size, become irregular in shape, and collapse inward facilitating membrane pairing and promoting fusion of the ends of the single-membrane structure engulfing some cytoplasm[412] (Fig. 2.18). The resulting double-membraned vesicles, autophagosomes, are decorated with lipidated LC3 protein, an autophagy protein sensor, late endosomal protein LAMP-1, and lysosomal cathepsin but lack the adaptor SQSTM1/p62. They have a deflated, crumpled exterior and an electron-dense interior.[137,324,392,472,493,637,678,679] Some virus-containing double-membraned vesicles will fuse with the lysosome prior to virus release. Fusion of the autophagosome with either the late endosome or lysosome is mediated by SNARE complexes composed of STX17, VAMP8, SNAP 29 on the surface

of the autophagosome, SNAP 47 that associates with the late endosome,[305] and the adaptor PLEKHM1.[321,335] By merging with the lysosome, the interior of the autophagosome is acidified. The influx of protons stimulates cleavage of VP0, a maturation step for many picornaviruses, releasing VP4 into the interior of the capsid as well as destruction of the outer membrane of the autophagosome. This step facilitates acquisition of and release of an enveloped virion.[80,592] Inhibition of autophagosome formation impairs RNA replication and virus release, but blocking acidification only impairs the cleavage of VP0 into VP2 and VP4.[592] During Coxsackievirus B3 and enterovirus D68 infection, $3C^{pro}$ cleaves proteins that mediate autophagosome maturation and flux including SNAP 29, SNAP 47, SQSTM1, and PLEKHM1.[137,472] Poliovirus infection also prevents induction of the mTOR–ULK1/ULK2 canonical autophagy pathway (reviewed in Ref.[534]). Inhibition of autophagosome maturation may favor picornavirus replication by augmenting the amount of cytoplasmic membranes for RO assembly and preventing RNA and/or protein degradation, as the intracellular virus concentration has been shown to significantly increase but extracellular virus titers decrease by a similar amount. How and when these membranes would be incorporated into the RO remains unknown as recycling of membranes is not observed during virus replication and infection up-regulates *de novo* phospholipid synthesis for this purpose.[261,317,494,723]

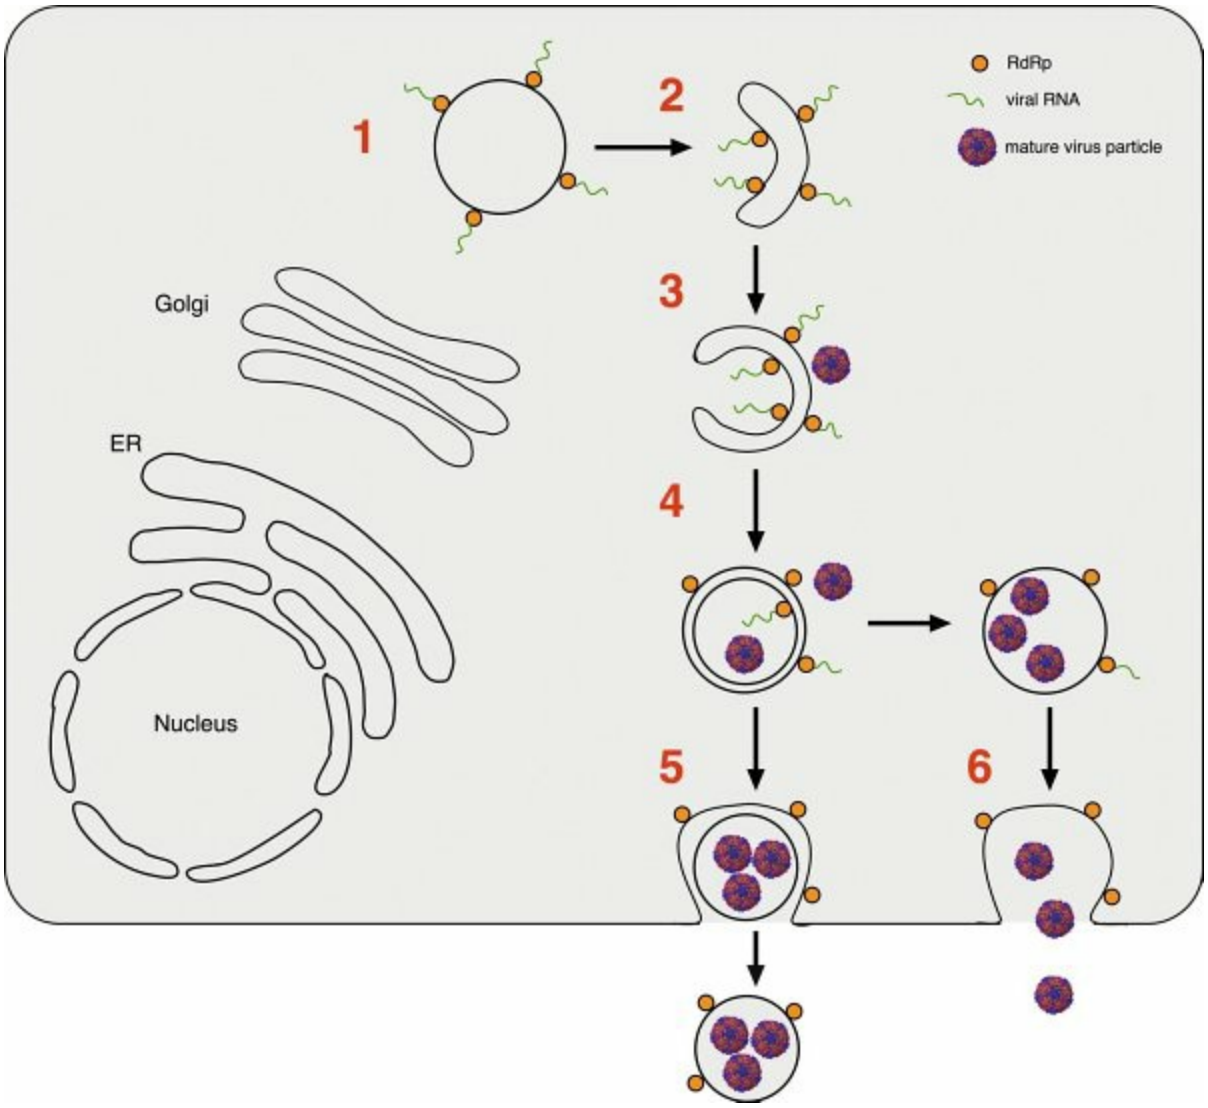

FIGURE 2.18 Schematic diagram of membrane rearrangement during picornavirus infection. *1*. Early during infection, virus-specific 3A protein is recruited to the surface of the cis-Golgi apparatus, bringing along $3D^{pol}$, $3CD^{pro}$, and the viral RNA. In addition, 3A stimulates relocalization of the Golgi proteins Arf1, GBF1, and PI4KIII*β*. *2*. As infection proceeds, an intertwined network of single-membrane tubular vesicles form, which are the predominant sites of virus replication. *3*. During the course of infection, the vesicles begin to collapse and invaginate inward, generating a double-membraned vesicle. *4*. As the ends fuse, cytosol is included within the lumen of the vesicle, giving it an

electron density. Genome replication and particle assembly occur on the inside and outside of the vesicle. *5*. Some vesicles will become preautophagosomal and recruit the lipidated form of LC3. The autophagosomal vesicles predominate. As these vesicles traffic toward the plasma membrane, they become acidified stimulating virion maturation. At the plasma membrane, the virus-filled autophagosomal vesicles fuse with the membrane, releasing virus into the extracellular environment in a nonlytic manner. *6*. Other vesicles remain single-membrane that, when filled with viral progeny, lyse and release the virion into the external environment.

Nonlytic release of hepatitis A virus occurs independent of autophagy. Similar to retrovirus release, which is dependent upon a stretch of 4 amino acids PPXY, P(S/T)AP, or (L)YPX$_{1/3}$L within the “L” domain of the Gag polypeptide to recruit the Endosomal Sorting Complexes Required for Transport (ESCRT) machinery via the adaptor ALIX, two “L”-like domains can be found within the hepatitis A virus VP2 protein.[187,313,587] These domains are on the surface of the particle and promote recruitment of ALIX, which in turn assembles the ESCRT complex. Together with ALIX–ESCRT, virus particles are trafficked to the plasma membrane and enveloped and bud into the extracellular environment.[187] The ROs of other enteroviruses such as poliovirus, Coxsackievirus B3, and rhinovirus have been found to be adjacent to sites of capsid synthesis. The colocalization of RNA synthesis with capsid formation suggests that RO may also be a platform for particle assembly, enabling for particles to be encapsidated in phosphatidylserine, a core component of RO membranes.[117]

Translation and Replication of the Same RNA Molecule

The genomic RNA of picornaviruses is not only mRNA but also the template for synthesis of negative-strand RNA. How does the viral polymerase, traveling in a 3′ to 5′ direction on the positive strand, avoid collisions with ribosomes translating in the opposite direction? It is thought that a

mechanism exists to avoid the two processes occurring simultaneously. *In vitro* experiments using inhibitors of protein synthesis demonstrate that, when ribosomes are frozen on the viral RNA, replication of the RNA is inhibited. In contrast, when ribosomes are released from the viral RNA, its replication is increased.[49] These results suggest that replication and translation cannot occur on the same template simultaneously.

A mechanism for regulating viral RNA translation and replication involves cleavage of poly r(C)–binding protein. This protein functions in IRES-dependent translation by binding stem–loop IV[83,211] (Fig. 2.12) and in viral RNA synthesis by binding stem–loop I[213,529] (Fig. 2.17). Poly r(C)–binding protein is cleaved by viral $3C^{pro}$; the cleaved protein can no longer stimulate IRES-dependent protein synthesis but is competent to participate in the initiation of viral RNA replication.[545] Another mechanism involves binding of 3CD to stem–loop I, which increases the affinity of poly r(C)–binding protein for stem–loop I and decreases it for stem–loop IV.[212] Cleavage of PTB by $3C^{pro}$ also leads to reduced viral translation.[33] The consequence of these modifications is that viral IRES-dependent translation is down-regulated and ribosomes are cleared from the viral mRNA, allowing unimpeded transit of RNA polymerase.

Experimental evidence indicates that some ribosome and RNA polymerase collisions do occur. This conclusion is based on the isolation of a poliovirus variant whose genome contains an insertion of a 15 nucleotide sequence from 28S ribosomal RNA (rRNA).[115] Apparently, the RNA polymerase collided with a ribosome, copied 15 nucleotides of rRNA, and then returned to the viral RNA template.

Discrimination of Viral and Cellular RNA

The RNA-dependent RNA polymerases of picornaviruses are template-specific enzymes. Poliovirus $3D^{pol}$ copies only viral RNA, not cellular mRNA, in infected cells. The purified enzyme, however, will copy any polyadenylated RNA if provided with an oligo(U) primer. This observation has led to the suggestion that template specificity probably resides in the interaction of replication proteins with sequence elements in the viral RNA. The cis-acting RNA elements located within the coding region of picornaviruses, which direct the uridylylation of VPg, are binding sites for

$3CD^{pro}$ (Fig. 2.17). The 3′-noncoding region of the viral positive-strand RNA contains an RNA pseudoknot conserved among picornaviruses that is believed to play a role in the specificity of copying by $3D^{pol}$.[328] Disruption of the pseudoknot by mutagenesis produces viruses that have impaired RNA synthesis, indicating the importance of the structure in the synthesis of negative-strand RNA. $3D^{pol}$ or $3CD^{pro}$ cannot bind to the 3′ end of poliovirus RNA unless 3AB is present. The interaction of 3AB–$3D^{pol}$ may determine the specificity of binding to the 3′ pseudoknot.

Despite experimental results that underscore the importance of the pseudoknot in RNA synthesis, polioviruses from which the entire 3′-noncoding region of the viral RNA has been removed are able to replicate.[97,685] This finding has led to the suggestion that template specificity imparted by terminal structures of RNA might be of greater importance early in infection. During the initiation phases of replication, the 3′ pseudoknot structure might facilitate template selection when few viral polymerase molecules are available and membrane association has not yet provided high concentrations of replication components. Later, determinants of template selection by the polymerase might include the membrane association of the RNA polymerase. Template specificity may also be conferred by the position of the $3D^{pol}$ gene at the very 3′ end of the viral RNA; translation places the polymerase at the 3′ end of the genome, ready for initiation.

A cloverleaf-like structure that forms in the 5′-noncoding region also plays an important role in template specificity (Fig. 2.17). The finding that a mutation in a cloverleaf structure in the 5′-noncoding region that affects RNA synthesis could be complemented by a suppressor mutation in $3C^{pro}$ led to the suggestion that $3C^{pro}$ might bind the cloverleaf and play a role in viral RNA replication.[19] It was subsequently found that $3CD^{pro}$ binds the cloverleaf structure in the positive strand, together with a cellular protein, now known to be poly r(C)–binding protein, that is required for complex formation.[17,18,529] The RNA-binding domain of $3CD^{pro}$ is contained within the $3C^{pro}$ portion of the protein, on the opposite face of the molecule from the site involved in proteolysis. Mutations within this domain abolish complex formation and RNA replication without affecting viral protein processing. $3CD^{pro}$, therefore, plays an important role in viral RNA synthesis by participating in formation of a ribonucleoprotein complex at the 5′ end of the positive-strand RNA. A

structural model of rhinovirus $3C^{pro}$ bound to stem–loop I shows that RNA binding induces changes in the proteinase active site, although their effect on catalytic activity is not known.[126] A role for these interactions in viral RNA replication is suggested in the model in Figure 2.17.

While the tertiary structures of the cre, IRES, and 3′-UTR of the picornavirus RNA are the best characterized and functionally understood, structural features can be found throughout the open reading frame. Several of these elements have been predicted bioinformatically.[755] Two of these elements are within the 3′ end of the coding sequence for $3D^{pol}$. Both elements are needed for efficient RNA replication as determined by recoding and reporter experiments.[102,649] Mutations of the RNA sequence within these elements are able to suppress alterations of $3C^{pro}$ suggesting that a functional interaction between the RNA and $3C^{pro}$ is necessary for efficient RNA replication.[102]

ORIGINS OF DIVERSITY

Misincorporation of Nucleotides

As with all other RNA-dependent RNA polymerases, those encoded in picornavirus genomes have very high error rates, because of misincorporation during chain elongation and the lack of proofreading ability in these enzymes. With error frequencies as high as one misincorporation per 10^3 to 10^4 nucleotides, RNA virus populations exist as quasispecies or mixtures of many different genome sequences.[166]

It has been suggested that RNA viruses exist on the threshold of error catastrophe, to maximize diversity and adaptability.[166] A moderate increase in error frequency would be expected to destroy the virus population. In one study, it was estimated that each poliovirus genome synthesized after multiple rounds of replication in an infected cell contains two point mutations.[144] In the presence of the antiviral drug ribavirin, each poliovirus genome contained 15 point mutations, and viral yields were 0.00001% of untreated cells. Similar observations have been made with FMDV[258] and Coxsackievirus B3.[244] These findings demonstrate that RNA viruses do exist

at the error threshold and that ribavirin is an RNA virus mutagen that inhibits virus replication by increasing the RNA polymerase error rate beyond the threshold.

High RNA virus error rates are believed to be necessary to enable persistence of the virus population under selective pressure. Consequently, viruses with less error-prone RNA polymerases should be at a competitive disadvantage in complex environments such as an infected animal. To test this hypothesis, a poliovirus mutant resistant to the antiviral effects of ribavirin was isolated.[553,722] Resistance to ribavirin was conferred by a single amino acid change, G64S, in $3D^{pol}$ that reduces errors during replication. The high-fidelity mutant virus replicated and spread poorly in mice and was unable to compete with a low-fidelity virus. The results indicate that mutations, and the formation of a diverse quasispecies, benefit viral populations, particularly in an infected animal. Analysis of a ribavirin-resistant mutant of FMDV reveals no restriction of the viral quasispecies.[23] This apparent paradox is explained by the observation that the RNA polymerase mutation increased the frequency of misincorporation of natural nucleotides while decreasing the frequency of the incorporation of ribavirin.

Recombination

Recombination, the exchange of nucleotide sequences among different RNA molecules, was first discovered in cells infected with poliovirus and was subsequently found to occur during infection with other positive-strand RNA viruses. It can occur by two different mechanisms: nonreplicative, the nonhomologous end joining of two different RNA molecules, or replicative, switching of templates. Nonreplicative recombination is highly inefficient and thought to minimally influence virus evolution.

Replicative recombination mainly occurs between nucleotide sequences of the two parental genome RNA strands that have a high percentage of nucleotide identity. This mechanism of RNA recombination is coupled with the process of genome RNA replication: it occurs by template switching during negative-strand synthesis, as first demonstrated in poliovirus-infected cells[368] and subsequently in cell-free extracts.[174,677] The RNA polymerase first copies the 3′ end of one parental positive strand, then switches templates, and continues synthesis at the corresponding position on a second parental

positive strand. Template switching in poliovirus-infected cells occurs predominantly during negative-strand synthesis because the concentration of positive-strand acceptors for template switching is 30 to 70 times higher than that of negative-strand acceptors. A prediction of the replicative mechanism is that recombination frequencies should be lower between different poliovirus serotypes, a prediction that has been verified experimentally. For example, recombination between poliovirus types 1 and 2 occurs about 100 times less frequently than among type 1 polioviruses (the poliovirus serotypes differ by about 15% in their nucleotide sequences).[366] This mechanism of genetic recombination is polymerase dependent and biphasic and drives virus evolution. It reflects the low fidelity of an RNA-dependent RNA polymerase as well as the absence of proofreading and repair enzymes.

Replicative recombination can be assessed experimentally in cell culture by infecting with viruses whose genomes contain with two different known lethal mutations[304,358,425] (Fig. 2.19). All progeny viruses will lack both mutations. The resolved x-ray crystal structure of elongating poliovirus $3D^{pol}$ identified amino acids within the thumb domain that directly interact with the RNA duplex. Alteration of these residues to alanine identified Leu 420 as critical for replicative recombination. The alanine substitution dramatically diminished genomic recombination by reducing the stability of $3D^{pol}$ elongation complexes without substantially affecting fidelity.[358]

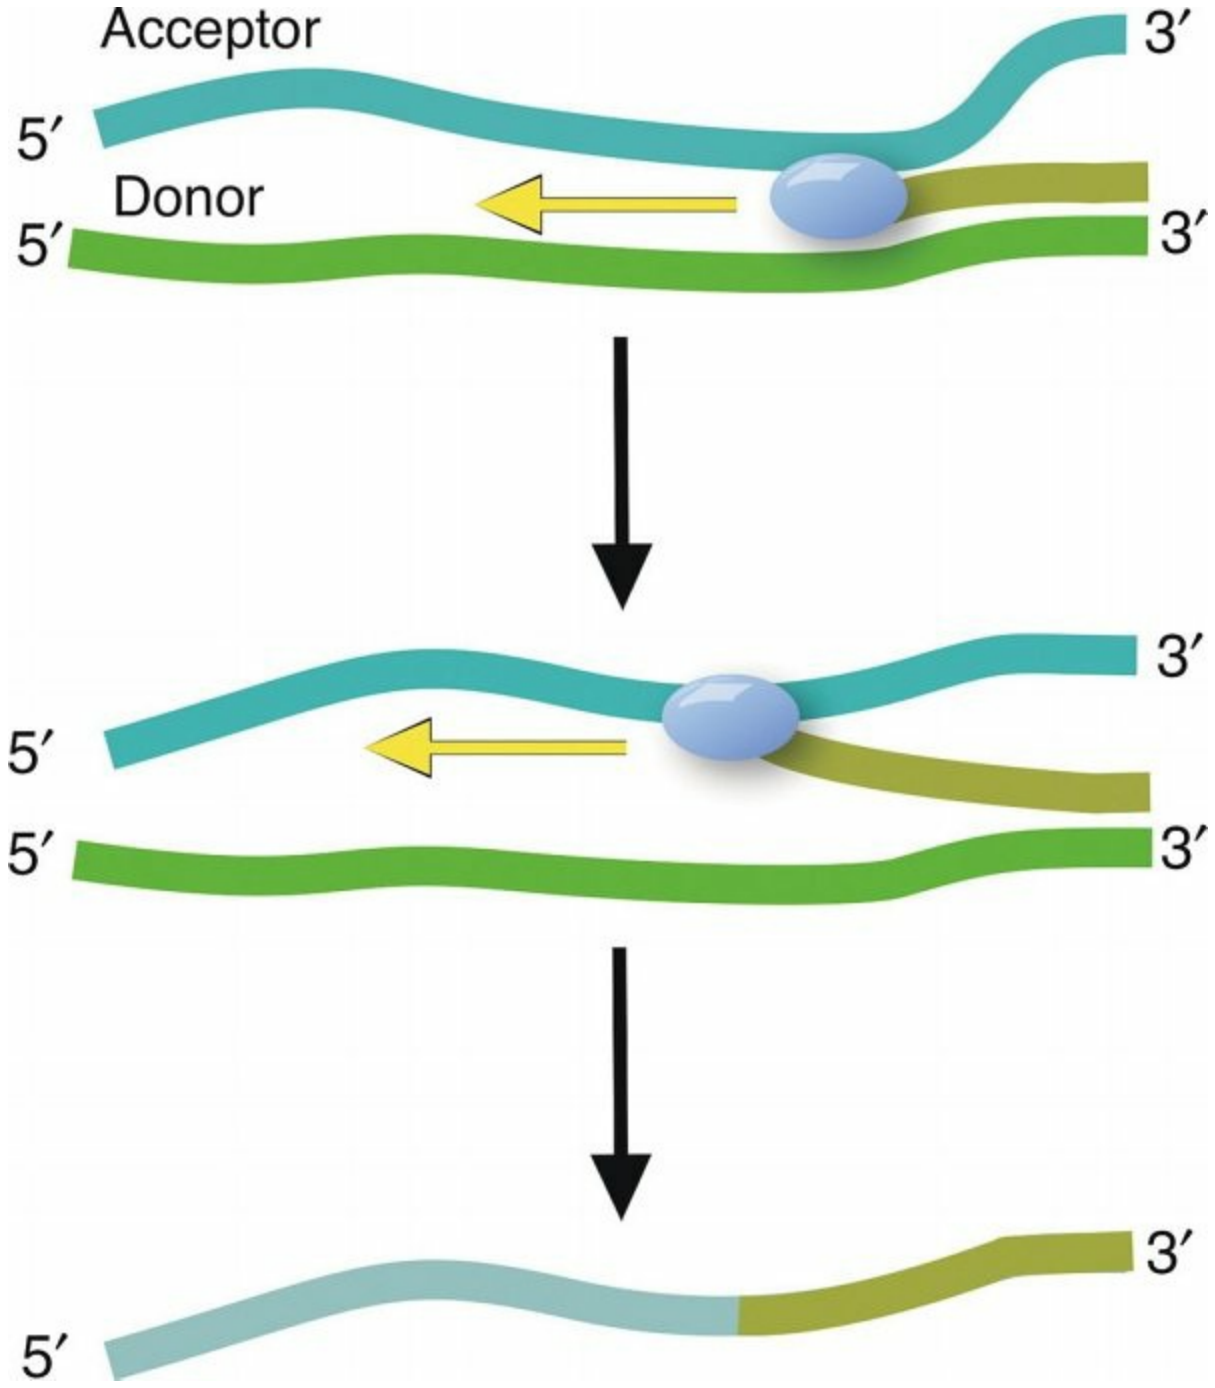

FIGURE 2.19 Schematic diagram of RNA recombination in picornavirus-infected cells by template switching or copy choice. Two parental genomes, the acceptor and donor, are shown. The RNA polymerase (*blue*) is shown copying the 3′ end of donor RNA and switching to the acceptor genome (*middle*). As a result of this template switch, the recombinant RNA shown is formed (*bottom*).

The frequency of replicative recombination, which is calculated by dividing the yield of recombinant virus by the sum of the yields of parental viruses, can be relatively high. In one study of poliovirus and FMDV, the genomic recombination frequency was 0.9%, leading to the estimation that 10% to 20% of the viral genomes recombine in one growth cycle. When poliovirus recombination is studied by quantitative polymerase chain reaction, obviating the necessity to select for viable viruses, the recombination frequency for marker loci 600 nucleotides apart is 2×10^{-3}, similar to estimates obtained using selectable markers.[331] RNA recombination also occurs in natural infections. For example, intertypic recombinants among the three serotypes of Sabin poliovirus vaccine strains are readily isolated from the intestines of vaccinees; some recombinants contain sequences from all three serotypes.[104] The significance of these recombinants is unknown, but it has been suggested that such viruses are selected for their improved ability to replicate in the human alimentary tract compared with the parental viruses. However, results from studies in which PVR transgenic mice were infected with a variant of poliovirus sensitive to the innate immune response demonstrated the efficiency by which replicative recombination influences virus evolution and ultimately pathogenesis.[760] Recombination in nature has also been demonstrated among nonpolio enteroviruses[639] (reviewed in Ref.[427]).

Codon Usage

Redundancy of the genetic code allows for most amino acids to be specified by multiple codons. Not all codons are used at the same frequency, and the regularity at which they are used is cell and virus specific. The under- or overrepresentation of a codon suggests that there is a bias for how an amino acid is encoded. Most vertebrate and plant RNA viruses have low CpG and UpA dinucleotide frequencies, as do the mRNAs of their host cells. For RNA viruses such as picornaviruses, this bias may influence not only translation rates but stability of critical structures that modulate RNA metabolism, replication, genome packaging, and particle stability.

When the frequency of CpG and UpA dinucleotides in the viral genome is increased by mutagenesis, viral replication is impaired. An example is echovirus 7: engineering of viruses with increased frequencies of CpG and UpA in an approximately 1-kb region of the genome reduced viral replication efficiency.[30] A similar effect is observed for human immunodeficiency virus

type 1; the replication deficiency is reversed by knockout of the cell gene encoding the zinc-finger antiviral protein, ZAP.[674] The implication is that ZAP identifies non–self RNA by its higher CpG composition, possibly targeting it for degradation. Whether ZAP is involved in restricting replication of echovirus 7 or other picornaviruses that have been modified to have higher CpG/UpA dinucleotides remains to be determined.

Alteration of codon pair frequencies of capsid-coding regions has been used to produce polioviruses with attenuated pathogenicity. Such attenuated viruses might be safe vaccine candidates as the hundreds of changes introduced into the viral genome are not likely to revert.[129] It has been suggested that alterations of codon pair frequency have the unintended consequence of increasing CpG and UpA frequencies, which would also attenuate viral replication.[700]

The generation of polioviruses with altered codon pair frequencies has made it possible to study how codon usage affects mutational robustness and evolutionary capacity.[399] A comparison of wild-type poliovirus with a variant harboring hundreds of synonymous mutations in the capsid-coding region revealed that changing the position of a virus in sequence space affects its mutant spectrum, evolutionary trajectory, and virulence. Similar experiments with other viruses have led to the principle that the sequence space occupied by a virus population is important for its ability to adapt to new environments.

ASSEMBLY OF VIRUS PARTICLES

Morphogenesis of picornaviruses has been studied extensively because the 60-subunit capsid is relatively simple, and the assembly intermediates can be readily detected in infected cells (Fig. 2.20). During the synthesis of the P1 protein, the capsid protein precursor, the central β-barrel domains form, and intramolecular interactions among the surfaces of these domains lead to formation of the structural units. Once P1 is released from the P2 protein, the VP0–VP3 and VP3–VP1 bonds are cleaved by proteinase $3CD^{pro}$. These cleavage sites are located in flexible regions between the β-barrels; considerable movement of the amino termini and carboxyl termini occurs after cleavage, but the contacts between β-barrels are not disturbed.[303] In the

mature capsid, the carboxyl termini of VP1, VP2, and VP3 are on the outer surface of the capsid, whereas the amino termini are on the interior, where they participate in an extensive network of interactions among protomers. This process produces the first assembly intermediate in the poliovirus pathway, the 5S protomer, the immature structural unit consisting of one copy each of VP0, VP3, and VP1.

FIGURE 2.20 Morphogenesis of picornaviruses. The capsid protein precursor, P1, folds nascently, is cleaved from P2, and then is further cleaved to VP0 + VP3 + VP1 by $3CD^{pro}$. Protomers (5S) self-assemble into 14S pentamers, and pentamers assemble into 80S empty capsids. Glutathione is necessary for assembly of 14S pentamers into 150S provirions. In one model of encapsidation, RNA is threaded into the empty capsid, producing a 150S provirion in which VP0 is uncleaved. Another possibility is that pentamers assemble around the RNA genome and that empty capsids are storage depots for pentamers. Cleavage of VP0 is the final morphogenetic step that produces the infectious 160S virion. The proteinase responsible for the cleavage of VP0 is unknown.

Five protomers then assemble to form a pentamer, which sediments at 14S. Based upon *in vitro* experiments, it was thought that the protomers self-assembled into pentamers and no cell proteins function during this process; however, the addition of L-buthionine sulfoximine, a compound that selectively inhibits glutathione synthesis, significantly decreases the production of infectious rhinovirus, poliovirus, coxsackievirus, and other enterovirus C viruses.[431,642,682] The observed replication impairment can be overcome with the addition of glutathione. The decrease in the formation of mature virus particles was found to be independent of protein synthesis and RNA replication, suggesting that glutathione may function during particle assembly. Glutathione, a small non–protein thiol reducing agent found within the cell, helps maintain the redox state of the cell by either functioning as a cofactor for reactions catalyzed by glutathione peroxidases and glutathione S-transferases or directly interacting with cysteine residues.[457,569] Maintenance of the proper oxidative state of the protomers is necessary for their structure, conformation, and ability to self-assemble into pentamers. Viruses that are resistant to the depletion of glutathione or the presence of L-buthionine sulfoximine were found to have amino acid substitutions in both VP1 and VP3, along surfaces at the protomer interface. These variants are also resistant to heat inactivation, suggesting that glutathione may function to

stabilize protomer–protomer and/or pentamer–pentamer interactions necessary for assembly of the 14S pentamer and production of infectious virus.[431,682]

Cleavage of P1 is required for assembly of the pentamer.[521] This conclusion is supported by examination of the virion structure. The *β*-cylinder at the fivefold axis of symmetry is formed from the N-termini of neighboring VP3 molecules; the cylinder is surrounded by a bundle composed of the amino termini of VP0 and VP1. The cell chaperone proteins Hsp 70, Hsp 90, and p23 are required for both precursor processing and protomer and pentamer assembly of many picornaviruses including cardioviruses, enteroviruses, and FMDV; however, no chaperone protein is thought to be required for cleavage of the P1 region of the hepatitis A virus polyprotein. Hsp 90 and p23 interact with unprocessed P1, protecting the polypeptide from misfolding and proteasomal degradation. Pharmacologic inhibition of Hsp 90 reduces the assembly of infectious particles by preventing the first cleavage event necessary for protomer formation between P1-2A and assembly of pentamer subunits. Virus variants resistant to inhibitors of Hsp 90 have never been identified, suggesting that complexity of capsid folding precludes the emergence of alternate folding pathways.[217,218,378,408,433,491,499,600,699,717,735] A second interpretation of the data is that Hsp 90 can act as a chaperone at both the protein and RNA levels, to overcome the evolutionary constraints imposed by protein stability, aggregation, and rate of synthesis.[216]

Pentamers are structurally important intermediates in the assembly of all picornaviruses.[86,603] They can self-assemble *in vitro* or *in vivo* into 80S empty capsids (Fig. 2.20). The structure of this particle reveals differences in the network formed by the N-terminal extensions of the capsid proteins on the inner surface of the shell, compared with the native virion.[51] In empty capsids, VP4 and the entire N-terminal extensions of VP1 and VP2 are disordered, and many stabilizing interactions that are present in the mature virion are not present. The final morphogenetic step involves cleavage of most of the VP0 molecules to VP4 + VP2. The proteinase that carries out this final maturation cleavage has not been identified. The VP0 scissile bond is located on the interior of empty capsids and mature virions and is inaccessible to viral or cellular proteinases. The presence of a conserved serine in VP2 near one of the cleaved termini led to a model that cleavage

occurs by a novel autocatalytic serine protease-like mechanism in which basic viral RNA groups serve as proton abstracters during the cleavage reaction.[28] Replacement of serine 10, however, does not impair VP0 cleavage.[280] In another hypothesis, a conserved histidine in VP2 is involved in catalysis, together with the viral RNA.[51,150] Substitution of this histidine with different amino acids lead to lack of infectivity or highly unstable particles, supporting the involvement of VP2 histidine 195 in mediating VP0 cleavage during assembly.[296] Cleavage of VP0 establishes the ordered N-terminal network, an interlocking seven-stranded β-sheet formed by residues from adjacent pentamers. This network results in an increase in particle stability and the acquisition of infectivity.

During its synthesis, the P1 capsid protein precursor is linked to myristic acid at the amino-terminal glycine residue of VP4 that is exposed after removal of the initiation Met residue.[125] The myristate groups, which form part of a network of interactions between subunits that form when protomers assemble into pentamers, cluster around the fivefold axis of symmetry and stabilize the β-cylinder that is made by the amino termini of five copies of VP3. The results of mutagenesis indicate that the myristate group plays a role in stabilizing pentamers and, therefore, virions.[20,438–440,481]

How the RNA genome is encapsidated remains an unsolved problem. Packaging motor proteins encapsidated the genomes of many bacteriophages into preassembled procapsids. While no picornavirus protein is known to have packaging motor activity, one model of assembly could include the introduction of newly synthesized viral RNA into these partially assembled particles to form the provirion,[327] in which the capsid protein VP0 remains uncleaved. This assembly model would seemingly require an opening in the empty capsid through which the RNA can enter. Examination of the high-resolution x-ray crystallographic structure of these particles does not provide evidence for such an opening.[51] This finding does not exclude this morphogenetic pathway because the pore might be dynamic and not observed in the crystals. In an alternative morphogenesis pathway, 14S pentamers assemble with virion RNA to form provirions. In this model, for which there is some experimental support,[511] the empty capsids found in infected cells serve as storage depots for 14S pentamers.

The RNA genomes of plant viruses are encapsidated via protein–protein

and RNA–protein interactions.[111,198] This mechanism does not appear to be the means by which picornaviruses acquire their genomes.[334] The picornavirus encapsidation process is highly specific with only VPg-conjugated positive-strand RNA, and not viral mRNA, negative-strand viral RNA, or any cellular RNA incorporated into the virion.[507,509] Yet, VPg is probably not an encapsidation signal because VPg-containing negative-strand RNA is not packaged despite the observation that genomic RNA lacking VPg is never encapsidated.[507,510] No packaging signal, structure, or sequence has been identified within the picornavirus genome. The coupling of encapsidation to viral RNA synthesis may explain the selective packaging of viral positive-strand RNA. In infected cells, newly synthesized RNA is packaged into virions within 5 minutes, whereas incorporation of capsid proteins in virions requires at least 20 minutes.[40] The pool of viral RNA available for packaging, therefore, is small, and the pool of capsid proteins is large. If capsid formation is inhibited with *p*-fluorophenylalanine, the accumulated RNA cannot be packaged after removal of the inhibitor.[273] These results suggest that packaging of the viral genome is linked to RNA synthesis and would explain why only RNA containing VPg are encapsidated. This conclusion is questioned by findings showing that inhibition of virion assembly by hydantoin, which targets the 2C protein, does not affect genome replication. Furthermore, when hydantoin is removed from infected cells after RNA synthesis is complete, and in the presence of an inhibitor of replication, normal levels of virions are produced.[515] Yet, a temperature-sensitive alteration in 2C protein allows for uncoating to occur at low temperature.[407] These results suggest that RNA encapsidation is dependent upon interactions between 2C protein and VP1 and VP3.[419,734,738] For Aichi virus, the L protein, instead of 2C protein, participates in RNA encapsidation. Removal of the C-terminal 50 amino acids of L protein of Aichi virus prevents the transition of empty capsids to mature virions.[619]

Cryo-EM reconstruction of the Ljungan virus particle revealed that the RNA genome maintains an ordered structure of within the virion: 15 nucleotides associating with the N-terminus of VP3 near the fivefold axes. This observation suggests that the Ljungan genome may be encapsidated via a mechanism similar to that observed for insect picorna-like viruses in which a capsid protein functions as an RNA chaperone. Compaction of the genome occurs via electrostatic interactions between short regions of the RNA, in a

sequence-independent manner, and 20 highly basic residues found at N-termini of VP3 that line the interior surface. A condensed structure of nucleic acid with icosahedral symmetry results. This model is supported by the observation that empty capsids are not found during parechovirus infection. A similar model has been proposed for the encapsidation of the hepatitis A virus genome but is contrary to the model based upon interaction between structural and nonstructural proteins in the RNA replication complex as proposed for poliovirus and the identification of a packaging signal in the Aichi virus genome.[419,620] Experimental data in which poliovirus was recoded to enhance the number of underrepresented synonymous codon pairs suggest that acquisition of the genome and assembly may occur via a two-step assembly mechanism that combines the ideas above: (a) interaction between capsid protein and the replication structure, including proteins and newly synthesized genomes and (b) a coordinate condensing of the genome resulting in an array of hairpin structures to promote RNA–protein interactions to complete the assembly and promote stability of the particle.[648]

EFFECTS OF VIRAL REPRODUCTION ON THE HOST CELL

Inhibition of 5′ End–Dependent mRNA Translation

In cultured mammalian cells, poliovirus infection results in inhibition of cellular protein synthesis. By 2 hours after infection, polyribosomes are disrupted, and translation of nearly all cellular mRNA stops and is replaced by viral mRNA translation (Fig. 2.21). Poliovirus mRNA, but not capped mRNA, can be translated in extracts from infected cells. In such extracts, the eIF4GI/eIF4GII component of the translation initiation complex eIF4F has been cleaved.[185,605,692] Cleavage of eIF4G separates the N-terminal eIF4E–binding domain of eIF4G (p100) from the C-terminal fragment (Fig. 2.22). The assumption that the C-terminal fragment of eIF4G cannot support the translation of capped mRNA has been proven incorrect.[11] It is now thought that picornavirus-induced translational inhibition is not solely due to the inability of p100 to support capped mRNA translation but to the viral RNA outcompeting host cell mRNA for the limiting concentration of p100.

Optimal function of the IRES does require the C-terminal fragment of eIF4G, which, as discussed previously, is necessary to anchor 40S ribosomal subunits to the IRES. Although both eIF4GI and eIF4GII are cleaved in poliovirus- and rhinovirus-infected cells, the kinetics of shutoff of host translation correlates with cleavage of eIF4GII and not eIF4GI.[245,671]

FIGURE 2.21 Inhibition of cellular translation in cells infected with poliovirus. **A:** Protein synthesis in poliovirus-infected and uninfected cells at different times after infection. Poliovirus infection results in inhibition of host cell translation beginning about 1 hour after infection. The increase in translation beginning 3 hours after infection is caused by the synthesis of viral proteins. **B:** Polyacrylamide gel showing inhibition of cellular translation. At different times after infection (top of each lane), cells were incubated with ^{35}S-methionine for 15 minutes; the cell extracts were then fractionated on an SDS-polyacrylamide gel. By 5 hours after infection, host translation is markedly inhibited and replaced by the synthesis of viral proteins, identified at the right.

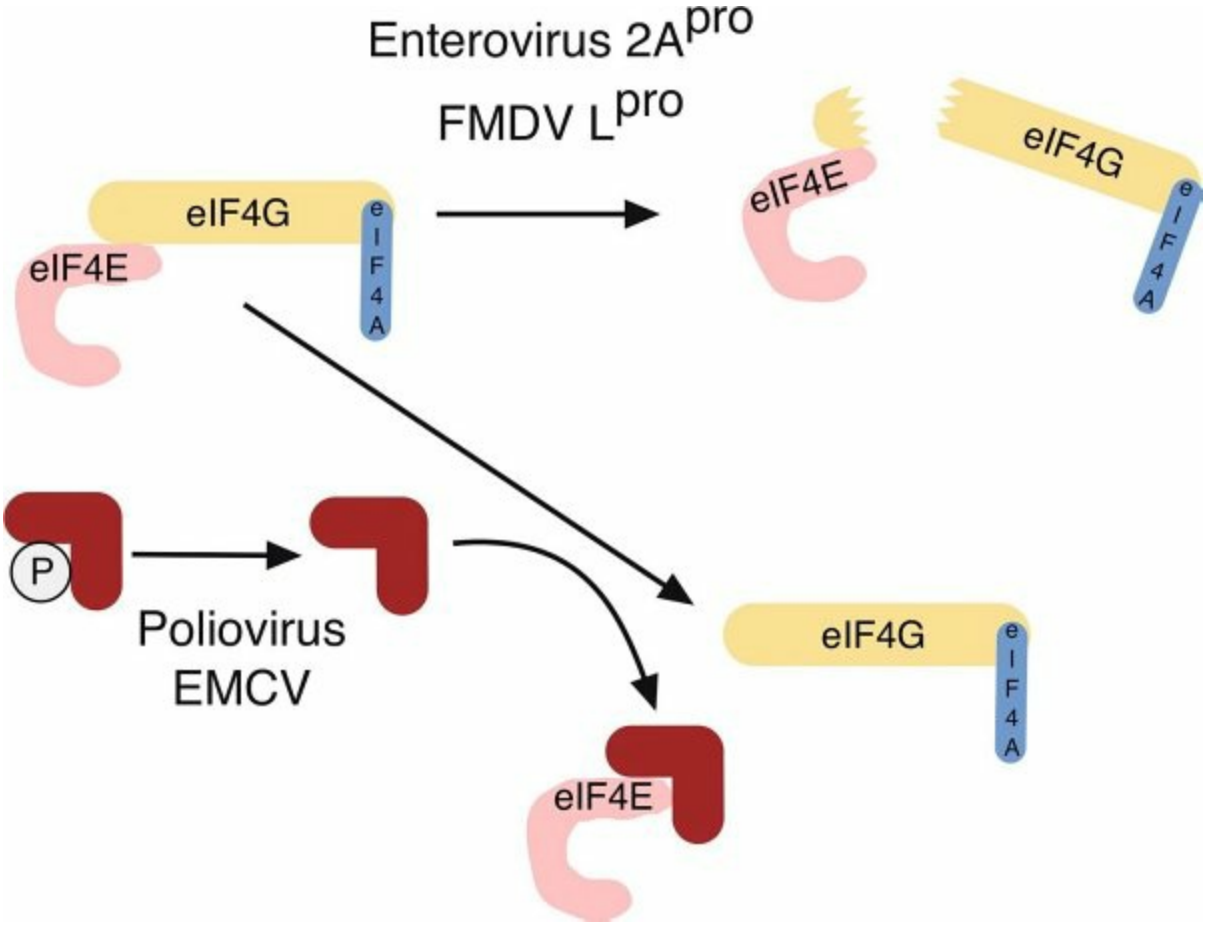

FIGURE 2.22 Two mechanisms for regulating eIF4F activity in picornavirus-infected cells. The proteins 4E-BP1 and 4E-BP1 bind eIF4E and prevent it from interacting with eIF4G. 4E-BP1 binds eIF4E when it is dephosphorylated, an event that occurs in cells infected with poliovirus and EMCV. Cleavage of eIF4G takes place in cells infected with poliovirus, rhinovirus, and foot-and-mouth disease virus, among others. Cleavage reduces the efficiency of translation of capped messenger RNA (mRNA). 5′ End–dependent initiation is inhibited because capped mRNA cannot compete with viral mRNA for the translation machinery.

Both forms of eIF4G are cleaved by protease $2A^{pro}$ of poliovirus and rhinovirus.[245,671] *In vitro* cleavage of eIF4G by purified $2A^{pro}$ of rhinovirus is inefficient unless eIF4G is bound to eIF4E.[269] This finding indicates that eIF4G is cleaved not as an individual polypeptide but rather as part of the eIF4F complex. Binding of eIF4E to eIF4G may induce conformational changes in eIF4G that make it a more efficient substrate for the protease. Poliovirus $2A^{pro}$ efficiently cleaves eIF4GI, but not eIF4GII, consistent with the differential cleavage of these proteins during virus infection.[245] The L^{pro} protein cleaves eIF4GI in cells infected with FMDV. The cleavage sites in eIF4GI for the two proteinases are different: L^{pro} cleaves between Gly-479 and Arg-480, whereas $2A^{pro}$ cleaves between Arg-486 and Gly-487.[367,391]

Modulation of eIF4F Activity

Three related low molecular weight cell proteins, 4E-BP1, 4E-BP2, and 4E-BP3, bind to eIF4E and inhibit translation by 5′-end–dependent scanning, but not by internal ribosome entry (Fig. 2.22).[539] 4E-BP1 is identical to a protein called PHAS-I (phosphorylated heat- and acid-stable protein regulated by insulin), which was previously known to be an important phosphorylation substrate in cells treated with insulin and growth factors.[414] Phosphorylation of 4E-BP1 *in vitro* blocks its association with eIF4E. Binding of either 4E-BP1 or 4E-BP2 to eIF4E does not prevent it from interacting with the 5′ cap but does inhibit binding to eIF4G. Consequently, active eIF4F is not formed.

eIF4G and the 4E-BP have a common sequence motif that binds eIF4E. Treatment of cells with hormones and growth factors leads to the phosphorylation of 4E-BP1 and its release from eIF4E. Those mRNAs with extensive secondary structure in the 5′-noncoding region, which are translated poorly, are preferentially sensitive to the phosphorylation state of 4E-BP1. As expected, translation by internal ribosome binding is not affected when 4E-BP1 is dephosphorylated. Binding of extracellular ligands leads to phosphorylation of 4E-BP through a signaling pathway that includes the mammalian target of rapamycin.[756]

Infection with several picornaviruses causes alteration of the phosphorylation state of 4E-BP1 and 4E-BP2 (Fig. 2.22). Infection of cells with EMCV causes inhibition of cellular translation, but in contrast to the shutoff that occurs in poliovirus-infected cells, shutoff of cellular protein synthesis occurs late in infection and is not mediated by cleavage of eIF4G. Infection with EMCV induces dephosphorylation of 4E-BP1, which then binds eIF4E to prevent it from forming eIF4F.[179] Translation of cellular mRNA is inhibited, but that of the viral RNA is not because it contains an IRES. Dephosphorylation of 4E-BP1 also occurs late in cells infected with poliovirus, but this event does not coincide with inhibition of cellular translation, which occurs earlier in infection.[225] Inhibition of translation by dephosphorylation of 4E-BP1 also influences the ability of the cell to productively combat viral infection by reducing production of type I IFN.[130]

Efficient translation initiation is hypothesized to be dependent upon formation of a closed loop of mRNA. Circularization of the RNA is mediated by the interaction of eIF4G bound at 5′ end of the RNA and poly(A)–binding protein bound to the poly(A) tail at the 3′ end. The initial synthesis of picornavirus-specific proteins is stimulated by the interaction of eIF4G with poly(A)–binding protein.[463,672] Like eIF4G, poly(A)–binding protein is cleaved during enterovirus infection by viral proteinases $2A^{pro}$ and $3C^{pro}$; however, the kinetics of poly(A)–binding protein cleavage are slower than those of eIF4G.[337] Cleavage of poly(A)–binding protein is necessary but not sufficient for efficient inhibition of cellular translation; instead, cleavage of this protein is believed to participate in the switch from RNA translation to replication (see *Translation and replication of the same RNA molecule*).[87] The effect of poly(A)–binding protein cleavage during this switch is controversial, as depletion of poly(A)–binding protein from cell lysates did

not reduce virus production.[670] The cellular polyadenylation factor CstF-64 is cleaved by enterovirus 71 $3C^{pro}$ proteinase, impairing the addition of poly(A) to host cell mRNAs.[748]

Formation of the eIF4F complex can also be regulated by miRNAs. During enterovirus infection, transcription of miR-141 is enhanced. Because multiple binding sites for this miRNA are found within the 3′-noncoding region of eIF4E mRNA, levels of eIF4E and consequently the eIF4F complex are reduced, and cellular protein synthesis is impaired.[299] Viral translation is unaffected as it does not require eIF4E.

The production of double-stranded RNA during infection with many viruses leads to activation of PKR, phosphorylation of eIF2α, and inhibition of translation. It occurs very late in the replication cycle of poliovirus.[519] Like most cellular mRNAs, the polyprotein begins with a methionine encoded by an AUG codon, and early in infection, initiation of protein synthesis requires the ternary complex of eIF2-GTP-met-$tRNA_i$. Late in infection, phosphorylation of serine 52 of the alpha subunit of eIF2 prevents the recycling of the ternary complex after initiation. However, poliovirus-specific protein synthesis continues throughout infection. It is thought that initiation of translation late during infection occurs independently of eIF2.[747,753] The exact mechanism for this mode of initiation is not well understood but is thought to be dependent upon the generation of a fragment of eIF5 that functions in a similar manner as eIF2 in recruiting the initiating tRNA to the small 40S ribosomal subunit while bound to the mRNA.[753] The proteolytic activity of $2A^{pro}$ is believed to be required to enable poliovirus mRNA translation in the absence of eIF2.[584]

Stress-Associated RNA Granules

Sequestering of mRNA away from the translation apparatus in processing (P) bodies and stress granules is another mechanism by which cellular mRNA translation can be impaired.[16] P bodies and stress granules are two nonmembranous cytoplasmic aggregates composed of RNA and protein, including many proteins involved in mRNA translation. These granules are believed to form when translation is inhibited in the presence of intracellular and extracellular stresses, including viral infection. When stress conditions are alleviated, the mRNAs found in these aggregates can either be

deadenylated and degraded or returned to the pool of actively translated RNAs.

Stress granules are thought to be nucleated upon two cellular proteins, T-cell–restricted intracellular antigen-1 (TIA-1) and the RasGAP SH3 domain–binding protein 1 (G3BP). Reduction of either protein impairs formation of stress granules, and overproduction of either component stimulates formation of these aggregates.[224,690] Stalled translation complexes consisting of mRNA, eIF4E, eIF4G, eIF4A, eIF3, poly(A)–binding protein, and phosphorylated eIF2*α* are found within these granules. The presence of phosphorylated eIF2*α* is a hallmark of stress granules. Formation of stress granules is enhanced during early picornavirus infection and correlates with the inhibition of cellular translation but is independent of eIF2*α* phosphorylation. Late in infection, the viral proteinase $3C^{pro}$ cleaves RasGAP SH3 domain–binding protein 1la, disassembling stress granules, an event required for efficient viral replication. The presence of an altered form of cleaved RasGAP SH3 domain–binding protein 1^{Q326E} prevents the disassembly of stress granules and impairs viral replication.[751] Instead, a noncanonical form of stress granules remains, an aggregate containing only TIA-1.[562,752] The opposite is observed during infection with members of the *Discistroviridae*: cricket paralysis virus infection prohibits stress granule formation as defined by foci of the *Drosophila* homologs of TIA-1 and RasGAP SH3 domain–binding protein 1, Rox8 and Rin. Addition of potent inducers of stress granules such as arsenite and pateamine A to the culture medium is unable to overcome viral inhibition.[361]

Processing (P-) bodies are a second type of non–membrane-bound aggregate found in the cytoplasm. These aggregates, which are the sites of RNA deadenylation and mRNA repression, are composed of proteins such as the decapping enzymes Dcp1a and Dcp2 and proteins that mediate mRNA deadenylation including Pan3, the CCR4/Not 1 complex, Xrn-1, a 5′-3′ RNA exonuclease, and the DEAD-box helicase p54/Rck. In uninfected cells, P-bodies are the consequence of micro-RNA (miRNA)–mediated repression.[186] Ultrastructural analysis of these granules suggests that there is an anchoring core composed of proteins required for repression with proteins mediating decay on the periphery. The protein that bridges between the two regions of the aggregate is p54/Rck.[138] P-bodies are found in proximity to both the ribosome and mitochondria. Although cellular mRNA translation is inhibited

during picornavirus infection, the RNA is not degraded, possibly due to inhibition of P-body formation. The $3C^{pro}$ proteinase of poliovirus cleaves several P-body components including Xrn1, Dcp1a, and Pan 3, disrupting P-body formation.[172]

Inhibition of Cellular RNA Synthesis

Infection of cells with picornaviruses leads to a rapid inhibition of host cell RNA synthesis catalyzed by all three classes of DNA-dependent RNA polymerase. RNA polymerases I, II, and III from poliovirus-infected cells are enzymatically active, suggesting that accessory proteins may be the target of transcriptional inhibition. Studies of *in vitro* systems have demonstrated the inhibition of specific transcription factors required by each of the three RNA polymerases. The RNA polymerase factor TFIID, which is a multiprotein complex, is inactivated in poliovirus-infected cells.[374] This inactivation appears to be caused, at least in part, by cleavage of a subunit of TFIID, the TATA-binding protein, by protease $3C^{pro}$.[764] A pol III DNA–binding transcription factor, TFIIC, is also cleaved and inactivated by $3C^{pro}$.[127] The target of $3C^{pro}$ is a subunit of TFIIIC, which contacts the pol III promoter. The pol I transcription factors SL-1 (selectivity factor) and UBF (upstream binding factor) are inactivated in poliovirus-infected cells by $3C^{pro}$, resulting in inhibition of pol I transcription.[42,610]

Because poliovirus replication occurs in the cytoplasm, cleavage of RNA polymerase transcription factors requires that the viral proteinase $3C^{pro}$ enters the nucleus. $3C^{pro}$ lacks a nuclear localization signal (NLS), but the precursor $3CD^{pro}$ enters the nucleus by virtue of an NLS in protein $3D^{pol}$. Transcription factors in the nucleus are then cleaved by either $3CD^{pro}$ or $3C^{pro}$ that is released by autocatalysis.[633] Rhinovirus 16 $3CD^{pro}$ has also been shown to enter the nucleus.[15]

Inhibition of Nucleocytoplasmic Trafficking

Infection of cells with picornaviruses leads to the disruption of nucleocytoplasmic trafficking. One mechanism by which this is achieved is the proteolysis of nucleoporins, proteins that constitute the nuclear pore complex. In cells infected with poliovirus, two protein components of the

nuclear pore complex are cleaved, Nup153 and Nup62.[264,265] The proteinase responsible for cleavage of Nup62 in rhinovirus-infected cells is $2A^{pro}$.[528] This cleavage results in the cytoplasmic accumulation of nuclear proteins, some of which, such as La protein[638] and SRp20,[194] are required for viral mRNA translation. The rates and processing profiles of Nups by $2A^{pro}$ proteinases of different rhinoviruses vary widely.[744] The rhinovirus $3C^{pro}$ and its precursor $3CD^{pro}$ are imported into the nucleus, leading to the degradation of nuclear pore components.[220]

Another mechanism of disruption of nucleocytoplasmic trafficking involves the L protein of cardioviruses (the 2A protein of these viruses is not a proteinase). The L protein binds directly to the Ran-GTPase, a key regulator of nucleocytoplasmic transport.[570] Infection also leads to phosphorylation of nucleoporins Nup62, Nup153, and Nup214.[572] Staurosporine, a broad-spectrum protein kinase inhibitor, and ERK and p38 MAP kinase inhibitors block Nup phosphorylation and restore normal nuclear trafficking.[571] Inhibition of Nup activity is therefore achieved by phosphorylation in cardiovirus-infected cells and by proteolysis in cells infected with enteroviruses.

The disruption of nucleocytoplasmic trafficking by picornaviruses not only provides cytoplasmic access to nuclear proteins needed for viral replication but blocks the export of cell mRNAs with antiviral activity produced as part of the innate immune response.

Inhibition of Protein Secretion

Transport of both secretory and plasma membrane proteins is blocked in picornavirus-infected cells.[165] The 2B and 2BC proteins block protein secretion from the Golgi apparatus, and the 3A protein blocks vesicular traffic from the ERGIC to the Golgi complex.[44,76,164,616] Inhibition of protein secretion by poliovirus protein 3A is not required for viral growth in cell culture.[163] Protein 3A inhibits protein transport by binding to and inhibiting GBF1, a guanine exchange protein that is needed for activity of Arf1 and is required for the transport through the secretory pathway.[65] Cells infected with the poliovirus mutant 3A-2, which has a single amino acid change in the protein, have reduced inhibition of protein transport.[164] This amino acid

change abrogates binding of 3A to GBF1 and therefore does not inhibit activity of the protein.[749,750] Because the 3A protein prevents secretion of cytokines[163] and major histocompatibility complex I (MHC-I)–dependent antigen presentation,[157] it is likely to modulate the innate and adaptive immune responses of the host and, therefore, the outcome of infection. Consistent with this hypothesis, when the 3A mutation is introduced into the genome of Coxsackievirus B3, the variant is less pathogenic in mice, although the mechanism of attenuation is not known.[750] Inhibition of protein secretion in cells infected by FMDV is caused not by protein 3A but by protein 2BC.[471]

Metabolic Reprogramming

Virus are obligate intracellular parasites and their reproduction cycles require the host metabolic machineries, as no known viral genome encodes all components, including the ribosome, necessary for their replication. Consequently, the production of infectious virus is dependent upon the cell's biosynthetic pathways supplying macromolecules, which in turn leads to dramatic elevations in the bioenergetic demands of cell. To adjust for these demands, the metabolic pathways of the cell are altered. As discussed in *Cellular site of RNA synthesis*, picornavirus infection stimulates the uptake of fatty acids and *de novo* phospholipid synthesis. Infection also enhances sugar uptake and the reprogramming of anabolic pathways such as glycolysis and oxidative phosphorylation, as well as gluconeogenesis needed to enhance amino acid, enhance nucleotide synthesis, and maintain energetic homeostasis of the infected cell. Consequently, rhinovirus infection is impaired in the presence of the glycolysis inhibitor 2-deoxyglucose.[259]

Cell Death and Virus Release

When cells are productively infected with poliovirus, they develop the characteristic morphologic changes known as *cytopathic effects*. These include condensation of chromatin, nuclear blebbing, proliferation of membranous vesicles, changes in membrane permeability, leakage of intracellular components, and shriveling of the entire cell. The cause of cytopathic effects is unknown. One hypothesis is that leakage of lysosomal contents is partly responsible.[263] Although cellular RNA, protein, and DNA

synthesis are inhibited during the first few hours of infection, they cannot account for cytopathic effects.

When poliovirus reproduction is hindered by certain drugs or other restrictive conditions, cell death occurs through induction of apoptosis.[686] Although certain manifestations of cytopathic effects and apoptosis are similar (e.g., chromatin condensation and nuclear deformation), the pathways leading to their induction differ.[3] During productive infections of cultured cells with poliovirus, apoptosis is blocked by a virus-encoded inhibitor.[686] Viral replication and central nervous system injury in mice infected with poliovirus, however, are associated with apoptosis.[228] Viral inducers of apoptosis include proteins 2C, $2A^{pro}$, and $3C^{pro}$,[46,231,420] and inhibitors of apoptosis include L^{pro}, 2B, and 3A.[106,163,219,500,765] The ability of different strains of Theiler murine encephalomyelitis virus to induce apoptosis may be a determinant of disease. The TO strain of Theiler virus, which causes a persistent demyelinating disease in mice, encodes an additional protein, L*.[118] This protein is produced by initiation from an AUG that is 13 nucleotides downstream from the initiator AUG of the polyprotein, in a different reading frame. In contrast, nondemyelinating isolates of the virus (e.g., GDVII) do not encode L*. It was subsequently found that L* has antiapoptotic properties in macrophages and is critical for virus persistence[219] and prevents antiviral cytotoxic T-cell activation.[765] The ability of L* to inhibit apoptosis may be a key factor in determining whether infection of mice results in acute disease or persistence and demyelination.

PERSPECTIVES

Since the identification in 1908 of poliovirus as the etiologic agent of poliomyelitis, research on the virus has waxed and waned. With each lull in activity, questions were raised about whether it was productive to continue research on the virus. Each time, new technologies emerged that allowed the field to advance and become active once again. Today, research on poliovirus continues, as the difficulties have been encountered in the effort to globally eradicate this virus. Nevertheless, work on other picornaviruses has become highly productive, and research on a wide range of cardioviruses, aphthoviruses, enteroviruses, and members of many other genera flourishes.

Many questions remain about nearly every stage of the replicative cycle, and an unprecedented array of experimental techniques and reagents are available to address them. Genome-wide editing screens are being applied to picornaviruses and have already identified hundreds of cell genes that not only are required for picornavirus infection but regulate replication.[140,141] It can be anticipated that cellular genes will be identified whose products participate in all aspects of the picornaviral replication cycle, from receptor binding and entry to macromolecular synthesis, assembly of new virus particles, and release. Studies of these processes will contribute to understanding questions about how the viral RNA is released from the capsid, whether RNA synthesis proceeds in infected cells as has been learned from *in vitro* systems, how replication complexes are produced in infected cells, and how the viral RNA enters the virion and becomes folded to fit in a very small space. Because poliovirus is a model system, its study provides a unique opportunity to address fundamental questions in virology. The polio eradication program has made impressive gains—as of this writing in July 2019, there have been fewer cases of poliomyelitis than there were of enterovirus D68–associated paralytic disease. When the time comes when research on poliovirus must cease, the picornavirus field will be ready to move on to other fascinating subjects. As viral discovery in general has greatly accelerated in the past 5 years, the size of the *Picornaviridae* has grown remarkably. With this growth come new opportunities to study fascinating new viral systems, one of which might someday become the next model system for this virus family.

HISTORY

The history of enteroviruses (EVs) is very much the history of poliovirus (PV). In fact, many of the PV milestones are landmarks in the study of EV and, in fact, all of virology.

Poliomyelitis is believed to be an ancient disease. It has been suggested that the depiction of a young man with an atrophic limb on an Egyptian stele from the second millennium b.c. represents a sequela of poliomyelitis.[243] The first clinical descriptions of poliomyelitis were made in the 1800s, with reports of cases of paralysis with fever. In 1840, von Heine[190] published a monograph more specifically describing the affliction. His contributions and

those published later by Medin from Sweden[335] led to paralytic poliomyelitis being referred to as *Heine-Medin disease*. Another early report, by Charcot and Joffroy,[80] described the pathologic changes in the anterior horn motor neurons of the spinal cord in poliomyelitis.

The 1900s began a new era in poliomyelitis investigations, and the beginning of an understanding of the infectious nature of this disease. Wickman[514] and others recognized the communicable nature of poliomyelitis, the importance of asymptomatic infected individuals in transmission of PV, and the role of enteric infection in disease pathogenesis. The role of the gastrointestinal tract in the initiation and spread of PV infection was later confirmed by Trask et al.[485] In a classic study, Viennese investigators Landsteiner and Popper[297] proved the infectious nature of poliomyelitis by successfully transmitting the clinical disease and its pathology to monkeys following inoculation of CNS tissue homogenates from human cases.

Despite this progress, a number of unfortunate misconceptions emerged about poliomyelitis that initially confused scientists and misdirected efforts for control. These misconceptions included a belief that the virus was exclusively neurotropic, that the nasopharynx was a major site for virus entry into the CNS, and that the virus spread to the nervous system before viremia and by way of the olfactory nerve. As a result of these misconceptions and the failure of several poorly conceived immunization attempts, some with rather disastrous results,[401] an atmosphere of pessimism existed by the middle of the 20th century concerning the eventual control of poliomyelitis, even among scientists working in the field. In 1945, Burnet[60] wrote, “The practical problem of preventing infantile paralysis has not been solved. It is even doubtful whether it ever will be solved.” The eventual realization that virus entered via the oral–gastrointestinal route and that CNS disease followed a viremia did much to boost hopes for effective immunization.[50]

Building on studies of others, Enders et al.[128] performed a landmark study showing that PV could be propagated in nonneural tissue culture. These investigations had implications for all of virology because they indicated, first, that PV grew in various tissue culture cells that did not correspond to the tissues infected during the human disease and, second, that PV destroyed cells with a specific cytopathic effect. Neutralization tests showed that PV

has three serotypes,[51] and serologic tests[29] confirmed that most infected individuals do not manifest clinical disease. These investigations laid a critical framework for the development of a vaccine, and they clarified a host of confusing data, such as the apparent presence of second attacks of poliomyelitis.

A variety of vaccines were subsequently produced, with the most well known being the Salk inactivated polio vaccine (IPV) delivered via the intramuscular route (licensed in 1955 in the United States) and the Sabin live, attenuated vaccine (oral polio vaccine [OPV]) delivered via the oral route (licensed in 1961–1962). The importance of these vaccines and the individuals who produced them can begin to be realized by noting that more Americans knew the name of Jonas Salk than the President of the United States. The real impact of these vaccines will ultimately be felt with the complete global eradication of poliomyelitis. The eradication will undoubtedly provide a fitting dramatic finale to the compelling story of poliomyelitis.

PV work has had a continuing significant impact on the field of molecular virology. PV was the first animal virus completely cloned and sequenced,[277,411] the first RNA animal virus for which an infectious clone was constructed,[412] and the first human virus that had its three-dimensional structure solved by x-ray crystallography.[201] In 1989, Mendelsohn et al.[342] identified the PV receptor, CD155, a finding that was followed by the generation of mice carrying CD155 as a transgene.[284,421]

Coxsackieviruses (group A) were first isolated during poliomyelitis outbreaks in 1947 from the feces of paralyzed children in Coxsackie, New York.[108] These isolates were obtained by inoculation of suckling mice, the pathogenicity in mice clearly differentiating these viruses from PV that did not paralyze mice. In the following year, the first coxsackievirus (CV) group B was isolated from cases of aseptic meningitis.[339] The original CV group A (CVA) isolates produced myositis with flaccid hind limb paralysis in newborn mice, whereas the coxsackievirus group B (CVB) produced a spastic paralysis and generalized infection in newborn mice, with myositis as well as involvement of the brain, pancreas, heart, and brown fat.

In 1951, echoviruses were first isolated from the stool of asymptomatic individuals.[426] Echoviruses received their name because they were *e*nteric

isolates, *c*ytopathogenic in tissue culture, isolated from *h*umans, and *o*rphans (i.e., unassociated with a known clinical disease). Subsequent studies have shown that echoviruses, in fact, do cause a variety of human diseases including aseptic meningitis, hepatitis, and orchitis, among others. After this period of rapid growth in the number of enteroviruses, there were several decades where new enteroviruses were uncommonly identified. This changed with the introduction of molecular detection methods, and the last 15 years have seen a rapid expansion in the number of recognized enteroviruses. This period of discovery is still in progress.

INFECTIOUS AGENTS

Physical and Chemical Properties

Enteroviruses are distinguished from other picornaviruses on the basis of physical properties, such as buoyant density in cesium chloride and stability in weak acid. Many aspects of enteroviral pathology, transmission, and general epidemiology are directly related to the biophysical properties and their cytolytic life cycle. The infectious virus is relatively resistant to many common laboratory disinfectants, including 70% ethanol, isopropanol, dilute Lysol, and quaternary ammonium compounds. The virus is insensitive to lipid solvents, including ether and chloroform, and it is stable in many detergents at ambient temperature. Formaldehyde, glutaraldehyde, strong acid, sodium hypochlorite, and free residual chlorine inactivate enteroviruses. Concentration, pH, extraneous organic materials, and contact time affect the degree of inactivation by these compounds. Similar inactivation is achieved when virus is present on fomites, although conditions may not be exactly comparable.[2] In general, most reagents that inactivate EV depend on active chemical modification of the virion, whereas most extractive solvents have no effect.

Enteroviruses are relatively thermostable, but less so than hepatitis A virus. Most enteroviruses are readily inactivated at 42°C, although some sulfhydryl-reducing agents and magnesium cations can stabilize viruses so that they are relatively stable at 50°C.[10,121] The relative sensitivity to modest elevations in temperature makes it possible to use pasteurization to inactivate

EV in many biologically active preparations.[197]

As with other infectious agents, ultraviolet light can be used to inactivate EV, particularly on surfaces. In addition, the process of drying on surfaces significantly reduces virus titers. The degree of virus loss by drying is related to porosity of the surfaces and the presence of organic material.[1] Many studies of EV inactivation have been conducted using PV as a model EV. A report describing strain-specific differences for glutaraldehyde inactivation among echovirus 25 isolates implies, however, that the assumption that PV is representative of all EV may not be valid.[77] The inactivation of infectivity may not be directly related to the destruction of the viral genome, because the polymerase chain reaction (PCR) can be used to amplify viral RNA, even after inactivation of virus has occurred.[321] This would suggest that reactivation of infectivity may be possible in some circumstances. In fact, some examples of recovered infectivity have been reported through increased multiplicity of infection in cell culture,[455,543] but the practical significance of these observations is not clear.

Antigenic Characteristics and Taxonomy

As described in Chapter 2, the picornaviruses are among the simplest RNA viruses, having a highly structured capsid with little place for elaboration. Yet, despite the limited genetic material and structural constraints, evolution within the picornaviruses has resulted in a large number of readily distinguishable members. This variability has been categorized antigenically as serotype.

In the case of human enteroviruses, each of the serotypes correlates with the immunologic response of the human host, protection from disease, receptor usage, and, to a lesser extent, the spectrum of clinical disease. These correlations, however, have only a partial relationship with the original classification of enteroviruses into polioviruses, coxsackie A or B viruses, and echoviruses, based on biological activity and disease: human CNS disease with flaccid paralysis (poliomyelitis); flaccid paralysis in newborn mice, human CNS disease, and herpangina (coxsackie A viruses); spastic paralysis in newborn mice and human CNS and cardiac disease (coxsackie B viruses); and no disease in mice and (originally) no human disease (echoviruses). Within each of these groups, isolates can be readily

distinguished on the basis of antigenicity as measured with antisera raised in animals. The original classification scheme broke down with the identification of viruses antigenically identical to known echoviruses that were found to cause disease in mice and humans. This and other inconsistencies led to the numbering of new EV serotypes starting with EV68 (now termed EV-D68). These antigenic groupings, which define the serotypes, became increasingly more complicated as the number of different viruses grew. Despite these limitations, the serotype remains the single most important physical and immunologic property that distinguishes the different EV. Most of the prototype EV strains are maintained in the American Type Culture Collection, Manassas, Virginia, and in many of the WHO collaborating reference laboratories.

Despite the importance of the antigenic properties, the introduction of molecular typing methods and a reassessment of the limitations of the old classification scheme led to the development of the current classification system that divides the members of the EV genus into species on the basis of genome organization and sequence similarity as well as biological properties (see Tables 3.1 and 3.4, 3.5, 3.6).

TABLE 3.1 Picornavirus genera, species[a], and (sero)types with members known to infect humans

Genus and Species	No. of Types	Comments
Genus *Enterovirus*[b]		
Enterovirus A	25	5 types have been found only in nonhuman primates
Enterovirus B	63	4 types have been found only in nonhuman primates
Enterovirus C	23	
Enterovirus D	5	1 type has been found only in nonhuman primates
Rhinovirus A	80	
Rhinovirus B	25	
Rhinovirus C	56	
Genus *Parechovirus*[c]		
Parechovirus A	19	
Genus *Cardiovirus*[d]		
Cardiovirus A	2	Additional viruses not assigned to type
Cardiovirus B	14	
Genus *Cosavirus*[e]		
Cosavirus A	24	
Cosavirus B	?	
Cosavirus D	?	
Cosavirus E	?	
Cosavirus F	?	
Genus *Hepatovirus*[f]		
Hepatovirus A	1	Hepatitis A virus; also known to infect nonhuman primates
Genus *Kobuvirus*[g]		
Aichivirus A	1	
Genus *Salivirus*		
Salivirus A	1	Additional viruses not assigned to type
40 additional genera infecting mammals, birds, amphibians, reptiles, and fish		

[a]The classification scheme shown is from the Picornavirus Study Group of the International Committee on Taxonomy of Viruses (https://talk.ictvonline.org/ictv-reports/ictv_online_report/positive-sense-rna-viruses/picornavirales/w/picornaviridae; additional details from http://www.picornaviridae.com).

[b]*Enterovirus*: Eight additional species infect mammals other than humans. The types that constitute *Enterovirus A* through *Enterovirus D* are listed in Tables 3.4, 3.5, 3.6.

[c]*Parechovirus*: Two additional species infect mammals other than humans. PeV-A1 and PeV-A2 were formerly classified as echoviruses 22 and 23, respectively.

[d]*Cardiovirus*: One additional species infects mammals other than humans.

[e]Establishment of *Cosavirus C* is pending due to incomplete virus sequences. Types not established in species other than *Cosavirus A*.

[f]Eight additional species infect mammals other than humans.

[g]Two additional species infect mammals other than humans.

The human enteroviruses are now classified into four species: *Enterovirus A* (EV-A), EV-B, EV-C, and EV-D. In this system, members within an EV species

"share (i) a significant degree of amino acid identity of the P1, 2C, 3C and 3D

proteins; (ii) monophyly in phylogenetic trees; and (iii) essentially identical genome maps."[280,548]

Coding for the capsid proteins, the P1 region provides a reliable correlation between sequence relatedness and the traditional definition of serotype. This also appears to be true for the various individual capsid protein regions, with the exception of VP4; the VP4 sequence does not always correlate with serotype and, therefore, is not reliable for serotype identification.

The molecular studies have also provided a framework in which the EV antigenic relationships can be better understood. These studies suggest that the nucleotide sequence of VP1 can function as an excellent surrogate for the reference antigenic typing methods that use neutralization tests in order to distinguish EV serotypes. VP1 nucleotide sequence identity of at least 75% (85% aa identity) between an isolate and a serotype prototype strain suggests that the isolate is serotypically identical to the prototype (assuming that the next highest identity with other prototype strains is <70%). For example, a capsid sequence identity of 85.4% aa between CVA3 and A8 compared with a mean sequence identity among prototype strains of 71.5% confirmed the antigenic relationships that had previously been described, and suggested that these two viruses probably derived relatively recently from a common ancestor.[386] Similarly, capsid sequences with more than 96% identity confirmed the antigenic relationships between CVA11 and A15 and between A13 and A18[58]; as a result, CVA15 and A18 have been reclassified as A11 and A15, respectively. In this way, the use of VP1 sequencing studies has supported and clarified early serologic data and led to proposals regarding the classification of isolates into new EV serotypes.[387,388]

No general correlation is found, however, between sequence similarities with serotype in genome segments outside of the capsid region because of frequent recombination in the noncapsid regions. For example, sequencing studies have shown that phylogenetic trees constructed from sequences from varying genome regions of members of EV-C and *poliovirus* have incongruities between the capsid region and noncapsid regions,[58] suggesting that viruses with a PV capsid may recombine with these CV nonstructural protein coding regions to acquire different nonstructural protein sequences and, similarly, viruses with a CV capsid protein sequence may recombine to acquire different nonstructural protein sequences.[315,438] These findings imply

that recombination occurs between PV and other EV-C viruses within the nonstructural protein coding regions and this interchange of different nonstructural protein coding regions may lead to strains that become dominant due to selective advantages. The frequency of recombination in the noncapsid region supports the idea that serotype is defined by the capsid region and that limited correlations likely exist between the serotype of isolates and other phenotypic characteristics not associated with the capsid proteins. The findings also demonstrated that the phylogenetic clustering of prototype strains changes, depending on the nonstructural region that is analyzed.

Recombination within the nonstructural proteins was also found among EV-A and EV-B prototype members with other members of the same species, consistent with their classification into two separate species.[378,386] An analysis of multiple isolates within several EV-B serotypes[381] found relatively frequent interserotypic recombination of the noncoding regions, which appeared to occur at least once every 6 years for the isolates that were analyzed. Although no evidence was found of interserotypic recombination within the capsid (perhaps, because of structural constraints specific for a particular serotype), intraserotypic recombination within this region appeared to occur.

Additional sequencing studies showed that the 5′-untranslated region (UTR) of enteroviruses forms two clusters: the viruses of EV-C and EV-D constitute cluster I, whereas EV-A and EV-B constitute cluster II.[58,232]

Sequencing studies have also demonstrated significant similarities between human rhinoviruses and the human enteroviruses, resulting in a reclassification of the human rhinoviruses as members of three different species within the genus *Enterovirus*.[280]

In addition to the genetic relatedness, many different EV serotypes share some antigenicity. For example, PV1 and PV2 share a common antigen, and antigenic relationships also exist between coxsackieviruses A3 and A8, A16 and EV71, and A24 and EV70 and between echoviruses 6 and 30 and 12 and 29. When virions are disrupted by heating, particularly in the presence of detergent, nonsurface antigens are exposed that are shared broadly among many EVs.[343]

Despite this lack of understanding of molecular variation in virus

structure as measured by polyclonal antibodies, high-resolution studies of the virion surface have been particularly useful in identifying the targets of neutralization of EV by monoclonal antibodies.[202,400] Other less-investigated antigenic sites elicit immune responses that are not neutralizing but, nevertheless, contribute to serotype identity. The observed structure of some antigenic sites has been shown to span noncontinuous polypeptide chains, providing an explanation for why antigenicity of the virus is destroyed by disruption of the virion structure.

Antisera raised in animals to each of the enteroviruses are largely type specific and are used to determine serotype in a neutralization assay. The PV neutralizing antibody response is serotype specific, with the exception of some minor cross-reaction between PV1 and PV2. A monoclonal antibody has been described that reacts with this shared site that is not found on PV3.[492] As noted, heat-disrupted virions, particularly those heated in the presence of detergent, induce antibodies that react with many EVs.[343] These broadly reacting antibodies are generally not neutralizing, and at least one of these epitopes has been mapped to the amino-terminal region of capsid protein VP1.[441] Although measurable *in vitro* differences are found in antigenic properties among strains within a serotype, the significance of these differences during natural infection has not been determined. Several PV isolated during outbreaks have demonstrated different antigenic properties when compared with the reference vaccine strains.[175,228] In all cases, however, immunity derived from vaccination has been sufficient to provide protection and control of these strains.[54] In addition, even in the face of massive immunization campaigns, no antigenic escape mutants resistant to neutralization have ever been observed, and successive genotypes of PV have been eliminated. Natural antigenic variants have also been identified with panels of monoclonal antibodies for several nonpolio EVs.[184,402]

Propagation and Assay in Cell Culture

One of the prominent characteristics of enteroviruses is the cytolytic nature of growth in cell culture. For many years, PV was the prototype of a lytic viral infection. At the microscopic level, infection is usually manifest within 1 to 7 days, and sometimes within mere hours, by the appearance of a characteristic cytopathic effect, which features visible rounding, shrinking, nuclear

pyknosis, refractility, and cell degeneration (Fig. 3.1). The earliest effects can often be seen in less than 24 hours, often as soon as in 4 hours, if the inoculum contains many infectious particles. With fewer virions, however, visible changes are not generally recognizable for several days, although a sufficient number of cells are infected. In addition, some EVs either do not cause cytopathic effect at all or do so only after several passages. In general, once focal cytopathic effect is detected, infection spreads rapidly throughout the cell sheet with total destruction of the monolayer.

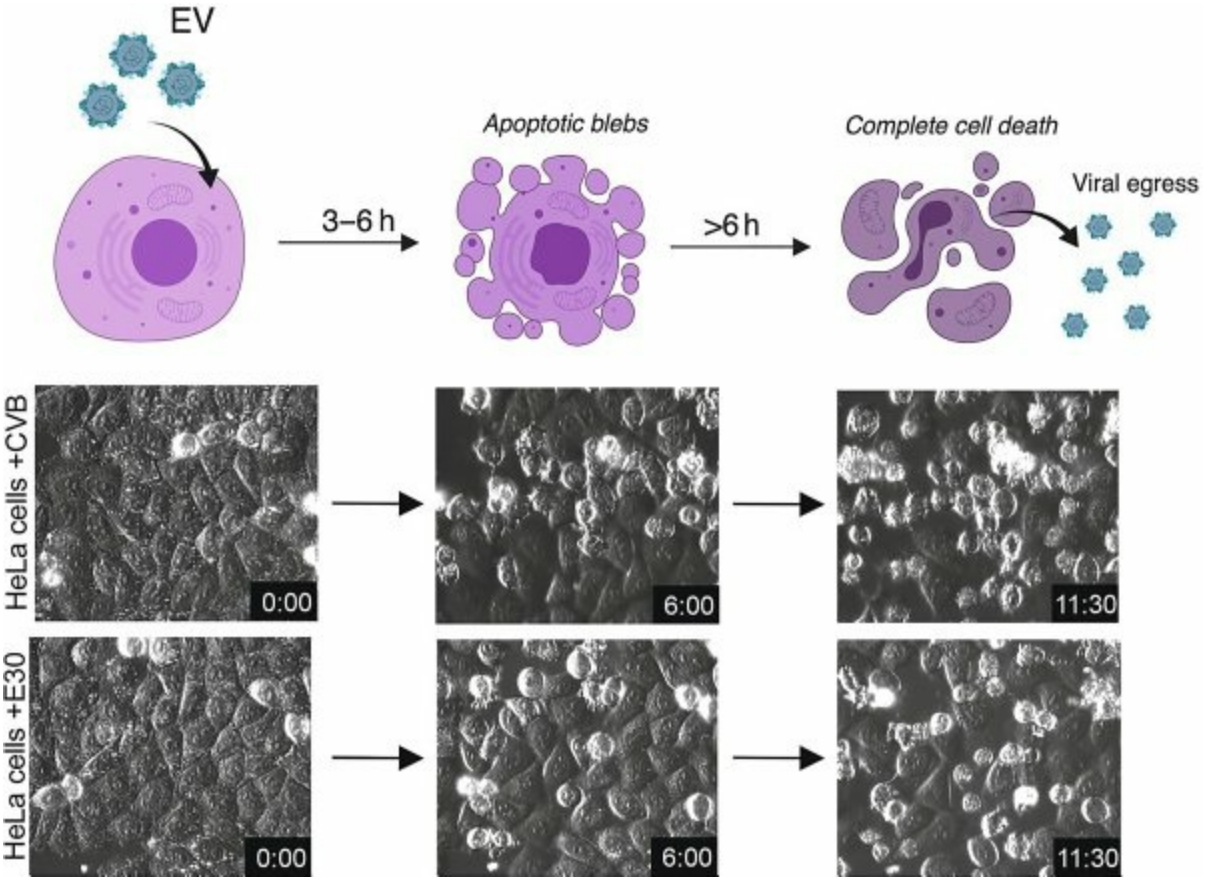

FIGURE 3.1 Enteroviruses commonly induce apoptosis, which is induced in cell culture models within 3 to 6 hours postinfection, with complete cell lysis by greater than 6 hours postinfection. **Top,** Schematic of the morphological changes induce by enterovirus infections, which can include cell blebbing and eventual cell lysis, which facilitates viral egress. **Bottom,** time-lapse imaging of HeLa cells infected with CVB or echovirus 30 demonstrates the timing

and magnitude of EV-induced cell death over a span of 11.5 hours post-infection. Time stamp at bottom right denotes hours post-infection. (Video 3.1, Video 3.2)

All known EVs can be propagated either in cell culture or in suckling mice, though for many of the newer EV, attempts to propagate have been limited and suckling mice are now seldom used. Most of the serotypes can be grown in at least one human or primate continuous cell culture. No cell line, however, can support the growth of all cultivable EVs. Even after many years of experimentation, a few serotypes (e.g., CVA19) can be propagated only in suckling mice. The typical host range of human EV in cell cultures or animals is shown in a broad, generalized way in Table 3.2 and is not clearly associated specifically with a given virus species. Infection of target cells depends on viruses binding to specific receptors on the cell surface. Collectively, the EVs use many different receptors. A practical adaptation resulting from the identification and genetic cloning of EV receptors is the introduction of the receptor into animals and cells that do not normally permit virus infection. This approach has resulted in both advances in understanding the pathogenesis of PV infection in a nonprimate animal model system and its practical application in the diagnostic laboratory. The L20B cells, which are murine cells that express CD155, are now used routinely to selectively isolate PV (see *Diagnosis*) as part of the global PV laboratory network supporting the poliomyelitis eradication initiative.[406]

TABLE 3.2 Usual host range of human enteroviruses: animal and tissue culture spectrum[a]

Virus	Antigenic Types[b]	Cytopathic Effect		Illness and Pathology	
		Monkey Kidney Tissue Culture	Human Tissue Culture	Suckling Mouse	Monkey
Polioviruses	1–3	+	+	–	+
Coxsackieviruses, group A	1–22, 24	±	±	+	–
Coxsackieviruses, group B	1–6	+	+	+	–
Echoviruses	1–33	+	±	–	–
Enteroviruses	68–121	+	+	–	–

[a]Many enteroviral strains have been isolated that do not conform to these categories.

[b]New types, beginning with type 68, are now assigned enterovirus type numbers instead of

coxsackievirus or echovirus numbers. Types 68 to 121 have been identified.

Major advances in the isolation and propagation of human-derived primary cells are beginning to advance our understanding of the possible interactions of EV with human cells *in vivo*. For example, the use of primary airway epithelia isolated from human nasal polyps grown at an air–liquid interface (ALI) has shown that EV-D68 alters mucociliary clearance and induces significant cytotoxicity in the epithelium.[130] Similarly, the isolation of human intestinal crypts, which can be propagated in the presence of growth factors that induced the differentiation of intestinal stem cells into all of the major cell types present in the gastrointestinal tract, has been used to study the impact of EV infection on intestinal structure and function.[125,163] These studies have revealed that different EVs target distinct cell types in the human GI epithelium and exhibit differences in their ability to dysregulate barrier function. The continued development and application of these models to *in vitro* studies of EVs will likely provide important insights into a number of facets of EV biology.

Infection in Experimental Animals: Host Range

The natural host for all human enteroviruses is the human. Although serologically distinct picornaviruses with the same physical properties as those of human EV have been found in many animals, human beings do not usually have recognizable infections with these animal EVs. On the other hand, some animals are susceptible to experimental infection with human EV. These include nonhuman primates and CD155-transgenic mice for polioviruses, mice and some monkeys for coxsackieviruses A and B, monkeys for echoviruses, mice for EV-D68, and mice and monkeys for EV-A71. In some cases, mouse models of EV require ablation of host innate immune signaling through the deletion or inhibition of antiviral type I interferon (IFN) signaling. Human EV can infect nonhuman primates, perhaps related to the homology that several simian EVs share with human viruses, but the infections appear to be largely subclinical.[379,409] Among higher primates, chimpanzees and gorillas appear to be able to acquire PV infection and develop disease from humans through natural exposure.[122] CVB5 is closely related antigenically to the porcine EV causing swine vesicular disease, with about 50% genetic identity over the entire genome.

Genetic studies of a number of strains of swine vesicular disease virus, as well as epidemiologic information gleaned from outbreaks, strongly suggest that a human CVB5 was specifically introduced into swine decades ago and led to establishment in this new host.[551]

Although most coxsackie A viruses have been successfully grown in various cell culture systems, isolation from clinical specimens is sometimes unsuccessful, necessitating the inoculation of suckling mice. Inoculation of suckling mice and subsequent virus identification is a process analogous to that of cell culture inoculation. A blind passage in mice may be necessary if the inoculum is of very low titer or, possibly, because passage of the virus is needed for it to adapt to growth in mice. The two groups of coxsackieviruses can be distinguished by the distinct pathology that they cause in mice. With CVA infection, newborn mice develop flaccid paralysis and severe, extensive degeneration of skeletal muscle (sparing the tongue, heart, and CNS), and they may have renal lesions. Death usually occurs within a week. CVB infection proceeds more slowly and is characterized by spastic paralysis and tremors associated with encephalomyelitis, focal myositis, necrosis of brown fat pads, myocarditis, hepatitis, and acinar cell pancreatitis. Echoviruses, except for some isolates of echovirus type 9, do not generally cause disease in mice, but disease can be induced in neonatal mice expressing human homologs of echovirus receptors.[223,354] The expression of the human homolog of the EV71 receptor SCARB2 also sensitizes mice to EV71 infection, with disease resembling that observed in humans (including paralysis and death).[150,311]

Other Human Picornaviruses

In addition to the enteroviruses, rhinoviruses, and hepatitis A virus, other picornaviruses that infect humans have been recently discovered or previously considered to be enteroviruses and are now reclassified as a separate genus (Table 3.1). These genera are genetically distinct from the EV genus (Fig. 3.2), but share some physical and structural similarity with EV. On the basis of a very low genetic relationship, differences in viral proteins and processing, and a novel 2A protease, echoviruses 22 and 23 were reclassified as a new genus, *Parechovirus*. Additional members of this genus exist, including additional serotypes of human parechovirus (HPeV),[236] as well as a separate species first isolated in Swedish bank voles, Ljungan virus;

Ljungan virus has been associated with diabetes in its natural host and has been postulated to have a role in human disease.[370] The human parechoviruses (PeV-A; 19 types) cause a similar spectrum of illnesses as the EV and can often be detected in cerebrospinal fluid (CSF) from meningitis cases at a frequency similar to that of the EV.[499,518] Serologic studies suggest that HPeV infection occurs at an early age, as most children were seropositive by the age of 2 years.[3,244,471] HPeV3 has been associated with sepsis-like illness and central nervous system disease in infants.[41,52]

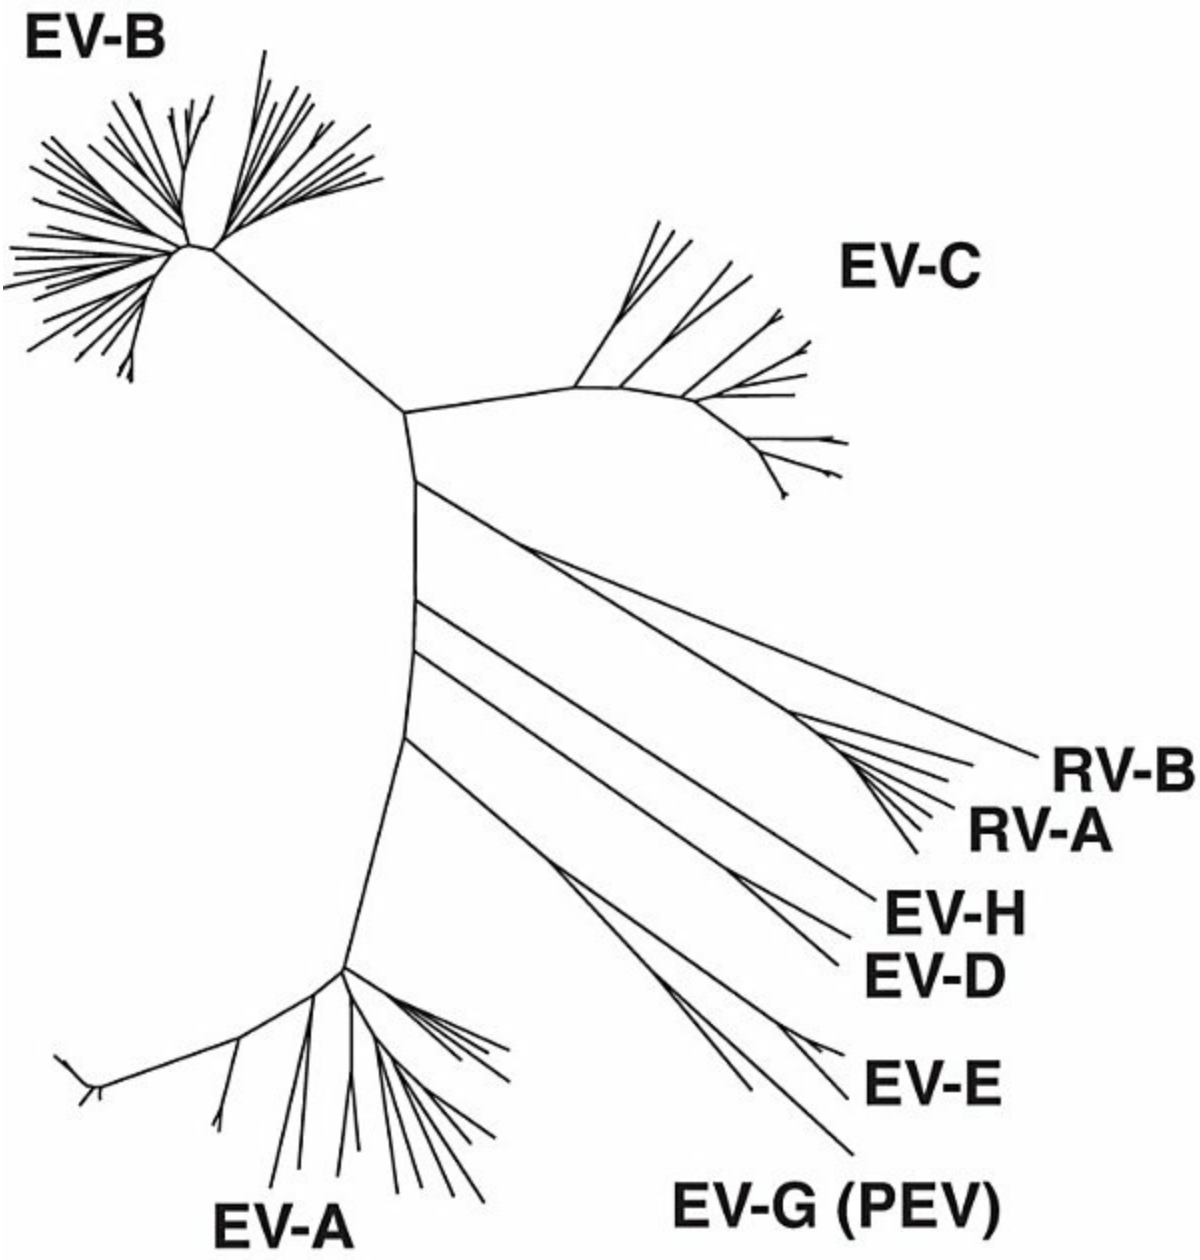

FIGURE 3.2 Dendrogram of genus *Enterovirus*. The figure illustrates the phylogenetic relationship among the prototype strains (see Tables 3.4, 3.5, 3.6) within the genus *Enterovirus* and the distinct grouping of isolates into each of the species of viruses that affects humans and other related animal enteroviruses based on the amino acid sequence of the P1 (capsid) coding region of the genomes. Species: EV-A (formerly human enterovirus A), EV-B (formerly human enterovirus B), EV-C (formerly human enterovirus C), EV-D (formerly human enterovirus D), RV-A (formerly human rhinovirus A), RV-B (formerly human rhinovirus B), EV-E (formerly bovine enterovirus), EV-G (formerly porcine enterovirus B), and EV-H (formerly simian enterovirus B). Not shown: EV-F (bovine enterovirus 2), EV-J (simian virus 6 and related viruses), and RV-C.

Another distinct picornavirus genus associated with human infection is *Kobuvirus*.[531] Although little is known about this virus, it appears that it is often associated with gastroenteritis in young children and infection is common, and distinct types cause diarrhea in cats and dogs.[65,307] Members of the genus *Cardiovirus* have also been associated with disease in humans, but they do not appear to be a major cause of human illness.[367,389] Viruses in the genus, *Salivirus*, are related to kobuviruses and have also been associated with gastroenteritis in humans.[205,306] Cosaviruses (genus *Cosavirus*) have been detected at a relatively high frequency in stool and have been isolated from children with diarrhea or gastroenteritis.[204,271,368] What is notable about all of these newer genera is that the molecular reagents for the detection of EV do not detect these viruses (see *Diagnosis*).

PATHOGENESIS AND PATHOLOGY

Entry into the Host

Virus infection normally requires that the virion attaches to the cell surface, and it was long imagined that each virus would have a single receptor. For PV, at least, this may be the case: the virus binds to the PV receptor (PVR[342]; now named CD155), a transmembrane glycoprotein in the immunoglobulin superfamily that mediates adhesion of NK cells and triggers their effector functions. PVR (human CD155) appears to be the major factor regulating the natural host range of PV, which is limited to humans and old world primates. CD155 homologs/orthologs have been identified and characterized in mice[355] and in new world monkeys; the extracellular domains share approximately 70% amino acid homology with hCD155, and these homologs do not support efficient PV binding or infection. Several laboratories have generated transgenic mice that express PVR, and, in many of the resulting models, PV was shown to induce neurological disease and paralysis following parenteral administration.[101,145,233,285,342,360,419, 420, 421,549] However, oral administration did not cause disease even when the PVR transgene was regulated by a promoter that drove protein expression in enterocytes and M cells; PV appeared to bind to the intestinal cells, but productive infection was not observed following oral inoculation of greater than 10^8 PFU of virus.[549] These findings are consistent with studies of humans and susceptible primates, in which hCD155 expression has been identified in many tissues, but productive infection is limited largely to the CNS. In mice, deletion of the receptor required for antiviral type I IFN signaling (the interferon-α/β receptor, IFNAR) permits PV entry into the CNS following inoculation by the intramuscular or intraperitoneal routes.[292,296] Thus, factors other than PVR expression play a key role in determining *in vivo* tropism, which may differ between species.

It is now generally accepted that some viruses, or viral strains, may have more than one receptor, perhaps expanding their potential host range. EV71, most frequently associated with hand-foot-and-mouth disease in children but capable of causing devastating neurological pathology,[465] has at least two receptors: scavenger receptor B2, SCARB2,[532] and P-selectin glycoprotein ligand-1, PSGL-1.[371] However, although EV71 binds with greater efficiency to PSGL-1, this binding may not be sufficient to induce genome release, which requires both SCARB2 and endosomal low pH.[533] EV-D68 may also utilize two cellular receptors, with some isolates binding to sialic acid[32] and all binding to the neuronal-specific intercellular adhesion molecule 5

(ICAM5).[510] Many CVA viruses appear to share a single receptor, KREMIN1, the murine homology of which is required for *in vivo* infection.[466]

Indeed, some viruses appear to interact with two different surface molecules on a single cell, perhaps in series, with one protein acting as the binding moiety, before "handing over" the virus to a second protein that facilitates its entry into the cell. This is thought to occur for some CVBs that bind to decay-accelerating factor (DAF, CD55) but then must interact with another protein, the coxsackievirus and adenovirus receptor (CAR), in order to enter the cell.[99] DAF also serves as an attachment factor for other EVs, including several echoviruses,[42] but similar to CVB, this binding is not sufficient to induce genome release. Instead, echoviruses utilize the neonatal Fc receptor (FcRn) as a primary receptor, but the precise role of this receptor in echovirus entry remains unclear.[354]

Site of Primary Replication

Human enteroviruses are spread by the fecal–oral route and respiratory droplets, so systemic infection requires the virus to cross the gastrointestinal wall, most of which is lined with epithelial cells that form a barrier to invasion. Perhaps surprisingly, given the many years of study, the primary site of PV infection and replication in the intestine remains unknown. PV has been identified in lymphoid tissues such as the tonsils[50] and in lymphoid aggregates, commonly termed Peyer patches (PP), that are present in the ileum of the small intestine. PP are overlaid with a specialized follicle-associated epithelium (FAE) that contains microfold (M) cells, which can transport certain molecules from the gastrointestinal lumen, across the epithelial layer, and into cells in the PP. Some studies suggest that PV may replicate within these epithelial cells and lymphoid cells,[251] while others suggest that the virus may be transcytosed through the M cell, subsequently establishing infection in an unidentified cell in the PP.[459] The cells in which CVB initially replicates are also uncertain; this issue is further clouded by the predominant use, in mouse models, of the intraperitoneal route of infection. As discussed above, the application of human stem cell–derived models of the intestinal epithelial (often referred to as "organoids" or "enteroids") has provided some insights into the cell-type–specific nature of EV infection

within the GI epithelium. Utilizing this model, it has been shown that echovirus 11 preferentially infected enterocytes, with infection also observed in enteroendocrine cells, but that mucus-secreting goblet cells were not permissive to infection.[125] Consistent with this, echovirus 11 infection induces profound loss of epithelial barrier integrity.[163] In contrast, EV71 infection of stem cell–derived GI epithelial monolayers does not induce any loss of epithelial barrier function, which might be attributed to its preferential infection of goblet cells.[163] However, given that the intestinal microbiome may be an important mediator of EV-GI epithelial attachment and infection, which is missing from these models, whether this specificity exists *in vivo* is unknown.[293,427]

HRV infects epithelial cells of the airways. Infection of the nasal epithelium causes few detectable pathological changes, even if rhinitis is quite severe, and—as is true for many virus-induced diseases—many of the symptoms appear to be caused by the host response, rather than by direct virus-mediated tissue damage.[516,517] In contrast to HRV, EV-D68 infection induces pronounced cytotoxicity in primary airway cells.[130]

Spread in the Host

Following replication in the GI tract, PV enters the blood, thereby potentially gaining access to all tissues. However, in most hosts, viral replication is highly restricted, being readily detected mainly in the CNS.[50] PV can enter the CNS in two ways. First, PV can access from the blood, where it cross the blood–brain barrier (BBB), perhaps independently of CD155.[534] Second, the virus (apparently in the form of an intact virion) can traffic by retrograde axonal transport, ascending the neuronal axon, perhaps in endosomes, with uncoating beginning once the virus reaches the cell body.[394], [395], [396] This may underpin provocation poliomyelitis, a phenomenon in which a traumatized limb is more susceptible to paralytic polio. The trauma may be directly associated with the virus, as reported in 1935, when it was noted that paralysis first appeared in (or was most severe in) the limb that had received an intramuscular inoculation of “pre-Salk” polio vaccine.[299] Such inoculation poliomyelitis also was observed in the “Cutter incident,” when an incompletely inactivated Salk vaccine was administered.[362] However, provocation poliomyelitis does not require that trauma and virus be

administered to the same limb; when PV was administered intravascularly to monkeys that had received innocuous injections into one limb, paralysis was more likely to develop in the injected muscles.[49] Provocation poliomyelitis also has been reproduced in a mouse model.[174] Mechanisms other than retrograde axonal transport may also contribute to this phenomenon. For example, the peripheral trauma may increase vascular permeability locally, in the region that innervates the injured muscle; this could explain why provocation poliomyelitis still occurs in traumatized limbs despite scission of the ipsilateral peroneal muscle.[361] In contrast, dissemination of CVB and other enteroviruses appears to occur largely by the hematogenous route given that viremia is frequently found.

Cell and Tissue Tropism

EVs exhibit broad cell and tissue tropism (Fig. 3.3). It has been proposed that the observed *in vivo* tropism of PV for the CNS may result from differing efficiencies of viral internal ribosome entry site (IRES) utilization by various host cell types. However, this explanation appears to be incorrect; the PV IRES is equally functional in many cell types *in vivo*, including those that do not support virus replication *in vivo*.[259] A key driver of PV tropism likely lies in the ability of a given cell type to induce antiviral signaling and respond to these signals. For example, CD155-transgenic mice lacking type I IFN signaling due to the deletion of IFNAR developed severe lesions not only in the CNS but also in the liver, spleen, and pancreas.[234] Thus, the absence of PV-induced damage and disease in immunocompetent mice expressing CD155 supports a model whereby type I IFN signaling directly limits PV neurotropism.

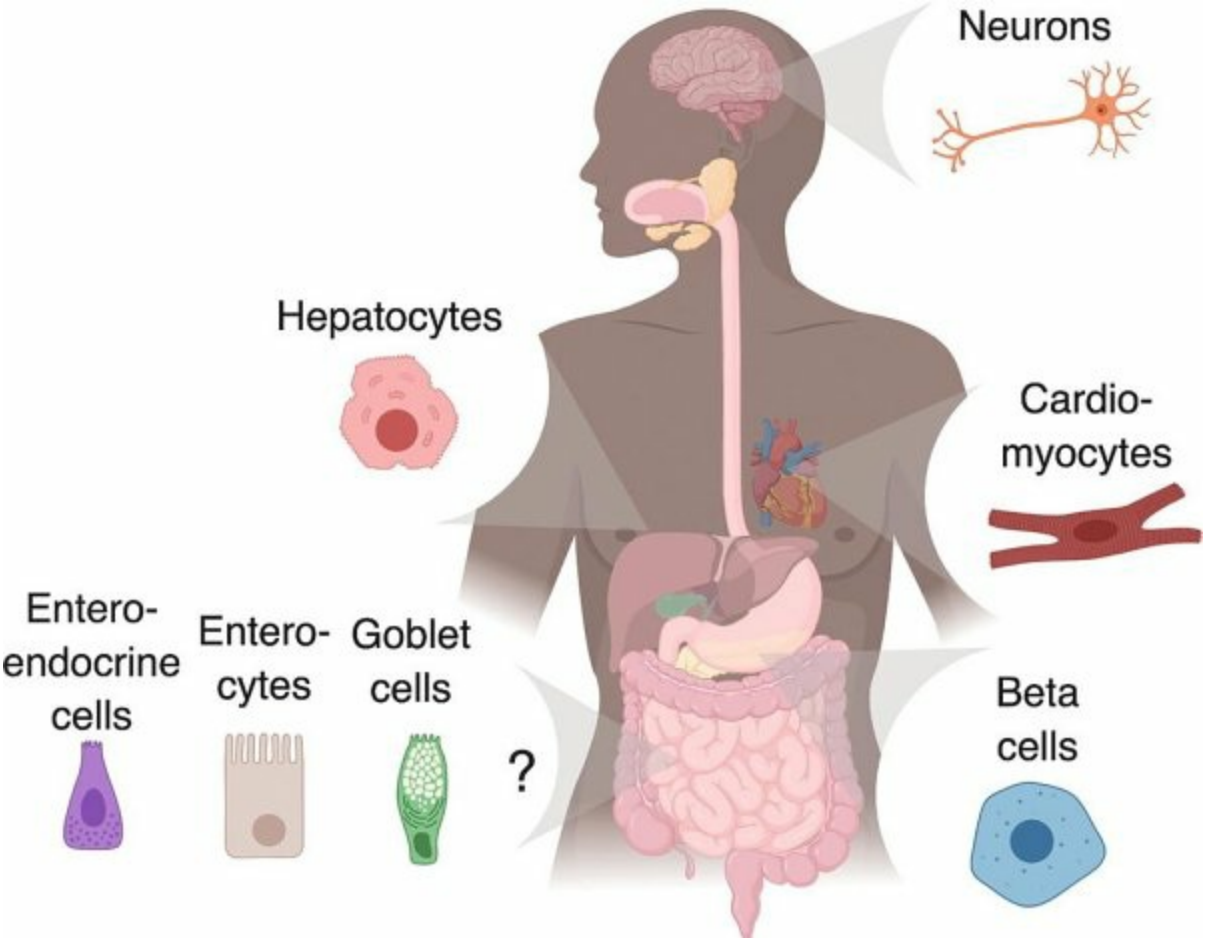

FIGURE 3.3 EVs exhibit broad cell and tissue tropism. The neuronal complications associated with EV infections can include direct infection of neurons. In the heart and pancreas, viruses like CVB replicate specifically in cardiomyocytes and *β*-cells, respectively. The cellular tropism at other tissue sites is less clear, but some evidence suggests specific cell types (including enterocytes, goblet cells, and enteroendocrine cell) could be targeted by EVs in the gastrointestinal tract. Other common tissues include the liver, with evidence that some EVs may preferentially replicate in hepatocytes, although the specific cell tropism remains unclear.

CVB3 can cause pancreatitis, myocarditis, and meningoencephalitis. Enteroviruses, and especially CVB, have been implicated in up to one-third

of human pancreatitis cases.[24,399,493] In the mouse model, the pancreas appears to be a major site of CVB3 replication.[340,341] CVB4 also causes pancreatitis,[415,416,496] the severity of which depends on the virus isolate that is used; a single amino acid change in VP1 appears to be largely responsible for switching the phenotype from mild pancreatitis to a more severe form.[64,178] In mice, CVB has been found in acinar cells, but not in the islets of Langerhans[434,498,501] by immunohistochemistry[25,496] and by *in situ* hybridization.[25,498,501] Expression of the CVB primary receptor CAR correlates with the observed pathology—the receptor mRNA is expressed at very high levels in acinar cells, but not in the pancreatic ducts or the islets of Langerhans,[250] consistent with the observation that CVB-infected mice do not develop hyperglycemia.[341,418] Deletion of CAR specifically from the pancreas in mice confers substantial, albeit incomplete, protection against organ damage during CVB3 infection,[250] suggesting that CAR expression is an important determinant of CVB-associated pancreatic dysfunction. In addition to receptor expression, the potency of antiviral signaling in pancreatic cell types may also explain the cellular tropism of CVBs in the pancreas. For example, α cells induce more potent antiviral signaling than do β cells in response to CVB infection, which might explain their ability to resist infection and evade autoimmune responses during infection.[329]

CVB has long been considered one of the principal causes of viral myocarditis[100] and this view has been confirmed in several reports.[19,129,324,326,328] CAR is expressed at high levels in cardiomyocytes,[375] where it is involved in heart development and cardiac function in mice.[26,82,120,314] Notably, CAR is expressed at high levels in neonatal rat cardiomyocytes but is expressed at low levels in adult rat cardiomyocytes.[257] This spatiotemporal expression has been speculated to explain the enhanced susceptibility of neonates to CVB-induced cardiac complications. *In vivo*, CAR expression on cardiomyocytes is required for CVB-induced myocarditis as mice lacking CAR specifically in these cells are protected from cardiac infection and disease.[250]

Several mechanisms have been proposed to explain CVB-mediated cardiomyocyte destruction. The first is direct virus-mediated damage. Human cardiomyocytes can be infected *in vitro*,[189,253] and infected cells are rapidly lysed.[195] These *in vitro* findings are corroborated by *in vivo* ultrastructural

studies of myocardial tissue, which show clear evidence of virus infection of cardiac muscle cells and cell death in mice.[161,200,278] The second is immunopathological damage. The inflammatory infiltrate contains $CD8^+$ T cells, natural killer cells, and macrophages,[81,159,193,452] and other studies have implicated $\gamma\delta$ T cells in CVB pathogenesis.[215,216,220,221] Finally, studies have implicated autoimmunity in CVB-triggered myocarditis.[215,364,432,433] One potential means by which this could occur is *via* molecular mimicry, that is, immunological cross-reactivity between viral and heart proteins, and there is evidence that this occurs at both the antibody[151,152] and T-cell[214,215,219] levels. Virus replication in the heart is a prerequisite for myocardial destruction, and this is difficult to reconcile with molecular mimicry; these data do not, of course, exclude a role for autoimmunity induced by other means, for example, by virus-driven exposure of sequestered cardiac antigens or to genetic factors that might predispose individuals to cardiac complications.

Although a rare polymorphism in the dsRNA sensor toll-like receptor 3 (TLR3) was identified in a patient who developed CVB-associated myocarditis,[164] and mice lacking TLR3 or are deficient in type I IFN signaling are more susceptible to CVB-induced cardiac dysfunction,[116,363] genetic variants in TLR3 or other IFN-associated factors are not commonly found in patients with viral-associated myocarditis.[36] Instead, many of these patients have homozygous variants in genes associated with inherited cardiomyopathies, suggesting that a genetic predisposition to cardiac dysfunction may sensitize individuals to CVB-induced myocarditis.

Most EVs are neurotropic and are associated with severe neurological outcomes including aseptic meningitis and acute flaccid myelitis. However, the specific factors that drive this tropism remain largely unclear. The receptors for many neurotropic EVs are expressed on diverse cell types within the CNS, suggesting that receptor expression is likely to play a role. In some cases, EV receptors are uniquely expressed in the CNS, such as ICAM5, which is a primary receptor for EV-D68[510] and is expressed almost exclusively in the CNS.[542] Given that expression of the human homologs of many EV receptors is sufficient to promote CNS infection and disease in mice,[150,223] neuronal tropism is likely influenced largely by receptor expression and/or localization. However, other factors, such as the degree of

viremia, host immune response, etc., also likely play important roles in this tropism given that neuronal complications are not observed in every infection.

The liver is also a primary site of EV-associated disease, with hepatitis and acute liver failure observed in infected infants and children. Hepatocytes are highly permissive to CVB infection when type I IFN signaling is inhibited or ablated *in vivo* or in human primary cells.[281] Like cardiomyocytes, this hepatic tropism has also been attributed to age-related changes in CAR expression, with hepatocytes from neonatal animals exhibiting higher levels of CAR expression and enhanced sensitivity to infection.[316] Echoviruses, in particular, are commonly associated with liver disease in infected neonates.[44] The mediators for the hepatic tropism of echoviruses are unclear, particularly given that few *in vivo* models exist to study this aspect of infection, but recent work in neonatal mice expressing the echovirus receptor FcRn recapitulates echovirus 11 infection in the liver.[354] In adult mice lacking IFN signaling, echoviruses replicate to high levels in the liver and induce apoptotic cell death (Fig. 3.4).

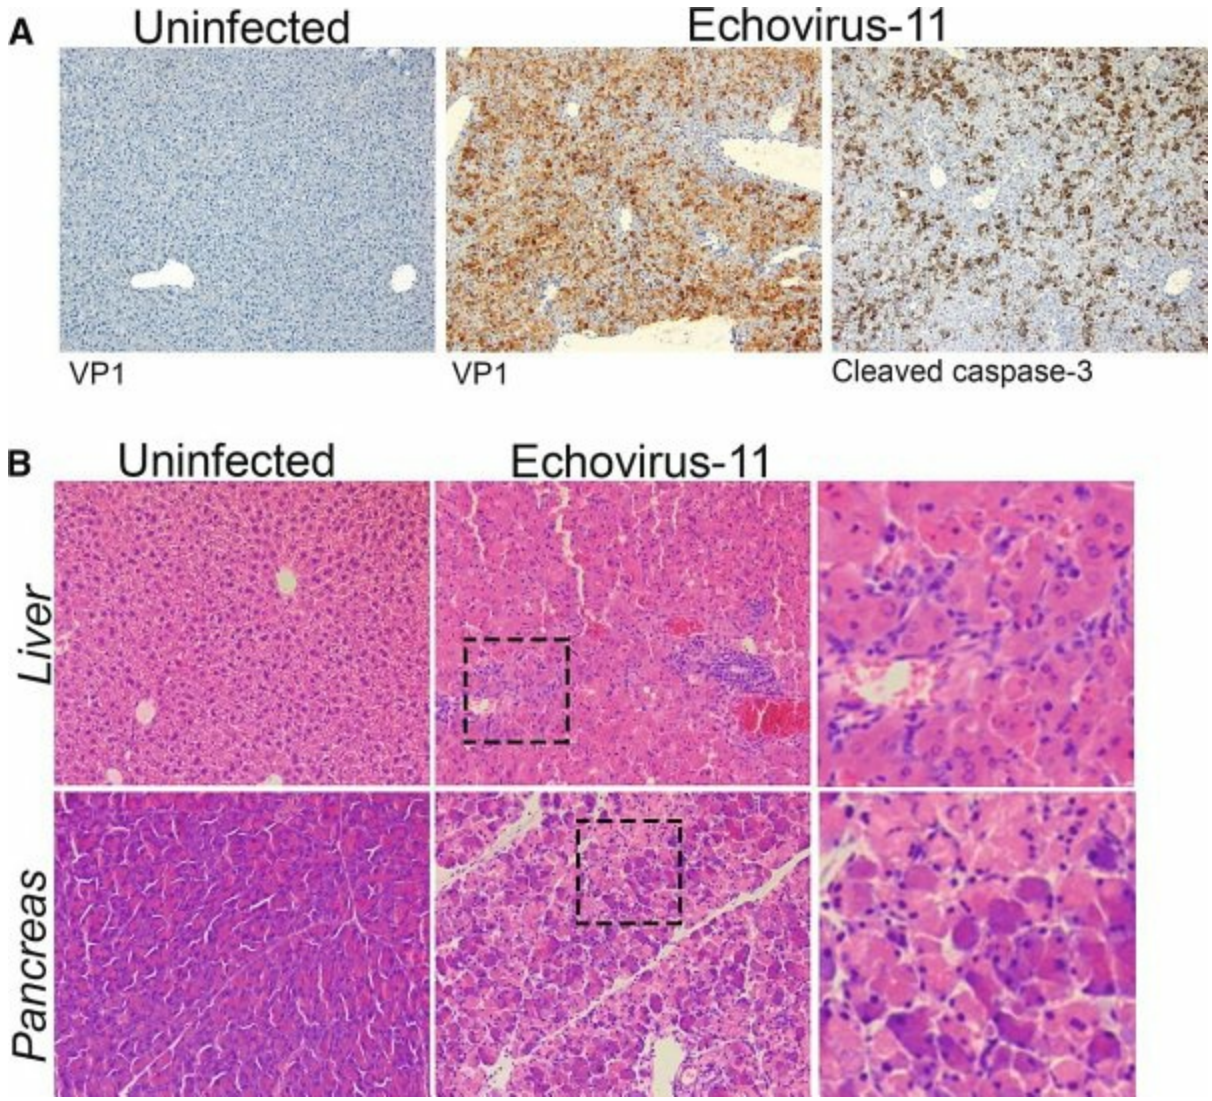

FIGURE 3.4 In adult mice lacking IFN signaling, echoviruses replicate to high levels in the liver and induce apoptotic cell death, as evidenced by immunohistochemistry for VP1 and cleaved caspase-3 in these animals **(A)**. Echoviruses also replicate to high levels in the pancreas of these animals and induce damage to acinar cells **(B)**.

Immune Response

Innate Immunity

The innate immune response plays a central role in regulating virus infection, as illustrated above by the important role that this pathway plays in regulating EV tissue tropism and pathogenesis in animal models. RNA viruses may trigger one (or more) of at least three pattern recognition receptors (PRRs): TLRs, RIG-I–like receptors (RLRs), and NOD-like receptors (NLRs, some of which assemble into larger structures termed inflammasomes). The interactions between enteroviruses and PRRs have been extensively studied with TLRs and RLRs, with fewer studies focused on enteroviruses and NLRs. The detection of "nonself" pathogen-associated molecular patterns (PAMPs) triggers the PRR-mediated expression of hundreds of genes, including a variety of cytokines, chemokines, and other proteins, some of which can directly counter virus infection (e.g., *p*rotein *k*inase regulated by *R*NA [PKR, discussed below] and IFNs), while others may regulate the development of the adaptive antiviral immune response. The roles of cell-surface and endosomal TLRs during EV infections have been evaluated in several *in vitro* and *in vivo* models (Fig. 3.5). Despite being considered primarily a bacterial sensor, given that it binds to lipopolysaccharide, TLR4 on human pancreatic cells is triggered by CVB4.[486] However, TLR4KO mice infected with CVB3 show reduced virus titers and myocarditis,[134] which suggests that TLR4 does not play a protective role in CVB3 infections of the heart, but its signaling exacerbates disease. A comparison of male and female mice confirmed that TLR4 signaling was correlated with the severity of myocarditis.[146] However, the administration of TLR4 stimulants such as LPS greatly increased the severity of CVB-induced myocarditis, suggesting that CVB-mediated triggering of TLR4 *in vivo* is likely to be submaximal.[298,423] The endosomal TLRs, TLR3, TLR7, and TLR8, have been implicated in the detection of CVB infection, and mice expressing a loss of function mutation in Unc93b, the ER-localized molecule required for the trafficking of these TLRs to the endosome, are more permissive to CVB3-induced tissue damage and infection.[295] TLR3 senses dsRNA molecules that are commonly produced during EV replication.[14] One study of CVB4 infection of TLR3-deficient mice suggested that TLR3 was almost indispensable for the innate response to this virus,[424] and, when compared to wild-type mice, TLR3KO mice showed increased mortality and developed more severe myocarditis following CVB3 infection.[363,511] Genomic screening of patients diagnosed with enteroviral myocarditis or dilated cardiomyopathy (DCM) revealed two

TLR3 sequence variants, both of which showed reduced responsiveness to ligand,[149] suggesting that a strong TLR3-triggered response may protect against enteroviral myocarditis. In addition, a rare polymorphism in TLR3 was identified in a patient who developed CVB-associated myocarditis.[164] However, another study reported that genetic variants in TLR3 are not commonly found in patients with viral-associated myocarditis,[36] who were instead homozygous for variants in genes associated with inherited cardiomyopathies, suggesting that a genetic predisposition to cardiac dysfunction may sensitize individuals to CVB-induced myocarditis. Other endosomal TLRs also can contribute to the control of CVB infections. For example, human cardiac inflammatory responses to CVB are reported to be dependent largely on TLR7 and TLR8,[487] both of which recognize ssRNA and other small molecules.[188] Contrary to the reported beneficial effects of a strong TLR3 response to enteroviruses, a strong TLR8 response may be associated with adverse outcomes in patients with EV-associated DCM.[445] In addition to canonical antiviral signaling, autophagy is also up-regulated by TLRs, and the most potent proautophagic effects are mediated by ssRNA/TLR7 signaling.[110] Autophagy functions in the clearance of damaged organelles to maintain normal homeostasis but can function in an antiviral capacity in some settings by delivering viral particles to the lysosomes, which are subsequently destroyed by cellular proteases. However, autophagy appears to function in a proviral manner during most EV infections. Early electron microscopy (EM) studies of PV-infected cells revealed an association between PV and double-membraned intracellular vesicles,[107] subsequently shown to be autophagy related.[449] Extensive membrane remodeling occurs in a PV-infected cell, mediated by the viral 2BC and 3A proteins,[468] and the resulting vesicles carry several autophagosome-related proteins.[478,479] A similar relationship between CVB and autophagic vesicles has been reported,[167] and there is a marked increase in double-membraned structures within CVB-infected cells, both in tissue culture[520,540] and *in vivo*.[263] *In vitro*, the proviral effects of autophagy on EV replication are relatively modest with PV,[238] CVB3,[520] CVB4,[540] or EV71,[213] with inhibition of this pathway reducing production of each of these viruses by approximately 1.5- to 4-fold. *In vivo*, the proviral impact of autophagy is striking, and mice with targeted deficiency in the required autophagy factor Atg5 in pancreatic acinar cells exhibit approximately 2,000-fold lower CVB3

titers in the pancreas, with corresponding reductions in pancreatic inflammation and damage.[16] In addition to replication, autophagy has also been proposed to facilitate the nonlytic release of enteroviruses.[45] However, given that this has only been evaluated using *in vitro* cell culture models, the relevance of this *in vivo* is unclear.

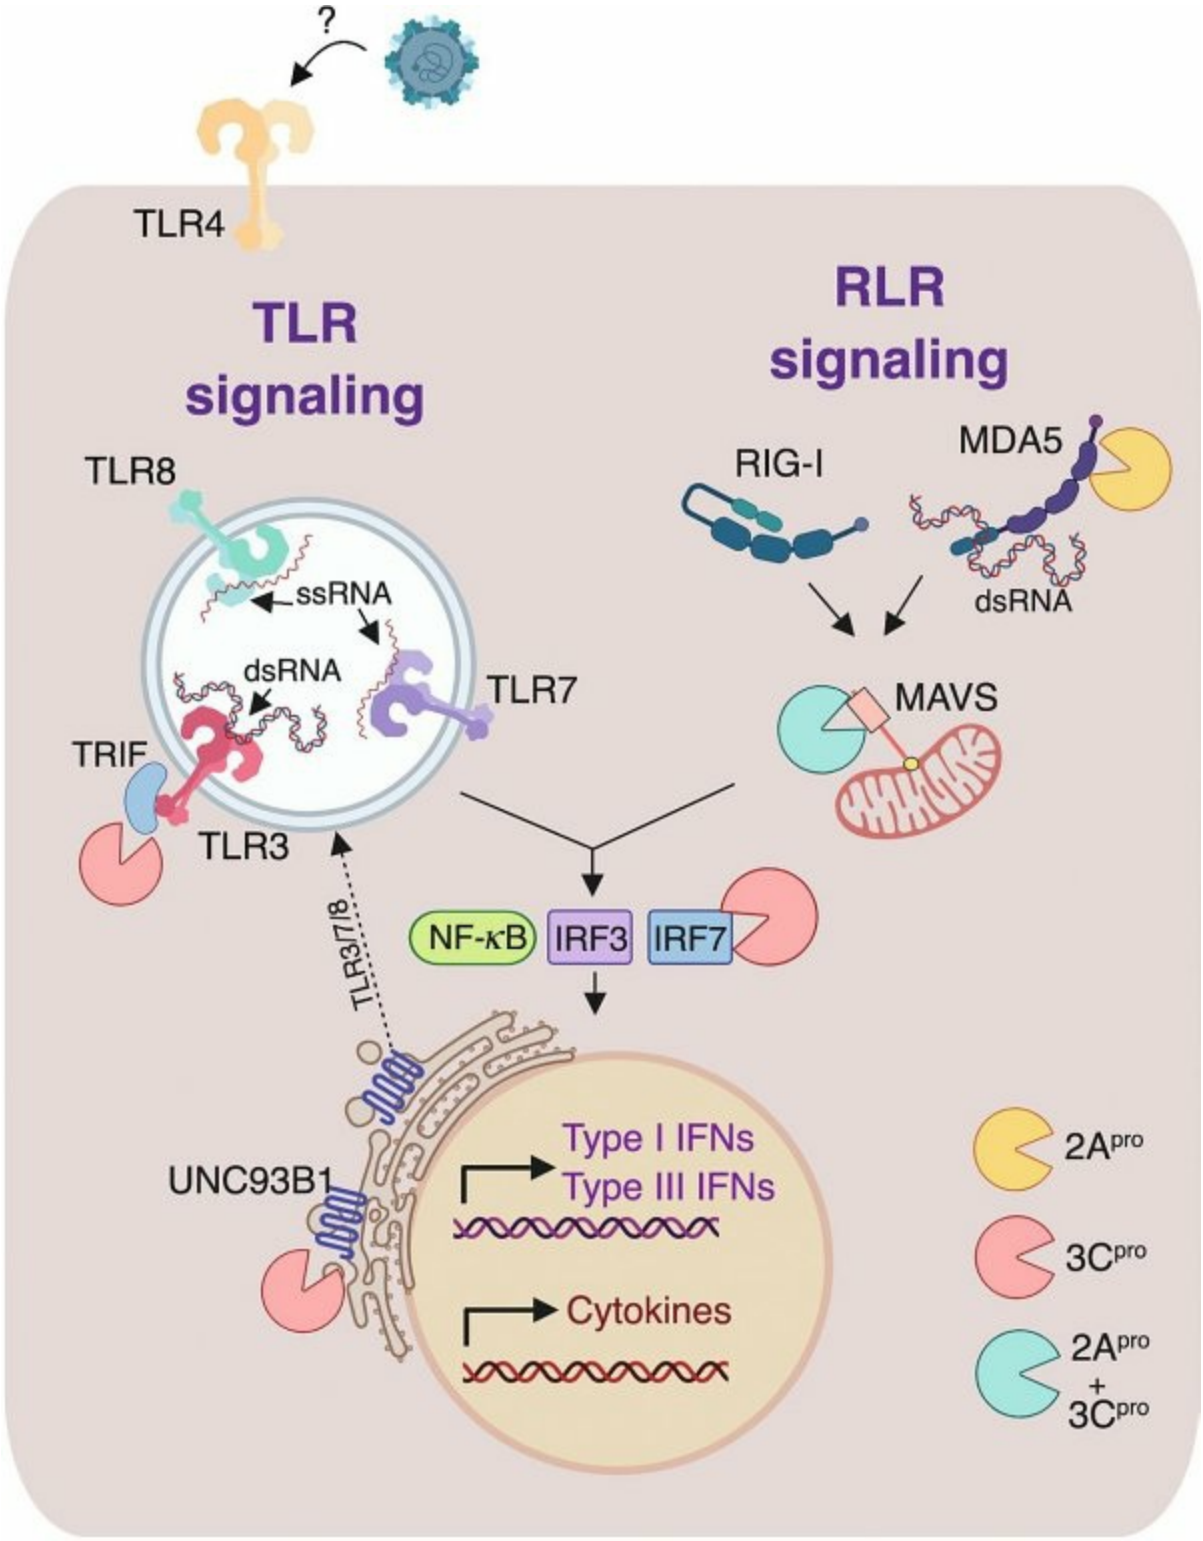

FIGURE 3.5 EV innate immune sensing and antagonism. EVs rely on their virally encoded $2A^{pro}$ and $3C^{pro}$ proteases to cleave essential components of the host innate immune response. These

include key pattern recognition receptors (PRRs) such as MDA5, essential components for PRR trafficking and function such as UNC93B1, and essential adaptors for downstream signaling including TRIF, MAVS, and IRF7.

Three RLRs have been identified: RIG-I, MDA5, and LGP2 (retinoic acid–inducible gene I, melanoma differentiation–associated gene 5, and laboratory of genetics and physiology 2, respectively). Unlike TLRs, these proteins are expressed in most cell types. All are activated by nucleic acids and are primarily cytosolic. Although RIG-I and MDA5 both detect dsRNA, they differ in their interactions with specific moieties on this RNA. Whereas the C-terminal domain of RIG-I binds to 5′-triphosphate or 5′-diphosphate groups,[166,207,407] MDA5 RNA recognition relies on RNA length and secondary structure, with long dsRNA serving as a primary determinant.[527] Once activated, both RIG-I and MDA5 signal to a shared downstream adaptor localized to the mitochondrial membrane, mitochondrial antiviral-signaling protein (MAVS). Many RNA viruses produce abundant dsRNA and ssRNA with 5′-ppp and, therefore, strongly activate RIG-I. In the absence of RIG-I, the innate response to several RNA virus families is abrogated.[318] The 5′ terminus of an enteroviral RNA lacks the 5′-triphosphate moiety, instead bearing a modified protein (VPg), and, for this reason, these viruses do not stimulate RIG-I. Infected cells appear to rely largely on MDA5 to alert them to the presence of picornaviral RNA. This sensor is activated by the cardiovirus EMCV,[158,258] and two publications using MDA5 knockout mice suggest that enteroviruses, too, trigger MDA5 signaling.[225,507]

In addition to PRR-mediated induction of antiviral signaling, several innate immune cell types, which can include dendritic cells, macrophages, and natural killer (NK) cells, also play roles in restricting EV infection. NK cells, which are part of the innate response to many viral infections, are important in protecting against CVB-induced pancreatitis in the mouse model[497] and have been implicated in age-related susceptibly to EV71 infection in neonatal versus adult mice.[553] The importance of NK cells in combating human enteroviral infections is unknown, but human NK cells can produce IFNγ in response to CVB-infected cells.[224] Many cells—exemplified by macrophages and dendritic cells—are phagocytic and engulf dead or

dying cells. Thus, although human DCs cannot be productively infected by CVB,[290] these cells can consume debris from CVB-infected cells, thereby potentially introducing viral materials to the cytosolic and intravesicular sensors, potentially inducing an antiviral state in the DCs.[291]

Effectors of the Innate Immune Response

As discussed above, the key role of type I IFNs in the control of enteroviral infections is supported by extensive *in vivo* data demonstrating that ablation of this pathway greatly enhances EV replication and influences tissue tropism and spread. In addition to type I IFNs (which include 13 IFN-α subtypes and a single IFN-β subtype), it is likely that other IFNs, most notably type III IFNs, are also important in the control of enteroviruses. Type III IFNs include IFN-λ1, IFN-λ2, and IFN-λ3 (also known as interleukin IL-29, IL-28A, and IL-28B[50,60]). Although a fourth type III IFN, IFN-λ4, exists, it is nonfunctional in a large subset of the world's human population due to a single nucleotide polymorphism (SNP) that causes a frameshift in the gene.[51,128] IFN-λs have emerged as key antiviral effectors that are preferentially induced in and detected by "barrier" cell types, including those of the gastrointestinal and respiratory tracts, the placenta, and the BBB.[512] Unlike the ubiquitous expression of the receptor for type I IFNs (IFNAR), the receptor for type III IFNs is largely restricted to cells at mucosal and other barrier surfaces.[201] The tropism of enteroviruses for barrier surfaces suggests that IFN-λs will likely influence important aspects of their pathogenesis. In support of this, recent studies in primary human stem cell–derived intestinal cells show that IFN-λs, but not IFN-β, are preferentially induced by EV71 and echovirus 11 infection and that inhibition of this pathway enhances viral replication.[163] In addition, CVB-infected primary hepatocytes induce type III IFNs, which confer a protective state.[312]

Once produced, type I and III IFNs induce hundreds of antiviral effectors called interferon-stimulated genes (ISGs) following receptor engagement. These effectors are directly antiviral, are often cytotoxic, and function to restrict viral replication. Several ISGs directly target enteroviruses by nonredundant mechanisms. High-throughput screening of hundreds of known ISGs identified many that restrict CVB infection.[450] The complete spectrum of ISGs that restrict EV replication, particularly *in vivo* and in relevant cell

types, remains to be elucidated.

Antagonism of the Innate Immune Response

Perhaps not surprisingly given their prevalence, enteroviruses are adept at attenuating antiviral signaling pathways to promote their replication (Fig. 3.5). They accomplish this antagonism through a number of mechanisms, most commonly utilizing the encoded proteases 2A and 3C to alter the ability of PRRs to sense them and/or activate signals downstream of this sensing. MDA5 and RIG-I are degraded in EV-infected cells *in vitro*, most commonly studied in HeLa cells, which interferes with the ability of these sensors to bind viral RNA.[33,136,439] Enteroviruses also target MAVS, the adaptor for both RIG-I and MDA5, further disabling this pathway.[136,358,508] Similarly, enteroviruses also attenuate TLR-mediated signaling by directed proteolysis of TLRs themselves or by targeting downstream adaptors, such as the TLR3 adaptor TRIF.[301,358,529] Accordingly, many cell culture models induce very little to no IFNs when infected with enteroviruses. However, the observation that EV replication is markedly enhanced in animal models lacking components of the innate immune sensing pathways and that primary cell–based models induce IFNs in response to infection suggests that this antagonism may be less efficient *in vivo*.

Adaptive immunity

Antibodies and $CD8^+$ T cells together provide a strong antigen-specific barrier against virus infections. Under normal circumstances, these two arms of the adaptive response complement each other. However, members of the EV species appear to be an exception to this general rule. Patients with X-linked agammaglobulinemia are highly susceptible to enteroviral infections,[347] and, after receiving live PV vaccine, such individuals may continue to shed virulent PV for up to approximately 20 years.[268,330] The near-absolute requirement for antibodies in protecting against enteroviruses has been confirmed in an animal model of CVB3 infection, using B-cell knockout (BcKO) mice; these mice cannot eradicate the virus, and high titers are present in many organs.[340] The above observations suggest that, for agammaglobulinemic hosts infected with an EV, there may be some deficit in the backup system that, for most viruses, is provided by $CD8^+$ T-cell

responses. This may, in part, explain why most studies of enteroviral infections, in mouse and in humans, have identified strong antibody responses, while $CD8^+$ T-cell responses—so easily detected in most virus infections—are weak (if detected at all). The *Enterovirus* genus is large, and the adaptive responses to only a select few enteroviral species will be discussed below.

Human enterovirus A

The best-studied pathogen in this species is enterovirus 71 (EV71). The virus triggers an IgM response that is detectable as early as 2 days postinfection,[488] as well as a strong neutralizing IgG response that recognizes epitopes in the N-terminal segment of VP1.[473] Neutralizing antibodies, when transferred to uninfected neonatal recipient mice, are able to protect against a lethal challenge infection.[546] Studies of knockout mice showed that B cells, in particular, were important for survival following EV71 infection and B-cell–deficient mice treated with virus-specific antibody either before or during EV71 infection had lower virus titers, less severe disease, and lower mortality.[310] Memory Th1 $CD4^+$ T-cell responses specific for three epitopes in VP1 have been identified in $EV71^+$ individuals,[143] but no $CD8^+$ T-cell epitopes have been reported.

Human enterovirus B

CVBs are the best-studied pathogens in this species and, as described above, can trigger severe acute and chronic diseases including myocarditis, DCM, pancreatitis, and aseptic meningitis. Infection by these viruses triggers a rapid and strong neutralizing antibody response. Virus-specific IgM appears during the first week of infection, followed by a strong neutralizing IgG response. The CVB3-specific IgM titer wanes over time, but IgG antibodies persist.[317] Work in T-cell–deficient (nude) mice indicates that at least some of the CVB-specific antibody response is T-cell independent,[187,444,522] although some studies suggest that $CD4^+$ T cells may be important for the induction of strong neutralizing antibody responses.[302] B cells appear to be targeted by CVB[340] and may provide a reservoir for the virus during persistent CVB infection. Viral RNA^+ cells, probably B cells, can be found in the splenic follicles and germinal centers[17,240,254,279,340]; approximately 1% of B cells

are infected with CVB3 *in vivo*, and these cells may accelerate the systemic distribution of virus.[340] T cells can help control CVB infection, although much less effectively than antibodies. *In vivo* analysis of CVB-specific T cells has been challenging because these viruses, despite replicating to high titers in mice, induce remarkably weak $CD8^+$ T-cell responses.[262,462] Nevertheless, some responses can be identified, exemplified by $CD4^+$ T-cell responses against epitopes expressed by CVB4.[177,179] $CD8^+$ T-cell responses are particularly meager. Epitopes in several viral proteins have been identified in human studies, but their detection required approximately 2 weeks of *in vitro* peptide antigen restimulation.[511]

Human enterovirus C

This species contains a number of coxsackie A viruses, but the most studied pathogen is PV, which induces a strong neutralizing antibody response that is necessary to control the infection. Virus infection and vaccination induce strong and long-lasting humoral responses,[97] but the immunity is not sterilizing and secondary infections of the gut can occur. Susceptibility to such reinfections, and subsequent shedding of PV, may be controlled by IgA.[59] PV-driven T-cell proliferation has been observed in infant vaccinees, and the responses appear to be cross-reactive across different enteroviruses.[248] However, PV-specific T-cell responses in OPV-vaccinated infants may be weaker than those in adults.[495] OPV induces MHC class II–restricted memory $CD4^+$ T-cell response targeted to epitopes in all four capsid proteins.[461] $CD8^+$ T-cell responses to PV vaccination are long-lived but—as is true for most CVB-specific responses—they became detectable only after several rounds of *in vitro* restimulation, suggesting that T-cell numbers *in vivo* were low.[504] Mice are not naturally infected by PV, but PVR-Tg animals have allowed the analysis of T- and B-cell responses and their roles in antiviral protection. Adoptive transfer of PV-primed B cells together with a VP4-specific $CD4^+$ T-cell clone protected PVR-Tg mice against a lethal challenge of PV, but neither cell population alone was protective, indicating that the virus-specific B cells required T-cell help.[327]

Release from Host

Virion assembly and RNA packaging of enteroviruses remain very poorly

understood. In most cell culture systems, enteroviruses are highly lytic and induce pronounced cell death signaling through both apoptotic and nonapoptotic pathways such as necrosis. The lytic nature of enteroviruses accompanies infection on both cell lines, in which cell blebbing and lysis can be observed within several hours of infection, and in primary cells. *In vivo*, enteroviruses induce profound cellular damage and the generation of cleaved caspase-3, a marker of apoptosis. Although enteroviruses are generally considered to be highly lytic—and, therefore, released from cells upon their lysis—early evidence from cell culture studies was consistent with PV release by nonlytic means.[403,490] It has been proposed that autophagy-mediated release of enteroviruses may occur, permitting the virus to exit a cell in a noncytolytic manner[238]; this proposed mechanism has been termed AWOL (*a*utophagy-mediated exit *w*ith*o*ut *l*ysis).[480] The release of enteroviruses into extracellular vesicles has now been documented for several enteroviruses including PV, CVB, and EV71.[45,84,482] Extracellular vesicles include microvesicles (100 nm to 1 μm in size), apoptotic blebs or bodies (50 nm to 5 μm in size), and exosomes (30–100 nm in size). These vesicles can be distinguished based upon size, cargo composition, and their intracellular site of origin. In cultured cells, enteroviruses have been detected both in large vesicles and in smaller exosomes. Some studies have even suggested that progeny virions are released in very large vesicles that can contain up to dozens of viral particles.[443] This method of egress would not only shield released particles from possible neutralizing antibodies but would also dampen signals that might induce inflammation, such as through the release of danger-associated molecular patterns (DAMPs) from lysed cells. It remains unclear whether the nonlytic release of enteroviruses occurs *in vivo* or plays any role in pathogenesis as all of the studies to date have been performed in cell culture systems.

Virulence

Viral virulence is a complex interplay between virus and host, and some of the contributing elements, such as receptor distribution and host responses, have been discussed above. Here, we shall focus on selected enteroviral sequences and proteins and their contributions to a virulent phenotype. Wild-type PV is more neurovirulent than the attenuated viruses that constitute the oral vaccine, and studies have identified, in all three PV serotypes, changes in

the 5′ noncoding region that can alter neurovirulence. For example, sequence comparison between the attenuated Sabin 3 virus and revertants from cases of vaccine-associated poliomyelitis showed that a single U-C change in the viral IRES, at position 472, conferred a growth advantage in the human intestine and resulted in increased neurovirulence although, on its own, the change was insufficient to confer full neurovirulence[133]; a second change, leading to an amino acid substitution in VP3, almost completely restored virulence.[513] Mutations in the IRES of PV types 1 and 2 also modulate the neurovirulent phenotype.[260,322,323] The *in vivo* neuroattenuating phenotype imposed by changes in the IRES, together with tissue culture studies showing apparent cell-specific effects of the IRES mutations,[181] led to the proposal that neuroattenuation might be explained by a neuron-specific reduction in usage of the mutated IRES. However, *in vivo* analyses have demonstrated that, while the Sabin 3 IRES sequence is indeed less effectively utilized in neurons, this defect also is observed in other cells and tissues.[260] Thus, another explanation was sought; the importance of type I IFNs in modulating PV neurovirulence *in vivo* has been described above. Cardiovirulence in CVB3 also has been mapped to various locations in the 5′ NTR, approximately 80 to 240 bases from the 5′ end of the genome,[78,127,489] although the capsid region, too, plays a part.[484] In contrast to the extensive mapping of the limits of, and functional domains within, the PV IRES, analysis of the CVB IRES has been limited.

Persistence

Although both PV and CVB are rapidly cytolytic in many of the cell types that they infect, both viruses can establish persistent or chronic infection in some tissue culture systems.[96,148,332,404] In neuroblastoma cells, PV persistence is associated with accrual of mutations in the capsid region,[403] and, for both PV and CVB, moving from cytolytic to persistent phenotype in cell culture may be inversely related to the capacity of the virus to adsorb to the receptor and/or to the level of receptor expression.[66,272,294] It has been reported that, during persistent infection of cultured cells that express low levels of CAR, CVB accumulated changes in the capsid that allow the variant virus to bind to novel (non-DAF, non-CAR) molecules, and this more promiscuous activity conferred a replicative advantage upon the variant.[67]

Cellular factors contribute to the establishment of PV persistence.[157] Cell cycle status may play a role in the case of CVB that does not replicate efficiently in tissue culture cells rendered quiescent by drugs or by serum starvation but undergoes productive and cytolytic replication when the cell cycle is triggered.[137,139]

Enteroviral persistent infections can take place under two general scenarios. *First*, a chronic productive EV infection can occur in immunocompromised hosts. As noted above, agammaglobulinemic individuals who received OPV may retain, and excrete, the virus for many years. One study of individuals with primary immunodeficiency who had developed vaccine-associated paralytic poliomyelitis found that approximately 1 in 5 secreted vaccine-derived PV at 6 months after their last OPV dose, but this frequency declined to 0% when the interval was 10 years.[272] The low prevalence of the underlying condition means that such persons are rare; only approximately 40 such individuals have been identified.[525] Fortunately, a more common potential cause of immunosuppression, HIV infection, seems not to correlate with PV persistence/shedding.[27,194] *Second*, immunocompetent hosts may carry virus (or, at least, viral RNA) for many years. Given the frequency of enteroviral infections, it is reasonable to suppose that this is the more common of the two types of EV persistence. In the vast majority of cases in which "enteroviral persistence *in vivo*" has been reported in immunocompetent hosts, infectious virus was not identified; rather, viral materials (most commonly, RNA) were reported and infectious particles, if sought, were not found. CVB RNA has frequently been detected by PCR in many analyses of cardiac biopsies from individuals with DCM[22,23,56,283] or inflammatory peripheral myopathy.[25] From results obtained in a murine model of polymyositis, the authors concluded that the RNA was maintained in double-stranded form, with little indication of virus mutation/evolution.[472] However, analyses of CVB3 genomes isolated from the hearts of persistently infected mice suggest that CVB persistence *in vivo* may be dependent upon the deletion of nucleotides at the 5′ end of the genome.[276] Several deletions were reported, some extending to nucleotide 49 and all affecting the 5′ cloverleaf structure that is considered vital for RNA replication. Importantly, the materials were infectious; although replicating very slowly, they could be maintained in culture and do not require a helper virus. The VPg protein was present on

several of the deletion mutant genomes, and, notably, approximately 25% of RNA encapsidated into virions was negative sense. The authors proposed that the encapsidation of negative strands might occur because the terminal deletions, by altering RNA replication, markedly reduced the ratio of positive to negative strands. Similar 5′-terminal deletion variants subsequently were identified in CVB3 that had been passed in primary tissue culture cells[59] and, critically, in a CVB2 genome isolated from the heart of a human who had succumbed to enteroviral myocarditis.[79] The poor infectivity of these mutated viruses may explain why infectious virus was not identified in the vast majority of previous studies in which EV RNA was found. To date, there is no evidence to suggest that these terminally deleted variants can be transmitted under normal circumstances.

EPIDEMIOLOGY

Demographics

Despite the nearly ubiquitous nature of EV infections and the wide variety of clinical presentations, the demographics of the various infections and diseases have some consistent characteristics. In particular, several factors, including age, sex and socioeconomic status, have largely predictable effects.

One of the most important determinants of EV infection outcome is age. Different age groups have different susceptibilities to infection, severity of illness, clinical manifestations, and prognoses following EV infection. Understanding these age effects on outcome of infection is complicated by the widely divergent prior history of infection and resulting immunity. Nevertheless, it is possible to make certain generalizations.

The largest amount and duration of virus shedding occur on primary infection with a given EV serotype. Because infection is so common, most primary infections occur during childhood. For these reasons, young children are probably the most important transmitters of EV, particularly within households. The greater exposure of children to virus during infection may make them more likely to have significant clinical symptoms. For example, in outbreaks of meningitis, children typically have higher rates of disease than adults.[167,235] Most studies, however, do not separately determine age-

specific infection rates and disease rates, and the relative rates at which adults are infected are not generally known.

The incidence of poliomyelitis is relatively low for the first 4 to 6 months of life in countries in which control through vaccination has not yet been achieved, because of the frequent presence of protective maternal antibodies. In these countries, an increased incidence is seen of paralytic disease in children older than 6 months compared with children in wealthier developed countries, presumably related to an earlier exposure to virus as a result of poor sanitary conditions. Ironically, areas with improved hygiene may have a decrease in infant exposure, leaving an older (unexposed) population susceptible to epidemic disease, with high rates of paralytic disease during an outbreak.[410] Adults are more likely to be severely affected in both developing and developed countries, tending to acquire paralytic poliomyelitis rather than nonparalytic CNS disease (i.e., aseptic meningitis), abortive illness, or asymptomatic infection.[71,72,208] The reason for the increase in severity later in life is unknown. A possible reason relates to the finding that fast axonal flow, which appears important in the spread of PV within the CNS,[246] increases with age. In addition, it may be that receptor expression or host factors important in replication change with age, as has been speculated to play a role with CVB.

Severity of a number of enteroviral diseases besides poliomyelitis may be strikingly age related. An indirect indication is that a delay in first infection with a number of EV increases risk of more severe disease. For example, exanthema associated with CVA and echoviruses is for the most part milder in children than in adults. On the other hand, some EVs cause more severe disease in newborns than in older children and adults, possibly inducing a fulminant *viral sepsis* with myocarditis, encephalitis, hepatitis, and sometimes death (see *Clinical Features, Neonate and Infant Disease*).[85,239] Outbreaks of hand-foot-and-mouth disease caused by EV-A71 have been associated with a significant CNS complication, fatal brainstem encephalitis, that was restricted largely to young children (see *Clinical Features: Meningitis and Encephalitis*).[286,320] In addition, EV-D68 has been associated with large outbreaks of serious acute respiratory illness (see Clinical Features: *Respiratory Infections*) and with cases of acute flaccid myelitis (see Clinical Features: *Acute Flaccid Myelitis*).

In general, encephalitis and aseptic meningitis caused by EV appear to be

most frequent among those 5 to 14 years of age rather than those older or younger. In a 10-year surveillance summary from the United States,[340] adults tended to be overrepresented among cases of severe disease (paralysis, encephalitis, meningitis, carditis) when compared with the age distribution of the EV-infected population as a whole. In another study, the mean age among patients with CVB meningitis (7.7 years) or pericarditis (9.9 years) was greater than the mean age of patients with CVB gastroenteritis (1.3 years).[117]

EV infections are more prevalent among persons of lower socioeconomic status and those living in urban areas.[180,241] In a study utilizing active surveillance of healthy children for EV infections in West Virginia during 1951–1953, the rate of isolations among children in a lower socioeconomic setting was two- to sevenfold higher than among children in a higher socioeconomic setting.[206] A similar study in Ghana during 1971–1973 further indicated that EV isolations were significantly more frequent among children in areas with poorer sanitation and in urban areas during both rainy and dry seasons.[398]

Paradoxically, poliomyelitis and possibly other EV diseases tend to be *diseases of development*. In the case of poliomyelitis, improvement in a country's hygienic and socioeconomic conditions (before vaccination programs) successfully reduces the incidence of paralysis caused by PV and leads to a transitional period in which there is a delay in age of first infection with a subsequent temporary increase in the paralysis-to-infection ratio. Before the introduction of the PV vaccine in the United States and other developed countries, paralytic poliomyelitis was disproportionately a disease of the middle and upper socioeconomic classes; this disease distribution was a result of infection at an older age, when paralysis was a more frequent complication. Ironically, the delay was a result of improved hygiene. The infant mortality rate, a general indicator of a country's level of health development, may be inversely correlated with the age-specific incidence of poliomyelitis.[337]

EV diseases, and possibly also EV infections, occur more frequently in males than in females,[162,352] although some exceptions have been described.[113] In numerous reports, the male-to-female ratio appears generally to range between about 1.2 and 2.5:1; that is, approximately 55% to 70% of such diseases occur in males. Male predominance tends to be greater for the

more severe diseases (e.g., CNS disease or carditis) than for less severe disease (e.g., pleurodynia, hand-foot-and-mouth disease, respiratory disease, acute hemorrhagic conjunctivitis, rash, or undifferentiated febrile illness).

The apparent predominance of enteroviral infections among males may have both sociologic and biologic explanations. Population-based measurements of infection (e.g., serosurveys), which should be gender neutral, have not consistently demonstrated a higher infection rate for males. Several additional explanations for the male predominance have been proposed on the basis of studies of infections in healthy children[153]: A longer duration of virus excretion occurs in males than in females (leading to increased chance of identifying infected males); a higher virus titer occurs in the feces of males (leading to a similar increase in diagnosis). Another possibility is that, indeed, more frequent infections occur in males because of a greater exposure to the pathogen, perhaps because of differences in the parental treatment and play habits of younger boys, and because of greater activity among older boys. An additional possibility is that males are more likely to develop a serious illness from a given EV infection than females. For example, the reason that human myopericarditis is more common in adolescent and adult males than in females (except in pregnant and postpartum women)[519] could be caused by sex-related endocrine effects leading to differences in disease susceptibility. The skewing of EV-related complications in males has also been observed in animals *in vivo*, where male mice exhibit higher levels of CVB replication in their intestines, which were proposed to be related to sex hormone– and type I IFN-related differences.[428]

Transmission

Enteroviruses can be isolated from both the lower and upper alimentary tracts and can be transmitted by both fecal–oral and respiratory routes. Fecal–oral transmission may predominate in areas with poor sanitary conditions, whereas respiratory transmission may be important in more developed areas.[209] The relative importance of the different modes of transmission probably varies with the particular EV and environmental setting. It is believed that almost all EVs, except possibly EV-D70, can be transmitted by the fecal–oral route; however, it is not known whether most can also be transmitted by the respiratory route. EV70 and CVA24 variant, the agents that cause acute hemorrhagic conjunctivitis, are seldom isolated from the

respiratory tract or stool specimens and are probably primarily spread by direct or indirect contact with eye secretions.[287] Enteroviruses that cause a vesicular exanthema presumably can be spread by direct or indirect contact with vesicular fluid, which contains infectious virus.

It is likely that EVs are transmitted in the same manner as are other viruses causing the common cold—that is, by hand contact with secretions (e.g., on the hand of another person) and autoinoculation to the mouth, nose, or eyes. Direct bloodstream inoculation, usually by laboratory accidents (e.g., needle sticks), can result in EV infection; however, neither blood transfusion nor mosquito or other insect bite appears to be a significant route of transmission. The isolation of EV from flies has led to a suspicion that houseflies (*Musca domestica*) and various filth flies may be vehicles of mechanical transmission.[170,229] No evidence indicates that venereal transmission is important.

Transmission within households has been well studied for both PV and nonpolio EV. Small children generally introduce EV into the family, although young adults make up the majority of index cases in some outbreaks of acute hemorrhagic conjunctivitis.[446] Intrafamily transmission can be rapid and relatively complete, depending on duration of virus excretion, household size, number of siblings, socioeconomic status, immune status of household members, and other risk factors.[180] Transmission has been generally found to be greatest in large families of lower socioeconomic status with a greater number of children 5 to 9 years of age and with no evidence of serologic immunity to the virus type. Not surprisingly, infections in different family members can result in different clinical manifestations.

Observations of household transmission of various EVs have documented that many infected contacts do not become ill and that the extent of secondary transmission varies with different EVs. Household secondary attack rates in susceptible members may be greatest for the agents of acute hemorrhagic conjunctivitis (EV-D70 and CVA24 variant) and for PV and of lesser magnitude for the coxsackieviruses and echoviruses. In some studies, secondary attack rates may be 90% or greater, although they are typically lower. New York Virus Watch data indicate that EV infections were more frequent among children 2 to 9 years of age and that secondary CV infections were more frequent in mothers (78%) than in fathers (47%).[282] In the same study, coxsackieviruses spread to 76% of exposed susceptible persons versus

25% of exposed persons who had detectable antibody to the infecting type; echoviruses infected 43% of those who were susceptible and only one person with antibody. The greater spread of polioviruses and coxsackieviruses may derive from longer periods of virus excretion.

Transmission occurs within the neighborhood and community, particularly where people congregate. In addition, as with many other viruses, EV can be rapidly transmitted within institutions when circumstances permit (e.g., crowding, poor hygiene, or contaminated water). School teams or activity groups and institutionalized ambulatory retarded children or adults may be at special risk.[12] Despite crowding, EV transmission is not usually accelerated to a noticeable degree in institutions where good sanitation is found.

EV transmission has also been observed *in utero* and has led to EVs being classified as members of the "TORCH" family of pathogens. TORCH pathogens include *T*oxoplasma gondii, *O*thers (*Listeria monocytogenes*, parvovirus B19, varicella zoster virus, and enteroviruses), *R*ubella, *C*ytomegalovirus, and *H*erpesvirus. EV infections during early pregnancy have been associated with miscarriage and other pregnancy complications. Adverse pregnancy outcomes have been observed for CVA,[392,545] CVB,[28,34,89,230,288] and echoviruses.[34,242,245,366,477] EVs have been recovered from both placental and fetal specimens in cases of fetal death, and women who experienced miscarriages had higher levels of CVB antibody levels,[40,147] supporting that *in utero* transmission and teratogenicity may occur during the context of a maternal infection. However, given that data on the prevalence of EV infections during pregnancy and the impact of these infections on the fetus are largely unknown, the impact of vertical transmission *in utero* remains to be fully explored or perhaps appreciated.

As a result of widespread but incomplete PV immunization, rare PV-susceptible enclaves have arisen. These usually consist of unvaccinated religious groups in countries with an otherwise high prevalence of PV immunity. Despite the barrier of millions of immune persons, PV outbreaks have occurred in some of these enclaves.[397] The frequency and ease of international travel may result in the continuous introduction of wild-type PV in all regions of the world, indicating that a large proportion of the population must be vaccinated if poliomyelitis epidemics are to be prevented. This suggests that herd immunity may be of only limited value in protecting

groups of susceptible persons who have regular contact with outside populations, and it raises questions about the risks that such groups may pose to the community at large.

Nosocomial transmission of various CVA and CVB and the echoviruses has also been well documented, typically in newborn nurseries. Hospital staff may have been involved in mediating transmission in some of these outbreaks. EV-D70, as well as CVA24 variant, is highly transmissible and can cause outbreaks in ophthalmology clinics when instruments are inadequately cleaned between patients. An apparent outbreak of CVA1, which included some fatal cases, has been reported in bone marrow transplant recipients.[483]

Although human EVs have been isolated from various environmental sources, humans are thought to constitute the only important natural reservoir.[123,135] Survival beyond a few weeks does not generally occur, although EV can survive for months in favorable environmental conditions; these favorable conditions include neutral pH, moisture, and low temperatures, especially in the presence of organic matter, which protects against inactivation. Simian enteroviruses have been identified that are closely related to a number of human viruses,[185,374,377,390,409] and human enteroviruses have been detected in free-living nonhuman primates,[391] but it is not known whether primates can serve as a reservoir for human infection.

Although little evidence suggests that EVs found in the environment are of public health importance, concern has been expressed about possible dangers of contaminated sources of water. Recreational swimming water has been investigated in several studies, and EVs have been isolated from swimming and wading pools in the absence of fecal coliforms and in the presence of *recommended* levels of free residual chlorine. CVB5 was isolated from an unchlorinated lake swimming area during an outbreak at a boy's camp in Vermont, although the outbreak itself was explained by person-to-person transmission. In one study, the relative risk of EV infection among children was found to be significantly higher for beach swimmers, especially for those less than 4 years of age.[103] These reports suggest that swallowing of contaminated pool or lake water may theoretically account for transmission, but no proof exists that this type of transmission is significant in recreational settings.

Enteroviruses have been found in surface and ground waters throughout the world. In the tropics, virus survival is more prolonged in groundwater because it is cooler than surface water. As in the case with swimming pools, EV can be found in these waters even after chlorination and even in the absence of fecal coliforms. In industrialized countries, EV transmission from potable water is apparently uncommon, but is a constant source of concern for public health investigators, because the usual conditions under which city drinking water is chlorinated may be insufficient to completely inactivate enteroviruses.

Enteroviruses have been isolated from raw or partly cooked mollusks and crustacea and their overlying waters.[167] Shellfish rapidly concentrate many viruses, including EV. These viruses can survive in oysters for 3 weeks at temperatures of 1°C to 21°C. To date, no outbreak of EV disease has been attributed to consumption of shellfish. Other foodborne transmission has been documented but is thought to be uncommon. A 1976 outbreak of aseptic meningitis attributed to echovirus type 4 was apparently caused by consumption of contaminated coleslaw at a large picnic (Centers for Disease Control and Prevention [CDC], unpublished data, 1976).

Enteroviruses, especially polioviruses, are regularly found in sewage. Enteroviruses are more prevalent in sewage from areas with low socioeconomic conditions or with large proportions of young children. In addition, sewage workers have been shown to have a higher prevalence of serum antibodies to EV than highway maintenance workers, which is consistent with an occupational risk.[93]

Soil and crops also provide conditions favorable to EV. Enteroviruses survive well in sludge and remain on the surface of sludge-treated soil and even on crops. Air samples from aerosolized spray irrigants using contaminated effluents have also been found to contain EV.[351] Survival of EV on vegetable food crops exposed to contaminated water or fertilizer has not been proved to be associated with virus transmission.

Prevalence and Disease Incidence

Incidence data about diseases caused by particular EV types can be derived from prospective longitudinal surveillance of a defined population or from a sample of the population in which the occurrence of disease or infection can

be reliably determined. The Virus Watch program in the 1960s in US cities exemplifies this type of surveillance study, in which specimens from subject children were obtained every 2 weeks for virologic evaluation.[98,282,467] Although difficult and extremely expensive, such prospective cohort studies avoid many of the pitfalls of passive surveillance, and they allow interpretations about both infection and disease incidence.

Less-useful information is based on passive case finding. Ascertainment may be incomplete because the surveillance system is likely to identify a case only if it is easily recognizable and diagnosed by someone who decides to report it. Because such data indicate neither how many ill persons were not reported nor how many ill persons had negative laboratory tests, the information is mostly of qualitative value; however, it may be useful in indicating trends. Despite these limitations, occasional reports do appear.[37,273]

In the United States, EV surveillance data are collected and analyzed by the CDC. The data have been reported irregularly since the beginning of the program in 1961.[273,350,353] In the United States, the only notifiable enteroviral diseases are poliomyelitis and encephalitis. These are reportable by diagnosis only (e.g., encephalitis) and not etiology (e.g., echovirus encephalitis). Such disease-based surveillance is the most accessible but least representative of all surveillance data.

EV excretion does not necessarily imply association with disease, because most such excretion is asymptomatic. This applies particularly to developing countries where EVs are ubiquitous and childhood infections commonplace and characteristically silent.

EV activity in populations can be either sporadic or epidemic, and certain EV types are associated with both sporadic and epidemic disease occurrences. The reported incidence or prevalence of a given EV disease may actually or artifactually be increased in an outbreak situation when sudden focus of attention improves diagnosis and reporting of cases, but this may also increase reporting of *noncases*. In addition, there may be a tendency for other strains to be excluded when a particular strain is predominant in a community; however, large communities with summer enteroviral disease typically support cocirculation of several different types simultaneously and in no particular pattern.

An important concept in understanding the epidemiology of the EV is variation: by serotype, by time, by geographic location, and by disease. This concept is illustrated in surveillance studies of nonpolio EV infections. For example, Figure 3.6 summarizes the data for the years from 1970 to 1998 for CVB3, echovirus 11, and echovirus 30 isolates in the United States collected and analyzed by the CDC. These data illustrate endemic and epidemic patterns of EV prevalence. The epidemic pattern, as typified by E11 and E30, is characterized by peaks in numbers of isolations followed by periods with few isolations.[273] These peaks may be sharp (1- or 2-year) or broad (multiyear) periods of increased virus isolations. For example, during the study period, several major epidemics occurred of echovirus 30 in the United States: outbreaks from 1981 to 1982, 1990 to 1994, and 1997 to 1998. By contrast, endemic viruses (e.g., CVB3) are isolated nearly every year and in similar numbers each year. Even with endemic viruses, larger outbreaks do occasionally occur, as with CVB3 in 1980. Similar endemic and epidemic patterns are seen for the other echoviruses and coxsackie A viruses.

FIGURE 3.6 Reported enterovirus isolations in the United States, 1970–1998. The graphs represent the percentage of total enterovirus isolations in a given year for each of three common serotypes, CVB3 (CB3), echovirus 11 (E11), and echovirus 30 (E30). Note that full scale for the CVB3 panel is 20%, whereas it is 50% for both of the echoviruses.

Variation by location is also a major characteristic of EV. Outbreaks can be restricted to small groups (e.g., schools and day care centers) or to select communities, or they may become widespread at the regional, national, or even international level. Outbreaks in small groups can sometimes be linked epidemiologically to a breakdown in hygiene practices. Even during national outbreaks of a specific serotype, the location of virus activity may not be uniform. During the period of 1990–1993, echovirus 30 was the most commonly isolated EV in the United States (Fig. 3.7). As can be seen in the figure, not all parts of the country had echovirus 30 isolates during the entire period. Some areas, such as the New England states, had extensive circulation in only 1 year, whereas other areas, such as the entire western United States, had extensive virus circulation for 3 or more of the 4 years. It is important to note, therefore, that aggregate national data can obscure significant regional and local variation in viral prevalence.

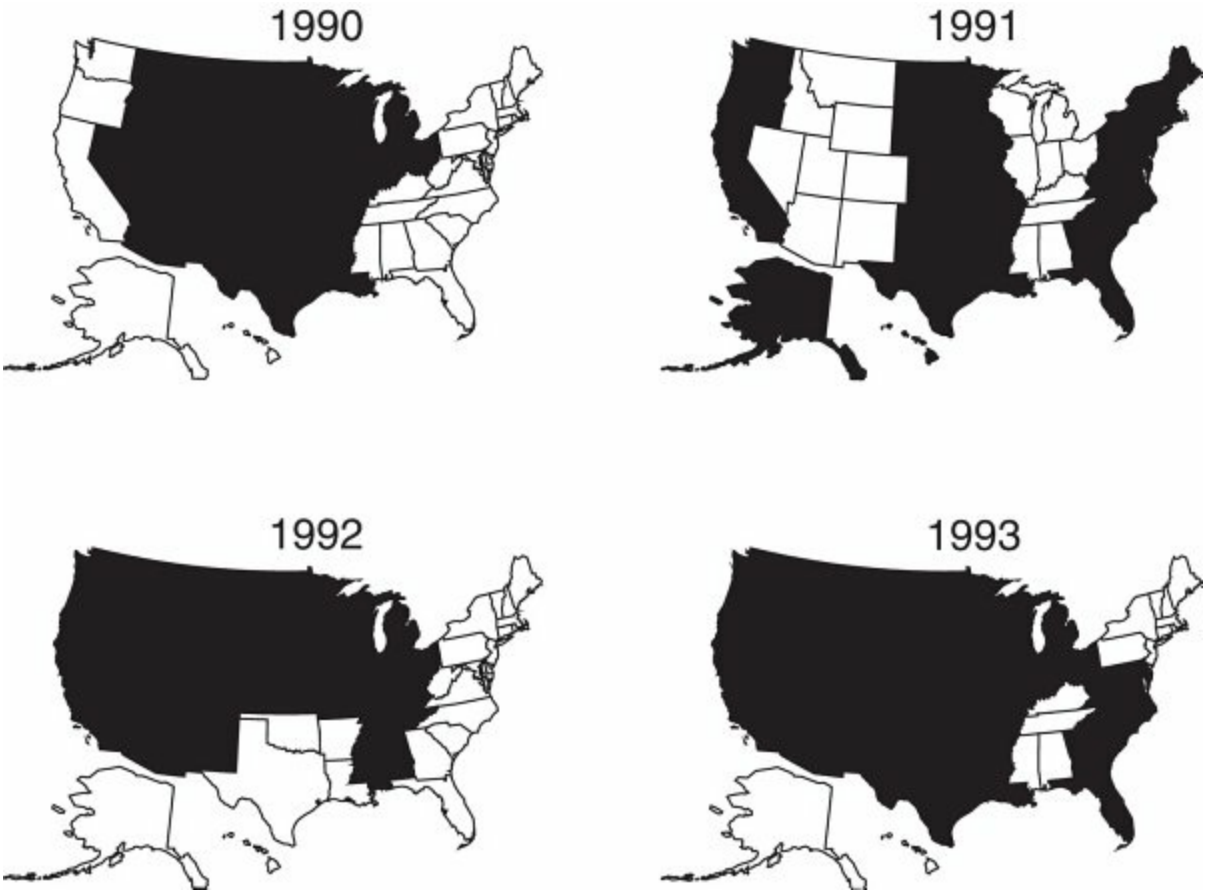

FIGURE 3.7 Geographic distribution of echovirus 30 isolates in the United States, 1990–1993. Maps represent regions of the United States where echovirus 30 was one of the three most common enterovirus isolates for the given year. States are *shaded* on a regional basis, because not all states report enterovirus isolation data.

In temperate climates, EVs are characteristically found during the summer and early autumn, although outbreaks can continue into the winter. In fact, naturally occurring EVs have a distinct seasonal pattern of circulation that varies by geographic area; in contrast, live attenuated PV (mostly vaccine strains) are isolated year-round, reflecting the routine administration of poliomyelitis vaccine to children. In tropical and semitropical areas, circulation tends to be year-round or associated with the rainy season. In the United States, 23 years of surveillance indicated that 78% of EV isolations

were made during the five summer or fall months of June to October.[273] In a 6-year study of viral CNS disease, 85% of enteroviral disease, compared with 12% to 26% of diseases caused by other viral agents, occurred between June and November.[350]

Many studies have examined the prevalence of antibodies to the EV in specific populations, as has been reviewed elsewhere,[338,348] with several important conclusions. First, the number of persons who have neutralizing antibody to any given EV is large, indicating a high incidence of past infection. A high incidence of recent infection is also suggested by surveys of IgM antibodies to EV, which typically show 4% to 6% positivity. Second, infections with one serotype of EV can boost antibody titers to other EV serotypes as measured by either IgM or neutralization. The pattern of the heterotypic response varies by serotype and among individuals. The nature of this heterotypic response has been explored through the identification of specific epitopes using monoclonal antibodies and peptide antisera.[176,441,530] Third, the pattern of antibody prevalence by serotype varies by geographic location, time, and age. Thus, prevalence data from different years and locations are not directly comparable. These three points must be considered when interpreting the findings of serologic studies of associations between EV infection and disease.

Molecular Epidemiology

Study of the molecular variation of viral proteins or nucleic acid may contribute significant epidemiologic information on viral diseases (see *Diagnosis*). Molecular epidemiologic studies have helped in our understanding of EV including the following: providing the opportunity for unequivocal strain identification, providing insights into EV classification and taxonomy, clarifying the origins of outbreaks, and allowing identification of strains transmitted between outbreaks. For the EV, and in particular PV, the primary method used to generate epidemiologic information is direct analysis of genomic variation using nucleic acid sequencing. Previously, both monoclonal antibodies and oligonucleotide fingerprinting were also used to study variation in PV and EV; however, these approaches are limited by their ability to show similarities and small differences only among relatively closely related viruses. Neither technique, however, is able to readily detect any patterns among seemingly unrelated virus isolates. The introduction of

the technique of genomic nucleic acid sequencing and its application to the study of wild PV isolates from different parts of the world has significantly extended the epidemiologic power of molecular studies.[425] By analyzing the random mutations that occur in the genome of different PV, closely related viruses were easily detected, and, in addition, more distantly related viruses were clustered into distinct geographic groupings of endemic circulation. This approach allowed epidemiologic links to be extended beyond those identified with other techniques.

Nucleic acid sequencing technology has been most comprehensively applied to studies of PV, where the information has proved valuable for supporting the global PV eradication program.[264,266,267] From these studies, it is possible to determine (a) if an isolated PV is related to vaccine virus, (b) similarities among isolates in an epidemic, and (c) differences among isolates from different geographic areas. By comparing the changes that are observed between virus strains, the geographic and temporal origin of a virus can be determined. Building on a nucleic acid sequence database of PV strains worldwide, it has been possible to develop rapid approaches to tracking wild PV strains.[11,313,359,425,552]

Studies on the molecular epidemiology of nonpolio EV have focused on the evolutionary inference derived from the comparison of virus isolates within a serotype over time, as well as the comparison of isolates from different serotypes and even between different genera within the *Picornaviridae*. Molecular epidemiologic studies using sequencing have been reported for CVB1, CVB5, echovirus 30, and EV71.[57,124,289,382,555] One of the studies of CVB5 isolates examined the pattern of genetic changes over three separate outbreaks in the United States. The nucleotide sequence from multiple isolates from the epidemics showed that each of the epidemics was caused by a single genotype. The genotype of CVB5 observed in the 1967 epidemic showed more similarity to the virus observed in the 1983 epidemic than to viruses isolated during the intervening years,[289] suggesting discontinuous transmission of epidemic CVB5 in the United States during this time. In an analogous manner, echovirus 30 genotypes have demonstrated an overlapping succession among the isolates characterized in the United States.[382] More than one genotype may be found in certain periods, and the displaced genotype can be found in other parts of the world after isolations have ceased in the United States for many years. In studies of

EV71 isolates, three distinct genotypes have been characterized.[57] Unlike the situation with echovirus 30 and more similar to the CVB5 example, the transition from one genotype to another occurred during a single year, 1987, and the older genotype has not been isolated since in the United States despite isolation in other parts of the world.

CLINICAL FEATURES

Most EV infections are asymptomatic. On the other hand, these viruses can cause a spectrum of clinically distinct syndromes when they lead to disease. Tables 3.3, 3.4, 3.5, 3.6 list the prototype EV strains and the illness, if any, in the person from whom the prototype virus was isolated. Individual serotypes generally lead to varied symptomatology and disease processes. Similarly, individual clinical disorders can generally be caused by a number of different EVs. On occasion, however, particular syndromes are associated with specific EV (Table 3.7). For example, acute hemorrhagic conjunctivitis is usually caused by the CVA24 variant or EV-D70. Acute flaccid paralysis (AFP) is usually caused by PV or EV-A71. The occasional isolates from cases of diabetes are usually CVB serotypes.

[a]Echovirus types 1 and 8 share antigens, type 1 having the broader spectrum. Type 10 was soon excluded from this group: it turned out to be a larger RNA virus and was reclassified as a prototypic reovirus. Type 28 was reclassified as rhinovirus type 1. Types 22 and 23 have been reclassified as members of the genus *Parechovirus* and are named parechoviruses 1 and 2; these viruses along with Ljungan virus represent the only members of this new genus. Type 34, DN-19, is now considered a prime strain of CVA24, rather than a distinct echovirus. Additional newer serotypes (EV73 and higher) are proposed new types defined on the basis of genetic sequence information.

TABLE 3.7 Clinical syndromes associated with infections by enteroviruses

Polioviruses, types 1–3 Paralysis (complete to slight muscle weakness) Aseptic meningitis Undifferentiated febrile illness, particularly during the summer
Coxsackieviruses, group A, types 1–24 Herpangina Acute lymphatic or nodular pharyngitis Aseptic meningitis Paralysis Exanthema Hand-foot-and-mouth disease (A10, A16) Pneumonitis of infants "Common cold" Hepatitis Infantile diarrhea Acute hemorrhagic conjunctivitis (type A24 variant)
Coxsackieviruses, group B, types 1–6 Pleurodynia Aseptic meningitis Paralysis (infrequently) Severe systemic infection in infants, meningoencephalitis, and myocarditis Pericarditis, myocarditis Upper respiratory illness and pneumonia Rash Hepatitis Undifferentiated febrile illness
Echoviruses, types 1–33 Aseptic meningitis Paralysis Encephalitis, ataxia, or Guillain-Barré syndrome Exanthema Respiratory disease Others: Diarrhea Pericarditis and myocarditis Hepatic disturbance
Numbered enteroviruses[a] Pneumonia and bronchiolitis Acute hemorrhagic conjunctivitis (EV-D70) Paralysis (EV-D68, EV-A71)[b] Meningoencephalitis (EV-D70, EV-A71) Hand-foot-and-mouth disease (EV-A71)

[a]Since 1969, new enterovirus types have been assigned enterovirus type numbers rather than being subclassified as coxsackieviruses or echoviruses. The vernacular names of the previously identified enteroviruses have been retained.

[b]Numerous additional types have been identified in stool from acute flaccid paralysis cases, but an etiologic link has not been confirmed.

Poliomyelitis

As is true for nonpolio EV, infection of most patients with PV does not result in disease or lead to any symptomatology. The most common symptomatic disease caused by PV, known as *abortive poliomyelitis*, is a mild febrile illness with or without gastrointestinal signs that occurs in 4% to 8% of individuals. The incubation period from infection to the onset of abortive poliomyelitis is usually 1 to 3 days, although symptoms can be seen as late as 5 days after infection. Less frequently, PV infection results in aseptic meningitis. This nonparalytic illness has the typical features of viral meningitis, with fever, headache, and meningeal signs but an absence of signs of CNS parenchymal involvement. The meningitis has a self-limited course and lasts for a few days to 2 weeks.

On average, only about 1 in 200 PV infections in a fully susceptible population results in the paralytic disease known as *poliomyelitis*. The incubation period from infection to the onset of paralysis is usually 4 to 10 days, although it can be as short as 3 days or longer than a month. The paralysis generally occurs 2 to 5 days after headaches occur and peaks within a few days. Usually, a prodrome occurs with sensory complaints and shooting or aching pains in muscle. The muscle pains may reflect replication of the virus in this tissue, which is known to occur. In children, it can be seen as a biphasic or *dromedary* course of neurologic involvement, and paralysis can occur as the initial symptom.

Paralysis is classified as either spinal or bulbar, depending on whether the spinal cord or brainstem, respectively, is involved. Not infrequently, the spinal form becomes associated with the bulbar form during the course of the disease, resulting in so-called bulbospinal polio. Spinal polio is usually asymmetric, flaccid, and limited to the extremities and trunk and varies from mild weakness to quadriplegia. Only about 10% to 15% of poliomyelitis cases are bulbar, a term indicating involvement of the motor cranial nerves or medullary centers controlling respiration and the vasomotor system.

Involvement of cranial nerves IX and X, those most affected, leads to paralysis of the pharyngeal and laryngeal muscles with resultant difficulty swallowing and talking. Involvement of other cranial nerves can lead to weakness of the face (VII) and tongue (XII). Most dreaded is involvement of the brainstem reticular formation, resulting in respiratory compromise, potentially requiring ventilatory support. Also seen is autonomic involvement, which manifests as abnormalities of sweating, urination, defecation, and blood pressure control. Recovery can be delayed significantly. Not infrequently, one extremity is left severely weak and atrophic, with a relatively normal contralateral limb.

The pathology of poliomyelitis is one of inflammation and destruction of the gray matter of the CNS, especially of the spinal cord. Motor neurons up and down the neuraxis can be infected, including upper motor neurons located rostrally in the brainstem and cerebral hemispheres in addition to the anterior horn lower motor neurons in the spinal cord. The widespread nature of the gray matter infection demonstrates that the disease is frequently a polioencephalomyelitis (i.e., inflammation of the gray matter of the brain and spinal cord) rather than merely a poliomyelitis (inflammation of the gray matter of the spinal cord). Interestingly, perivascular mononuclear inflammatory cells can persist for months, although virus is difficult to culture from the spinal cord after a week.[48] Although the focus of pathology in the spinal cord is in the anterior horn, abnormalities also occur outside the motor system in the posterior horn and intermediolateral column. Similarly, the brainstem shows involvement of a number of sensory cranial nerve nuclei and of the reticular formation in addition to the motor cranial nerve nuclei. Neurons die with evidence of chromatolysis followed by neuronophagia. Investigations of CD155-transgenic mice have reported that spinal cord neurons die by apoptosis.[156]

Poliomyelitis or AFP can occur as a result of infection with EV other than PV. EV-A71 emerged an important virulent neurotropic EV during the poliomyelitis eradication period. This virus causes epidemics of poliomyelitis-type disease, including bulbar disease.[90] In an EV-A71 epidemic in Bulgaria in 1975, a paralytic disease occurred in as many as 21% of approximately 700 patients, with a case fatality rate approaching 30%.[457] EV-A71 is also associated with epidemic encephalitis and meningitis (see *Clinical Features: Meningitis and Encephalitis*). EV-D70, a cause of

epidemics of acute hemorrhagic conjunctivitis, can lead to a severe and acute paralytic disease.[502] The incidence of paralysis is probably 1 of 10,000 infections.[243] These patients can also have cranial nerve palsies, autonomic abnormalities, and sensory signs. Sometimes, EV-D70 infections cause isolated cranial nerve palsies, most commonly involving the facial nerve. The eye disease is usually spread by direct or indirect contamination of the eye rather than the fecal–oral route. Some echoviruses and coxsackieviruses have also been associated with AFP (e.g., CVA7).[172]

Postpolio Syndrome and Amyotrophic Lateral Sclerosis

Patients with postpolio syndrome complain of new weakness, fatigue, and pain decades after paralytic poliomyelitis. One subgroup of this syndrome, called *postpoliomyelitis progressive muscular atrophy*, is an uncommon primary neurologic disorder manifested by slowly progressive atrophy of muscles with evidence of ongoing motor nerve damage.[68] Some investigators have reported a persistent PV infection in the spinal fluid or CNS tissue from patients with postpoliomyelitis progressive muscular atrophy,[304,305,356,406,454] but others have failed to confirm these findings.[247,336,440] One of the groups that originally reported EV genome in patients with postpolio syndrome later claimed that both patients and controls had evidence of enteroviral genome in the CNS.[357] Although the PV genome of a mouse-adapted mutant PV has been reported to persist at low levels following experimental infection of mice,[118] the only consistent evidence for persistent PV infection in humans has been found in individuals who are immunocompromised. We await more convincing data demonstrating that a persistent infection underlies the postpolio syndrome.

The issue of whether PV can persist in postpoliomyelitis progressive muscular atrophy has raised questions about whether PV or another EV is involved in amyotrophic lateral sclerosis, a chronic progressive weakening disease of unknown cause associated with death of motor neurons. A possible role for EV in amyotrophic lateral sclerosis seems unlikely given the immunocompetence of these patients and the noninflammatory pathology of the disease. Although some studies have reported enteroviral genomic sequences in tissues of patients with amyotrophic lateral sclerosis and motor

neuron diseases, a more investigation using a very sensitive molecular detection method failed to find evidence to support this hypothesis.[373]

Acute Flaccid Myelitis

Coincident with a large outbreak of EV-D68–associated severe respiratory illness in children in 2014, cases of what was later termed acute flaccid myelitis (AFM) were identified in multiple states.[15,451] Since 2014, AFM case numbers have peaked every other year.[333] EV-D68 has been implicated in a number of AFM cases, but virus has not been consistently detected in sterile-site specimens and the prevalence of other enteroviruses in non–sterile-site specimens nearly equals that of EV-D68.[333,451] The clinical spectrum, epidemiology, possible mechanisms of pathogenesis of AFM, as well as the role of EV-D68 and other enteroviruses remain under investigation.

Meningitis and Encephalitis

Aseptic meningitis is a nonbacterial inflammation of the meninges associated with fever, headache, photophobia, and meningeal signs in the absence of signs of brain parenchymal involvement.[437] The syndrome is the most common CNS infection, with 7,000 cases of aseptic meningitis reported per year in the United States and an actual incidence believed to be 10-fold higher.[435]

Enteroviruses are the main recognized cause of aseptic meningitis in both children and adults in developed countries. Enteroviruses were identified in 85% to 95% of cases in which a specific pathogen was cultured.[437] In one study, 62% of infants less than 3 months of age with aseptic meningitis had CVB as the etiologic agent.[255] Of note, aseptic meningitis is the most common clinical syndrome caused by EV that results in medical attention.

Enteroviruses should be suspected as the causative agent for aseptic meningitis occurring in the summer and fall in temperate zones. The seasonal increase in incidence of enteroviral aseptic meningitis is largely related to climate[408] and may result because the fecal–oral route of transmission is facilitated in warm periods when less clothing is worn.[243] Fever is common in patients with EV-induced aseptic meningitis, as with most cases of aseptic

meningitis. At times, the fever has a biphasic pattern, initially associated with constitutional symptoms and then returning with meningeal signs. One may see nonneurologic abnormalities associated with enteroviral meningitis (e.g., rash), which may be helpful in the diagnosis and identification of the particular enteroviral serotype.[243] For example, rashes have been associated with CNS disease caused by CVA5, CVA6, CVA9, and CVA16 and echoviruses 4, 6, 9, and 16. The rash associated with echovirus 9 meningitis can be petechial, resembling that seen with meningococcemia.

Encephalitis signifies that the brain parenchyma is infected and is not infrequently associated with a disturbed state of consciousness, focal neurologic signs, and seizures. The distinction between aseptic meningitis and encephalitis is important because the absence of parenchymal involvement in aseptic meningitis suggests a more benign condition and more favorable prognosis. Encephalitis is usually associated with aseptic meningitis, usually resulting in a meningoencephalitis.

Although a specific virus is not usually identified in most cases of encephalitis, and the number of cases in which an EV has been identified as the cause of encephalitis is low, EVs nevertheless rank second to herpes simplex virus and comparable to arboviruses as a recognized cause of encephalitis in the United States.[144,154] The New York State Department of Health found evidence of EV genome by PCR in the spinal fluid of 3 of 41 cases of encephalitis over the period from July 1997 to November 1998[212]; herpes simplex virus genome and arbovirus genome were each found in 5 cases.

Patients with EV encephalitis usually have a global neurologic depression in function, although occasionally seen are focal neurologic signs, resembling herpes simplex virus encephalitis.[344,349] Cases associated with an acute cerebellar ataxia have been reported in children infected with various EVs, including PV, echoviruses 6 and 9, and coxsackieviruses A2 and A9.[243] Other uncommon clinical manifestations reported include acute hemiplegia, opsoclonus–myoclonus, movement disorders, and Guillain-Barré syndrome.[243]

The meningeal syndrome is usually self-limited and benign, with evidence of improvement in days to a week. Deaths have been reported, however, following infection with a number of enteroviruses, including

CVB1 and echoviruses 9, 17, and 21.[243] Morbidity and mortality are also increased in the neonate. The neonate's disease tends to be especially severe when the disease appears soon after birth, perhaps reflecting perinatal spread of virus to the fetus from the mother, as discussed above. Mortality is increased in the neonate partly because the aseptic meningitis can be associated with systemic disease (e.g., hepatitis and myocarditis), as well as encephalitis. The largest study of recovered patients failed to find any neurodevelopmental abnormalities above levels seen in controls.[431]

Isolation of EV from CSF may be unsuccessful because a particular EV may grow poorly in cell culture or because inhibitory factors (e.g., neutralizing antibody) may be present in the spinal fluid. With the use of RT-PCR, EV genome may be found in a significant number of culture-negative spinal fluid samples from cases of aseptic meningitis. The potential usefulness of RT-PCR can be seen in a report of a Swiss epidemic of aseptic meningitis caused by echovirus 30, when the EV genome was identified using this technique in 42 of 50 spinal fluid cultures (84%) that were negative for virus isolation.[165]

In some areas of the world, epidemics of EV-A71[5,90,457,506,536] have been associated with a high incidence of aseptic meningitis as well as CNS parenchymal involvement; the CNS infection has caused AFP as well as a more varied clinical symptomatology.[337] As noted, EV-A71 is emerging as one of the most significant neurotropic EVs in some areas of the world. This virus circulates in the United States, and 26% of adults tested in a seroepidemiologic study in New York in 1972 had antibody.[114] An epidemic of EV-A71 infection in 1998 in Taiwan caused frequent CNS disease and more than 100,000 reports of hand-foot-and-mouth disease or herpangina (see *Respiratory Infections, Herpangina, and Hand-Foot-and-Mouth Disease*), which may correspond to 1 million actual cases of EV infection.[198] The patients with hand-foot-and-mouth disease had vesicular lesions on their hands, feet, mouth, and, at times, buttocks, whereas the patients with herpangina had vesicular lesions of the palate and pharynx. Of special concern was the finding of 405 severe cases with associated complications, 78 of which were fatal. Among the more severe cases, the case fatality rate in different areas ranged from 7.7% to 31.0%. Most of the hospitalized cases (80%) and the deaths (91%) were in children younger than 5 years of age. The most frequent complication was encephalitis. Other serious

complications, which were associated at times with encephalitis, included aseptic meningitis, myocarditis, and pulmonary edema and hemorrhage. It is unclear whether the pulmonary signs were related to viral invasion of the lungs or to brain injury from the viral encephalitis.

A review[212] of 41 hospitalized children with neurologic complications and culture-confirmed EV-A71 infection during the Taiwan epidemic in 1998 demonstrated an unusual and rather distinctive neurologic manifestation, brainstem encephalitis, or rhombencephalitis. The mean age of the 41 children was 2.5 years (with a range from 3 months to 8.2 years). There was frequently an associated condition: hand-foot-and-mouth disease in 68% or herpangina in 15%. The neurologic disease usually followed the initial illness of fever and skin or mucosal lesions, and it was manifested as rhombencephalitis (37 patients), aseptic meningitis (3 patients), and AFP (associated with the disease in 4 patients and following rhombencephalitis in 3 of the 4). At times, breathing difficulties and coma were seen in the patients with rhombencephalitis, progressing to death in 5 patients. The brainstem and spinal cord pathology was presumably related to direct viral injury, because virus was cultured from the spinal cord and brainstem of the 1 patient who underwent autopsy. Five of the patients who survived had neurologic sequelae. EV-A71 brainstem involvement was also seen during an epidemic in Malaysia in 1997, but not in earlier epidemics. In contrast, hand-foot-and-mouth disease and herpangina did not occur during the previous epidemics in Bulgaria and Hungary. It is not clear whether the changes in EV-A71 disease phenotype represent the emergence (or reemergence) of a more virulent strain or whether it is related to the serologic status of the at-risk populations.

The presence of immunodeficiency predisposes to a syndrome of EV-induced aseptic meningitis or meningoencephalitis, at times producing a persistent CNS infection. McKinney et al.[334] reviewed more than 40 cases of chronic enteroviral meningoencephalitis in patients with congenital immunodeficiencies, most commonly X-linked agammaglobulinemia. Clinical features were remarkably varied and included headaches, seizures, ataxia, a disturbed state of consciousness, motor deficits, personality changes with cognitive decline, and sensory disturbances. At times, patients had other associated abnormalities, such as a dermatomyositis syndrome (in 21 of 41 patients; see *Clinical Features, Muscle Disease*), rashes (16 of 35 cases), edema (20 of 40 cases), and hepatitis (15 of 32 patients). Although some

cases started abruptly, most tended to be slowly progressive, at times lasting years, and with a frequent fatal outcome. Most patients had a spinal fluid mononuclear cell pleocytosis with an increase in protein. Some cases at autopsy had evidence of inflammatory infiltrates in the heart, lungs, kidneys, adrenal glands, thyroid, and pancreas, in addition to the CNS. Immunosuppression of B-cell function with monoclonal antibody drugs can also lead to chronic enteroviral infection, with potentially serious consequences.[171]

Cardiac Disease

Myocarditis is an inflammation of the myocardium associated with damage that is unrelated to an ischemic injury. Myocarditis is frequently self-limited and subclinical, with few if any sequelae. On the other hand, the acute disease can lead to significant morbidity and even death. On the basis of well-established criteria, one study found evidence of myocarditis in approximately 1% of autopsies.[169]

In some cases, myocardial inflammation may persist, producing a chronic myocarditis that can progress to DCM.[76,252,432] In DCM, the heart is enlarged, with impaired function and evidence of heart failure but with little or no inflammation. The incidence of DCM in the United States has been reported to be 6 per 100,000 cases,[95] with approximately 100,000 new cases each year. Because of the high mortality of DCM, patients are frequent recipients of heart transplants, making up perhaps 50% of all cardiac transplant patients. Of note is the observation that nonpolio EVs, especially CVB3, cause acute and chronic myocarditis in experimental animals and that a contribution from the immune system to the chronic disease has been proposed (see *Pathogenesis*).

Acute Cardiac Disease

CVB has long been considered one of the principal causes of viral myocarditis[100] and this view has been confirmed in several recent reports.[19,129,324,326,328] Epidemiological and other studies suggest that 70% of the general public will be exposed to cardiotropic viruses and half of these individuals will develop acute viral myocarditis.[376] It is believed that 1.5% of enteroviral infections, including 3.2% of CVB infections, result in overt

cardiac signs or symptoms.[172] Myocarditis is a frequent autopsy finding in children who die of overwhelming CV infection.[255] The peak age group in which myocarditis caused by coxsackieviruses of the B group occurs is young adults, primarily between the ages of 20 and 39 years, with a higher prevalence among men.[521]

However, even the larger group of symptom-free individuals are at risk; collapse and death of young and vigorous individuals, especially during exertion, can result from catastrophic dysfunction of the electrical pathways in the heart, as a consequence of unsuspected acute viral myocarditis.[39,509] A remarkably high prevalence of asymptomatic myocarditis has been shown by necropsy studies of victims of violent or accidental deaths; in this relatively random human population, approximately 1% had active myocarditis.[169]

A summary of data from varied sources shows that the prevalence of enteroviral infection in acute myocarditis on the basis of serologic studies is 34% (214 positives in 636 patients) compared with 4% (44 of 1,139) of controls (199). However, these serologic studies demonstrating seroconversion with an EV do not prove that EV caused the cardiomyopathy, as they may result merely from an unrelated EV infection. In addition, evidence suggests that multiple EV can circulate at the time of an epidemic, so that isolation of an EV does not prove its role in a disease; for example, more than 10 EVs were recovered from the community during an echovirus 9 epidemic.[243]

A meta-analysis of data obtained from molecular studies (slot blot hybridization, *in situ* hybridization, and RT-PCR) published in 12 reports found 23% of cases (68 of 289) and 6% of controls (14 of 216) had evidence of EV genome in heart tissue, giving an odds ratio of 4.4 with a 95% confidence interval of 2.4 to 8.2.[30] These data, coupled with reports of positive virus isolations from the heart, indicate that EV may represent a common cause of acute myocarditis. The surprisingly large number of positive findings in controls is presumed to result from difficulties in obtaining appropriately controlled heart tissue.

Chronic Cardiac Disease

Human DCM has multiple causes, both inherited and sporadic. A prior history of enteroviral infection of the heart, especially with CVB, has been

implicated in sporadic human DCM.[31,467] Although the majority of patients with symptoms recover well from acute myocarditis, the disease can have serious long-term sequelae; some 10% to 20% of people with symptoms (i.e., ~20,000–40,000 patients per year in the United States) will develop chronic disease, progressing over time to DCM.[376,464] A summary of serologic data from multiple sources found that the prevalence of EV in DCM was 25% (64 of 260) compared to 10% of controls (26 of 255).[331] These serologic data suffer from the same drawbacks that are noted above.

In contrast to acute myocarditis, no reports are found of isolation of EV from chronic DCM, suggesting that the virus may have a restricted expression or disappear following the acute infection; however, some reports exist of EV VP1 antigen in the heart of patients with DCM and chronic coronary disease.[18]

The difficulty in isolating infectious virus led to studies probing affected tissues for persistent enteroviral genome. A meta-analysis of data from molecular studies described in 17 published reports found 23% of the patients and 7% of controls had evidence of enteroviral genome, giving an odds ratio of 3.8 with a 95% confidence interval of 2.1 to 4.6.[30] The meta-analysis data support an association between EV infection and chronic cardiac disease; however, it remains a possibility that RNA from other laboratory-based enteroviral studies contaminated test samples in the highly sensitive PCR studies. Most of the hybridization and PCR studies did not include sequencing of the viral genome and, therefore, failed to prove more directly that an EV was involved. In a few cases, however, partial sequencing was done of the RNA found in clinical samples; for example, Archard et al.[23] identified the amplified sequence as CVB. One proposed mechanism of viral persistence in chronic cardiomyopathies is 5′-terminal deletion of the genome, leading to chronic, low-level expression.[55,79]

Not all the viral genomic studies have been positive. One investigation involving a nested PCR failed to find evidence of EV RNA in 287 heart biopsy specimens from 38 patients with DCM and 39 patients with heart failure of unknown cause.[111] At least two other studies have also resulted in negative findings.[308,453] The lack of consistent, reproducible results regarding the presence of enteroviral genome in tissue from patients with cardiomyopathy indicates that further studies are needed under careful,

blinded conditions.

Muscle Disease Including Pleurodynia

The relationship of EV to inflammatory muscle diseases was initially recognized because of the myotropism of coxsackieviruses in suckling mice. This observation was fueled by the association of these viruses with epidemic pleurodynia on the Danish island of Bornholm. The latter disease, called *Bornholm disease*, is an acute febrile illness with myalgia, especially involving the chest and abdomen, but without muscle weakness. It has occurred as an epidemic and also sporadically in various locales. Relapses can occur. CVB3 and CVB5 are the most frequently recognized causative agents, although other EVs have also been isolated.[547] The limited information from muscle biopsy findings suggests that the inflammation in this disease may be confined to the endomysial part of the muscle and, therefore, is not a true myositis.[106]

Enteroviruses have been implicated in acute and chronic inflammatory muscle disease. The acute diseases, which are usually called acute polymyositis or myositis, are characterized by fever with myalgia, elevated muscle enzymes, and, at times, myoglobinuria. Chronic inflammatory muscle diseases, which are generally classified as polymyositis, dermatomyositis, or inclusion body myositis, have a subacute to chronic progressive weakness with a distinctive pathology on muscle biopsy. Dermatomyositis is distinguished from the other two inflammatory myopathies because it is associated with a characteristic rash.

The causes of chronic inflammatory myopathy are generally unknown. Hypotheses concerning the etiology of polymyositis and dermatomyositis include a direct virus infection, especially an EV infection, or an autoimmune process in which the virus infection triggers a reaction against muscle (see *Pathogenesis*). That coxsackieviruses cause acute and chronic inflammatory myopathy in experimental animals provides additional support for their involvement in human inflammatory muscle diseases. Investigations of these model systems may help clarify the pathogenesis of these diseases in humans.

Enteroviruses have been isolated from cases of inflammatory myopathies, but these isolations have generally been rare and from single cases with acute[43] or atypical clinical pictures.[475] The inability to isolate virus from

cases of chronic inflammatory myopathy has raised the possibility of a restricted expression of the virus with little infectious virus present. For this reason, investigators have probed muscle tissue from patients with inflammatory myopathy for picornaviral genome. Some reports involving slot blot or *in situ* hybridization studies of muscle tissues from patients with inflammatory myopathies have shown positive results using EV-specific probes.[544] In some cases, the product amplified in a RT-PCR has been identified as CV group B sequence.[22] In contrast, other studies using RT-PCR and nucleic acid hybridization have found negative results.[300,303,401] It remains a possibility that an EV could trigger an autoimmune inflammatory muscle disease and then disappear. Studies regarding the possible role of EV in chronic fatigue syndrome have similarly failed to find reproducible evidence of EV involvement.[106]

Of special interest with respect to the issue of EV involvement in inflammatory muscle disease is the observation that patients with immunodeficient states can manifest a disease similar to dermatomyositis with an accompanying persistent echovirus infection.[503,515] It should be noted, however, that questions have been raised whether these patients had a true myositis (i.e., inflammation of the muscle) or a fasciitis with interstitial inflammation in the endomysium.[106] The inflammatory muscle disease is associated with a chronic encephalomyelitis as well as a more disseminated disease in which EV, especially echoviruses, can be cultured from the spinal fluid (see *Clinical Features: Meningitis and Encephalitis*).[554] Although virus has occasionally been isolated from affected muscle, it remains unclear whether the dermatomyositis syndrome in patients who are immunodeficient is a result of direct virus invasion of the muscle or an immune-mediated disease associated with virus persistence. The existence of this syndrome similar to dermatomyositis demonstrates that echoviruses, and perhaps other EVs, can produce a chronic myositis in humans that is associated with persistent infection and chronic inflammation.

Diabetes

Both genetic and environmental factors, including EV infection, have been implicated in the cause of insulin-dependent diabetes (type 1 diabetes, T1D). A number of epidemiologic and serologic studies have demonstrated a

relationship between EV infection and the development of diabetes. D'Alessio[103] found that 15 of 84 cases (17.8%) of newly diagnosed T1D patients had evidence of IgM antibody against CVB, compared with 5 of 71 controls (7.0%). The individuals with IgM antibody were especially common in association with HLA antigen-DR3 positivity. A prospective study in Finland found a greater incidence of seroconversion of EV antibodies among children who developed T1D than among those who did not.[231] The antibody present in the prediabetic period was directed against a number of different EV serotypes, including CVA9, CVB1, CVB2, CVB3, and CVB5.[430] At times, the EV antibodies are associated with autoantibodies to GAD_{65} and other important targets.

Rare, but well-documented, isolations of CVB4 have come from the pancreas of patients with acute-onset as well as fatal cases of insulin-dependent diabetes.[417,422] Some of the isolates have been demonstrated to be diabetogenic when inoculated into certain mouse strains[540] and nonhuman primates.[541] Patients dying from coxsackieviral myocarditis can have an associated pancreatitis, including islitis. More recent investigations have involved probing tissues from patients for evidence of EV genome. An *in situ* hybridization study showed evidence of EV genome: in the islets of autopsy pancreases from 7 of 12 newborn infants who died of fulminant CV infection (and 6 of the 7 had islitis), in the islets of autopsy pancreases of 4 of 65 adults with T1D, and in 1 of the pancreatic control tissues from 40 nondiabetic patients.[539]

Although it is likely that EVs are capable of causing diabetes mellitus in animals and humans, it remains unclear how often this occurs in humans and what if any immune mechanisms are involved.

Several studies have implicated antibody or T-cell cross-reactivity between CVB and host proteins to explain many of the observed correlations.[132,217,218,364,365,432] However, *in vivo* mouse studies appeared to clarify these seeming discrepancies and suggested that virus-mediated damage and inflammation were directly responsible for CVB-induced T1D.[210] Pancreatic tissues from three of six T1D patients were found to contain CVB4-infected β cells, which was isolated and could infect β cells from normal patient samples (Dotta, 2007). Some studies have even suggested that *in utero* infection with CVB predisposes the fetus to the

eventual development of T1D postnatally.[500]

In addition to direct infection, the innate immune system also may play a role in EV-induced T1D (recently reviewed by Rodriguez-Calvo [Rodriguez-Calvo, 2019]). Human genome-wide analyses for nonsynonymous SNPs between healthy individuals and T1D patients identified the double-stranded RNA sensor melanoma differentiation–associated protein 5 (MDA5) as a T1D susceptibility locus.[463] MDA5 has been proposed to act as a key host sensor of CVB infection.[507] Consistent with a role for innate immune-mediated antiviral signaling in CVB-induced diabetes in a mouse model, β cells lacking functional type I IFN signaling through genetic deletion of the IFN-α receptor enhance CVB4-induced infection and T1D.[140]

However, despite many years of study, a causal role for CVB (or any EV) in T1D has not been directly demonstrated in humans, and the issue remains controversial. It is possible that, as has been proposed for pancreatitis, EVs are a cofactor in T1D, very rarely initiating disease in healthy islets, but tipping the balance in individuals who—unbeknownst to them—have ongoing islet inflammation and are in a prediabetic status.

Eye Infections

Acute hemorrhagic conjunctivitis is characterized by a short incubation period of 24 to 48 hours preceding a rapid onset of uniocular or binocular symptoms and signs. Patients manifest excessive lacrimation, pain, periorbital swelling, and redness of the conjunctiva (from subconjunctival petechiae to frank hemorrhages).[537] Keratitis with accompanying pain and possible visual impairment as well as anterior uveitis may be seen. The epidemic disease can also be associated with nonophthalmic symptoms and signs, such as neurologic dysfunction (see *Clinical Features*) and respiratory and gastrointestinal disturbances. The disease usually resolves without sequelae in 1 to 2 weeks.

The first pandemic of acute hemorrhagic conjunctivitis was recognized in 1969 in Africa. Within 2 years, two EVs, a new antigenic variant of CVA24 and a previously unknown EV serotype designated EV70 (now EV-D70), were implicated as causative agents responsible for the epidemics of this disease.[309] During the first pandemic from 1969 to 1971, hundreds of millions of people were likely to have been infected. Subsequent epidemics

of acute hemorrhagic conjunctivitis have continued in various locations throughout the world. Other EVs have also been recognized as causes of acute hemorrhagic conjunctivitis (e.g., echovirus type 7)[442] and as causes of sporadic conjunctivitis and keratoconjunctivitis.[261] The ocular disease caused by EV is often indistinguishable from acute hemorrhagic conjunctivitis caused by various adenovirus serotypes.

Respiratory Infections

Enteroviruses are a common cause of respiratory illnesses. Enteroviruses were isolated in 1.7% of 3,119 respiratory specimens submitted for viral culture from 1983 to 1994[86] and constituted 6.4% of all the viruses that were isolated from these specimens (54 of 838). Respiratory illness occurred in 15% of EV infections collected by the WHO from 1967 to 1974[172] and 21% of cases from the CDC obtained from 1970 to 1979.[20] The EV implicated in these respiratory infections included CVA (12.4%), CVB (20.3%), and echoviruses (12.6%).[172]

Enteroviral respiratory infections are more frequently associated with upper respiratory infections (e.g., the common cold, croup, and epiglottitis) than with lower respiratory infections (e.g., pneumonia). The infections are frequently subclinical, but if they cause clinical disease, it tends to be self-limited and mild, with a short incubation period of 1 to 3 days. More severe lower respiratory infections may be related to a higher dose of virus in the inoculum. In a series of infants with CVB infections, 30 of 77 patients had marked abnormalities (e.g., interstitial inflammation and hemorrhage), and 12 had virus isolated from the lung.[255]

EV-D68 was originally isolated in 1962 from children with bronchitis, bronchiolitis, and pneumonia in California.[447] Since then, it had been detected sporadically in the United States and elsewhere,[273] with small outbreaks identified. In the summer and fall of 2014, the largest recorded outbreak of acute respiratory illness due to EV-D68 occurred across the United States, with over 1,100 virologically confirmed cases from August through December, with the vast majority of cases occurring among children.[345] Since 2014, outbreaks of acute respiratory illness associated with EV-D68 have been identified globally.[203] Dyspnea, cough, and wheezing are some of the more prominent symptoms and patients with asthma were

disproportionately affected. A high proportion of patients have been admitted to intensive care units and have required ventilator support.[345]

Herpangina and Hand-Foot-and-Mouth Disease

Herpangina is a febrile illness of relatively sudden onset with complaints of fever and sore throat. Characteristic lesions are found on the anterior tonsillar pillars, soft palate, uvula, and tonsils and on the posterior pharynx. The illness, which has a predilection for the young, is usually self-limited and disappears within a few days. At times, the disease is associated with more significant clinical abnormalities (e.g., meningitis). Hand-foot-and-mouth disease is an illness associated with vesicular lesions of the hands, feet, mouth, and, at times, buttocks.

A number of EVs have been identified as causes for herpangina, including CVA and CVB serotypes; echovirus types 6, 9, 11, 16, 17, 22, and 25[86]; and EV-A71. The main causes of hand-foot-and-mouth disease are CVA10 and CVA16 and EV-A71,[172] though CVA6 has recently emerged as a frequent cause, with cases also occurring in adults.[4,414] Most of the affected adults are parents or caregivers of young children. The pathogenesis of the lesions seen in herpangina is not clear; however, experimental infection of rhesus monkeys with CVA4 may provide a model system for the study of the pathogenesis of herpangina. In this system, ingestion of the virus by the oral route leads to multiplication in the lower gastrointestinal tract, followed by viremia, and then multiplication in the oropharynx.[460]

Neonate and Infant Disease

Neonates are at increased risk from enteroviral infections. This increased susceptibility is present in humans as well as experimental animals infected with varied EV.[88] Enteroviruses are among the most common sources of viral nosocomial infections in neonatal intensive care units (NICUs) and might account for as much as 15% of these infections.[92]

The increased risk of neonates to EV infection was apparent in the prevaccine era with respect to PV. Although the incidence of paralytic disease among neonates approached 40% in those born to mothers with poliomyelitis at the time of delivery, the overall incidence of neonatal

poliomyelitis was an infrequent occurrence, perhaps related to the protective effect of maternal antibody.[528] Neonatal poliomyelitis generally had a shorter incubation period and a higher case fatality rate than found with disease later in life, demonstrating the increased susceptibility of immature hosts to EV infection. Infection of the mother early in gestation was associated with an increased risk of abortion, stillbirth, and prematurity.[88]

Nonpolio EV is a not infrequent cause of infection in neonates and infants. In a series from the CDC, EV isolates from patients less than 2 months of age included echoviruses (51%), CVB (45%), and CVA (4%).[353] Echovirus serotypes included 4, 9, 11, 17 to 20, 22 (now classified as HPeV1), and 31. A similar wide range of EV types was identified in a later review of CDC EV surveillance data for the period 1983–2003.[273] CVB1 to CVB4, E11, and E25 were significantly more common, whereas CVA16, E4, E9, E21, E30, and human parechovirus 1 (now termed PeV-A1) were less common among neonates than among persons aged ≥1 month.

The most frequent presentation in the neonate with nonpolio EV is asymptomatic infection.[241] Symptomatic cases most commonly manifest a self-contained febrile illness, at times associated with irritability and nonspecific signs of infection, making EV infection a leading cause of fever in the infant. A rash of variable character is seen in more than 30% of cases.[6] More serious infections can be seen, with the peak of symptoms correlating with viremia.[104] Nonpolio EVs are the most frequently identified cause of aseptic meningitis in infants less than a month of age and are believed responsible for more than a third of these cases.[456] An increased susceptibility of the neonatal CNS to CVB infection may be related to the virus' predilection for neonatal stem cells and the ability of the virus to damage these cells.[138,222] In a small series of patients with pneumonia in the first month of life, EVs were implicated in 15% of cases (6 of 40).[7] Usually, the mother has a history of fever or respiratory symptoms a week before the delivery, although mothers can be asymptomatic or have a more severe disease.

One of the serious infections caused by EV is a sepsis-like disease. In one series, EVs were implicated in 65% of infants less than 3 months of age admitted to the hospital for suspected sepsis.[105] In another series, evidence was seen of enteroviral genome in 80 of 345 infants less than 90 days of age

admitted to a medical center with suspected sepsis.[63] A number of other studies have yielded similar results, emphasizing the importance of EV as a cause for a sepsis-like syndrome among neonates and infants.[104] In fact, EVs tend to be a more common cause of this syndrome than bacteria in the summer and fall.[63] There may be extensive multiorgan involvement in severely affected cases, especially ones that go on to a fatal outcome; the organs affected include the liver, lung, heart, pancreas, and brain.

The incidence and severity of EV infections among infants can be better appreciated by reviewing a study conducted in Nassau County, New York, from 1970 to 1979.[255] Of 153,250 live births, 77 infants younger than 3 months required hospitalization for CVB infection. These 77 cases were from a pool of 602 infants who tested positive for CVB, demonstrating the high frequency of CVB infection in infants. The attack rate might have been even higher than was found, because the positive samples from this study were from only a limited number of infants hospitalized in the community. A total of 24 mothers had evidence of a viral-like infection occurring within a period from 10 days before delivery to 5 days after delivery. The most common syndrome that was seen was aseptic meningitis. Some of the infections in the infants were very serious, as evidenced by the finding that eight children died from overwhelming CVB infection. All but one of these eight had evidence of myocarditis.

Severe EV disease in the young is associated with an early age of illness, prematurity, a more severe illness in the mother, multiorgan disease, low socioeconomic status, bottle-feeding, specific EV types, and an absence of neutralizing antibody to the pathogen.[6] The level of maternal neutralizing antibody appears to be important both for determining the risk of developing infection and for modulating disease severity.[8] Long-term sequelae following neonatal myocarditis or CNS infection appear infrequent.[6,435]

As discussed above, nonpolio enteroviral infection can affect the fetus, inducing clinical abnormalities and causing overt disease in the neonate. Reports exist of abortion and stillbirth associated with maternal EV infections, although these are infrequent. The relationship between maternal EV infection and congenital anomalies in the newborn remains unclear.

A number of routes exist by which EV can cause neonatal disease. Studies have found evidence of placentitis and viral infection in fetal tissues.[6]

This would suggest that virus could be vertically transmitted from an infected mother to the fetus through the placenta, which forms the sole interface between the maternal and fetal compartments during pregnancy. No studies have investigated the ability of EV to infect placental tissue, but CVB can enter into primary human placental cells.[115] During delivery, virus could transmit to the neonate through feces or vaginal secretions. Infection can also occur from virus shed by other neonates or hospital staff in the nursery. In cases involving nursery outbreaks, implementation of infection controls (e.g., strict hand washing and the isolation of affected patients) has a role in prevention of new cases.

DIAGNOSIS

Differential and Presumptive Diagnosis

The process of diagnosing an EV infection or establishing that an EV infection produced a particular clinical syndrome can be complicated and challenging. This problem results from the biology and epidemiology of EV infections, as well as from limitations in current diagnostic methodologies. Although it is possible to demonstrate that a person is infected with an EV, this association does not necessarily prove likely disease causation. On the other hand, a presumptive diagnosis in certain epidemiologic and clinical situations can be possible with a high degree of certainty on clinical grounds alone.

Several related biologic properties complicate the diagnosis of EV-induced disease. The first is that most virus replication and infection typically occur in the respiratory and gastrointestinal tract. These infections are often asymptomatic, with few if any systemic clinical signs. Because these infections are extremely common, even random sampling of healthy individuals can demonstrate EV infections at substantial rates. For this reason, the simple recovery or detection of virus from certain nonsterile sites does not establish a firm linkage to disease, and it may be merely coincidental.

A second difficulty is that even when illness results from the EV infection, most of the signs and symptoms are relatively generic and usually

lack specificity. The collection of appropriate clinical specimens for detection is critical to laboratory confirmation of EV infection. For example, the exclusive use of CNS specimens to diagnose meningitis and encephalitis limits the sensitivity for detection of infection. While it is possible to detect EV in the CSF from meningitis cases, it is uncommon to find virus in the CSF from cases of encephalitis wherein is seen a reasonable suspicion of EV as the cause; in other cases, the virus can be readily recovered from CSF, such as during the recent outbreaks of fatal EV71 encephalitis.[21] In general, however, the specimen with the highest sensitivity for establishing an acute infection is a stool specimen, regardless of clinical presentation,[346] followed by respiratory tract specimens. The difficulty with virus detection in some clinical conditions may be further compounded because virus shedding from the gastrointestinal and respiratory tracts may stop before the onset of symptoms, and, therefore, sensitivity for virus detection may be lower.

Sometimes, a presumptive diagnosis can be made on the basis of limited information because of the pronounced seasonality of EV infection in temperate latitudes and the tendency for EV to cause community outbreaks. For example, cases of aseptic meningitis occurring during the late summer and early autumn have a high probability of EV etiology. In this situation, a presumptive diagnosis of an EV infection could be made on the basis of signs and symptoms, exclusion of other nonviral pathogens, and detection in a specimen from some nonsterile site. Another example pertains to epidemic acute hemorrhagic conjunctivitis; in this case, the identification of an EV (either CVA24 variant or EV70) from a small number of patients precludes the need for further testing of specimens from other patients in that community with similar symptoms.

Laboratory Diagnosis

Molecular detection

The application of molecular biology techniques to clinical virology has significantly changed approaches to EV diagnostics (see *Epidemiology*). Because of distinct advantages in speed, many of these procedures have supplanted traditional methods of detection and characterization such as virus isolation in cell culture. As with virus isolation and serotyping, the molecular methods attempt to detect the presence of EV in a specimen and, in some

procedures, to further characterize the detected virus. The techniques can be grouped on the basis of their infrastructure and technical requirements and the types of specimens to which they are applicable. The most commonly used tests are based on the PCR, which is used primarily to detect EV genome in cell cultures, clinical specimens, and biopsy or autopsy tissues.[186,380,523] Additional procedures utilize genomic sequencing for the characterization of EV at the highest levels of specificity.

By far the most common use of PCR for EV diagnosis is the direct detection of virus in clinical specimens.[35,237,369,494] Numerous variations on the details of the procedures are found, but all methods that can generically detect EV have several common features. The most important property of these tests is that the primers are targeted to amplify the 5′-UTR of the virus genome. Several pan-EV real-time RT-PCR assays have been licensed for use in various countries, either as stand-alone assays or as part of a syndrome-specific multipathogen panel. The major advantage of the pan-EV PCR is that rapid detection of an EV is possible, even with very small amounts of clinical specimens such as spinal fluid. It is also possible to detect EVs that do not readily grow in cell culture. As with all PCR, the sensitivity of amplification of RNA from biologic specimens is extremely variable, depending on the nature of the specimen (e.g., stool).[474] Because of high-sequence conservation among enteroviruses and rhinoviruses in the 5′-UTR target sites, many "pan-EV" PCR assays cross-react with rhinoviruses,[182,380] though careful primer and probe selection can minimize this effect.[256,319,369] Some commercial take advantage of the cross-reactivity to broaden the specificity of detection in respiratory samples, labeling the result "RV/EV-positive." A recent meta-analysis showed that empirical EV testing in febrile infants could reduce hospital costs and length of stay in the absence of a positive test for other causes of the illness (e.g., if blood cultures and other molecular tests are all negative).[505]

By changing the target for amplification, it is possible to characterize a particular EV using the PCR. Because the antigenic property of viruses that defines serotype is a property of the viral capsid proteins, certain sequences correspond to this conserved antigenic property within the capsid-coding region of the virus. Extensive studies of the capsid region of PV isolates have led to the design of primers that can selectively amplify isolates from a single serotype but not from other isolates of heterologous serotypes.[275] This is

accomplished, despite the high rate of synonymous nucleotide substitutions, through the use of inosine in the primer synthesis. In an analogous manner, the ability of PV to uniquely bind to the CD155 is also an intrinsic property of the capsid proteins. The amino acids that are involved in receptor binding have been well characterized from studies of the three-dimensional structure of the virion. When primers are designed that correspond to these presumably PV-specific sequences, amplification is observed with all PV isolates but not with other EVs.[274] It has been possible to extend these principles to other EV receptor groups and serotypes and to provide tools for rapid serotype characterization of EV without the requirement for cell culture procedures.

A goal in virus identification is knowledge of the sequence of the viral genome. Encoded within this sequence are determinants for all the biologic properties that are attributable to a given virus. Therefore, the nucleic acid sequence information of a virus represents its ultimate characterization. All important information about a virus could potentially be obtained directly by PCR in conjunction with nucleic acid sequencing if all the molecular correlates of viral phenotypic determinants were understood. At present, however, the genetic location for many properties of the virus remains uncertain. Nevertheless, it is possible at present to use sequence information to assign an EV isolate to a particular serotype.[372,383], [384], [385,523] The molecular typing system is based on RT-PCR and nucleotide sequencing of all or a portion of the genomic region encoding VP1. The serotype of an unknown isolate is inferred by comparison of the VP1 sequence with a database containing VP1 sequences for the prototype and variant strains of all human EV serotypes. The following guidelines have been suggested:

> "(i) a partial or complete VP1 nucleotide sequence identity of ≥75% (>85% amino acid identity) between a clinical EV isolate and serotype prototype strain may be used to establish the serotype of the isolate, on the provision that the second highest score is <70%; (ii) a best-match nucleotide sequence identity of <70% may indicate that the isolate represents an unknown (that is, new) serotype, and (iii) a sequence identity between 70% and 75% indicates that further characterization is required before the isolate can be identified firmly."[387]

Using these guidelines, strains of homologous serotypes can be easily discriminated from heterologous serotypes and new serotypes can be identified. This method can greatly reduce the time required to type an EV

isolate and can be used to type isolates that are difficult or impossible to type using standard immunologic reagents. The technique is also useful to rapidly determine whether viruses isolated during an outbreak are epidemiologically related.

Virus isolation

Many of the detailed procedures for the established laboratory diagnosis of EV infections using virus isolation have been described.[168] The traditional techniques for detecting and characterizing EV rely on the time-consuming and labor-intensive procedures of viral isolation in cell culture and neutralization by reference antisera. Isolation of EV from specimens using appropriate cultured cell lines is often possible within 2 or 3 days and remains a very sensitive method for detecting these viruses. The best specimens for isolation of virus are, in order of preference, stool specimens or rectal swabs, throat swabs or washings, and CSF. Throat swabs or washings and CSF are most likely to yield virus isolates if they are obtained early in the acute phase of the illness. For cases of acute hemorrhagic conjunctivitis, the best specimens are conjunctival swabs,[537] although occasionally virus can be isolated from tears.[538] Since the major pandemic in 1981, however, isolation of EV-D70 from patients with acute hemorrhagic conjunctivitis has been very difficult, and molecular methods provide the only sensitive method to detect this agent.[458]

The procedure for virus isolation involves inoculation of appropriate specimens onto susceptible cultured cells. No single cell line exists that is capable of growing all human enteroviruses. It is common practice to use several types of human and primate cells to increase the spectrum of viruses that can be detected.[87] Even with a variety of cells, however, several CVA serotypes fail to propagate in culture. The coxsackieviruses, including those that do not grow in cell culture, can be isolated and propagated in suckling mice.

As a consequence of current PV eradication activities and the importance of PV as a public health problem, specific diagnostic procedures have been developed to detect this virus. In general, PV grows well on a variety of primate and human cell culture lines, but it cannot be distinguished from other EVs solely on the basis of cytopathic effect. Polioviruses are unique in

the use of CD155, which is distinct from receptors used by all other EVs to infect cells. This receptor has been transfected and expressed in a murine cell line that normally cannot be infected by most EV but is permissive to viral replication when the viral genome is present within the cell. One of these stably transfected murine cells, L20B, can grow PV and has been exploited selectively to isolate PV, even in the presence of other EVs.[211] When a specimen is inoculated onto these cells and a characteristic EV cytopathic effect is seen, the virus can be presumptively identified as a PV. A few strains of certain nonpolio EV serotypes are able to grow on the parent murine cells, however, and therefore growth on L20B cells is not a definitive identification of PV, and confirmatory testing is required.

Virus isolates may be typed by molecular methods as described for direct typing in clinical specimens, above. Attempting virus isolation may be useful in a case where typing is considered important (e.g., the index case in an outbreak or investigation of a nosocomial outbreak), the EV is of very low titer in the clinical specimen, and direct molecular typing is unsuccessful. For clinical management of routine cases, however, it is seldom critical to identify the specific nonpolio EV type. A high index of suspicion for an EV infection can be developed by reflecting on the clinical picture, the virus isolate's cytopathic effect and cell culture systems utilized, and knowledge of basic EV epidemiology.

Antibody tests

Serologic diagnosis of EV infection can be made by comparing titers in acute and convalescent phase (*paired*) serum specimens. In general, however, EV serodiagnosis is more relevant to epidemiologic studies than to clinical diagnosis (see *Epidemiology*). The most basic serologic test is that of neutralization in cell culture. Many serologic studies rely on the detection of IgM antibody as evidence for recent EV infection, and this is now widely used as an alternative to the neutralization test. Several groups have developed an enzyme-linked immunosorbent assay (ELISA) for EV-specific IgM.[38,325] These tests have been found positive for nearly 90% of culture-confirmed CVB infections and can be performed rapidly. The ELISA has been successfully applied for epidemiologic investigations of outbreaks,[160] as well as for specific diagnostic use.[109]

In most cases, the IgM ELISA test is not serotype specific. Depending on the configuration and sensitivity of the test, from 10% to nearly 70% of serum samples show a heterotypic response caused by other EV infections. This heterotypic response has been exploited to measure broadly reactive antibody and the assay used to detect EV infection generically.[53,470] In attempting to characterize the exact nature of the response using different antigens, it is clear that the human immune response to EV infection includes antibodies that react with both serotype-specific epitopes and shared epitopes.[149] Despite this problem, which is inherently biologic, a fairly high concordance of results remains between assays of different configurations.[199] In summary, the IgM assays that are generally used in epidemiologic studies have very good sensitivity and appear to be very specific for EV infection; however, these assays detect heterotypic antibodies resulting from other EV infections and, therefore, cannot be considered strictly serotype specific.

PREVENTION AND CONTROL

Treatment

Although no currently available drug treatment for enteroviral infections is in clinical use, the effectiveness of a variety of drugs *in vitro*, as well as in animal models, has been documented. In addition, varied new directions for future therapeutic intervention are being pursued.

Pilot studies have been conducted administering intravenous immunoglobulin in neonates suspected of having enteroviral infection.[8] Pooled immunoglobulin delivered intravenously or via a shunt into the spinal fluid has also been used in patients who are agammaglobulinemic with chronic encephalitis and meningitis associated with nonpolio enteroviruses. Patients who are immunodeficient with persistent EV infections, including PV infections, represent a particular challenge to effective treatment. Although intravenous immunoglobulin may protect these patients from poliomyelitis and may appear to stabilize and improve some of the infections, the disease may progress; most of these infections, however, spontaneously cease. In some cases, efficacy may be limited by inadequate amounts of the relevant antibody in the immunoglobulin pool (e.g., if the infection involves

an unusual and rare EV serotype), as well as problems in the delivery of adequate levels of antibody to the infected cells. One report documented the failure to clear persistent PV excretion despite treatment with intravenous immunoglobulin, breast milk, and ribavirin (195a). Interestingly, a successful clearance of PV may apparently follow intercurrent diarrheal infections caused by other pathogens, perhaps because of damage to gut lymphoid tissue, which acts as a main site of PV replication.[272]

A number of specific antiviral compounds have been developed to target enteroviral proteins and steps in the virus' life cycle. The *WIN compounds* and related derivatives, which were originally shown to be effective against rhinovirus, have shown the most consistent results and have been those most studied mechanistically. These drugs bind a hydrophobic site near the surface of the virion called the *pocket*,[550] which lies in the floor of the *canyon* where the virion binds to the cellular receptor. By binding to the pocket, these compounds are believed to interfere with viral attachment and uncoating. Variations in activity of WIN compounds against different picornaviruses are presumably related to the particular fit of the drug into the pocket of a specific EV strain. Oral administration of WIN 54954 significantly decreased the number of upper respiratory infections following challenge with CVA21 (i.e., 3 of 27 patients in the treated group had an upper respiratory infection vs. 15 of 23 in the placebo group) with decreased associated symptoms and viral titers.[448] Adverse reactions, however, curtailed further investigations with this drug. Pleconaril or VP 63843 is a pocket-binding compound with a broad *in vitro* inhibitory activity against 95% of the 215 nonpolio EVs that were tested.[405] Significant activity was noted against some serotypes, such as echovirus 11. A randomized, double-blind study involving the administration of pleconaril following a challenge with CVA21 showed statistically significant decreases in viral shedding in nasal secretions, nasal mucus production, and total respiratory illness symptom scores in patients treated with pleconaril compared with subjects treated with placebo.[448] Another phase II trial of the same drug against enteroviral meningitis showed a statistically significant decrease in disease duration (9.5 days in the placebo group vs. 4.0 days in the controls).[436] A subsequent study, however, failed to have the statistical power to show efficacy in infants with enteroviral meningitis.[9] A problem with all of these antiviral compounds is that mutant viruses resistant to the drug can arise. In the case of resistance to rhinovirus,

the mutant viruses tend to have bulky amino acid substitutions that sterically block entry of the drug into the pocket.[192] These mutant viruses may not be as significant a problem as expected, because drug-resistant CVB3 mutants that appeared in tissue culture following exposure to the WIN compounds tended to be attenuated when inoculated into mice.[173]

Enviroxime is an antiviral drug that targets nonstructural protein 3A, leading to a block in the synthesis of plus-strand viral RNA. Although this compound inhibits EV and rhinovirus *in vitro* infections, it is toxic and not effective in humans.[119] Resistance to enviroxime is determined by changes in the amino acid at position 30 in protein 3A.[191]

An antiviral strategy promoted recently involves the use of drug-sensitive dominantly inhibitory viruses, generated as a result of a targeted drug treatment, which interfere with growth of drug-resistant viruses.[102,476] Regions of the virus that can serve as targets for drugs that lead to the generation of these dominant defective viruses include (a) the capsid and polymerase-coding region, because of the proteins' oligomeric properties (i.e., there is interference during interactions with the respective wild-type protein); (b) cre and VPg (genome-linked virus protein), perhaps because their malfunction leads to inhibitory intermediates; and (c) 2A, perhaps because the uncleaved intramolecular cleavage of VP1-2A is inhibitory during assembly of the virus capsids. The 2A proteinase seemed to be an especially attractive target because of its inability to be rescued in *trans* and the dominant inhibition of the uncleaved product on virus growth.

Vaccines

Efforts have been initiated to develop a vaccine against EV71, and several approaches have been evaluated in animal models. Mice immunized with a DNA vaccine encoding VP1,[491,526] or with synthetic peptides encoding B-cell epitopes from vp1,[141] mount a neutralizing VP1-specific IgG response; passive transfer of vaccine-induced antibodies to neonatal mice conferred substantial protection against a normally lethal EV71 challenge.[142] A virus-like-particle (VLP) vaccine induced a strong and sustained neutralizing IgG response.[91] Finally, transgenic mice have been developed in which VP1 is expressed in the milk of nursing mothers; EV71-specific antibodies were induced in the suckling pups.[91] In both of the latter studies, the antibody

responses protected neonatal mice against a normally lethal EV71 challenge.[83,91]

Poliovirus Vaccine and Eradication

The efforts to control PV over the last 60+ years benefitted from having more than one excellent vaccine, because both the inactivated (killed) vaccine of Salk administered by injection and the oral attenuated vaccine of Sabin were available. Both of these vaccines result in production of anti-PV antibody (Fig. 3.8) with subsequent protection from disease.[365,469] Although there has been a continuing advocacy for one or the other vaccine over the years, it is clear that each has advantages and disadvantages (Tables 3.8 and 3.9) and that appropriate circumstances exist for the use of each. As polio eradication efforts expanded in the developing world, it became evident that the question of the role of each of these vaccines is more complicated than originally thought. In the developed world, with the incidence of PV declining dramatically and VAPP the only significant source of disease associated with PV, many countries either never used OPV or switched to IPV. Like many other countries, the United States switched from OPV to the exclusive use of IPV in 2000 (with a routine schedule at 2 months, 4 months, 6–18 months, and 4–6 years of age). The main benefit from this change was the elimination of VAPP, and subsequent studies have shown that this was accomplished.[13]

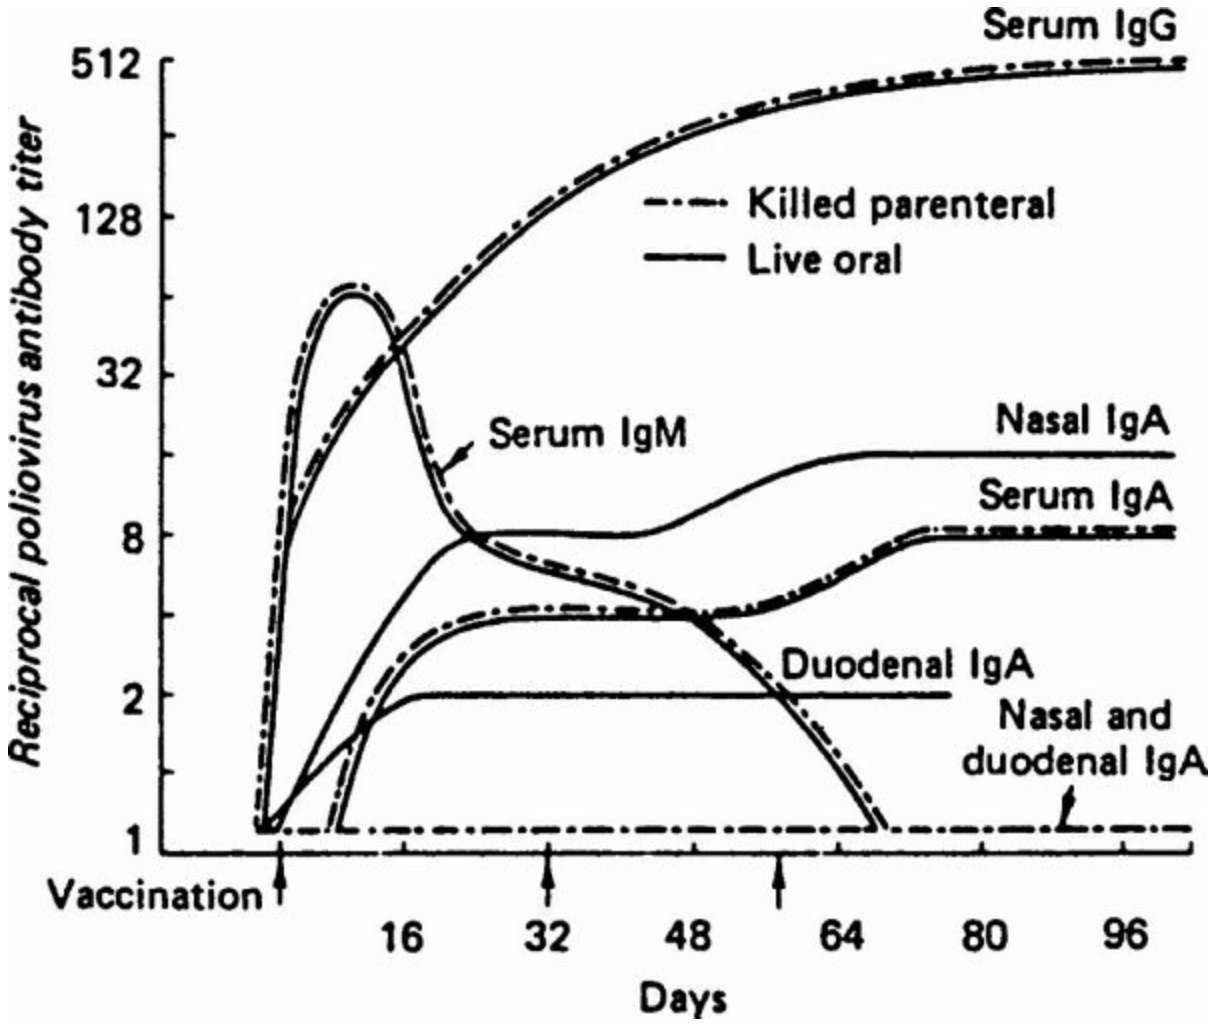

FIGURE 3.8 Serum and secretory antibody responses to oral administration of live attenuated polio vaccine and to intramuscular inoculation of killed PV vaccine.

(From Ogra PL, Karzon DT. Formation and function of poliovirus antibody on different tissues. Prog Med Virol 1971;13:156–193, Ref.[393])

TABLE 3.8 Killed poliovirus vaccine: advantages and disadvantages

Advantages
Safe because inactivation ensures no infectious virus exists
Can be used in immunodeficient and immunosuppressed individuals
Provides excellent systemic immunity
Disadvantages
Requires intramuscular injection with repeated doses
More expensive than live vaccine
Potential hazards because of the use of wild seed virus in production
Reduced intestinal immunity compared with natural infection

TABLE 3.9 Live poliovirus vaccine: advantages and disadvantages

Advantages
Confers strong systemic and intestinal immunity
Relatively inexpensive
Provides herd immunity because virus is excreted into the environment, expanding immunity
Oral delivery
Relatively safe
Disadvantages
Can mutate to neurovirulent form, causing vaccine-associated paralytic poliomyelitis
Contraindicated in immunodeficient and immunosuppressed individuals
Requires monkeys for safety testing
Can lead to circulating vaccine-derived polioviruses causing outbreaks of poliomyelitis

In 1988, in part based on the rapid progress of eradication activities in the

Americas, the World Health Assembly unanimously adopted a resolution calling for the global eradication of PV before the end of the 20th century (http://polioeradication.org/wp-content/uploads/2016/07/19880513_resolution-2.pdf). This resolution was reaffirmed in May of 1999, 2004, and 2011, and an acceleration of activities was urged with particular focus on the remaining endemic areas.

Four fundamental components constitute the strategy to eradicate PV.[227] First is the achievement and maintenance of high levels of routine immunization. With the accelerated activities resulting from the Expanded Program on Immunization of the WHO, routine coverage with three doses of OPV in children under 1 year of age reached nearly 90% of the world's children by 1990; however, maintenance of these levels has not been completely successful, and some erosion of routine immunization has occurred. Because of the inability of routine immunization to control PV circulation in many developing countries, the second element of the strategy is the use of National Immunization Days for the delivery of vaccine to all children under 5 years of age in a very short period of time, usually from one to a few days.[46] The mass immunization interferes with the spread of wild PV through a rapid increase in population immunity and abruptly decreases the *chains of transmission* in a country. This strategy was used in many early immunization efforts in the 1960s and was applied successfully in Cuba to achieve and maintain the elimination of PV from that country following three successive years of annual campaigns.[429] Multiple rounds in a given year are now routinely carried out for all endemic countries, and the National Immunization Days have grown in an extraordinary way as more countries have adopted this strategy. Some campaigns now represent the largest public health activities on record and often represent the largest multinational health events as well.

The third basic element of the strategy is the use of surveillance based on cases of AFP.[47] One of the major differences between the smallpox eradication program and the efforts to eradicate PV is the low rate of clinical disease following PV infection. Because less than 1% of infected susceptible individuals will develop paralytic illness, most infections are not clinically recognized. Following increased immunization, there are still fewer susceptible individuals who can be paralyzed, but immunity only partially prevents infection and therefore transmission can continue in partially

immune populations with only a small number of cases evident. This creates a further challenge for finding the virus because of this complicated dynamic between immunity, disease, and surveillance.[249] Therefore, unlike smallpox, where almost all infections were symptomatic, PV is difficult to detect because most infections are sub-clinical. To improve the sensitivity of detecting PV infection and yet achieve a practical system, surveillance was developed around the unique clinical presentation of paralytic poliomyelitis. To avoid the requirement for extensive neurologic examinations, which are not feasible in many developing countries, the surveillance was simplified to include any case of AFP. This system reports many other diseases in addition to poliomyelitis, such as Guillain-Barré syndrome, transverse myelitis, and traumatic neuropathy. This loss of specificity, however, is compensated for by a gain in sensitivity, because most cases of true poliomyelitis are reported. The incidence of non–PV-induced flaccid paralysis is also used as an indicator of surveillance sensitivity (>2 case per 100,000 population under 15 years of age is considered an operational indicator of adequate quality), although it is not clear if the expected rate is the same in different countries or would be expected to be constant over time. Regardless, AFP surveillance has proved to be remarkably efficient for detection of wild PV circulation.

Once an AFP case is detected, the remaining part of surveillance is focused on detection of the virus. Two stool specimens are collected from all cases of AFP and tested in a global network of laboratories to attempt isolation of PV.[226] The major advantages of this surveillance system are simplicity, practicality, and reasonable sensitivity for detection of PV. The major disadvantages are the requirements (a) to rapidly collect, transport, and test a large number of specimens from all areas of the world and (b) have high-quality laboratory testing. Despite these challenges, a global network of 146 laboratories was established and has been able to process more than 200,000 fecal specimens every year since 2011 and provide this information in a timely manner to the eradication program.[74]

The last element of the eradication strategy is the use of *mopping-up* activities.[112] This strategy focuses on an area or country where the previous three parts of the program have successfully reduced the number of PV cases to a small number and where surveillance has localized the remaining reservoirs of transmission. It is then possible to intensify immunization activities in those targeted communities that contain the remaining circulating

virus, or the last *chains of transmission*. These intensified activities usually involve active searches in communities for children, including house-to-house or boat-to-boat immunization.[69] Teams visit all residences in the area and ensure that children are not missed for vaccination. With further reduction of PV circulation to only parts of a limited number of countries, further increase in vaccine coverage was achieved by more focused supplemental immunization activities (SIA). These immunization campaigns were focused on the remaining reservoirs of polio circulation within the endemic countries and conducted many times nearly year-round. At the late stages of the eradication program, the distinction between SIA and the original National Immunization Days has become blurred as greater flexibility of scope and timing has been introduced.

These four elements of PV eradication strategy have proven successful in most of the world. Because of this intensified effort, by the end of 2018, only two countries continued to report ongoing PV circulation. Since the program began, almost all countries are now free of indigenous PV circulation. This can be seen in Figure 3.9, where in 1988 PV was found on all the continents (except Australia), with estimates of more than 350,000 cases of PV each year. In 2011, the number of countries with PV was only 16, and by 2014, all of the Americas, Europe, Southeast Asia, and the Western Pacific Regions have been certified to be free of PV.[75] The only countries with endemic PV cases in 2018 were in South Asia (Pakistan and Afghanistan). The African Region reported its last case of wild PV in 2016. A weekly progress report on the global efforts to eradicate PV is provided on a Web site of the WHO.[524]

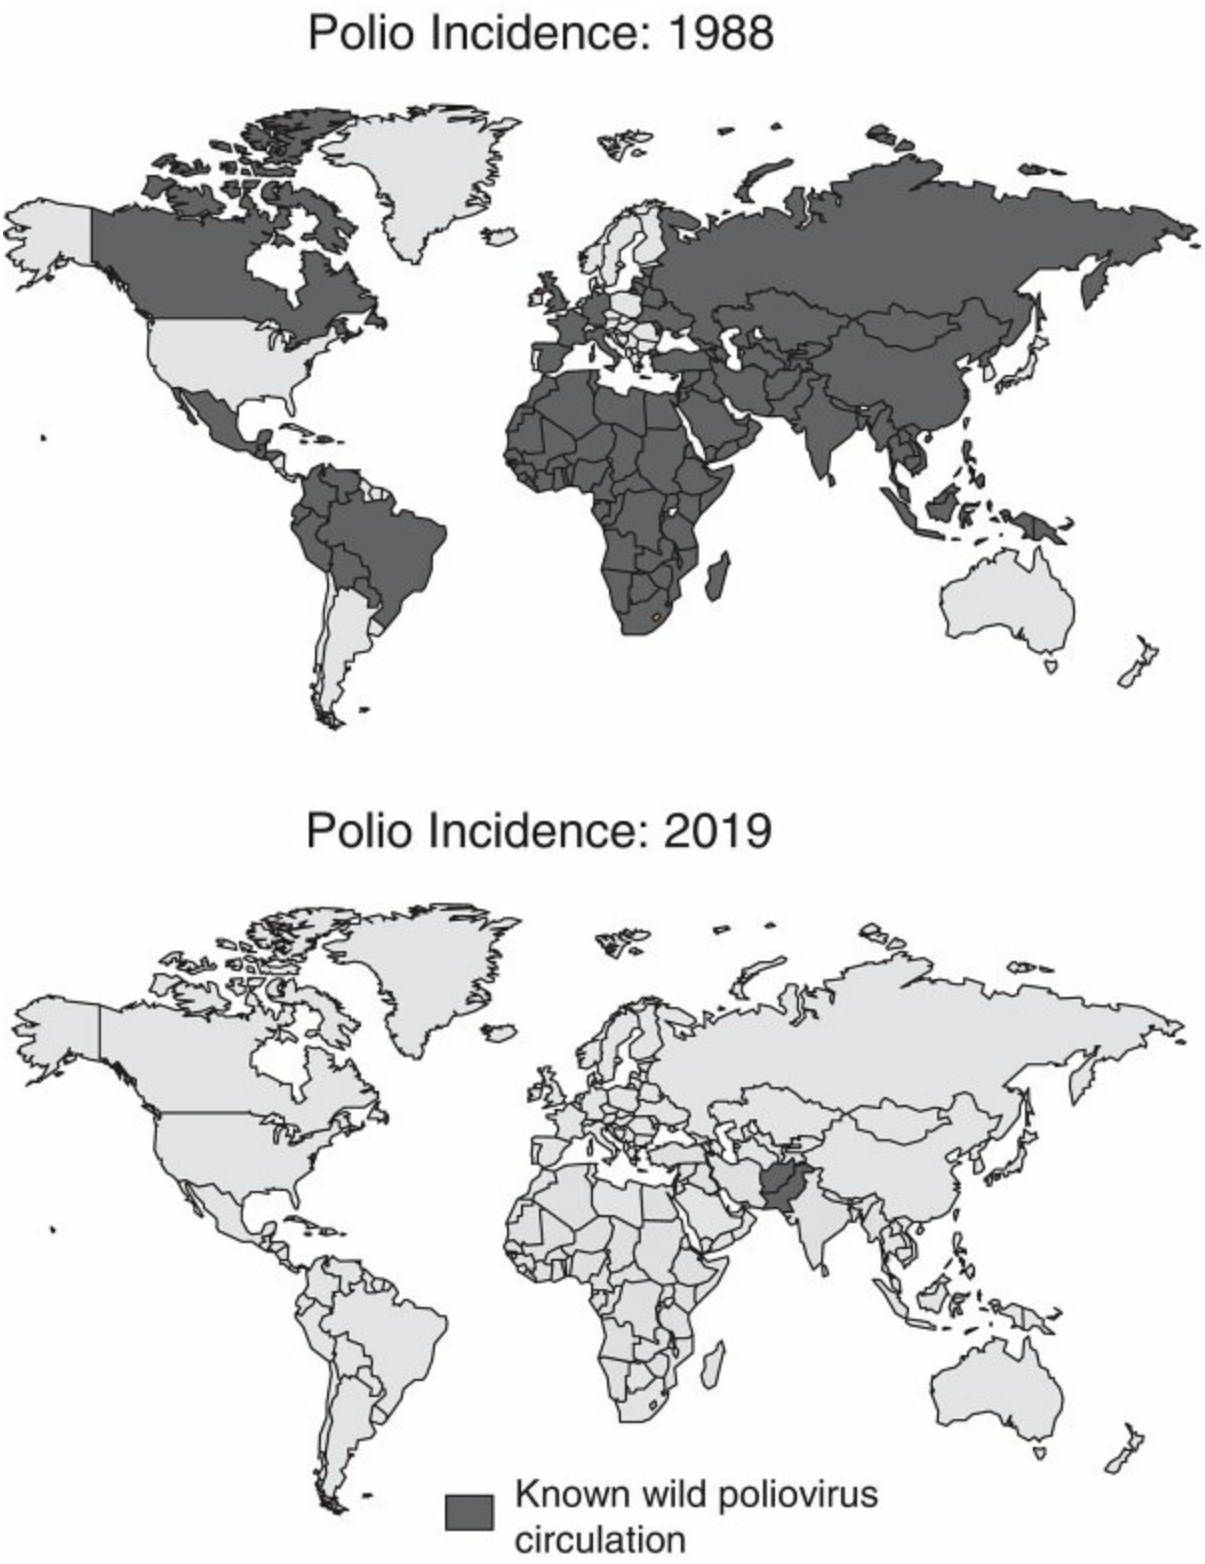

FIGURE 3.9 Incidence of poliovirus in 1988 versus 2019.

Numerous unknowns and potential obstacles remain to be faced in the eradication efforts. Because of the inherent insensitivity of detecting PV infection, it is important that surveillance quality be achieved and maintained for a period of time. Although the exact length of time required to be assured of success is not known in all circumstances, the minimal requirement for certification is 3 years. Previous experience indicates that if excellent surveillance is achieved and maintained, PV genotypes that have not been detected for a period of 1 year will not be detected ever again.[265] This has been true for more than three dozen genotypes that have been eliminated from circulation.

After wild virus circulation is interrupted, the accidental release of viruses from laboratories or vaccine-manufacturing facilities will represent a significant risk to the PV-free world. Therefore, it will be necessary to institute proper containment of the virus. A plan for these steps of containment has been drafted and will be implemented in phases as eradication proceeds. In the first pre-eradication phase, preparation for later phases is to be undertaken by conducting an inventory of all institutions and laboratories that have wild PV or potentially infectious materials. This survey for wild PV and potentially infectious materials has been completed in the polio-free regions of the world and has been completed in more than 100 countries, including the United States.[70] Wherever possible, use of vaccine strains of PV in the laboratory should be substituted for wild strains. In the second phase, after the last wild PV has been isolated anywhere in the world, all work with wild PV will be done at a higher biosafety level of containment (BSL-3/polio). Once all countries and regions have been certified as being free of circulating PV, and once all laboratories have properly contained, referred, or destroyed their PV stocks and potentially infectious materials, the Global Certification Commission will declare wild PV eradicated. The last phase of containment will occur sometime in the future when the decision is made to stop vaccination with OPV. At that time, all infectious PV will need to be in containment. The containment requirements for this last phase are being developed. In addition, the special containment needs associated with IPV production are being assessed. Of particular concern are the current use of wild strains and the associated risk of an accidental release of virus during vaccine production. One way to limit this danger that is under consideration and active development is to prepare the IPV from the live Sabin attenuated

vaccine strains.[94]

Once eradication of wild PV is achieved, the only disease caused by PV in the world will be as a result of the use of live OPV. In most parts of the world that continue to use OPV, the disease burden caused by VAPP already exceeds that of wild PV and has for some time. In addition, the continued use of OPV also poses a risk for outbreaks from vaccine-derived polioviruses (VDPV). VDPV are derived from OPV, but differ from the OPV strains and from the frequent PV isolates seen soon after vaccination with OPV by having more than 1% nucleotide changes in the coding region for VP1. The demarcation of more than 1% is somewhat arbitrary, but is consistent with prolonged replication that may be associated with circulation of the virus. After observations of several recent outbreaks of VDPV, this definition has been modified for PV type 2 to be greater than 0.6% difference from the parent vaccine strain. Most OPV-like isolates and most PV excreted from patients with VAPP have less than 1% nucleotide change in the VP1 coding region and, therefore, are not classified as VDPV because the duration of infection is short and because random mutations do not accumulate and become genetically fixed as observed with VDPV and WPV.

VDPV fall into three groups: (a) circulating VDPV (cVDPV), (b) immunodeficiency-associated VDPV (iVDPV), and (c) ambiguous VDVP (aVDPV) in which the source of infection is unknown. Although recognized as a potential problem associated with OPV for more than 40 years, the occurrence of multiple outbreaks involving cVDPV in 26 different countries within the last 19 years has explicitly demonstrated this risk.[524] The first documented cVDPV outbreak of poliomyelitis occurred on the island of Hispaniola in 2000–2001, with 21 virologically confirmed cases in Haiti and the Dominican Republic and with many more apparent cases from which no specimens were collected.[269,270] Since this outbreak in Hispaniola, cVDPV outbreaks have occurred in numerous countries, including the large multiyear outbreak of type 2 cVDPV in Nigeria.[61] In addition, cVDPV have been recognized retrospectively in other countries, particularly Egypt, where the type 2 cVDPV virus was endemic for possibly 10 years.[535] Similar to wild PV, cVDPV often recombine with other species C enteroviruses during circulation, although nonrecombinant cVDPV have been observed. cVDPV circulate in regions that have inadequate vaccine coverage along with an absence of natural infection from circulating wild PV of the same serotype.

The strains are of particular concern because they cause paralytic disease and have a capacity for sustained person-to-person transmission similar to wild PV of the same type.[131] The presence of cVDPV underscores the importance of maintaining excellent surveillance, the need to maintain high vaccine coverage, and the continued risk from suboptimal use of OPV, even in polio-free areas of the world.

Although not as great a concern as cVDPV, an issue that complicates PV eradication is the demonstrated excretion of iVDPV, in at least a few examples, for periods of more than a decade. The occurrence of iVDPV is rare, however, even in immunosuppressed patients. Although both iVDPV and cVDPV can occur in the absence of any recombination, recombination has only been observed in the case of iVDPV with other vaccine PV strains and not with other members of EV-C. This is presumably because of the absence of EV-C coinfections in the tissue supporting the chronic PV infection, in contrast to the frequent recombination observed between vaccine strains that occur in normal vaccinees. Interestingly, prolonged excretion with PV in immunodeficient individuals occurs with viruses derived from OPV and not with wild PV.[272] This may be because the greater neurovirulence of wild PV would be expected to lead to a uniformly fatal outcome in immunosuppressed individuals or because individuals with severe immunodeficiencies are likely to live in PV-free countries and, therefore, are only exposed to vaccine strains. Currently, no evidence indicates that patients with cell-mediated deficiencies are at increased risk for chronic PV infections. Prolonged excretion of PV has not been observed in studies undertaken specifically to look at human immunodeficiency virus–infected children and adults.[183,194]

Included in the VDPV group are ambiguous VDPV (aVDPV) in which the source of infection is unknown (e.g., VDPV isolates from environmental sources), no known immunodeficiency is found in the patient, or the isolate is associated with an AFP case, but without clear virologic or epidemiologic evidence of circulation.[62] For example, in more than 10,000 vaccine-related isolates studied in WHO Network laboratories in 2011, there were 67 cVDPV (from six recent outbreaks).[73,524]

Because of the risks evident from VAPP and VDPV, the WHO has concluded that continued use of OPV following wild PV eradication is incompatible with the ultimate goal of polio eradication. Therefore, sometime

after the eradication of wild PV, all use of OPV for routine immunization will stop. This has significant implications for immunization policy decisions and raises two very important basic questions regarding the management of risks: What vaccination policies will be recommended for PV? How will future PV outbreaks or cases be controlled after OPV use has stopped? In the absence of any reported wild PV type 2 since 1999, the world has embarked on significant change to the routine vaccination recommendations with a focus on the withdrawal of type 2 containing OPV. The first step was the declaration of the eradication of indigenous wild PV type 2 in September 2015. The second step was the recommendation to introduce at least one dose of IPV into the routine program in all countries to provide continued type 2 immunity. The last step was the synchronized global switch in the more than 100 OPV-using countries from the trivalent OPV having all three types, to a bivalent OPV containing only types 1 and 3 in April 2016.[524] Despite the logistical and regulatory challenges, this effort was largely successful.[413]

One anticipated challenge that occurred after the switch was the detection of ongoing circulating VDPV type 2. To address the need to respond to these outbreaks, a stockpile of monovalent type 2 OPV was manufactured to be released only by authorization of the Director General of WHO. This control was needed to limit the exposure to the population of a live OPV strain that would have the potential risk of creating new circulating VDPV type 2 because of the outbreak response. Three years after the switch, the world is still struggling to complete this last step in the removal of all live type 2 PV from circulation in the world, one of the ultimate goals of eradication. These challenges with the removal of type 2 OPV will provide lessons for the final removal of the remaining type 1 and 3 OPV. This will provide the stage for future long-term polio vaccination policy.

Ideally, it should be possible to describe accurately all of the advantages and disadvantages of choices related to future vaccination policy. It is difficult, however, to estimate and quantitate risks for all populations associated with the cessation of OPV use because of inadequate knowledge about type-specific reversion of vaccine strains and viral genetic determinants for neurovirulence and transmissibility. It is also not clear what protective benefits are possible in the absence of high levels of routine IPV use. An attempt to use elements of decision analysis and disease modeling has been made to try to provide better information regarding risk assessments.[126,481]

Regardless of decisions made about immunization policies, future generations will have an increasing susceptibility to PV as immunization becomes the only source of immunity. For this reason, another key component of activities related to posteradication risk management is the establishment of a global stockpile of vaccine to respond to any outbreak in the future. In most developed countries in temperate climates, IPV has proved very effective in preventing outbreaks in the general population and may remain the vaccine of choice for small outbreaks in the countries. Much remains unknown about the potential for IPV to control PV circulation in developing countries because IPV induces a lower level of mucosal immunity than OPV.[155] Because OPV is the only vaccine that has ever been demonstrated to stop circulation of PV in developing countries, it will likely remain the vaccine of choice for the global stockpile. If an outbreak does occur, it is reasonable to expect that it will be caused by a single serotype in a specific place or time, prompting the maintenance of monovalent OPV strains in the stockpile. The use of monovalent OPV strains will eliminate the need to introduce undesirable additional strains into the population. Details remain, however, about the response plans and the use of the stockpile that need to be completed. In addition, issues remain about what should be done at the boundaries of the response population. It may be that the process of eliminating OPV may be as complicated and difficult as the process of eradicating the wild virus.

When the eradication program began, it was assumed that the vaccines available at the time were sufficient for the successful achievement of the goal. With the growing knowledge of the risks associated with OPV and the possible difficulties associated with either continuing or stopping its use in the future, hindsight indicates that the availability of additional options would be highly desirable. In the intervening years, many new approaches to vaccinology have been developed, raising the possibility of developing new PV vaccines (e.g., genetically engineered PV, noninfectious DNA, or immunogenic peptides). Despite the significant difficulties involving testing these new interventions, it seems appropriate to continue active investigations in this area.[196]

The world has endured the crippling effects of PV for millennia, yet the end of these particular viruses is approaching. It is possible that the next edition of this chapter will treat PV quite differently, possibly even as a

historic footnote, rather than a major focus of public health activities.

PERSPECTIVES

For 25 to 50 years before the identification of acquired immunodeficiency syndrome, much of human virology was focused on PV. With the eradication of PV imminent, the picornavirology field is changing and will never be the same again. It is somewhat ironic to realize that, despite the incredible advances in our understanding of the molecular aspects of PV and the availability of extraordinarily powerful molecular tools for studying PV, the eradication of poliomyelitis will become a reality as a result of the use of the Salk and Sabin vaccines, vaccines that were generated empirically in the middle of the last century before the breakthroughs in our understanding of the molecular biology of PV.

But perhaps, it is unfair to belittle the achievements of modern techniques in the eradication of PV. Certainly, the tools of molecular biology were and will continue to be important in monitoring and tracking PV and identifying strains; it also may be that new technology and knowledge will make a better PV vaccine. Novel diagnostic methods developed to assist in surveillance of poliomyelitis are likely to aid in the identification of new enteroviruses, provide better and more accurate descriptions of the epidemiology of EV infections, and lead to new anti-EV drugs, nonpolio EV vaccines, and a better understanding of the relationship of EV to acute and chronic human disease.

What new directions will drive the field of picornavirology? Pressure exists to develop new antiviral treatments and vaccines. New antiviral approaches will take advantage of knowledge of virus receptors, structures of capsid and nonstructural proteins, and immunologic features of the disease. New vaccines will be pursued and developed. The ability of EV71 to mount large epidemics and to be a major cause of neurologic disease, especially AFP, is likely to have already generated special interest with respect to vaccine development. The many diseases that the coxsackieviruses cause also make this group of viruses of great interest from the point of view of vaccine development. In addition, investigations of coxsackieviral diseases may clarify the pathogenesis of virus-induced autoimmune diseases.

Despite the development of new treatments and vaccines, enteroviruses

will still be very much with us, even after the eradication of PV.

Perspective

The family *Caliciviridae* is composed of small (27–40 nm), nonenveloped, icosahedral viruses that possess a linear, positive-sense, single-stranded RNA (ssRNA) genome. The 11 genera of the family are *Norovirus*, *Sapovirus*, *Bavovirus*, *Lagovirus*, *Minovirus*, *Nacovirus*, *Nebovirus*, *Recovirus*, *Salovirus*, *Valovirus*, and *Vesivirus*.[625] The major human pathogens in the family are the noroviruses and sapoviruses, which cause acute gastroenteritis. Important veterinary pathogens include vesiviruses such as feline calicivirus (FCV), which causes a respiratory disease in cats, and lagoviruses such as rabbit hemorrhagic disease virus (RHDV), which causes an often-fatal hemorrhagic disease in rabbits. This chapter provides a description of the family *Caliciviridae*, with major emphasis on the noroviruses because of their prominent role in sporadic and epidemic gastroenteritis.[5]

HISTORY

The establishment of a viral etiology for gastroenteritis in humans was a decades-long process that was hampered by the fastidious nature of many of

these viruses for growth in cell culture.[255] Volunteer studies carried out in the 1940s and 1950s in the United States and Japan played a major role in establishing that filterable, nonbacterial infectious agents can cause enteric disease.[255] An important advance occurred in 1972 with the discovery of Norwalk virus (NV) by Kapikian et al.[256] Stool material from a rectal swab obtained from an ill individual involved in a gastroenteritis outbreak that had occurred at an elementary school in Norwalk, Ohio, in October 1968 was administered to adult volunteers as a bacteria-free filtrate and serially passaged to other volunteers, inducing acute gastroenteritis in certain individuals.[140,141] Virus particles (named Norwalk virus for the location of the original outbreak) were visualized in stool material from these volunteers by the technique of immune electron microscopy (IEM)[256] (Fig. 4.1). Hawaii virus (from a family outbreak of gastroenteritis that occurred in Honolulu in 1971) and Snow Mountain virus (from an outbreak in a Colorado resort camp in 1976) were subsequently discovered in 1977 and 1982, respectively, and shown to be antigenically distinct by IEM.[144,591] Norwalk virus would become the prototype strain for these and other “small round structured viruses,” known now as the noroviruses.

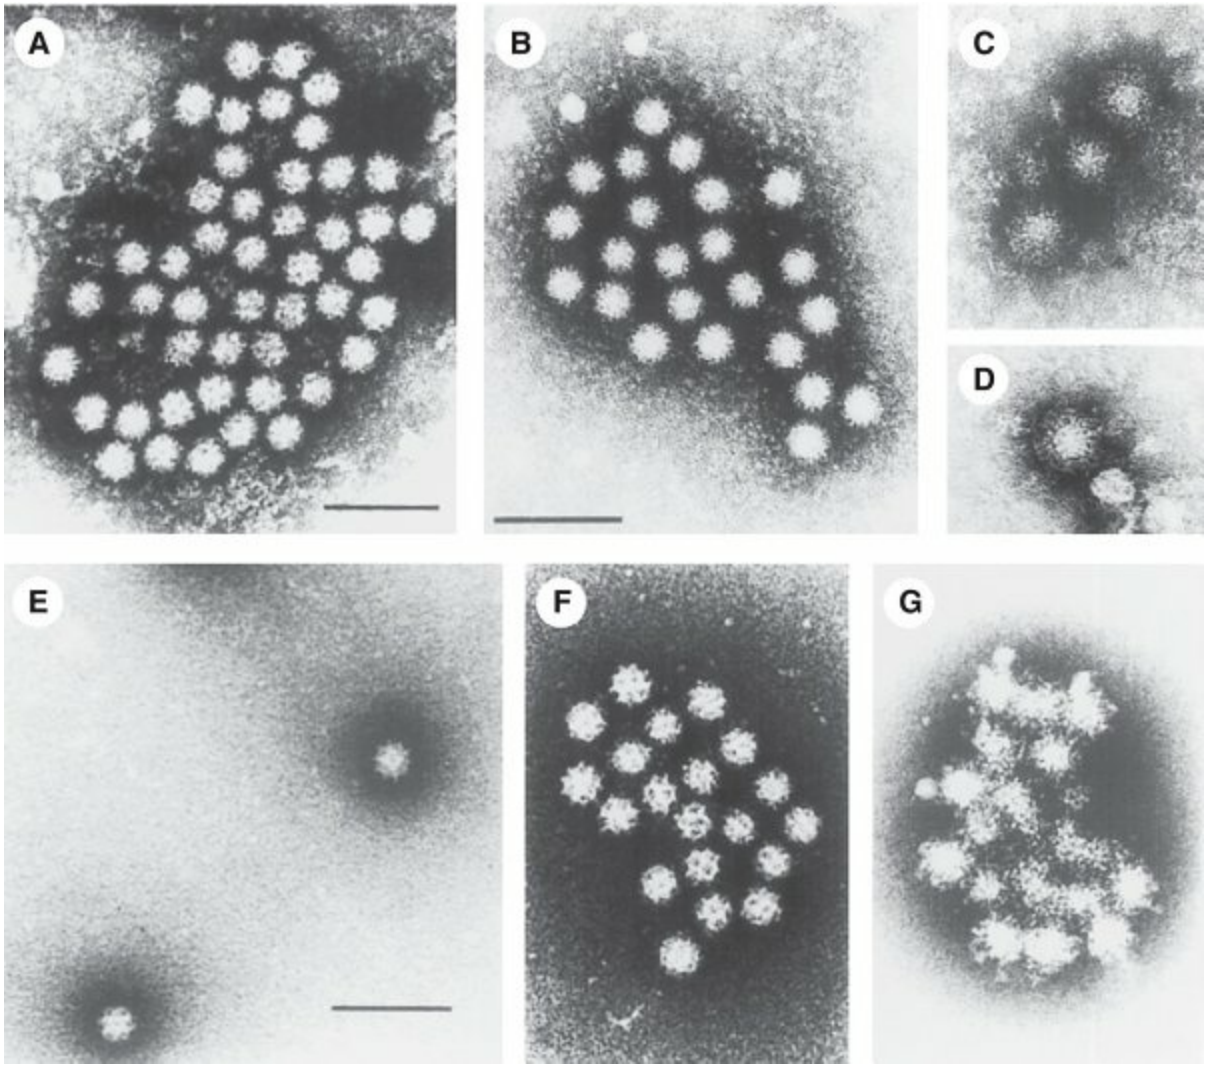

FIGURE 4.1 Norwalk virus (NV) (genus *Norovirus*) and Sapporo virus (genus *Sapovirus*) in stool material. **A:** NV particles in a stool filtrate visualized by immune electron microscopy (IEM). **B:** An aggregate observed after incubation of NV stool filtrate with a 1:5 dilution of volunteer's prechallenge serum. Particles have a light coating of antibody molecules. The amount of antibody present on this aggregate was given a rating of 1 to 2 to 2+, and the serum was given an overall rating of 1 to 2+ on a scale of 1 to 4. **C, D:**Three single particles **(C)** and one individual particle **(D)** observed after incubation of the NV stool filtrate with a 1:5 dilution of the same volunteer's postchallenge convalescent serum. Particles are heavily

coated with antibody molecules. At high antibody levels (antibody excess), large aggregates may not be seen. The amount of antibody was given a rating of 4+, and the serum was given an overall rating of 4+ on a scale of 1 to 4. **E:** Sapporo virus particles in stool material visualized by direct electron microscopy (EM). The distinct, hollow cup-like structures are apparent. **F:** Sapporo virus particles after incubation with guinea pig hyperimmune serum. The amount of antibody was given a 1+ rating. **G:** An aggregate observed after incubation of Sapporo virus stool filtrate with guinea pig hyperimmune serum. The amount of antibody was given a rating of 4+ on a scale of 1 to 4. (**A–D** from Kapikian AZ, Wyatt RG, Dolin R, et al. Visualization by immune electron microscopy of a 27-nm particle associated with acute infectious nonbacterial gastroenteritis. *J Virol* 1972;10:1075–1081, with permission; **E–G** from Nakata S, Kogawa K, Numata K, et al. The epidemiology of human calicivirus/Sapporo/82/Japan. *Arch Virol* 1996;(Suppl 12):263–270, with permission.)

In 1976, the teams of Madeley and Cosgrove[373] and Flewett and Davies[168] reported the presence of viruses in the stools of children that showed a striking morphologic similarity to previously characterized animal caliciviruses that were known to exhibit “classical” distinct cup-like depressions on the surface of the virion. Chiba et al.[110] described a “classical” calicivirus, associated with gastroenteritis, in infants and young children living in an infant home in Sapporo, Japan, in 1977. Another virus (later designated Sapporo/82/Japan) that exhibited classical calicivirus morphology was subsequently detected from this same infant home and characterized antigenically by IEM[422] (Fig. 4.1). The Sapporo virus would become the prototype strain for the “Sapporo-like viruses” or “classical caliciviruses,” known now as the sapoviruses.

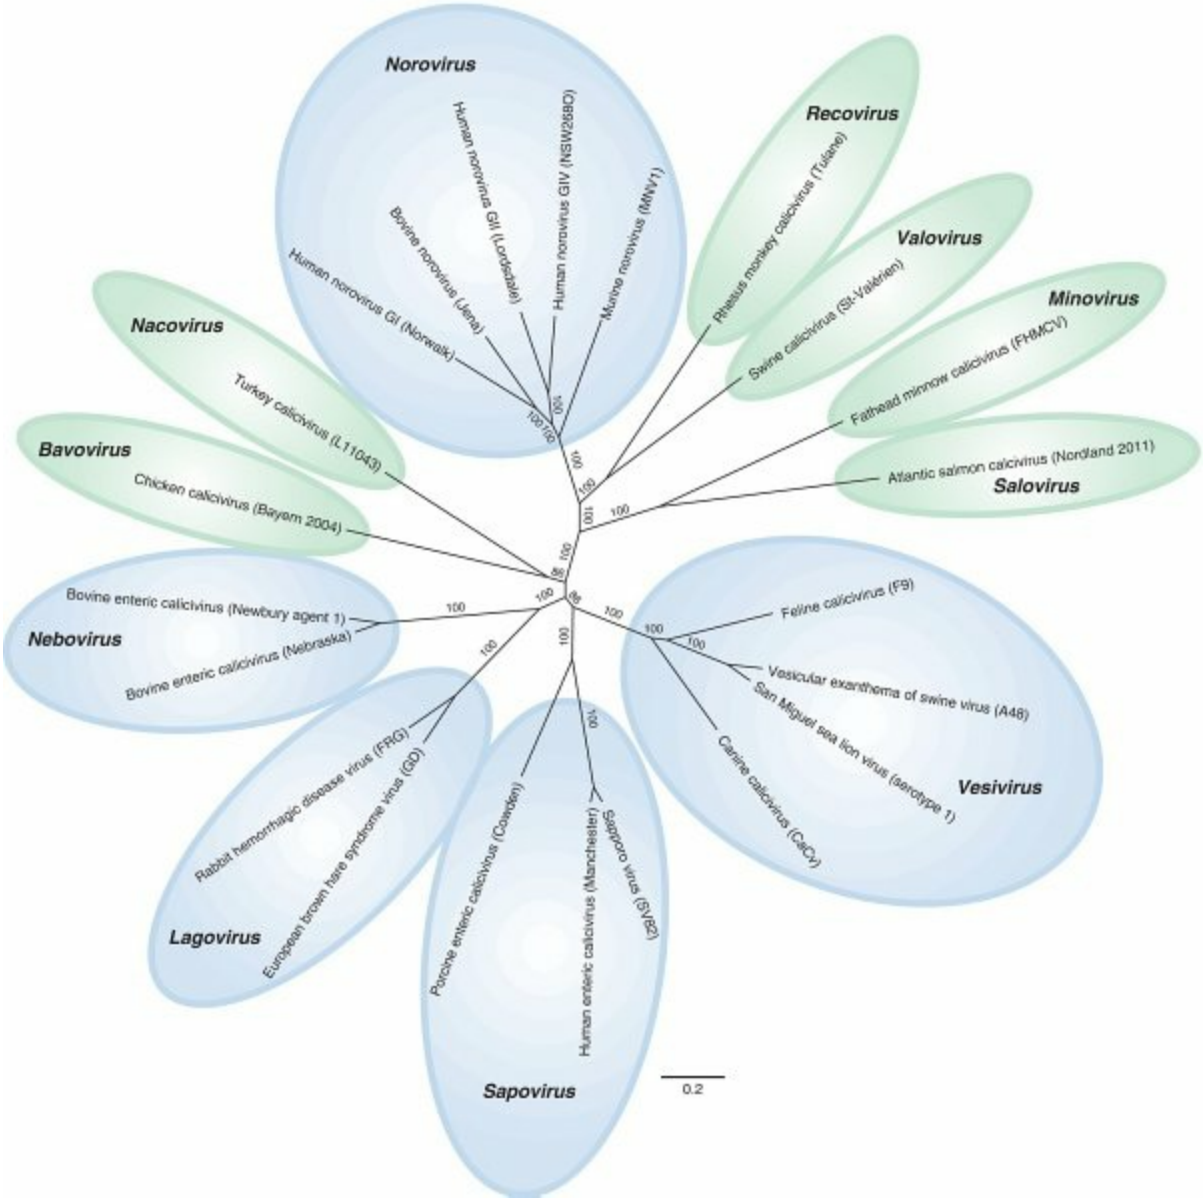
In the late 1980s, the stool filtrate derived from the Norwalk, Ohio, outbreak was fed to adults in volunteer studies to obtain adequate quantities of virus particles to characterize the viral genome.[242] This major advance by

Jiang et al.[242] established the classification of NV as a member of the *Caliciviridae*. The complete RNA genome sequences of NV and the closely related Southampton virus were determined and found to be organized into three major open reading frames (ORF1, ORF2, and ORF3) with a polyadenylated 3′ end[211,245,317,319] (see *Genome Structure and Organization*). The ORF1 was shown to encode a large polyprotein that was proteolytically processed into the mature nonstructural proteins.[345,348] The ORF2 encoded the major capsid protein, VP1, and ORF3 encoded a minor structural protein, VP2. The human noroviruses initially segregated into two major phylogenetic groups within what would become the genus *Norovirus* of the *Caliciviridae* that were designated as genogroups I (GI) and II (GII), with NV belonging to GI and the Hawaii and Snow Mountain viruses belonging to GII.[332,630] In addition, sequence analysis of the "classical caliciviruses" confirmed that they were distinct from the noroviruses, ultimately forming a separate genus, *Sapovirus*, within the *Caliciviridae*.[318,344,388,450]

CLASSIFICATION

Members of the virus family *Caliciviridae* have a virion protein, genome (VPg)-linked, positive-sense RNA genome that is polyadenylated and surrounded by a nonenveloped, icosahedral capsid of 27 to 40 nm in diameter. The capsid is constructed predominantly from a major structural protein, VP1, of approximately 60,000 Daltons (D). The 11 genera of Caliciviridae—*Norovirus*, *Sapovirus*, *Bavovirus*, *Lagovirus*, *Minovirus*, *Nacovirus*, *Nebovirus*, *Recovirus*, *Salovirus*, *Valovirus*, and *Vesivirus*—each represent a distinct phylogenetic clade in the family[625] (Fig. 4.2A). Within each genus, one or more species has been defined based primarily on genetic relatedness, and the current taxonomic structure of the *Caliciviridae* is shown in Table 4.1. Below the level of species in certain genera (*Norovirus* and *Sapovirus*), provisional genetic typing systems (consisting of genogroups subdivided into genetic clusters or genotypes) have proven useful in epidemiologic studies (see *Molecular Epidemiology*). The striking genetic diversity of noroviruses associated with human disease is illustrated in a phylogenetic analysis of strains representing different genotypes within GI, GII, and GIV (Fig. 4.2B).

A Family: ***Caliciviridae***



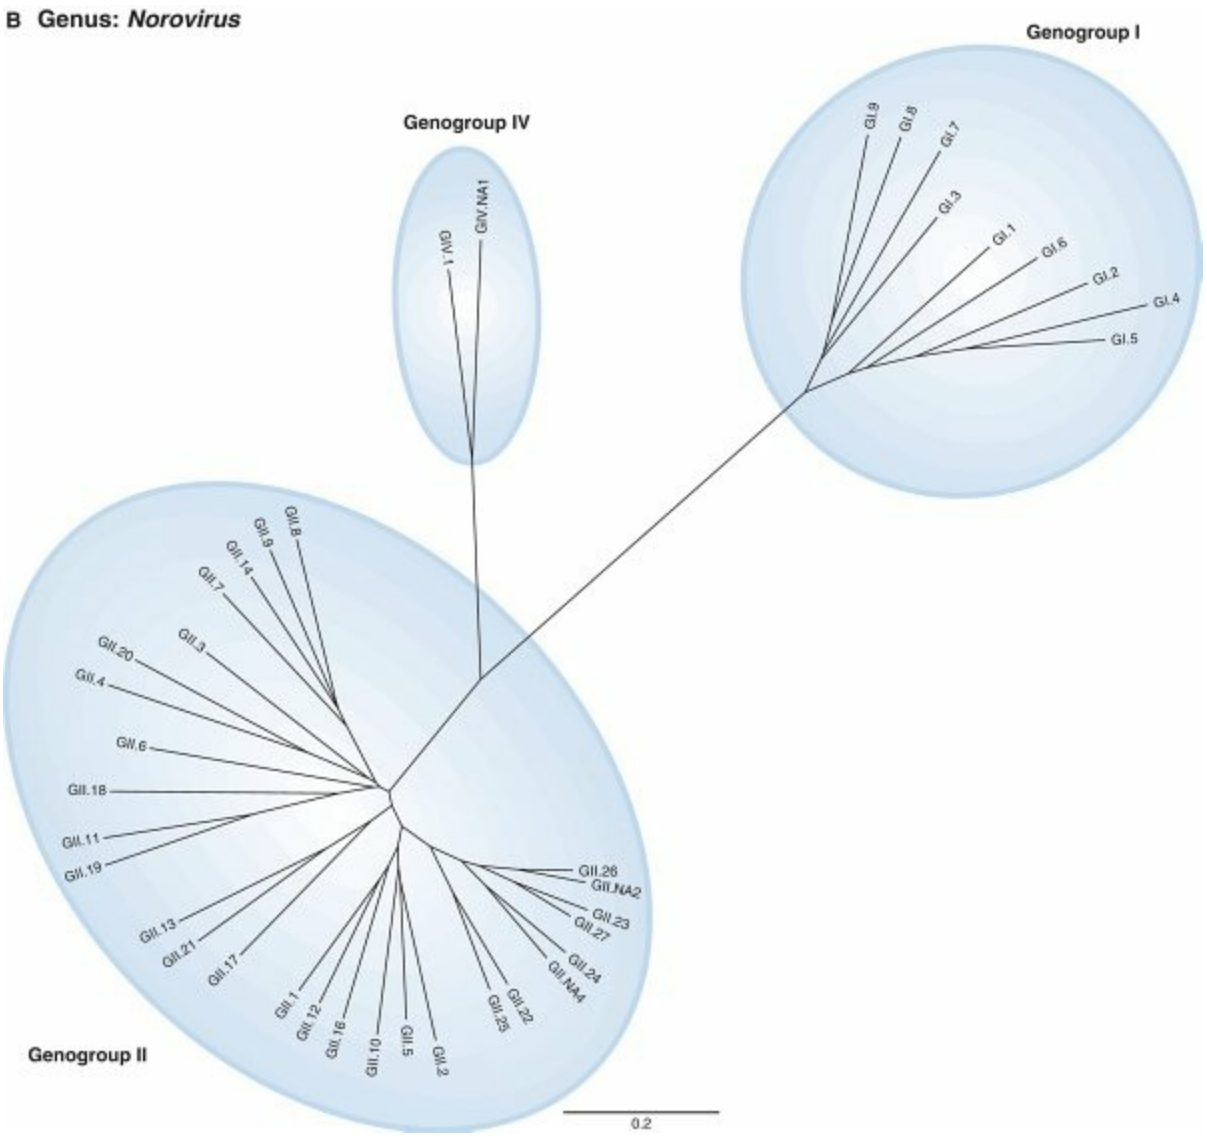


FIGURE 4.2 A: Phylogenetic relationships among representative members of the family *Caliciviridae*. The 11 established genera are *Norovirus*, *Sapovirus*, *Bavovirus*, *Lagovirus*, *Minovirus*, *Nacovirus*, *Nebovirus*, *Recovirus*, *Salovirus*, *Valovirus*, and *Vesivirus* according to the International Committee on Taxonomy of Viruses, with new genera recently approved shaded in *green*.[625] To generate this dendrogram, full-length genomic sequences were first aligned with the ClustalW algorithm in the MacVector, Inc. (Cary, NC) software package. Additional evolutionary analysis was conducted with the MEGA software package. Finally, phylogenetic

relationships were inferred using the neighbor-joining method,[510] with the evolutionary distances computed by the Jukes-Cantor method.[249] The statistical support for tree nodes was evaluated by bootstrap analysis (1,000 replicates). The tree was drawn to scale, with branch lengths in the same units as those of the evolutionary distances used to infer the phylogenetic tree. **B:** Phylogenetic relationships among the VP1 proteins from three representative genogroups (I, II, and IV) within the genus *Norovirus* that are characteristically associated with gastroenteritis in humans. This genotyping system is employed as an epidemiological tool to track the spread of genetically diverse noroviruses in susceptible populations (see Epidemiology and Table 4.5). (Analysis and figure from S.V. Sosnovtsev.)

TABLE 4.1 Taxonomic structure of the *Caliciviridae*

Genus	Species	Representative Strain[a]	GenBank Accession Number of Reference Genome
Bavovirus	*Bavaria virus*	Bavovirus/chicken/DE/2004/Bavaria V0021	HQ010042
Lagovirus	*Rabbit hemorrhagic disease virus*	Lagovirus/rabbit/DE1988/RHDV-FRG	M67473
	European brown hare syndrome virus	Lagovirus/hare/FR/1989/EBHSV-GD	Z69620
Minovirus	*Minovirus A*	Minovirus/fathead minnow/US/2012/FHMCV	KX371097
Nacovirus	*Nacovirus A*	Nacovirus/turkey/DE/2011/TC L11043	JQ347522
Norovirus	*Norwalk virus*	Norovirus/human/US/1968/Norwalk	M87661
Nebovirus	*Newbury 1 virus*	Nebovirus/bovine/UK/1976/Newbury-1	NC_007916
Recovirus	*Recovirus A*	Recovirus/rhesus macaque/US/2004/Tulane	EU391643
Salovirus	*Nordland virus*	Salovirus/salmon/NO/2011/Nordland	KJ577139
Sapovirus	*Sapporo virus*	Sapovirus/human/JP/1982/Sapporo	HM002617
Valovirus	*St. Valérien virus*	Valovirus/porcine/CA/2006/St. Valérien AB90	FJ355928
Vesivirus	*Vesicular exanthema of swine virus*	Vesivirus/porcine/US/1948/VESV-A48	AF181082
	Feline calicivirus	Vesivirus/feline/US/1958/FCV-F9	M86379

[a]The cryptogram is organized as follows: Genus/host of origin/country of origin/year of occurrence/strain name.

VIRION STRUCTURE

Calicivirus virions exhibit $T = 3$ icosahedral symmetry. The capsid contains

90 dimers of the VP1 capsid protein that form a shell from which 90 arch-like capsomeres protrude at the local and strict twofold axes.[79,105,268,478,480,481,662] The dimers form two classes, A/B and C/C, with 60 A/B dimers located at the icosahedral quasi fivefold axis and 30 C/C dimers at the quasi twofold axis. The major capsid protein VP1 is organized into two major domains designated shell (S) and protruding (P) domain that are connected by a hinge region, as represented in a diagram of the NV VP1 (530 aa in length)[478] (Fig. 4.3). The N-terminal amino acids of VP1 form the N-terminal arm (NTA) that is found in the interior of the capsid and links the dimeric subunits (Fig. 4.3). The S domain is the most highly conserved region of the VP1 and forms a smooth inner shell that surrounds the RNA genome. The S domains of the A/B and C/C dimers adopt a "bent" versus "flat" conformation, respectively, to conform to the icosahedral $T = 3$ shape.[662] The P domains form the arch-like protrusions that emanate from the shell and contain the dimeric contacts. This domain is further subdivided into the P1 and the P2 subdomains. The P1 subdomains form the sides of the arch of the capsomeres and position the highly variable P2 subdomain at the top of the arch. These arches are arranged in such a way that 32 large hollows are formed at the icosahedral five- and threefold positions that appear as cup-like structures on the surface of caliciviruses (*calici* is derived from the Latin word *calyx*, or cup). Cryo-electron microscopy and computer image processing studies of representative caliciviruses show subtle variation in the capsid structures that are consistent with their differences in appearance by negative-stain EM that can range from a feathery appearance (many noroviruses, such as *Norwalk virus* in Fig. 4.1A) to the presence of sharply defined "cups" (many sapoviruses, such as Sapporo virus in Fig. 4.1E and the vesiviruses).[105,480] The exposure of the variable P2 domain on the surface is consistent with its role as the major antigenic site and in binding to cellular receptors and attachment factors.[83,276,351,429,478,528,575]

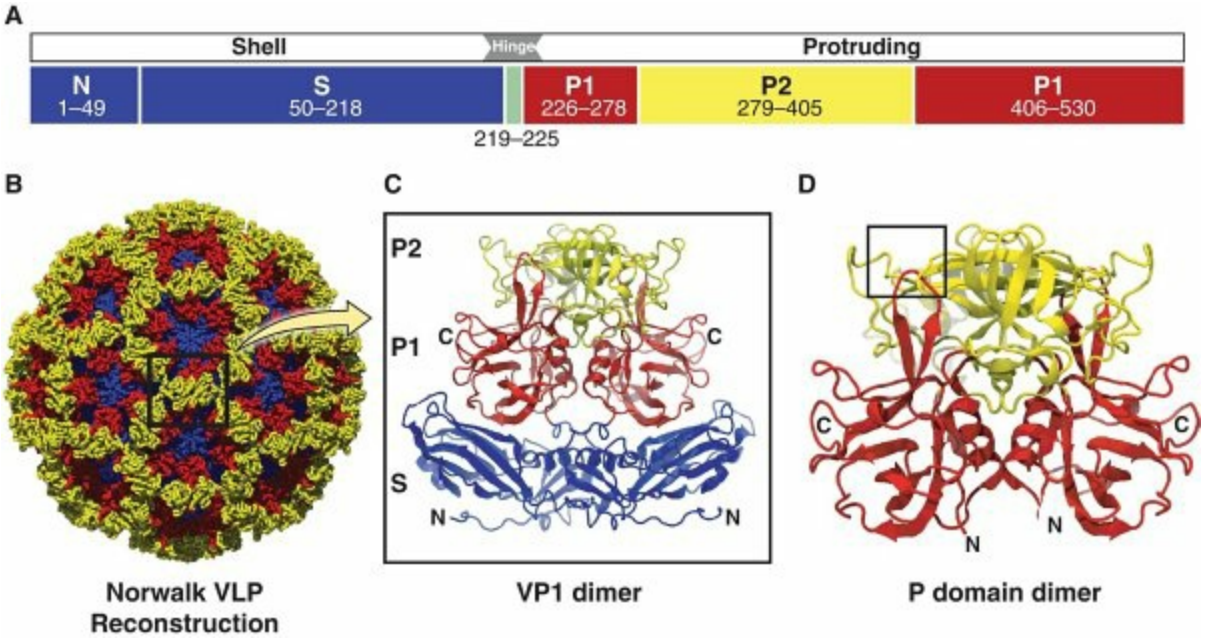

FIGURE 4.3 Organization of the norovirus major capsid protein, VP1. **A:** The Norwalk virus major capsid protein VP1 is 539 amino acids (aa) in length and is organized into two major parts, shell (S) and protruding (P), connected by a hinge (H) region. The aa borders of the defined domains are N-terminal (N) arm, 1 to 49; S, 50 to 218; hinge, 219 to 225; P1, 226 to 278 and 406 to 530; and P2, 279 to 405. **B:**(Adapted from Prasad BV, Hardy ME, Dokland T, et al. X-ray crystallographic structure of the Norwalk virus capsid. *Science* 1999;286:287–290.) Model of the *T* = 3 Norwalk virus whole capsid, determined at 3.4-Å resolution.[478] The capsid is composed of 90 dimers of VP1, with the S, P1, and P2 domains shown in *blue*, *red*, and *yellow*, respectively. The box highlights the arrangement of a VP1 dimer as it is displayed on the surface of the virion. **C:** Three-dimensional ribbon representation of a VP1 dimer derived from x-ray crystallography studies of Norwalk virus rVLPs at 3.4-Å, showing the presentation of the P2 domain at the top of an arch supported by two P1 domain "arms".[478] The S domain forms the internal scaffold of the virion that surrounds the RNA genome and positions the arch to the virion surface. The N-terminus (N)

and C-terminus (C) of the VP1 are indicated. **D:** Three-dimensional ribbon representation of a P domain-only dimer, determined at 1.4-Å resolution.[112] The *box* highlights the location of an HBGA carbohydrate-binding site mapped within the P2 domain (see Fig. 4.11). (Images provided by B.V.V. Prasad.)

Structural comparisons of caliciviruses have shown major points of flexibility in the capsid protein. One region of flexibility is in the hinge between the S and P domains. As a result of this flexibility, the capsid protein in these viruses exhibits two distinct conformations, “closed” and “elevated.” In the structures of NV, San Miguel sea lion virus (SMSV), and FCV, the capsid protein exhibits a “closed” conformation in which the P domain interacts closely with the S domain,[105,457,479] whereas, in the structures of murine norovirus (MNV), RHDV, and Vietnam026 (human norovirus GII.10), the capsid protein exhibits an “elevated” conformation in which the P domain is rotated by about 40 to 53 degrees and significantly raised relative to the S domain[209,269,607] (Fig. 4.4). The biologic consequences or triggers for these movements are currently unknown. The other region of flexibility is within the P domain. X-ray crystallography of the MNV P domain captured a surface-exposed loop within the P domain in two conformations, “open” and “closed”.[268] Engineered mutations that locked the loop into a closed conformation allowed the virus to escape neutralization by a potent neutralizing monoclonal antibody (A6.2) that had been mapped to this loop.[298] Molecular dynamics simulations suggest that escape from another neutralizing antibody (2D3) similarly affects the conformational relaxation of the MNV P domain even though the escape mutation is located distally from the antibody binding site at the top of the P domain.[299] The binding of bile acid has recently been shown to affect the conformation and stability of loop structures in the MNV P domain and enhance receptor binding.[275] Therefore, it is likely that capsid flexibility is an inherent feature of calicivirus virions and that this is critical during successful infection and pathogenesis.

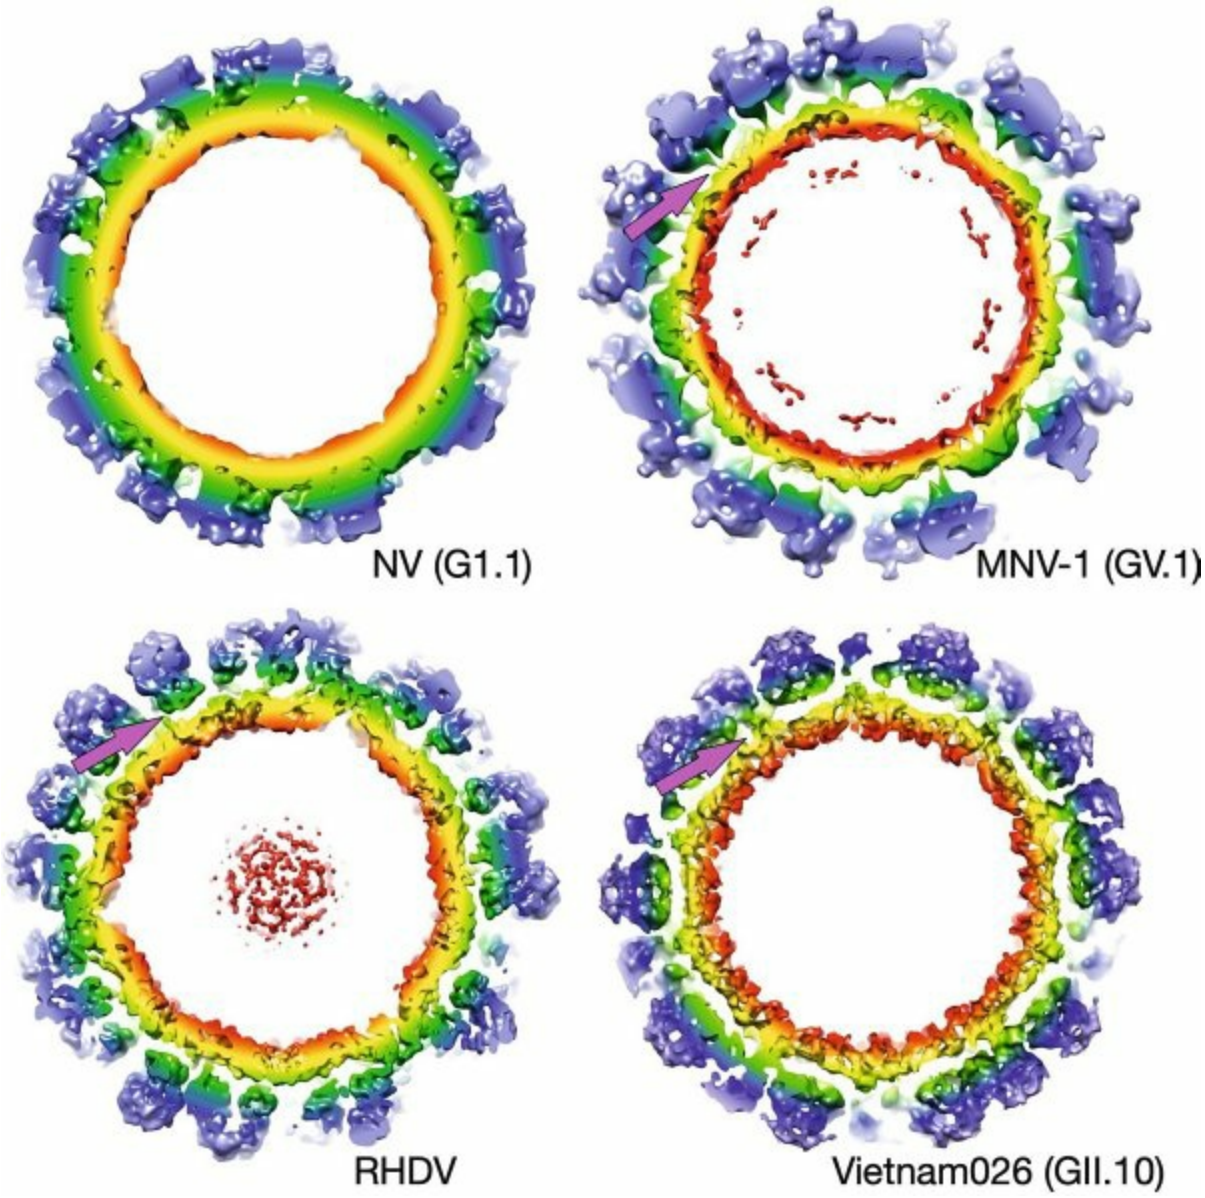

FIGURE 4.4 Calicivirus capsid reconstructions. Shown are central slices of the surface renderings of representative caliciviruses. The crystal structure of Norwalk virus (G1.1) was used to produce its corresponding image,[478] while the remaining three MNV-1,[269] RHDV,[268] and Vietnam026[209] were derived from their cryo-EM image reconstructions. The figures are colored according to radius with the *red hues* being the shortest radii and *purple* being the longest. The *pink arrows* indicate the region of flexibility between the S and P domain, where the P domain is "elevated" above the S

domain. In contrast, the Norwalk virus P domain interacts closely with the S domain in a “closed” conformation. (Images provided by T. Smith.)

Infectious virions also contain a minor capsid protein VP2 that associates with the S domain on the interior surface of the virion.[629] Roles for VP2 in viral entry (see below *Stages of Replication*) and assembly have been proposed.[115,629] Inside the virion, VP1 and VP2 interact via a highly conserved patch of residues in VP1 (IDPWI motif) that is located at the junction of the NTA and S domain. In particular, the first isoleucine residue of this motif (Ile-52 in NV) lies so that the two Ile-52 residues in a VP1 dimer are at the center of a negatively charged belt spanning the inner surface of the S dimers. Mutation of this residue ablates VP2 incorporation into particles. The VP1-interacting domain of VP2 was mapped to amino acids 108 to 152.[183] Computational analysis revealed that this region in VP2 is hypervariable in GII.4 human norovirus strains, suggesting that VP1 and VP2 covary in virus evolution, such that when mutations in VP1 arise, VP2 adapts to the changed conformation.[95] Coevolution and strong selective pressure for a functional VP2[547] are consistent with VP1 and VP2 interactions that would be required to create a proposed VP2-constructed portal emanating from the capsid for the release of genomic RNA[115] (see below *Stages of Replication*) (Fig. 4.5).

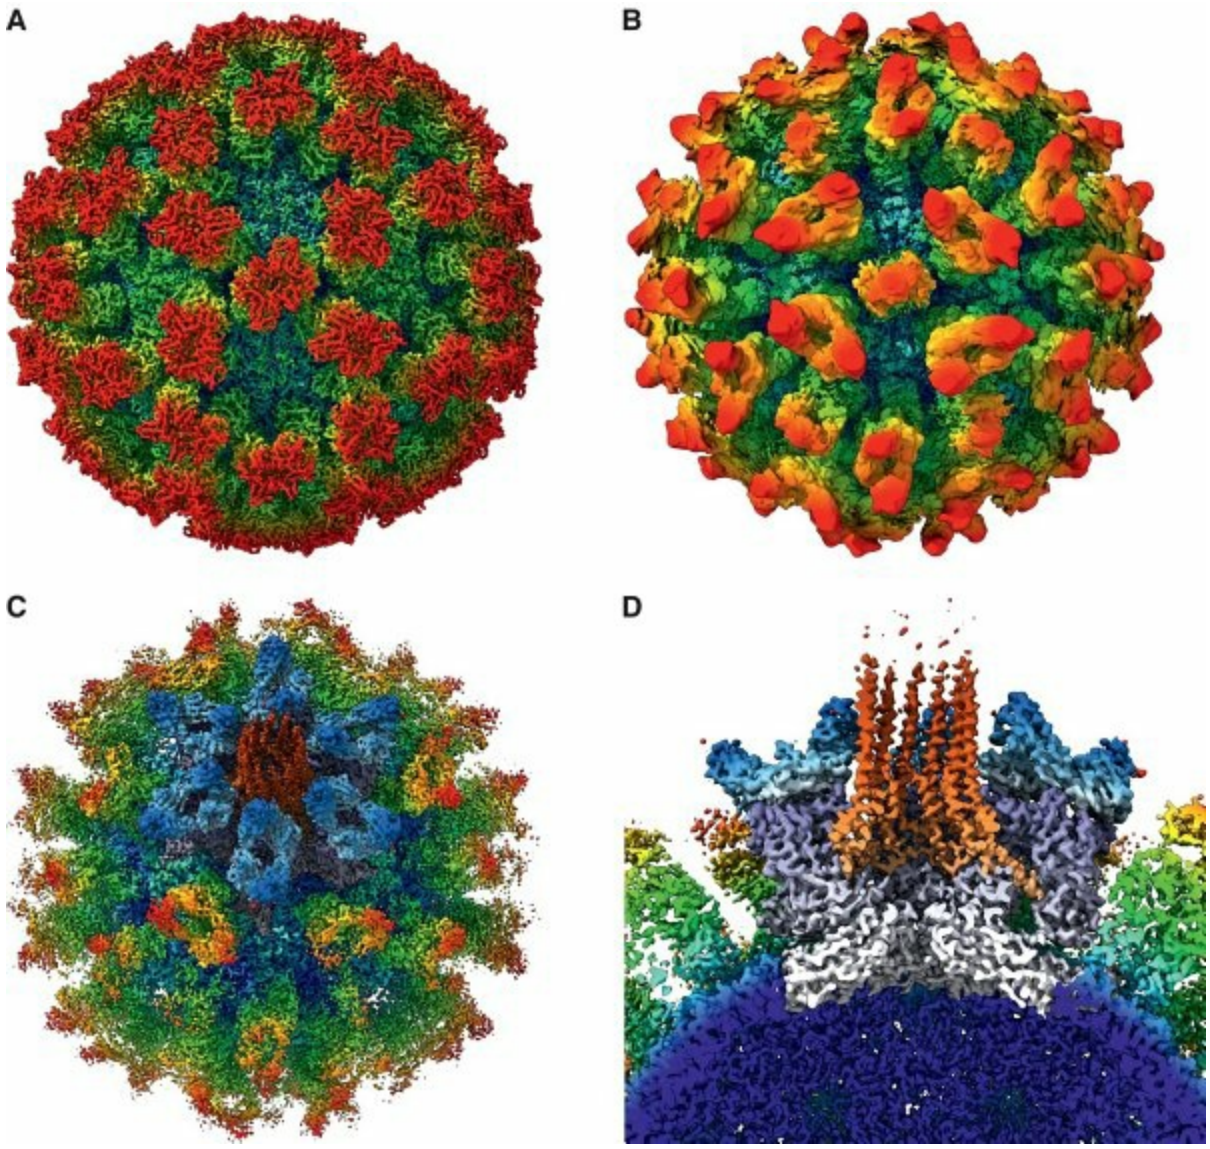

FIGURE 4.5 A: Structure of Feline calicivirus (FCV) strain F9, solved by cryogenic electron microscopy (cryo-EM) with imposition of icosahedral symmetry. **B:** Incubation of virus in the presence of a soluble fragment of feline junctional adhesion molecule A (fJAM-A) leads to binding of the receptor fragments to the outer face of the capsid P domains. Following receptor binding, the capsid undergoes conformational changes that break icosahedral symmetry—resulting in poorer resolution of the P domains and receptor. **C:** A low-symmetry reconstruction of the FCV-fJAM-A complex revealed the presence of a large portal-like

assembly on the capsid surface, comprising 12 copies of the minor capsid protein VP2. The portal is located at a unique threefold symmetry axis (VP1, purple; fJAM-A, blue; VP2, orange). **D:** A close-up view of the portal-like assembly reveals an opening (indicated by *arrow*) in the capsid shell at the portal axis. (Images provided by D. Bhella and adapted from Conley MJ, McElwee M, Azmi L, et al. Calicivirus VP2 forms a portal-like assembly following receptor engagement. *Nature* 2019;565:377–381.)

Calicivirus VP1 proteins have the ability to self-assemble into virus-like particles (VLPs), a process that is efficient and does not require RNA or VP2.[244,328] However, coexpression of VP2 increases VLP stability and resistance to proteases.[51,335] This self-assembly feature has been especially useful in the study of the fastidious caliciviruses, because recombinant (r) VLPs have served as a surrogate for native virions[192,244,246] and are the basis for current vaccine development approaches (see *Vaccines*). Calicivirus VLPs self-assemble into two classes of particles. The $T = 3$ symmetry particles are made from 180 copies of rVP1 (~38 nm in diameter), while smaller VLPs (~23 nm in diameter) with $T = 1$ symmetry are composed of 60 copies of VP1.[38,79,640] In $T = 3$ particles, the NTA is involved in interlocking the S domains of VP1 capsomeres. Whether the NTA determines the switch between the two types of particles is unclear at present. The NTA was not visible in x-ray structural studies of $T = 1$ VLPs of FCV,[79] and N-terminal truncation mutants of NV VP1 did not result in smaller particles.[52] In contrast, N-terminal truncations of the RHDV VP1 formed $T = 1$ VLPs.[38]

Knowledge of the capsid structure has also informed studies of capsid assembly. Capsid assembly is thought to occur in a series of successive steps that are highly dependent on solution pH, ionic strength, and VP1 concentration.[27,534] Based on the extensive dimer interfaces observed in the crystal structure of the recombinant NV capsid, a dimer of VP1, existing in equilibrium between “bent” and “flat” conformations, is proposed as the initial building block for the capsid assembly.[478] In support of VP1 dimers as the initial building block, norovirus VLPs disassemble into stable dimers of VP1, which can under the right conditions reassemble into particles.[27,534,602]

Subsequent capsid assembly is proposed to involve association of pentamers of these dimers linked by an interstitial dimer, with the VP1 dimers adapting a bent or a flat conformation as required to form a closed icosahedral shell. Such a capsid assembly model predicts the coexistence of 10-mers (one pentamer of dimers) and 20-mers (association of two pentamers of dimers) as intermediates. Any pentamers of dimers were too transient to be detected by time-resolved small-angle x-ray scattering (SAXS) data in VLP assembly of a bovine norovirus VP1.[603] However, the data showed the existence of a stave-shaped intermediate with dimensions consistent with two pentamers of dimers connected by a single interstitial dimer (i.e., 11 dimers)[603] (Fig. 4.6). Formation of quasi 6-fold symmetry, as observed in the $T = 3$ structure, would be anticipated to be a kinetically slow process that would occur only upon interlocking of intermediates into the final capsid (Fig. 4.6). Such contacts would require a switch in and neutralization of the negative charge of the NTA of VP1 around the quasi 6-fold axes. NTA charge neutralization is thought to be achieved by interaction with the internally located, positively charged VP2.[607,629] Consistent with this, VLPs produced by coexpression of VP2 and VP1 in contrast to VP1 alone are more stable and structurally homogenous.[51]

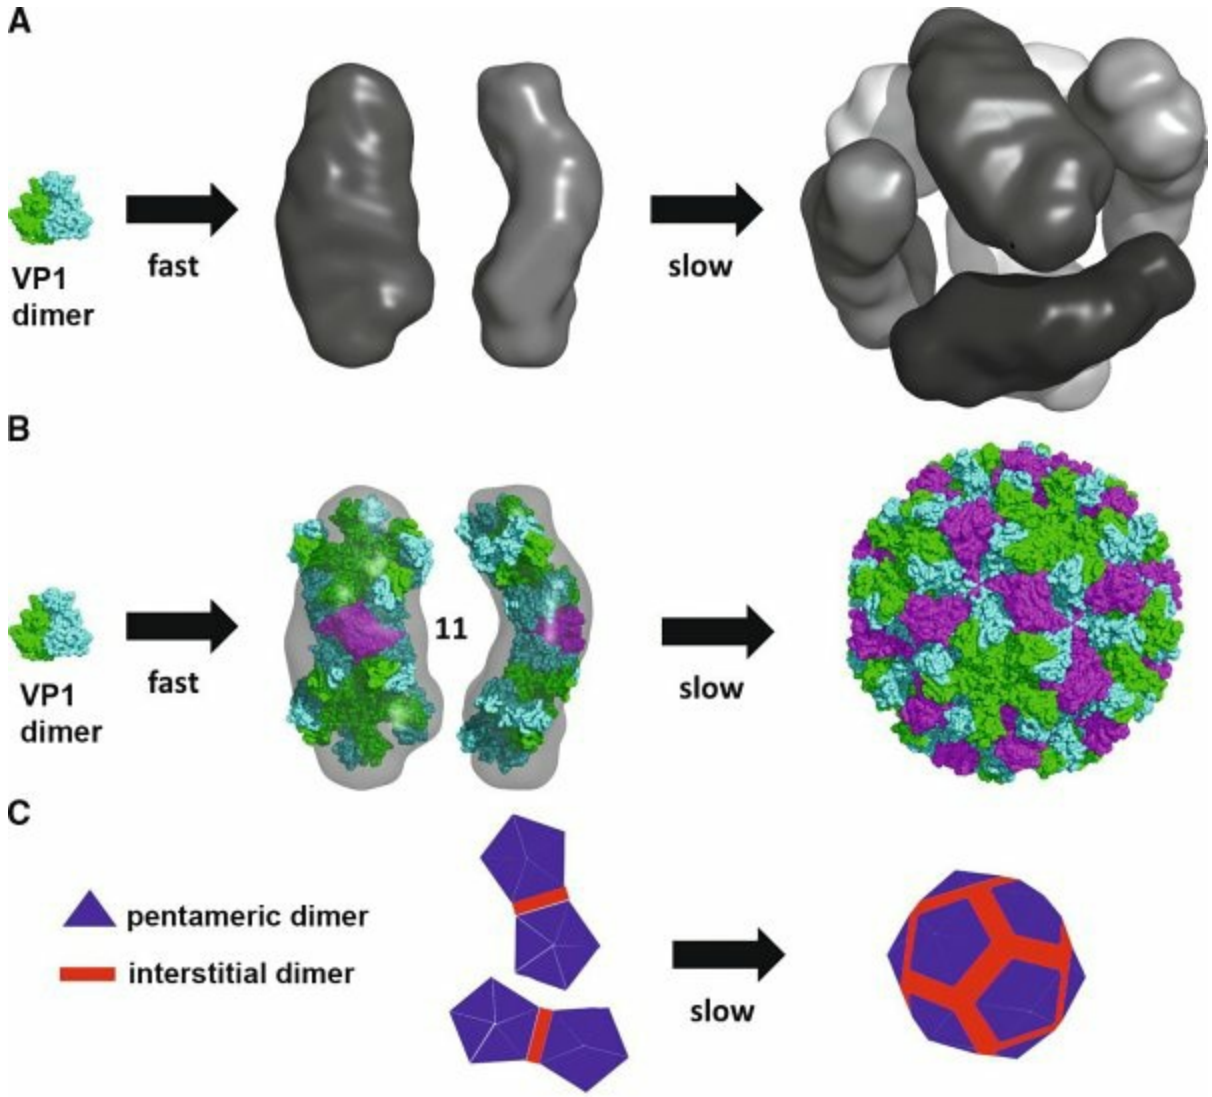

FIGURE 4.6 Norovirus capsid assembly model. All assemblies in A and B are drawn to the same scale. **A:** Small-angle x-ray scattering reconstruction shows that the VP1 dimer (*left*) of the capsid protein of a norovirus forms 10- or 11-dimer stave-like intermediates (*middle*) when assembling into the capsid. The intermediates are proposed to interlock to form the capsid (*right*).[603] **B:** A possible model for the intermediate consisting of 11 dimers is shown. VP1 dimers (*left*) assemble into two pentamers of VP1 dimers that are linked via an interstitial dimer (*middle*, *pink*), which self-assemble into the $T = 3$ capsid (90 dimers, *right*). The model is based on pieces of the NV capsid atomic structure.[478]

In this scheme, the quasi sixfold axes are completed only at the final stage and imply neutralization of negative charges in the NTA,[607] a process that may be assisted by the positively charged VP2 (not shown). **C:** Cartoon of the 11-dimer intermediate structures (*left*) and a self- assembled capsid (*right*). (Images provided by S. Bressanelli; adapted from Tresset G, Le Coeur C, Bryche JF, et al. Norovirus capsid proteins self-assemble through biphasic kinetics via long-lived stave-like intermediates. *(J Am Chem Soc* 2013;135:15373–15381.)

The inherent ability for calicivirus capsid self-assembly has facilitated genetic engineering and expression of modified and subviral forms of the capsid that have proven useful in several areas of research. For example, norovirus VLPs with a surface-exposed polyhistidine tag can be noncovalently modified to serve as nanocarriers,[296] while chimeric VLPs expressing foreign epitopes show utility as vaccine platforms.[124] The S domain alone has been engineered to provide a nanoparticle platform for peptide expression.[658] Engineering of the P domain via modifications of the C-terminus results in generation of subviral particles termed “P particles” or “small P particles.” These particles are assembled from 12 dimers of the P domain with $T = 1$ symmetry and have facilitated structure and function studies of the viral capsid.[572] Recombinantly expressed P domains from noroviruses, which form “P dimers,” are recognized by antibodies and carbohydrates similarly to intact VLPs[574] and have been a critical tool in the field. In fact, most structural information on histoblood group antigen (HBGA) carbohydrate and antibody binding has originated from studies of recombinant P domain.[83,112,306,528,539,540,577,582]

GENOME STRUCTURE AND ORGANIZATION

Caliciviruses have a linear, single-stranded, positive-sense RNA genome (ranging from ~6.4 to 8.5 kb [kilobases] in length) (Fig. 4.7A). Genomes

characteristically begin with a 5′-end terminal pGpU sequence that is covalently linked to a small protein, VPg. A short conserved region (CR) at the 5′ end is repeated internally in the genome near the beginning of a subgenomic-sized RNA transcript that is coterminal with the 3′ end of the genome.[218,319,404,410,426] The nonstructural proteins are encoded beginning near the 5′ end of the genome, and the structural proteins (VP1 and VP2) are encoded toward the 3′ end of the genome in the region corresponding to a subgenomic RNA. Calicivirus genomes are organized into two or more major ORFs, depending on the genus. Viruses in the genera *Norovirus*, *Recovirus*, and *Vesivirus* encode the VP1 structural protein in a separate ORF (ORF2), whereas those in *Bavovirus*, *Lagovirus*, *Minovirus*, *Nacovirus*, *Nebovirus*, *Salovirus*, *Sapovirus*, and *Valovirus* encode a VP1 that is contiguous with the large nonstructural polyprotein in ORF1 (Fig. 4.7B). All caliciviruses have a relatively small ORF near the 3′ end that encodes the minor structural protein, VP2. The VP2 is variable in size (12,000–30,000 D) and sequence identity among the caliciviruses.[85,524] MNV genomes analyzed thus far also contain a unique conserved ORF (ORF4)[586] overlapping with and beginning near the 5′ end of ORF2. ORF4 encodes a protein of 23,800 D (designated VF1) that has been implicated in modulation of the host immune response.[397,674] Some sapoviruses have a predicted ORF3 overlapping the capsid encoding region in ORF1, but a protein product has not been verified.[164,523]

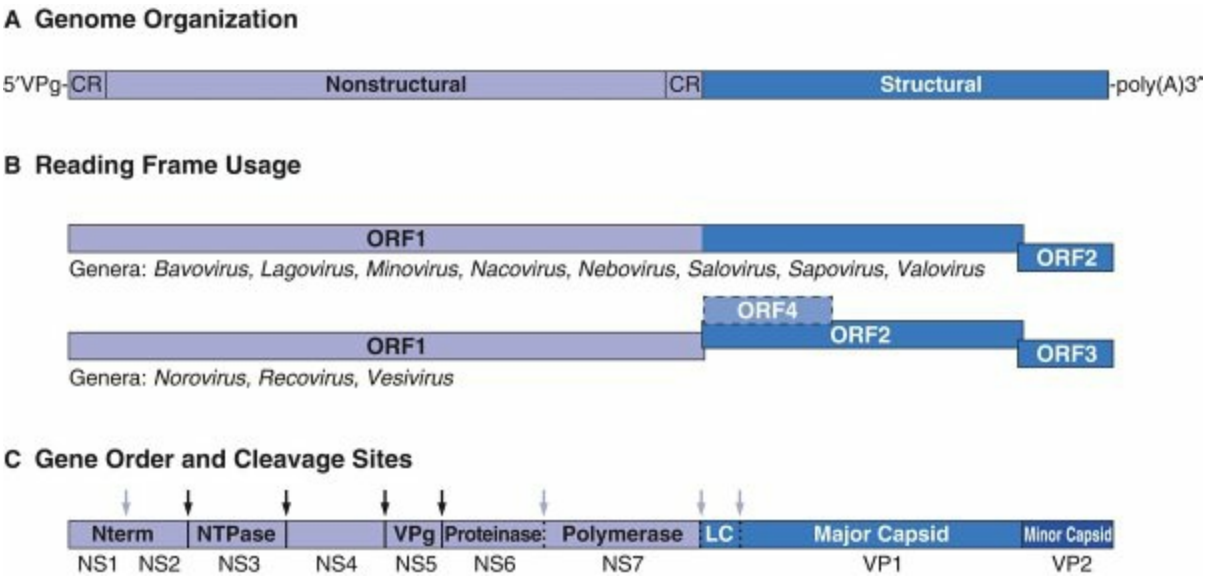

FIGURE 4.7 Comparative features of calicivirus genomes. **A:** The

positive-sense RNA genome is covalently linked to a VPg protein at the 5′ end and polyadenylated at the 3′ end. Nonstructural proteins are encoded beginning from the 5′ end of the genome, and the structural proteins are encoded toward the 3′ end. A conserved region (CR) of nucleotide sequence is shared between the 5′ end of the viral genome and the 5′ end of an abundant subgenomic RNA species produced during replication that serves as a template for translation of the viral structural proteins. **B:** Calicivirus genome organization. Calicivirus genomes are organized so that the major capsid protein coding sequence is either in frame or not with the upstream nonstructural protein sequence. The genera of the *Caliciviridae* associated with each type of organization are indicated. A unique ORF4 has been identified in MNV, comprising genogroup (V) of the genus *Norovirus.* **C:** A large polyprotein (encoded in ORF1) is translated from the viral RNA genome, and it is processed into precursors and final products by a virus-encoded protease. The proteolytic processing strategy varies among the caliciviruses, but all viruses encode domains for at least seven protein functions indicated here as nonstructural (NS) proteins NS1 through NS7.[548] An extra cleavage site is present in the ORF1 of most caliciviruses in which the capsid protein sequence is in frame with the nonstructural polyprotein encoded in ORF1. Cleavage at this site is thought to release the VP1 from the polyprotein so that the RNA-dependent RNA polymerase (NS7) can adopt an active conformation early in the replicative cycle. A cleavage site unique to the vesiviruses is present to release the leader of the capsid protein (LC), from a capsid precursor encoded in ORF2.[552] Mapped cleavage sites conserved and utilized among all calicivirus genera are indicated with a *dark arrow*; cleavage sites that vary in utilization among the family are indicated with a *light arrow* (see text).

Reverse genetics systems based on full-length infectious cDNA clones (and positive-sense RNA transcripts derived from these clones) have been developed for a number of caliciviruses, including FCV and Hom-1 (*Vesivirus*),[545,551,595] porcine enteric calicivirus (PEC) (*Sapovirus*),[99] Tulane virus (*Recovirus*),[636] RHDV (*Lagovirus*),[347] MNV (*Norovirus*),[17,103,512,632,664] and human norovirus (*Norovirus*).[20,267,453] A replicon-bearing continuous cell line derived from the NV genome was also developed[100] and has provided a useful platform for evaluating inhibitors of human norovirus replication. Transposon insertional mutagenesis scanning of the FCV[2] and MNV[590] genomes has been applied to genetic engineering of inserted (albeit unstable over multiple passages) foreign sequences.

Viral Proteins

Structural Proteins

Three proteins are found in mature calicivirus virions: VP1, VP2, and VPg.[546] The VP1 (~60,000 D), which is the major structural protein of the virus, is present in 180 copies (90 dimers) per virion.[478] The predominance of VP1 in the formation of the viral capsid structure (see *Virion Structure*) is consistent with its critical role in determining the antigenic phenotype of the virus and its interactions with host cells.

The VP2 (12,000–29,000 D) is considered a minor structural protein because it is less abundant in virion particles.[182,183,546] Evidence for a direct interaction between the VP1 and VP2 capsid proteins has been reported for both NV[95,182,183] and FCV[134,253] (See *Virion Structure*). Recent structural studies of FCV have shown that VP2 forms a portal at a specialized vertex of the capsid for the release of genomic RNA from the endosome[115] (See *Virion Structure*). Consistent with a role in the initiation of infection, the ablation of VP2 expression in an infectious FCV complementary DNA (cDNA) clone by the introduction of a stop codon in its reading frame did not abolish RNA replication; however, infectious virions could not be recovered without an intact VP2.[547]

The VPg is covalently linked to the genomic and subgenomic RNA in infected cells[148,219] and is a minor component in virions at an estimated one

or two copies per particle.[518,546] Although the VPg is present in virions, it likely functions primarily as a nonstructural protein during replication (see *Nonstructural Proteins*).

Nonstructural Proteins

Caliciviruses derive their mature nonstructural proteins (designated here as NS1 through NS7) by proteolytic cleavage of a large polyprotein encoded in ORF1 (Fig. 4.7C).[544] The length of the uncleaved polyprotein precursor is approximately 200,000 D (excluding in-frame VP1 capsid protein sequences). This large precursor has never been observed, most likely because proteolytic processing is rapid and cotranslational.[345,348,553] The proteolytic cleavages are mediated by a virus-encoded cysteine proteinase ($NS6^{Pro}$).[66] The location of the cleavage sites in the ORF1 polyprotein that define the borders of the final nonstructural protein cleavage products has been determined for calicivirus strains representing the genera *Norovirus*,[48,345,348,548] *Vesivirus*,[549] *Lagovirus*,[302,650] and *Sapovirus*.[451] Some variation is seen among the proteolytic processing strategies, but the overall gene order of the calicivirus nonstructural proteins is conserved. The lagoviruses, represented by RHDV, have the highest number (six) of mapped cleavage sites. The polyprotein of RHDV is cleaved at these six sites to release seven final products (designated as NS1 through NS7 in Fig. 4.7C and Table 4.2). Five cleavage sites for the norovirus ORF1 polyprotein (represented by Southampton virus) have been mapped that release six mature products.[345,348] The noroviruses differ from the lagoviruses in that a protease cleavage site has not been directly mapped in the extreme N-terminal protein, although evidence suggests that additional processing (or modification) of the protein can occur in cells.[525,548] For example, at least 10 protease-containing precursors were identified in MNV-infected cells, whose activity is temporally and spatially regulated.[152] The vesivirus cleavage map (represented by FCV) contains five mapped cleavage sites to release six mature nonstructural proteins, and each cleavage event is essential in the virus replication cycle.[549] The vesiviruses show yet another variation in processing, in that no evidence exists for efficient viral protease–mediated cleavage between the protease (Pro) and polymerase (Pol) proteins, even in virus-infected cells.[385,549,553] In addition, vesiviruses bear a unique cleavage

site in the capsid protein precursor protein that is processed by $NS6^{Pro}$ to release the leader of the capsid (LC) from the major capsid protein, VP1[552,598] (Fig. 4.7C). The predicted nonstructural protein cleavage map of human sapovirus strain, Mc10, shows an overall similarity with that of the vesiviruses.[451] Sapoviruses (and several other caliciviruses in which the capsid region is in frame with the nonstructural polyprotein) bear an additional protease cleavage site in the ORF1 polyprotein between the polymerase and capsid coding regions. A number of stable precursor proteins have been described also for the caliciviruses, and it is likely that these proteins have unique functions in replication beyond those of the fully processed mature forms.[544]

TABLE 4.2 Calicivirus nonstructural proteins

Calicivirus Nonstructural Protein (NS)	Common Designations	Reported Properties (Virus[b])	References
NS1	p5.6, p16	Cleavage and release essential for replication (FCV)	549
		Cytoplasmic and nuclear localization (RHDV)	612
NS1/2 or NS2[a]	N-term, p48	Binding partner with host cell VAP-A (HNV)	159
		FFAT mimic motif interacts with VAP-A (MNV)	394
		Golgi colocalization and disassembly (HNV)	167
		C-terminal hydrophobic region (HNV)	159,167
		Smooth ER membrane proliferation (HNV)	136
		Proximal association with lipid droplets (MNV)	136
		Predicted hydrolase domain (HNV)	136
		Determinant of colon tropism and persistence in mice (MNV)	67,440
		Bears caspase cleavage sites (MNV)	548
		Inherent structural disorder and multimerization (MNV)	33
NS3	NTPase, p39	NTP binding, hydrolysis of NTP (RHDV, HNV)	381,471
		ATP-dependent RNA helicase activity (HNV)	334
		Induction of membrane rearrangements (HNV)	136,661
		RNA chaperone–like activity (MNV, HNV)	205,334
		Lipid and microtubule associated (MNV, HNV)	120
		Suppresses IRF3 activation (FCV)	663
NS4	"3A-like," p20, p22	Forms stable precursor with VPg: proposed VPg anchor (FCV)	549
		Inhibits actin cytoskeleton remodeling (HNV)	222
		ER/Golgi trafficking antagonist (HNV)	529
		Induction of single-, double-, and multimembraned structures (HNV)	136
NS5	VPg	Present in virions, covalently linked to RNA (VESV, FCV)	80,219
		Sequence homology with eIF1A (HNV, FCV)	553
		Binding partner with eIF3 (HNV)	128
		VPg-linked translation requires eIF4a unwinding activity (FCV, MNV, PSV)	102,228
		Binding partner and translation function with eIF4E (FCV, PSV)	188,227
		Binding partner with eIF4G (MNV)	113
		Nucleotidylated by RdRP at conserved tyrosine (RHDV, HNV)	47,372
		Conserved tyrosine essential for replication of virus (FCV, NV)	406,560
		Functions in protein-primed RNA synthesis (NV)	503
		Linked to cellular trans-Golgi network protein 2 RNA in cells (NV)	560
		Compact helical core domains with flexible N and C termini (FCV, MNV)	327
NS6	Proteinase (Pro)	Proteinase activity, cysteine in active site (HNV, FCV, RHDV, SV)	66,348,448,553
		Mediates cleavage of ORF1 polyprotein (HNV, FCV, HSV, RHDV)	348,449,553,649
		Mediates cleavage of capsid precursor protein, PreVP1 (FCV)	553
		Cleaves cellular proteins (FCV, HNV)	153,315,647
		Structural analysis shows chymotrypsin-like folding (NV)	421
		RNA-binding activity	627
NS7	Polymerase (Pol), RdRP	Contains RdRP motif hYGDDhhY/V (FCV, HNV, RHDV, HSV)	242,388,403,424

Calicivirus Nonstructural Protein (NS)	Common Designations	Reported Properties (Virus[b])	References

[a]The predominant form of the N-terminal ORF1 protein in noroviruses consists of an NS1/NS2 precursor that is not cleaved by the virus-encoded proteinase. In this table, the known properties of the norovirus NS1/NS2 protein are listed under NS2.

[b]Virus abbreviations: FCV, Feline calicivirus, and VESV, vesicular exanthema of swine virus, in genus *Vesivirus*; RHDV, rabbit hemorrhagic disease virus, in genus *Lagovirus*; HNV, human norovirus, and MNV, murine norovirus, in genus *Norovirus*; HSV, human sapovirus, and PSV, porcine sapovirus, in genus *Sapovirus*.

The calicivirus dipeptide cleavage recognition sites are consistent with those described for the picornavirus 3C cysteine proteinase.[212] The calicivirus cleavage sites identified thus far have either a negatively charged glutamic acid (E) or polar glutamine (Q) in the first position (designated P1). More variation exists within the second position of the dipeptide cleavage site (designated P1′). Studies of the calicivirus proteinase substrate specificity have shown some tolerance in the P1′ position at certain cleavage sites.[212,552,649] The conformation of the protein surrounding the dipeptide recognition site is also important for efficient cleavage by the proteinase.[212,553]

The availability of proteolytic cleavage maps for the calicivirus nonstructural polyproteins has enabled studies that elucidate the functions and structures of individual proteins. Biochemical studies first confirmed enzymatic activities in calicivirus proteins corresponding to an NTPase (NTPase or $NS3^{NTPase}$),[381] a chymotrypsin-like cysteine proteinase (Pro or $NS6^{Pro}$),[66] and an RNA-dependent RNA polymerase (Pol or $NS7^{Pol}$).[618] The three-dimensional structures for the latter two enzymes have been reported. The norovirus Pro shares structural similarities with classical chymotrypsin-like serine proteases.[166,235,419,421,543,669] A cleft containing the active site catalytic residues (His 30, Glu 54, and Cys 139 for Norwalk virus) involved in substrate cleavage is located between the N-terminal β-barrel and the C-

terminal twisted β-sheet domains. Substrate-binding pockets are shown to undergo slight conformational changes in response to sequence variations in the polyprotein cleavage sites.[417] Comparison of a recently determined structure of catalytically active GII.4 norovirus protease with that of the GI.1 Norwalk virus shows a similar overall organization, but with noticeable conformational changes in the substrate-binding pockets and also in the three catalytic residues, which are arranged in a slightly different conformation (Fig. 4.8).[626,669] Furthermore, an Arg residue (R122) is located within the active cleft that is observed to make a cation-pi interaction with the catalytic His residue (Fig. 4.8, inset), thereby affecting GII.4 protease sensitivity to pH. Such differences might be important in the design of norovirus protease inhibitors among diverse strains. The norovirus RNA-dependent RNA polymerase has a classical "right-hand" (finger, thumb, and palm) organization,[436,668] with the C-terminus of the protein positioned in the active site cleft (Fig. 4.9A). Modeling of the interaction of Pol with an RNA template in the presence of manganese and CTP shows that the initiation of RNA synthesis occurs within the active site cleft (Fig. 4.9B–D). Binding of the primer/template RNA duplex displaces the C-terminal tail away from the active site, allowing the central helix of the thumb domain to position itself for interaction with the primer strand and minor groove of the primer–template duplex.[668] Two divalent metal ions (likely Mg^{2+} in cells) help mediate catalysis by forming coordination bonds with three highly conserved aspartic acid residues and the nucleoside triphosphate (NTP). After nucleotidyl transfer has occurred, the pyrophosphate is released from the enzyme. The primer–template duplex is predicted to translocate in a manner that places the newly incorporated nucleotide into the same position as that of the 3′ end of the primer strand immediately prior to nucleotidyl transfer. This translocation process provides the space needed to form the binding site for the next incoming nucleoside triphosphate.

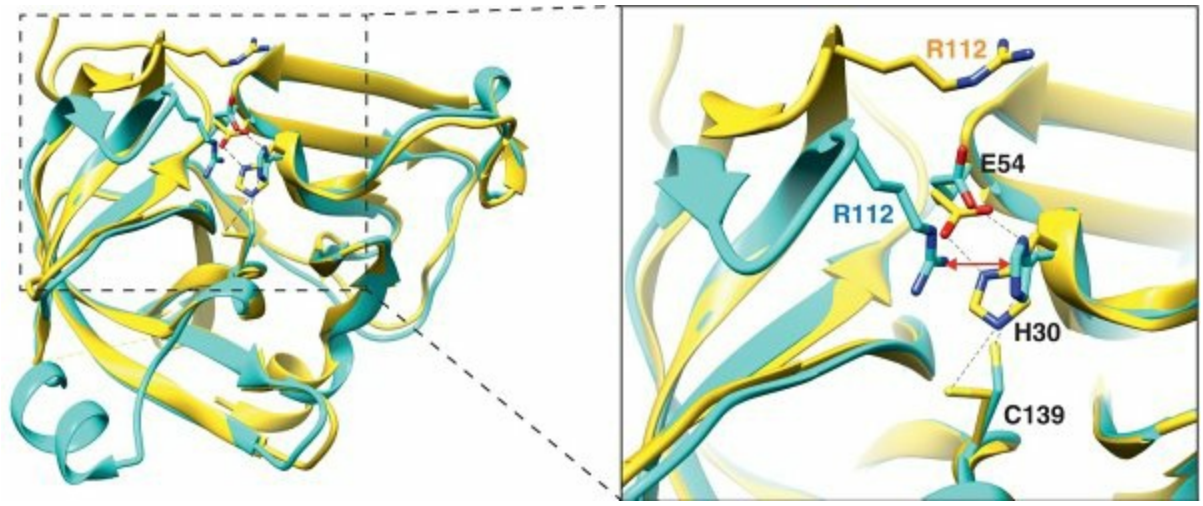

FIGURE 4.8 Comparison of GI and GII norovirus protease active sites. Structural overlay of GII.4 HOV (*cyan*; PDB: 6NIR) and GI.1 Norwalk virus (*yellow*; PDB: 2FYQ) proteases. The **inset** shows the structural changes of bII-cII loop between HOV and NV proteases. Active site residues H30, E54, and C139 and the S2 substrate–binding pocket residues R112 are shown as stick models with nitrogen and oxygen atoms colored in *blue* and *red*, respectively. The cation-π interaction between R112 and H30 in HOV protease is indicated by a *red double arrow*. (Images provided by L. Hu and B.V.V. Prasad; adapted from Viskovska MA, Zhao B, Shanker S, et al. GII.4 norovirus protease shows pH-sensitive proteolysis with a unique ARG-HIS pairing in the catalytic site. *J Virol* 2019;93(6). doi:10.1128/JVI.01479-18; Zeitler CE, Estes MK, Venkataram Prasad BV. Structure and function studies of the mapped calicivirus nonstructural proteins encoded in ORF1 are summarized in Table 4.2. The activities of replicative enzymes NS3 (NTPase), NS6 (proteinase), and NS7 (polymerase) are established, and knowledge of their structure has informed investigations of targeted inhibitors. The NS5 (VPg), required for the infectivity of genomic RNA, is multifunctional, playing a role in both translation and RNA replication. The remaining proteins (NS1, NS2, and NS4) have all been associated, in some capacity, with intracellular membrane interactions. These interactions are likely important in forming a scaffold for the assembly of viral replication complexes in the cell,[136,239,588] and elucidation of their effects on host cell pathways may also inform the design of therapeutic interventions.

STAGES OF REPLICATION

Replication Strategy

The calicivirus replication strategy shares many features with those of other positive-strand RNA viruses (Fig. 4.10).[588] Caliciviruses attach and enter the cell, the RNA genome is released, and translation of the VPg-linked genome occurs via the host cell machinery. Certain newly translated viral proteins interact with the host cell to establish defined sites of virus replication (characteristically involving reorganized intracellular membranes), while other proteins function as replicative enzymes. Newly synthesized positive-strand RNA genomes are covalently linked to VPg and packaged into virions that are released from cells via lytic and nonlytic mechanisms. The replication cycle of a calicivirus is rapid: new viral progeny can be detected within hours after infection.

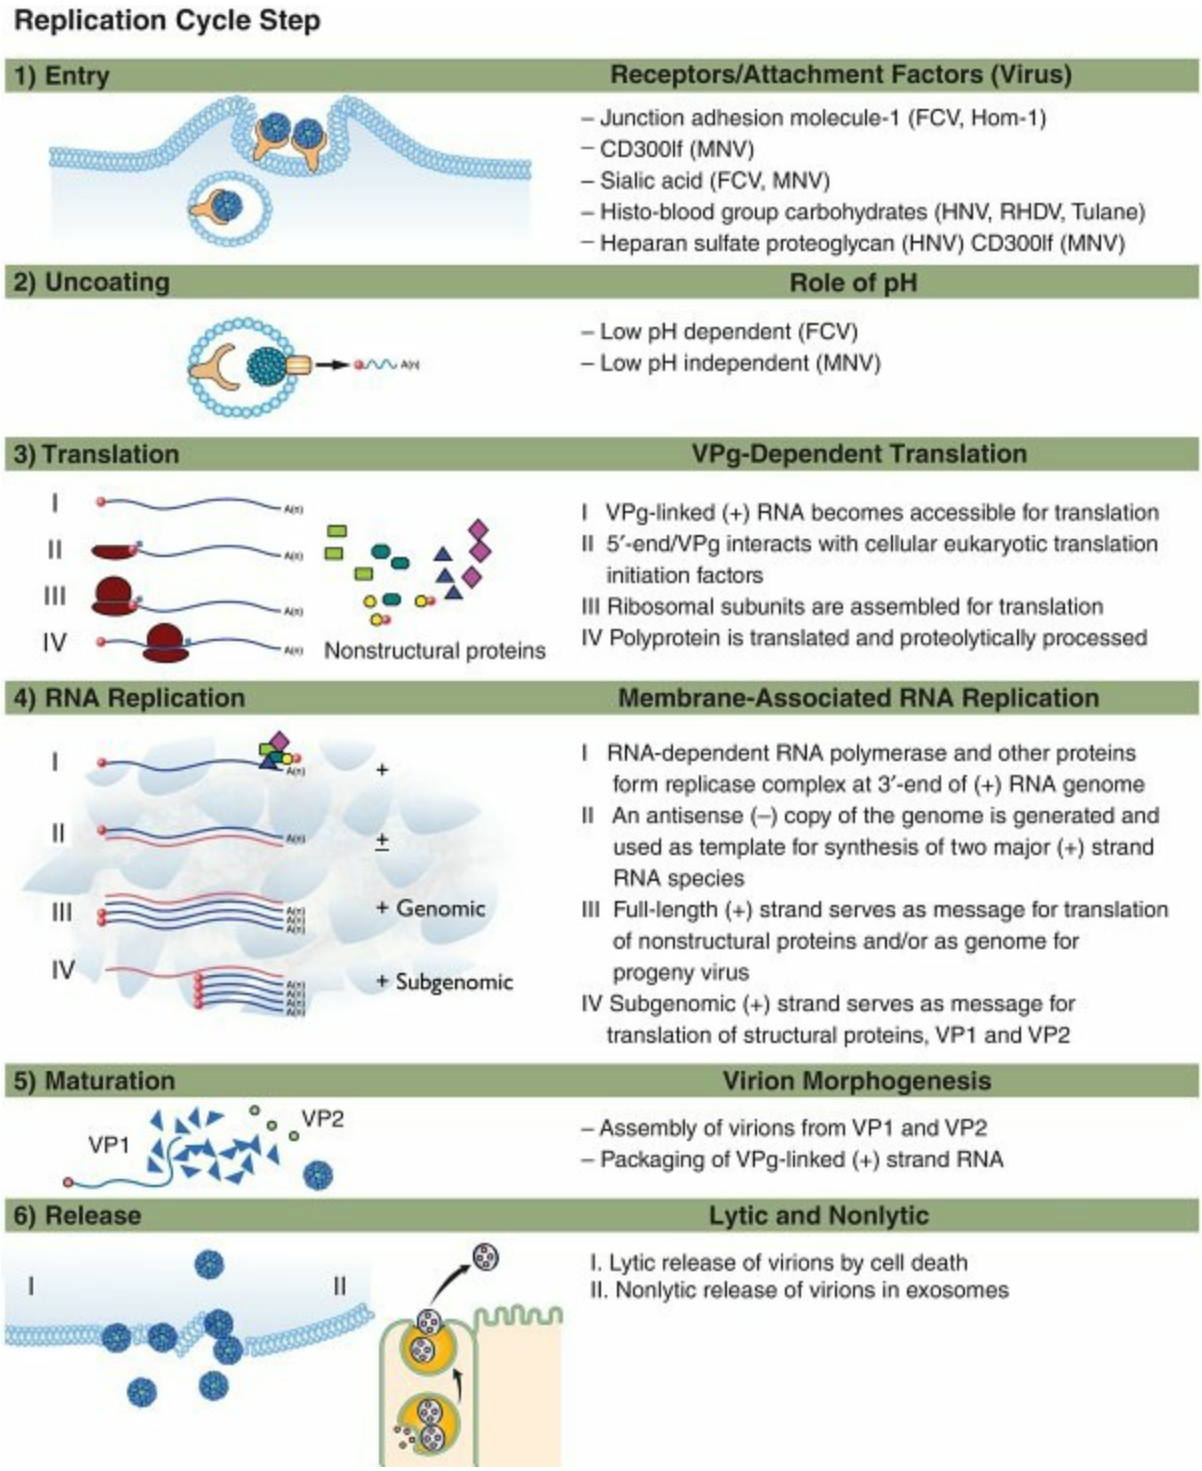

FIGURE 4.10 Schematic diagram of the proposed replication strategy of the caliciviruses. Consistent with other positive-strand RNA viruses, the replication cycle of a calicivirus involves the following stages: (1) entry, (2) uncoating, (3) translation, (4) RNA

replication, (5) maturation, and (6) release, as reviewed in the text.

Mechanism of Attachment

Many caliciviruses interact with host cell surface glycans that serve as attachment factors to facilitate infection (Fig. 4.11). The specificity of these interactions plays an important role in the determination of host range and tissue tropism, and there is considerable diversity among calicivirus strains in their glycan binding profiles (Table 4.3). Human and bovine noroviruses bind to various HBGA carbohydrate moieties, heparan sulfate proteoglycans, and sialylated glycans.[10,382,571,579,635,666] MNVs recognize sialic acids on glycolipids and N- and/or O-linked glycoproteins.[580,581] Glycan interactions have been described for lagoviruses,[443,444,484] recoviruses,[576] sapoviruses,[280,670] and vesiviruses.[310,558] Structure and function studies have verified a number of these interactions and defined the location of glycan binding sites on calicivirus capsids[83,112,305,376] (Fig. 4.12). Additional binding ligands for noroviruses have been noted (such as bacterial HBGA-like moieties), but their role in the initiation of infection is not known.[10]

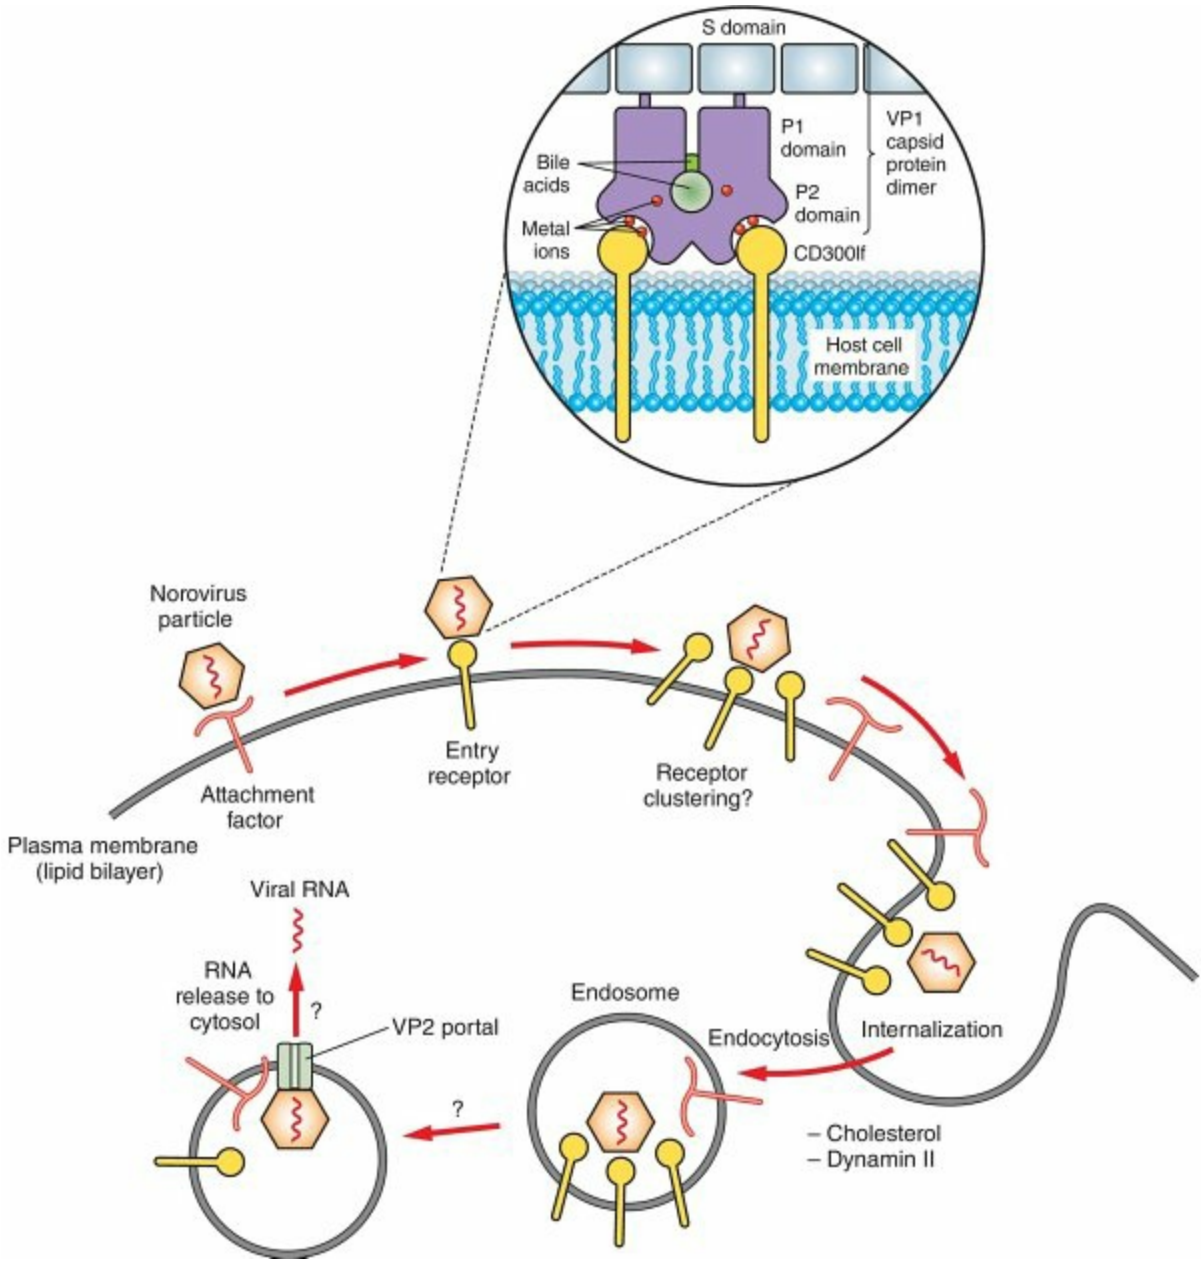

FIGURE 4.11 Schematics of calicivirus entry into host cells. Caliciviruses bind to host cells via interaction with glycans, which serve as attachment factors. This is followed by engagement with a proteinaceous entry receptor. These receptor interactions likely trigger receptor clustering and initiate internalization of virus particles by the endocytic pathway. The uptake pathway differs among caliciviruses. Murine norovirus uptake is pH independent[469] but dependent on cholesterol and dynamin

II[180,468] and via a nonclathrin and noncaveolin pathway. *Feline calicivirus* entry is pH dependent and via clathrin-mediated endocytosis.[557] Porcine sapovirus entry requires dynamin II, cholesterol, and actin to enter via clathrin-mediated endocytosis.[542] Escape from the endosome may then be mediated by the minor capsid VP2, which forms a portal across the endosomal membrane in FCV infection.[115] **Inset:** In the case of murine norovirus, interaction with the proteinaceous receptor CD300lf[455] occurs in place of the natural lipid ligands with CD300lf and is facilitated by cofactors bile acids and cations.[429]

TABLE 4.3 Glycans associated with binding to calicivirus capsids

Glycan Moiety	Virus	References
Histoblood group antigens (HBGA)	**Human norovirus GI and GII** (H type 1, H type 2, H type 3)	83,112,230,343,382,507

Bivalve mollusks HBGA-like glycans	**Human norovirus**	321,597

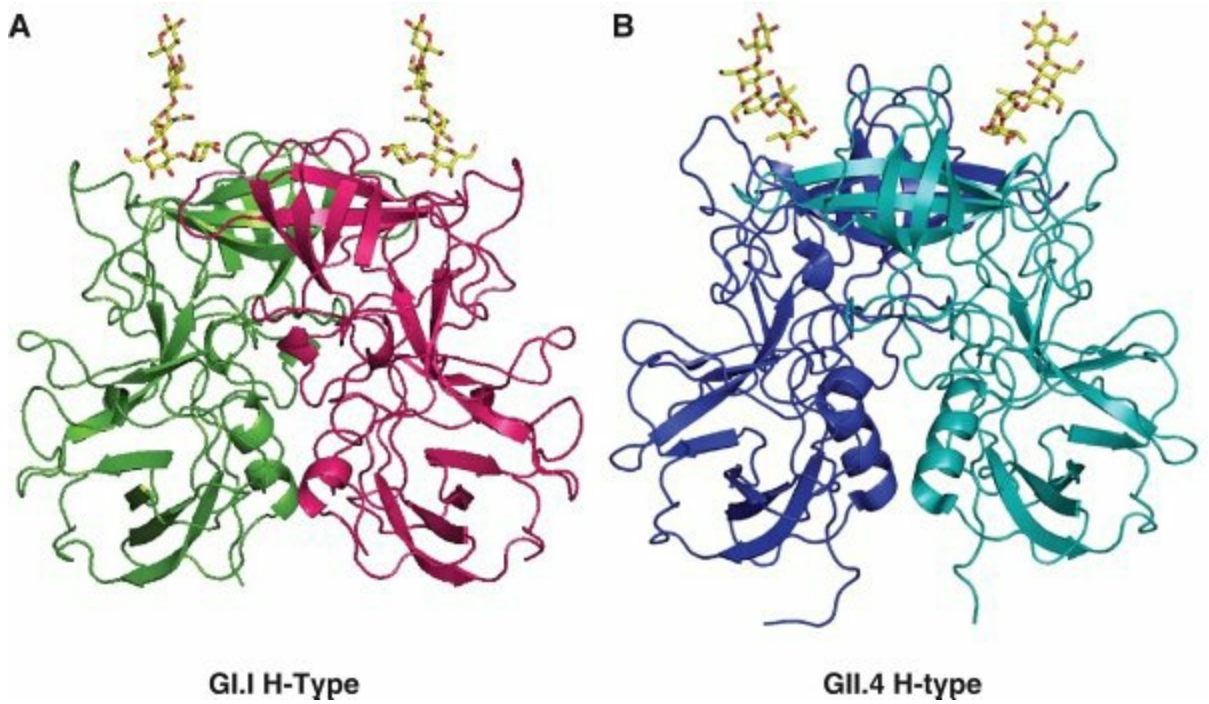

FIGURE 4.12 Interaction of representative norovirus VP1 dimers with H carbohydrates from histoblood group antigens. For both GI.1 and GII.4 noroviruses, HBGA carbohydrates interact with the distal surface of the capsid, but differences in these interactions have been noted. **A:** The Norwalk virus (GI.1) carbohydrate-binding site contains residues that project from a well-structured antiparallel *β*-sheet near the P domain dimeric interface and favors a precise and limited recognition of a terminal Gal-Fuc or Gal-acetamido combination. **B:** In contrast, the VA387 (GII.4) binding site is formed by residues located in two surface-exposed loops near the P domain dimeric interface that broadly recognize a terminal fucosyl moiety. (Images provided by B.V.V. Prasad with data adapted from Cao S, Lou Z, Tan M, et al. Structural basis for the recognition of blood group trisaccharides by norovirus. *J Virol* 2007;81:5949–5957; Choi JM, Hutson AM, Estes MK, et al. Atomic resolution structural characterization of recognition of histo-blood group antigens by Norwalk virus. *Proc Natl Acad Sci U S A* 2008;105:9175–9180.)

Following the interaction with carbohydrate attachment factors, caliciviruses interact with a proteinaceous entry receptor. The identity of the first experimentally verified cellular receptor was for FCV, the junction adhesion molecule-1 (JAM-1, also called JAM-A), an immunoglobulin-like cellular membrane protein.[374] A homologous protein, human JAM-1 (JAM-A), also serves as the receptor for Hom-1 vesivirus.[551] FCV interacts with feline (f) JAM-1 through binding of the P2 domain of the capsid to the distal membrane domain (D1) of fJAM-1 and triggers irreversible conformational changes in the virus capsid.[53] Mutational analysis has confirmed two residues in the viral capsid that bind to the receptor.[364] The second verified proteinaceous receptor for caliciviruses is the MNV entry receptor CD300lf (also named CLM-1, CMRF35, MAIR-V, LMIR3). It was independently identified by two groups through an unbiased CRISPR/Cas9 screen in BV2 (murine microglial cells) or RAW 264.7 cells (murine macrophages) using multiple MNV strains.[201,454] CD300lf is a cell surface-expressed, immunoglobulin (Ig)-like domain-containing, lipid-binding protein (e.g., ceramide, phosphatidylcholine, phosphatidylserine). MNV binding and infection are blocked by incubation with an anti-CD300lf antibody, soluble CD300lf ectodomain, or deletion of the gene. Expression of murine CD300lf or the related molecule CD300ld (which have highly homologous ectodomains), but not human CD300f, makes cells susceptible to MNV infection, including non-murine cells. CD300lf is the primary receptor *in vivo* since CD300lf-deficient mice are resistant to MNV infection as indicated by the absence of fecal shedding.[454] Thus, receptor availability is a major determinant of species specificity and tissue tropism. Mutational and structural analysis identified residues in the CC' and CDR3 loops of CD300lf and the capsid P2 domain that mediate the interaction.[201,276,429,454] Virus binding to the receptor occurs in the same location as lipid binding, making this interaction an example of viral mimicry of a natural ligand.[429] Furthermore, the receptor binding site on the viral capsid overlaps with the epitopes of two neutralizing antibodies (named A6.2, 2D3), suggesting inhibition of receptor binding as one mechanism of neutralization.[276,429] The binding affinity between one CD300lf molecule and one viral capsid protein is low (KD ~ 25 μM) in biochemical assays,[429] indicating other factors strengthen the interaction. Structural and functional analysis identified divalent cations and bile acids (especially GCDCA) as cofactors that enhance

binding and infection[275,429] (Fig. 4.11, inset). The binding sites for two bile acid molecules and three cations in each capsid protein are distant from the CD300lf binding site, and none of these interactions induced structural rearrangements in the MNV P domain visible by crystallography.[429] Clustering of CD300lf molecules to increase avidity is another proposed factor that likely strengthens the interaction between the virion and the receptor (Fig. 4.11). Other proteins that facilitate calicivirus entry have also been identified. Specifically, the tight junction protein occludin was shown to directly bind to porcine sapovirus and to function as a coreceptor, while claudin 1 did not directly bind to the virus but facilitated infection and was thus proposed to serve as an entry factor.[6] In addition to CD300lf, MNV-1 also binds to the extracellular domains of murine CD36, CD98 heavy chain (CD98), and transferrin receptor 1 TfRc, which promoted binding to dendritic cells (CD36) or murine macrophages (CD98 and TfRc) in a cell-type–specific manner.[70]

Mechanism of Entry and Intracellular Trafficking

Following engagement with viral receptors, clustering of receptors in membrane domains may contribute to virion internalization (Fig. 4.11). Consistent with receptor clustering are the following data: (a) Engagement of HBGAs on glycolipids by human norovirus VLPs results in invaginations in unilamellar vesicles and VLP clustering,[463,508] (b) MNV entry is dependent on cholesterol,[180,468] virion binding leads to the aggregation of detergent-resistant membrane domains,[29] and (c) inhibition of synthesis of sphingolipid and ceramide, molecules required for membrane fluidity and dynamics, is critical for CD300lf cell surface arrangement and MNV infection.[455] Endocytic uptake of MNV further requires dynamin II, but not clathrin, caveolin, or low pH[180,468,469] (Fig. 4.11). FCV, on the other hand, requires low pH and is endocytosed via a clathrin-mediated uptake pathway.[309,557] Its internalization was proposed to be initiated following binding to fJAM-1 and disruption of the fJAM-1 homodimer.[115] In the case of porcine sapovirus, virions are internalized by clathrin- and cholesterol-mediated endocytosis that requires dynamin II and actin rearrangement and traffic to late endosomes via early endosomes in complex with the coreceptor occludin.[6,542]

Uncoating

The uncoating events that allow the calicivirus positive-sense RNA genome to become accessible to the cellular translational machinery have not been defined in detail. However, similar to other viruses, receptor engagement, low pH, and/or ion flux in endosomes may all serve as triggers for RNA release into the cytosol (Fig. 4.11). Uncoating is a rapid process: MNV genome was released within 1 hour after infection[468] but independent of pH.[469] Consistent with a pH-independent trigger, norovirus (NV) VLPs are stable under acidic conditions, but disassociation occurs under alkaline conditions.[534] In FCV, binding to the cellular receptor induces a conformational change in the capsid,[53] which ultimately leads to the formation of a portal vertex at a unique 3-fold axis.[115] A dodecameric assembly of VP2 protrudes from this vertex to form a channel through which viral RNA is released from the endosome into the cytosol[115] (Fig. 4.11). Intriguingly, no significant structural rearrangements are observed upon CD300lf binding to the MNV P domain.[429] However, no structural information of the full-length VP1 capsid protein or virions during receptor binding is currently available.

Translation

Calicivirus genomic RNA in virions requires the presence of the covalently linked VPg protein in order to establish an infection after release (or transfection) into cells.[80] The initiation of translation of the incoming positive-strand genome is likely mediated through interactions of the VPg protein with the cellular translation machinery.[102,128,188] Direct interactions of host cell proteins with viral RNA may also mediate translation efficiency.[198,199,220,259] Calicivirus replication is associated with an inhibition of host cell translation, and the viral proteinase ($NS6^{Pro}$) has been shown to cleave certain cellular proteins involved in translation, which may, in part, give the viral RNA a competitive advantage.[315] The ORF1 of the virus is translated first to produce a large polyprotein, which is processed rapidly into precursors and products by $NS6^{Pro}$ at several essential cleavage sites.[549] Certain of these nonstructural proteins and their precursors function to set up replication sites within the host cell,[30,136,239] while others (such as the RNA-dependent RNA polymerase, $NS7^{Pol}$) play a direct role in replication of the

viral RNA (Table 4.2).

An abundant VPg-linked subgenomic positive-strand RNA serves as a bicistronic message for translation of the structural proteins, VP1 and VP2.[218,426] Regulation of translation of VP2 from the subgenomic RNA (translated at ~20% of the levels of VP1) was mapped to an upstream RNA sequence element in the 3′-end VP1 coding region of approximately 70 nucleotides designated as the termination upstream ribosomal binding site (TURBS).[200,401,402,638] The TURBS site contains two motifs, one of which mediates base pairing between the viral subgenomic messenger RNA and the cellular 18S ribosomal subunit.[402] This interaction may function as a "tether," positioning the ribosome for immediate reinitiation of translation following termination of translation of the VP1 gene.[367] Translation of the VF1 protein, encoded in an alternative ORF[4] within the VP1 coding region of the MNV genome, likely occurs through a leaky scanning mechanism.[397]

Replication of Genomic Nucleic Acid

As with all other positive-strand RNA viruses, the replication of calicivirus RNA is associated with host cell membranes.[30,136,193,239] A marked rearrangement of intracellular membranes occurs, and evidence exists for the initiation of RNA replication in a perinuclear site that contains membranes associated with endoplasmic reticulum, trans-Golgi network, and endosomal membrane markers.[30,136,239] This early replication complex is localized proximal to the microtubule-organizing center in MNV-infected cells, with VP1 associated with the redistribution of acetylated tubulin to the complex.[238] The initiation of synthesis of an antisense (negative) strand RNA from the genomic RNA template occurs beginning at the 3′ end of the genomic positive-strand RNA, and interactions with a number of cellular proteins with viral RNA have been identified that could play a role in RNA transcription and replication.[199,355,516] The negative-strand RNA, in turn, serves as a template for transcription of two major positive-strand RNA species corresponding to the full-length genome (genomic RNA) and the approximately one-third of the genome toward the 3′ end (subgenomic RNA).[426]

The calicivirus RNA genome bears conserved regions of secondary structure,[368,476,536] and functional RNA regulatory elements have been

mapped both internally and near the ends of the genome.[8,31] Transcription from the start site for the subgenomic RNA species on the negative-strand template (nt 5,296 of RHDV) was found to require an upstream sequence of 50 nt for full polymerase activity in *in vitro* studies,[410] consistent with its role in the formation of a subgenomic promoter. The corresponding region of MNV was mapped also as bearing a promoter for subgenomic RNA synthesis from the negative-strand template[336,665]

Assembly

A two-stage process has been proposed for the maturation of calicivirus (FCV) particles.[301] The first stage involves the rapid aggregation and assembly of capsid precursor proteins into 5S subunits that then pass through several intermediate forms (with varying stability) to form stable 15S subunits. The second stage involves the association of 15S subunits with newly synthesized RNA genomes to form infectious particles (that sediment at 170S). Protein–protein interactions have been detected between the FCV VPg (covalently linked to the RNA genome) and the capsid precursor as well as between the RNA-dependent RNA polymerase $NS7^{Pol}$ and the capsid precursor, suggesting that these interactions may be related to packaging of the newly synthesized RNA into the viral capsid.[253] In addition, successful assembly of the infectious FCV virions was linked to an efficient expression of the virus minor capsid protein, VP2.[547]

The VPg-linked genomic and subgenomic positive-strand RNA species are found in FCV and RHDV particles of distinct densities, indicating that they are not packaged together in the same virion.[404,425] The incorporation of subgenomic RNA into the lower density (LD) particles suggests that a packaging signal is located within the 3′ terminal 2,400 nucleotides of the genome. It has been suggested that LD particles (which would not be infectious) may be associated with FCV strains of higher virulence, but their function, if any, in the virus life cycle is unknown.[425] The existence of defective interfering (DI) particles has been suggested, but not confirmed experimentally for caliciviruses.[486]

Release

Virus progeny can be detected in cell culture medium within hours of

infection, prior to visible cytopathic effect and cell lysis. One mechanism for this early nonlytic release may involve the egress of viruses within exosomal vesicles, utilizing intracellular membrane trafficking pathways.[515] Eventually, calicivirus-infected cells undergo cell death and lysis, and it is presumed that the majority of progeny viruses are released during this process. The triggering of apoptosis has been associated with calicivirus infection both *in vitro*[12,64,172,423,550] and *in vivo*,[104,270,413,418,490,604] and apoptotic changes in cellular membranes may be one of the death mechanisms by which cells lyse and release viral particles.

PATHOGENESIS AND PATHOLOGY

Caliciviruses cause a broad range of diseases in many different animal hosts (Table 4.4). This section will focus on the noroviruses, but there are important common themes in pathogenesis shared by all caliciviruses. Illnesses range from mild to life threatening, and evidence exists for the emergence of calicivirus strains with increased virulence. Asymptomatic infections occur in susceptible populations,[360,474] and shedding of virus can occur days to weeks after resolution of acute symptoms.[25,177,288,499] Caliciviruses can establish a chronic carrier state in a number of hosts, with varying proposed mechanisms of persistence.[121,191,617]

TABLE 4.4 Pathogenesis and disease manifestations of representative calicivirus strains

Calicivirus Strain	Genus	Host	Site of Replication[a]	Clinical Disease[b]
Norwalk virus	*Norovirus*	Human	Enteric	Gastroenteritis
Jena virus	*Norovirus*	Cattle	Enteric	Gastroenteritis
Murine norovirus (MNV-1-like)	*Norovirus*	Mouse	Distal SI, lymphoid	Acute systemic but limited disease[c]
Murine norovirus (CR6-like)	*Norovirus*	Mouse	Colon (tuft cells)	Persistent, asymptomatic
Pistoia virus	*Norovirus*	Lion	Enteric	Hemorrhagic enteritis
Canine norovirus	*Norovirus*	Dog	Enteric	Gastroenteritis
Porcine norovirus CH6	*Norovirus*	Pig	Enteric	Gastroenteritis
Sapporo virus	*Sapovirus*	Human	Enteric	Gastroenteritis
Porcine enteric calicivirus (Cowden)	*Sapovirus*	Pig	Enteric	Gastroenteritis
Mink enteric calicivirus	*Sapovirus*	Mink	Enteric	Gastroenteritis
Rabbit hemorrhagic disease virus	*Lagovirus*	Rabbit	Liver, systemic	Organ dysfunction, pulmonary hemorrhage[e]
Rabbit calicivirus	*Lagovirus*	Rabbit	Liver	Asymptomatic
European brown hare syndrome virus	*Lagovirus*	Hare	Liver, systemic	Organ dysfunction, pulmonary hemorrhage[e]
Bovine enteric calicivirus (Newbury-1 virus)	*Nebovirus*	Cattle	Enteric	Gastroenteritis
Bovine enteric calicivirus (Nebraska virus)	*Nebovirus*	Cattle	Enteric	Gastroenteritis
Feline calicivirus	*Vesivirus*	Cat	Mouth, upper respiratory	Stomatitis, pneumonia
Feline calicivirus-VS	*Vesivirus*	Cat	Systemic	Fulminant organ dysfunction[f]
San Miguel sea lion virus (SMSV)	*Vesivirus*	Sea lion	Mucosal, systemic	Skin (flipper) lesions, pneumonia
Canine calicivirus (No. 48)	*Vesivirus*	Dog	Enteric	Gastroenteritis
Vesivirus isolate 2117	*Vesivirus*	Unknown	Unknown	Unknown[g]
Hom-1 (SMSV to human)	*Vesivirus*	Human	Mucosal	Skin lesions
Tulane virus	*Recovirus*	Monkey	Enteric	Gastroenteritis
St. Valérien virus (AB90)	*Valovirus*	Pig	Enteric	Not established
Bayern virus	*Bavovirus*	Chicken	Enteric	Not established

[a]Site of replication is based on observed pathological effects in tissue and, in some cases, confirmed by immunohistochemistry. For many caliciviruses, the primary site of replication in the host has not been fully established. In general, infection outcome in the family *Caliciviridae* can range from asymptomatic (subclinical) to lethal.

[b]The characteristic clinical disease associated with each representative calicivirus strain is shown. St. Valérien virus[316] and Bayern virus[654] were detected in screening surveys of nonselected stool specimens: the clinical disease outcome has not been established. *Norwalk virus*, representative of the human noroviruses associated with acute gastroenteritis, is generally associated with self-limiting vomiting and diarrhea of 24- to 48-hour duration. However, the illness can be severe and life-threatening in certain individuals (see text).

[c]Most variants of the MNV-1 strain of murine norovirus are lethal only in certain mice that lack an innate immune system, but evidence exists for varying pathogenicity among MNV strains and variants.[265,586]

[d]Sapporo virus, representative of the human sapoviruses associated with acute gastroenteritis, has most often been associated with self-limiting gastroenteritis in younger age groups, as opposed to norovirus, which occurs in all age groups.[109]

[e]Rabbit hemorrhagic disease virus was first recognized as a highly lethal disease in rabbits, but there are a wide range of disease manifestations in lagomorphs.[323]

[f]Feline calicivirus strains have emerged in recent years designated as “virulent systemic” (VS) that are

associated with high morbidity and mortality in cats. In addition, the virus can cause a persistent, asymptomatic infection in cats.[485]

[g]Vesivirus 2117 was discovered as a contaminant in cultured Chinese hamster ovary cells.[447]

Adult volunteer studies have been successful in defining important features of human norovirus gastroenteritis, pathogenesis, and immunity.[255] Presently, there is no animal model that directly recapitulates the full range of disease symptoms observed in humans (see *Clinical Features*),[651] but animals in which evidence for infection has been reported following challenge with human noroviruses include gnotobiotic piglets[104] and calves,[554] monkeys[498,561] and chimpanzees,[63,657] and immunocompromised mice.[578] In addition, much information about norovirus biology has been learned from MNV infection of mice as detailed below.[263]

Entry into the Host

Noroviruses enter the body predominantly via the oral route. Studies in human volunteers demonstrated that the Norwalk, Hawaii, Montgomery County, and Snow Mountain viruses induced gastroenteritis when administered orally.[140,141,247,331,411,555,656] Virions are acid stable, consistent with an ability to survive passage through the stomach. Indirect evidence from epidemiologic studies suggests that human noroviruses can enter also via aerosols, such as those generated by the explosive vomiting that often occurs during illness.[86,90,289,383,384,464] During experimental infection, MNV is also infectious via intranasal and intracerebral routes during experimental infection,[265] while human noroviruses establish an enteric infection in gnotobiotic piglets[104] and chimpanzees[63] when administered by the intravenous route.

The mechanism by which caliciviruses enter the host following exposure by various routes remains ill-defined. Studies with MNV have demonstrated a critical role for microfold (M) cells as the portal of entry into the host intestine.[264] M cells are specialized intestinal epithelial cells primarily located in follicle-associated epithelium overlaying mucosa-associated lymphoid tissues. These cells transcytose particulate antigen from the lumen into the host interior. Mice deficient in Peyer patches (small intestinal lymphoid follicles) and associated M cells are resistant to oral infection with

at least two MNV strains (MNV-1 and MNV.CR3).[297] Furthermore, antibody depletion of M cells via successive rounds of anti-RANKL antibody administration in Balb/c mice significantly reduced MNV infectious titers in multiple intestinal sites and in fecal shedding.[187] The ability of MNV to be transcytosed across an intestinal epithelial monolayer via M cells was also recapitulated in cell culture.[186] No infection of M cells was observed either *in vitro* or *in vivo*, consistent with the absence of expression of the MNV receptor CD300lf in this cell type. Thus, M cells are not an MNV target cell but instead mediate viral transport across the epithelial monolayer for subsequent infection of target cells. Whether M cells play a similar role during infection with other noroviruses or caliciviruses in general is unknown.

Site of Primary Replication

The tissue site of primary replication has been established for MNV. Depending on the virus strain, infection initiates in Peyer patches of the distal small intestine (MNV-1 strain), or in the cecum (MNV.CR3 strain), following M cell transcytosis.[187,190] For other noroviruses, there is evidence for primary replication in the upper intestinal tract. Consistent with this, human intestinal enteroids derived from the small intestine (jejunum, duodenum, ileum) but not the large intestine (colon) support human norovirus infection *in vitro.*[118,160] Further support comes from *in vivo* analysis. Jejunal biopsies of volunteers who develop gastrointestinal illness following oral administration of Norwalk or Hawaii virus exhibit histopathologic lesions.[4,142,520,521] Histologic lesions are not observed in the gastric fundus, antrum, or rectal mucosa of volunteers with NV-induced illness.[644] During acute infection, a broadening and blunting of the villi of the proximal small intestine and infiltration of mononuclear cells occur. Characteristic jejunal lesions have also been observed in volunteers who were fed NV or Hawaii virus but who did not become ill.[398,520,521] Cellular infiltrates and villus blunting are also observed in pediatric patients infected with human norovirus[413] and in duodenal biopsies from immunocompetent individuals with acute norovirus gastroenteritis.[604] For large animal caliciviruses, blunting and atrophy of the villi is observed in the small intestines of pigs infected with PEC, a sapovirus,[169] and in newborn calves infected with Jena

virus, a bovine norovirus.[458]

Cell and Tissue Tropism

MNV has an established dual target cell tropism of immune cells and tuft cells, a specialized intestinal epithelial cell type.[652] Cellular tropism is determined by expression of the viral receptor CD300lf on cells,[454] but genetic differences among MNV strains may influence *in vivo* tropism. Consistent with this, CD300lf-expressing immune cells in gastrointestinal lymphoid tissues have been established as the primary target cells for many MNV strains (such as MNV-1) during acute infection.[190] Certain other MNV strains (such as CR6) have been detected in rare CD300lf-expressing tuft cells[645] during persistent infection. It is not yet clear whether these strains also infect tuft cells during the initial infection to establish the persistent reservoir. MNV also infects inflammatory monocytes and neutrophils, which can promote dissemination of the virus under certain conditions.[617] The *in vivo* tropism for immune cells is largely recapitulated *in vitro*, whereby MNV infects macrophages, dendritic cells, and T and B cells in culture.[190,248,653]

The cellular tropisms of other noroviruses will not be clarified until their entry receptors are identified. To date, immunofluorescence studies of intestinal biopsies from immunocompromised patients detected norovirus capsid antigen-positive cells in enterocytes at the villus tips and cells positive for CD3, CD68, or DC-SIGN, which are markers for T cells, macrophages, and dendritic cells, respectively.[260] In this same study, co-localization of capsid and nonstructural protein expression was observed only in enterocytes, leading the authors to conclude that epithelial cells could support viral replication.[260] A non-epithelial tropism is consistent with a previous study in humans, in which Sakai virus (a GII norovirus) was shown to bind to cells within the lamina propria and Brunner glands of human duodenum but not the epithelium.[94] However, in another binding study, NV virus VLPs bound to the surface of epithelial cells in human biopsies, but not lamina propria.[382] Chimpanzees infected with NV displayed NV capsid antigen-positive cells within the lamina propria of the upper small intestine.[63] GII.4 human norovirus antigen was detected in macrophages in immunocompromised mice[578] and in enterocytes in the duodenum and jejunum of gnotobiotic piglets.[104] Lastly, macrophages, dendritic cells, and lymphocytes were

positive for GII human norovirus capsid protein in miniature piglets.[527] Taken together, these data implicate the involvement of epithelial and non-epithelial cell types during human norovirus infection. However, binding of virus or VLPs to tissue or the presence of capsid antigen in cells may not necessarily reflect active replication. Thus, it will be critical in the future to confirm these findings with additional evidence such as the detection of negative-sense RNA as was demonstrated with MNV.[190]

Two newly developed *in vitro* culture systems support a possible dual-tropic nature of human noroviruses. Some GII human noroviruses infect established human B-cell lines in culture.[248] Infection is dependent on the viral attachment factor HBGA, in synthetic form or expressed by commensal bacteria. In a second cell culture model, multiple human norovirus strains were shown to replicate in human intestinal organoids derived from the small intestine.[160] Only differentiated cultures enriched in mature enterocytes (i.e., absorptive columnar intestinal epithelial cells) supported infection. Bile enhanced or was required for viral replication in a virus genotype-dependent manner. This culture system also recapitulated the dependence of some genotypes on HBGAs. However, in contrast to the B-cell system, HBGAs were expressed on the surface of the intestinal epithelial cells.

While noroviruses infect many different mammals, bovine norovirus is the only other norovirus whose cellular tropism has been investigated to date. Following Jena virus infection of calves, intestinal epithelial cells stained positive for capsid antigens in the cytoplasm, while macrophage-like cells in the lamina propria and Peyer patch domes contained capsid antigen-positive granular deposits.[458] Whether the latter represent phagocytosed infected epithelial cells as proposed by the authors or bona fide infected cells remains to be determined. To date, no cell culture system has been described for bovine noroviruses to verify the cellular tropism.

Taken together, the long-held assumption that noroviruses exclusively infect intestinal epithelial cells has changed over the past decade. Recent data support a more complex tropism and interplay of intestinal epithelial and nonepithelial cells during norovirus pathogenesis. Additional studies in humans with fully functioning immune systems and with norovirus strains from different genogroups as well as different mammalian hosts are required to reveal the complete extent of the cell and tissue tropism for viruses across the family.

Spread in the Host

Following virus replication at the initial site of infection, noroviruses can spread inside the host beyond the initial site of replication in the intestine. In the case of MNV, the extent of extraintestinal spread is strain dependent. The acutely replicating strain MNV-1 (isolates CW3 or CW1) and the persistently replicating strain MNV.CR3 can spread to mesenteric lymph nodes and the spleen but less frequently to the liver or lung.[418,580] Other persistent strains (e.g., MNV.CR6, MNV-3) typically do not spread beyond the mesenteric lymph nodes.[252,437] Spread to secondary lymphoid tissues is mediated by CD11c-positive dendritic cells, since MNV.CR3 is unable to spread to the mesenteric lymph nodes or spleen when these cells are depleted from mice.[150] In the case of MNV-1, systemic spread was mediated by recruitment of susceptible monocytes and neutrophils following virus-triggered inflammation.[617]

Human norovirus RNA has not been detected in the sera of immunocompetent infected adult volunteers.[432] However, there are reports of the detection of norovirus RNA in various clinical specimens, suggesting that under certain conditions, the virus might spread beyond the initial site of infection in the intestine. Viral RNA has been detected in the serum and cerebrospinal fluid of a 23-month-old patient with encephalopathy.[241] Norovirus has also been associated with cases of benign convulsions with mild gastroenteritis[277] and more severe outcomes of encephalitis/encephalopathy, particularly in very young children.[531] However, only stool samples were tested for viral RNA, and/or viral RNA was undetectable in the cerebrospinal fluid. Additional studies have also detected human norovirus RNA in the serum of some patients, suggesting viremia occurs under some circumstances, such as in the context of very young patient age, increased disease severity, and/or high viral loads during acute norovirus gastroenteritis.[233,494,567]

Immune Response

Immunity to noroviruses in humans is poorly understood. Human norovirus infections can be symptomatic or asymptomatic, with up to one-third of individuals being asymptomatically infected.[431] Resistance to norovirus

illness involves a complex interplay between host genetics (see *Mechanisms of Attachment*), immune status, and exposure to evolving norovirus strains. Studies in the MNV mouse model have demonstrated that innate immune responses control the extent of norovirus infection, while adaptive immune responses are critical in clearing infection.

Innate Immunity

The innate immune response is of critical importance in limiting norovirus infection and initiating memory-generating adaptive responses. Human norovirus replication is inhibited by exogenous type I, II, or III interferon (IFN) treatment *in vitro* and *in vivo.*[100,127,250,482] A screen of known interferon-stimulated genes (ISGs) in NV replicon-containing cells identified IRF1, RIG-I, and MDA5 as potent anti-norovirus effectors, while RTP4 and HPSE had moderate antiviral activity.[127] Paradoxically, no IFN-β responses or ISGs are induced during human norovirus RNA replication (GI.1 and GII.3) following transfection or addition of VLPs in transformed cells.[127,482] However, no data are yet available regarding innate antiviral responses during human norovirus infection in primary cells. Innate immune responses are also critically important in the control of MNV infections.[35] Indeed, MNV-1 causes a disseminated, lethal infection in certain mouse strains deficient in components of the innate immune system (i.e., STAT1, IFNAR/IFNAGR double knockout, or IRF3/5/7 triple knockout)[265,320] and replicates to higher titers in mice deficient in pattern recognition receptors (specifically MDA5, TLR3, and NLRP6) or interferon signal transduction components (IRF1, IRF3, IRF7).[379,585,631] Similarly, HOIL-1 (heme-oxidized IRP2 ubiquitin ligase-1), a component of LUBAC (linear ubiquitin chain assembly complex), which mediates type I and III IFN induction via MDA5 and IRF3, also reduces viral infection.[371] For the persistent MNV.CR6 strain, mice with the aforementioned defects display higher viral loads and increased fecal shedding (i.e., IFNLR1 −/−, STAT1−/−) or systemic infection (i.e., IFNAR−/−). In most cases, increased viral replication is also seen *in vitro* in bone marrow–derived macrophages and dendritic cells lacking these molecules, confirming the essential role of IFN signaling for control of MNV infection at the cellular and host level. One of the ISGs that has been further investigated during infection is ISG15. It limits MNV infection early in the viral life cycle during entry or uncoating.[500] Taken together, a picture

emerges whereby type I IFNs control systemic MNV infection in myeloid cells, while type III IFNs control persistent infection in tuft cells. Opposing these multiple host defense mechanisms is the viral protein VF1 (virulence factor 1), which delays the IFN response via an unknown mechanism.[397] Other mediators of the intrinsic host response also exhibit anti-MNV activity. Specifically, autophagy-related gene proteins (i.e., Atg5, Atg7, Atg12, Atg16L1) mark viral replication complexes and recruit interferon-inducible GTPases to block viral replication in an IFN-dependent manner.[54] In addition, a recent genome-wide CRISPR activation screen in HeLa cells expressing the MNV receptor CD300lf identified a number of genes with anti-MNV activity that functioned not only in IFN signaling and cytokine responses but also in genes involved in RNA polymerase expression and embryogenesis.[454] Transcriptomic analysis showed that innate immune pathways are major response pathways of cells to MNV infection.[154,330]

Other caliciviruses have also been shown to be sensitive to various types of interferon *in vitro*, and infections are limited by ISGs.[98,100,101,283,346,408,663]

Adaptive Immunity

Information about human norovirus immunity comes largely from human volunteer studies and vaccine trials, and identifying determinants of protective immunity is still an area of active investigation. Early volunteer studies in adults established that protection from reinfection is relatively short, ranging from 2 months to 2 years, in susceptible individuals.[247,462,492] Investigations of natural human norovirus infections in children indicated protection of up to 3 years.[58] In contrast, a mathematical model estimated the duration of human norovirus immunity to be slightly longer, ranging from 4 to 9 years.[537] Protective immunity induced by a single MNV infection waned after a few months.[674]

The discovery that NV and other human noroviruses utilize HBGAs as attachment factors has led to the development of assays to measure HBGA carbohydrate–blocking activity (or “blockade”) of serum antibodies.[350] Since antibodies that block binding of norovirus VLPs to HBGA glycans correlate with protection from illness in adult volunteers, HBGA-blocking assays have been used as surrogate tests for neutralization in the absence of traditional

cell culture-based virus neutralization assays.[339,492] Application of this technique in the first efficacy study of norovirus vaccines in adult volunteers showed a correlation between levels of prechallenge HBGA-blocking titers and protection from illness.[22] A hemagglutination-inhibition assay (HAI) was another surrogate assay used to analyze serum antibodies and was shown also to correlate with protection from illness in volunteers challenged with NV.[125,237] Studies in adult volunteers further demonstrated that higher titer prechallenge or postchallenge serum antibodies that blocked norovirus binding to HBGA glycans correlated with protection from gastroenteritis.[22,492] In addition, development of a rapid mucosal IgA response (indicating prior exposure to NV or a related norovirus) was also associated with resistance to illness following challenge with NV.[341] In another NV challenge study, NV-specific salivary IgA and NV-specific memory IgG cells were identified as correlates of protection from gastroenteritis, while prechallenge levels of NV-specific fecal IgA correlated with reduced viral loads.[489] In the case of a GII.4 volunteer study, higher prechallenge levels of serum IgA antibodies were also associated with less illness and a lower frequency of infection.[23]

The anti–norovirus antibody responses following primary infections in children are not only short-lived but also of low avidity.[442] Primary infections in children generate blocking antibodies that provide homotypic protection, while heterotypic protection develops over time and with additional infections.[59,378] Studies indicate that during the first year of life, a child may have one to three norovirus infections.[60,362,509] Higher avidity antibodies were detected in older children following repeat infections and protection correlated with the ability to block HBGA binding.[442] Timing of the first norovirus infection appears to be determined by the quality of the maternal antibodies. In a study following two children from birth to age 8, higher titer, greater avidity, and increased HBGA-blocking ability of maternal antibodies correlated with longer protection and a later time point in life of the first infection.[58]

The antibody responses that develop to human noroviruses can be strain, genotype, genogroup, or intergenogroup specific. Strain-specific or genotype-specific epitopes are often located in the hypervariable VP1 P2 domain,[84,176] while more broadly reactive epitopes are commonly found in the more

conserved VP1 S and P1 domains.[123,460] Similarly, antibodies to MNV directed against the P domain are strain or genotype specific, while the S domain antibody was broadly cross-reactive and even recognized human norovirus VLPs.[300] However, only antibodies directed to the MNV P domain had neutralizing activity.[269,300]

An *in vitro* culture system for human norovirus has enabled analysis of true neutralizing activities.[160] Characterization of a panel of pandemic GII.4 Sydney reactive human monoclonal IgG and IgA antibodies identified three major antigenic epitopes in the P domain, and most showed neutralization capabilities in the two surrogate neutralization assays: of those tested, all inhibited norovirus replication in human intestinal enteroid monolayers.[13] The majority of tested mAbs had lower neutralization titers than blockade or HAI titers, indicating that the true neutralization assay is more sensitive than either surrogate assay and thus that additional factors beyond glycan interaction contribute to virus neutralization.

In addition to B-cell responses, human norovirus infection also leads to Th1-skewed immunity with some Th2 involvement. When cell-mediated immune responses were studied in volunteers following oral immunization with NV rVLPs, an increase in IFN-γ in the absence of IL-4 production was detected, consistent with a dominant Th-1 pattern of cytokine production.[566] Serum sample analysis from two human norovirus challenge studies with NV demonstrated a rise in Th1 (IFN-γ, IL-2, IL12p70, TNF-α) and Th2 cytokines (IL-6, IL-10) as well as IL-8 and MCP-1 in infected versus uninfected volunteers.[434] Cytokines peaked at day 2 postchallenge. In a study of 15 volunteers infected with Snow Mountain virus (GII.2), significant increases in serum IFN-γ, IL-2 (Th1 cytokines), and IL-5 (a Th2 cytokine), but not IL-6 or IL-10, were detected on day 2 after challenge.[340] Depletion of CD4+ cells prior to stimulation of peripheral blood mononuclear cells with norovirus antigen led to a decrease in IFN-γ, implicating these T cells as the major source of this cytokine.[340] The Th1 cytokines IFN-γ and TNF-α, but also the Th2 cytokine IL-6, were secreted following stimulation of PBMCs with GII.4 VLPs.[477] IFN-γ is also secreted following VLP stimulation of PBMCs from eight healthy human donors previously infected by human norovirus.[377] This study also identified a peptide in the VP1 S domain from two donors as a CD8+ T-cell epitope. Evidence for cross-reactive T-cell epitopes shared

among different norovirus genogroups and genotypes was found in mice immunized with human and MNVs VLPs.[349]

The combined action of T and B cells is critical to clear human norovirus infection since the lack of functional T- and B-cell responses in immunocompromised patients results in chronic norovirus infection.[91,191] Immune reconstitution following gene therapy and improvement of T-cell levels have both been associated with clearance of chronic human norovirus infection.[130,648]

A similar picture has emerged from studies of the MNV model. Mice lacking T cells and/or B cells (i.e., Rag1−/−, μMT−/−, Ighm−/−) or their function are persistently infected by the acute strain MNV-1, while transfer of antibody, splenocytes, or T cells reduced persistent viral loads and could clear infection.[88,89,265,673] In contrast, persistent MNV strains (e.g., MNV.CR6) elicited fewer virus-specific T cells and generated less effective T-cell responses compared to acute MNV-1 infection.[599] While the MNV.CR6-specific CD8+ T cells were functional, they were unable to detect viral replication in intestinal epithelial tuft cells, an immune-privileged site, enabling persistence[600] (see *Persistence*).

Taken together, individual human volunteer studies have identified several antibody-based correlates of protection from illness or infection.[488] Work in the mouse model has also indicated a role for cell-mediated and innate immunity in protection. Future studies with larger cohorts will be needed to identify the best predictor of protection while simultaneously increasing our knowledge of human norovirus immunity.

Release from Host and Transmission

Noroviruses are released from the enteric tract of the host in feces and have been detected also in vomitus.[194,195,274,396] Viral RNA can be detected in feces before the onset of symptoms and shedding in stool can last several days to weeks in immunocompetent individuals[25,179,189,197,452] and even longer in immunocompromised patients.[21,191] Studies of the natural history of norovirus in a community found that 26% of the examined 99 patients shed virus (detected by RT-PCR) up to 3 weeks after the onset of illness, with the highest rate (38%) of prolonged shedding in children younger than 1 year of

age.[499] This observation indicates that infected individuals recovering from norovirus illness can continue to shed virus beyond the symptomatic period, a finding that has implications in the management of outbreaks.[445] In addition, a time-course study comparing shedding of 102 asymptomatic and symptomatic individuals detected no difference in the duration of shedding (average 8–60 days) and peak amounts of virus shed.[584] Norovirus RNA has been detected in washings from the mouths of individuals who experienced norovirus infection for several days after symptoms subsided, suggesting that oral-to-oral transmission of norovirus might occur.[287] The detection of norovirus RNA in the sera of children with gastroenteritis has been reported, but it is not known whether this RNA corresponds to that of circulating infectious virus (viremia) or noninfectious (inactivated) virus present in circulating immune cells.[567]

Noroviruses are spread by several modes of transmission. The predominant modes of transmission for the noroviruses are person-to-person contact and food- or waterborne spread.[313] Contamination of surfaces and objects by infected individuals can lead to inadvertent exposure.[357] Several epidemiological investigations have also linked exposure to noroviruses in air or in aerosolized vomitus with infection.[65,87,286,289] However, in infected volunteers, norovirus RNA in vomitus is less frequent and detected at lower amounts than in stool samples.[26]

The explosive nature of some norovirus outbreaks, in which a large number of persons become ill within 24 to 48 hours, indicates that infection is often acquired from a common source. This was suggested in the original NV outbreak, but a common-source exposure could not be identified.[3] Later, a review of 38 human norovirus-associated outbreaks suggested that a common source of infection was likely in 31 (82%).[257] The vehicle of transmission was water in 13 instances and food in 4 others. Secondary transmission was observed in most outbreaks, with attack rates ranging from 4% to 32% and being highest in children under 10 years of age. The median duration of the 38 outbreaks was 7 days (ranging from 1 day to 3 months). The number of individuals who became ill ranged from 2 to 2,000, with the attack rate being higher in common-source outbreaks (median 60%, range 23%–93%) than in primary person-to-person outbreaks (median 39%, range 31%–42%).[258] A similar attack rate from children with norovirus diarrhea

(33%) was observed in a household transmission study, while the attack rates of asymptomatic controls were lower (18%).[178] The efficient transmission of human caliciviruses by contaminated food and water vehicles has raised concerns about public safety in a global market economy.[491]

The infectious dose for noroviruses is low, with an estimated median infectious dose of 18–1,015 genome equivalents.[583] Another human volunteer challenge study determined the 50% human infectious dose for NV at approximately 1,230 genome equivalents for blood group O and A individuals and approximately 2,800 for all secretor-positive individuals.[26] Exposure to higher levels of virus likely increases the risk of illness.[363] In a study that examined norovirus fecal load, higher numbers (>100-fold) of norovirus genome copies were detected in individuals shedding GII (median, 3.0×10^8 genome copies per gram feces) strains compared to GI (median, 8.4×10^5 genome copies per gram feces).[96] It was proposed that the higher levels of GII shedding might account for a higher transmissibility of these viruses through the fecal–oral route.[96] However, high levels of GI shedding have also been reported: the median peak of GI NV shed in the stool of 16 volunteers was 9.5×10^{10} genome copies per gram feces.[25]

Noroviruses are remarkably stable. Norwalk virus retains infectivity for volunteers following (a) exposure of the stool filtrate to pH 2.7 for 3 hours at room temperature, (b) treatment with 20% ether at 4°C for 18 hours, or (c) incubation at 60°C for 30 minutes.[141] Norwalk virions remain infectious when stored in groundwater at room temperature in the dark for as long as 61 days, and RNA could be detected in such samples after storage at room temperature for 3 years.[526] Using the new human intestinal organoid culture system, GII.4 noroviruses in human stool samples have for the first time been tested directly for their inactivation patterns.[118] Virions were not completely inactivated by 5-minute incubation in 70% ethanol or 70% isopropanol, although some reduction in viral infectivity was observed. However, infectivity was effectively destroyed by 1 minute in greater than 50 ppm chlorine, while viral RNA was only destroyed at concentrations of greater than 600 ppm. This demonstrates that previous human norovirus inactivation studies using measurements of RNA integrity should be re-evaluated using the more sensitive infectivity–based culture systems.

Although norovirus virions are highly stable and are shed at high levels,

the viral RNA-dependent RNA polymerase introduces many mutations, the majority of which are expected to be lethal.[513] Furthermore, the host's gastrointestinal tract is large (i.e., the human intestine is the size of half a badminton court)[217] and covered with host mucins that can inhibit norovirus VLP binding to HBGAs and Caco-2 cells.[596] Thus, how noroviruses maintain their high infectivity and achieve high recombination rates (which requires coinfection of cells with at least two virions) was puzzling. A recent study has provided evidence of multiple murine and human norovirus particles packaged into membrane-cloaked vesicles in the stool of infected hosts.[515] Studies in the rotavirus mouse model demonstrated that these virion-containing vesicles improve viral infection. Previous studies have also demonstrated that multiple norovirus virions bind to various bacterial species.[11] In the case of poliovirus, this concentration of virions on intestinal bacteria facilitated coinfection and recombination.[156] These data suggest that aggregation of virus particles via vesicles or bacteria likely increases norovirus coinfection rates and complementation via recombination, which results in increased infectivity and viral shedding.[405]

Virulence

Virulence determinants are being defined mechanistically for MNV but have not been well defined for the human noroviruses. Studies with MNV have identified determinants that fall into three general groups: host determinants (see *Immune Response*), virus determinants, and the microbiota[35] (see below).

Viral Determinants

The ability to genetically manipulate MNV has resulted in the identification of various roles in pathogenesis for multiple viral proteins. The viral proteins NS1/2, virulence factor 1 (VF1) encoded by ORF4, and both the major and minor capsid proteins VP1 and VP2 are known to play critical role during pathogenesis. The nonstructural protein NS1/2 (N-term) determines colonic tropism and viral persistence[440] (see *Persistence*). VF1 antagonizes the antiviral innate immune response, and thus VF1-deletion viruses are attenuated *in vivo*.[397] VF1 may also play a role in the induction of protective immunity via regulation of cytokine induction.[674] VP1 is linked to virulence.

Specifically, a single amino acid (residue 296) in the variable P2 domain of VP1, which arises during tissue culture passage and persistent infection, contributes to virulence of MNV.[32,556,653,675] Viruses with a lysine at this position are more virulent and cause increased lethality in mice, while those with a glutamic acid are attenuated. However, the importance of this residue differs depending on mouse background, and additional virulence determinants are present in the VP1 P domain that contribute to viral replication, histopathology, and lethality in STAT1-deficient mice.[556] Although not sufficient, the S domain may also contribute to virulence.[556] Additional residues in the VP1 P1 and P2 domains contribute to *in vitro* B-cell (but not macrophage) growth and replication *in vivo*.[675] Lastly, studies of viruses from the same cluster revealed that VP2 controls antigen presentation in B cells and macrophages *in vitro* and induction of protective immunity *in vivo*.[673,674] Specifically, VP2 of the MNV-3 strain, which induced higher systemic and mucosal antibody responses compared to MNV-1, induced upregulation of antigen presentation in macrophages and enhanced protective immunity.[674] In contrast, VP2 of MNV-1 (but not MNV-3) induced upregulation of antigen presentation molecules on B cells, which contributed to the control of acute MNV-1 infection.[673] These striking cell-type and virus-strain–specific differences observed with MNV suggest that similar phenomena likely exist for human noroviruses and animal caliciviruses. Indeed, virus strain–specific differences in clinical outcome, ranging from asymptomatic infection to life-threatening diarrhea, are observed[234] (Table 4.4).

Norovirus–Microbiota Interactions

Noroviruses encounter members of the microbiota (a collection of bacteria, viruses, fungi, and other microorganisms) during intestinal infection. Human noroviruses, for example, bind to selected pathogenic and nonpathogenic bacterial species.[11,407] Binding was mediated by HBGA-like molecules on the bacteria.[407] It remains unclear whether interactions can be mediated by other factors or whether other noroviruses can similarly bind to bacteria. The microbiota influences viral pathogenesis by direct and indirect mechanisms.[261] Direct effects of bacterial binding to human noroviruses described to date are (a) increased heat stability[333] and (b) enhanced

attachment and infection of human BJAB B cells by human norovirus.[248] Indirect mechanisms are those whereby the microbiota induces host cell responses that affect viral pathogenesis via innate or adaptive immunity. Interestingly, MNV can replace the beneficial effects of the microbiota via type I IFN signaling in the absence of commensal bacteria.[272] Studies in the MNV system have revealed multiple reciprocal interactions between the host, the virus, and the microbiome. In IL10- or ATG16L1-deficient mice (i.e., models for inflammatory bowel disease), MNV infection causes intestinal inflammation in the presence of the microbiota.[44,82] MNV can also exacerbate intestinal inflammation and lethality during bacterial superinfection by enhancing host responses.[282] Commensal bacteria are critical for the establishment of persistent MNV infection in a mechanism dependent on intact IFN-λ responses.[34] In the case of acute MNV infection, commensal bacteria and host secretory immunoglobulins are needed for a homeostatic environment conducive to infection, as the lack of secretory immunoglobulins or commensal bacteria leads to reduced infection.[610] Commensal bacteria also suppress the maintenance of an antiviral antibody response. For human noroviruses, a link between the abundance of specific bacterial species, host genetics, and antinorovirus IgA antibodies is observed.[501] Another member of the microbiota, helminths, also has immunomodulatory functions. Colonization of the host by helminths resulted in immune skewing that resulted in reduced antiviral immunity to MNV infection and thus elevated viral loads.[456,645] While these examples speak to the ability of the host and the microbiota to influence norovirus pathogenesis, norovirus infections under some circumstances may also influence the bacterial communities in the intestine. A subset (~20%) of human norovirus–infected patients exhibited bacterial dysbiosis characterized by increased *Proteobacteria*.[428] Bacterial communities remained mostly unaltered during infection of mice with multiple MNV strains under standard housing conditions.[427] However, dramatic alterations in the intestinal bacteria were observed under malnutrition conditions in mice.[221] Therefore, a complex network of interactions occurs between the host, the microbiota, and noroviruses.

Persistence

Human noroviruses have been associated with prolonged infections in immunocompromised patients, including those with primary immunodeficiencies and transplant patients.[470] For example, nine adult patients receiving kidney allografts and undergoing immunosuppression were shown to shed norovirus for periods ranging from 97 to 898 days.[519] Another study described a chronic norovirus infection lasting at least 6 years in an immunocompromised patient with X-linked syndrome.[138] Chronic norovirus shedders can contribute to nosocomial transmissions[562] and were proposed to be a source of emergent norovirus infections.[262] However, the full contribution of chronic norovirus infections to disease burden remains unclear.

The ability of noroviruses to persist in infected hosts is well established for MNV, and differences in pathogenicity have been documented among MNV strains. While MNV-1 (isolated following a series of intracranial injections in RAG/STAT1-deficient animals)[265] causes an acute and rapidly cleared infection in immunocompetent animals, certain other MNV strains (characteristically isolated from feces) can establish persistent infection in the intestine with shedding for at least 35 days.[439,586] Studies using MNV have demonstrated that persistence occurs in the face of a robust cytotoxic T-cell response[600] but the infection can be cleared by the action of the innate immune response, specifically IFN-λ.[34,437,563] Genetic studies with the acute MNV-1.CW3 and persistent MNV.CR6 strains revealed a unique role for IFN-λ in the intestinal epithelium in concert with the viral NS1/2 protein in establishment of persistence. NS1/2, and in particular a single amino acid residue (glutamic acid at position 94), is necessary and sufficient for replication in the large intestine and persistence.[440] The reservoir of persistent norovirus infection is in intestinal epithelial cells, specifically tuft cells.[326,645] The ability of MNV.CR6 to persist in these specialized intestinal epithelial cells is dependent on the NS1 protein, which antagonizes IFN-λ–mediated antiviral immunity.[326] Hence, chimeric MNV-1 carrying the MNV.CR6 NS1 gene or MNV-1 infection of mice lacking the IFN-λ receptor similarly leads to persistence. In addition, the viral capsid protein VP1 further contributes to persistence in a dose-dependent manner since high infectious doses of MNV-1.CW3 only established persistent infection when carrying both the mutation in NS1 (E94) and VP1 of MNV.CR6.[437] When MNV-1.CW3 was carrying its own VP1, however, high doses elicited strong stimulation of type I and III

IFN responses in Peyer patches and mesenteric lymph nodes, leading to eventual clearance.[437] Interestingly, depletion of the intestinal microbiota via antibiotics also prevented the establishment of persistent MNV.CR6 infection.[34] The phenotype did not occur in IFNLR-deficient animals, further pointing to the importance of IFN-λ during persistent norovirus infection in the intestine. On the other hand, type I IFNs only play a role during systemic infection, and deletion of IFNAR on CD11c-positive myeloid cells permits persistence of MNV-1.[438] Furthermore, adaptive immunity does not regulate intestinal persistence, although it is required for clearing systemic infections.[88] Taken together, MNV persistence is controlled by a combination of viral (NS1, VP1, and maybe others) and host factors (in particular, IFN-λ) and further modulated by the microbiota.

EPIDEMIOLOGY

Age

Noroviruses have been associated with infection and disease in all age groups.[202] Age is a risk factor for severe disease, with infants and young children (<5 years old)[213,473] and older adults (>65 years old)[342] at highest risk. A review of pediatric cases in over 5,000 infants and young children in 23 countries found that approximately 70% of noroviruses illnesses occurred between 6 and 23 months of age, with less than 15% occurring in the first 6 months of life.[532] Norovirus infection has also been detected in neonates[400,609] and preterm infants,[18] with varying clinical manifestations.

Morbidity and Mortality

Although precise data on morbidity and mortality are not available,[9] recent estimates confirm their predominant role in diarrheal disease. Global estimates of norovirus illness have projected nearly 700 million cases and 218,800 deaths annually.[5,43] In the surveillance period following efficacious rotavirus vaccination in pediatric populations, norovirus has emerged as the single most important cause of life-threatening gastroenteritis in infants and young children.[74,303,466] In a review of 39 published studies that surveyed

severe gastroenteritis in individuals older than 65 years of age, norovirus was responsible for an approximate 10% to 20% of hospitalizations and 10% to 15% of all-cause gastroenteritis deaths.[342]

Morbidity is reflected in the number of hospitalizations due to norovirus disease. In the United States, an estimated 71,000 hospitalizations were associated with norovirus gastroenteritis each year, at a cost of $493 million per year, and an estimated 570 to 800 deaths.[202,358] In Germany, an estimated 53,000 to 90,000 hospitalizations per year were attributed to norovirus gastroenteritis with an annual cost of €31 to 43 million.[308] An estimated 4,000 to 11,000 hospitalizations per year were associated with norovirus in Canada.[415] Of patients hospitalized in Canada from 2001 to 2004, noroviruses were responsible for a mean hospitalization incidence rate of 1.6 cases per 100,000, and the average age of hospitalized patients was 59 years old.[506] Over this 4-year period, 43 deaths were attributed to noroviruses, making it a leading cause of mortality among the enteric pathogens studied.[506] In England, noroviruses were the second largest cause of hospitalization due to gastroenteritis (after *Campylobacter*)[511] and have likely been underestimated.[622] This results in an estimated 0.3 to 1.2 years of healthy life lost per thousand cases of norovirus.[214] Noroviruses are also an important cause of illness in China, detected in 29% of adults and the elderly and 22% in children 6 to 35 months old with acute gastroenteritis.[672] An estimated 171,000 hospitalizations per year in Japan were modeled from a review of medical insurance claims.[97] In Lebanon, noroviruses were detected in 11.2% of stool samples from children less than 5 years old presenting with acute gastroenteritis to six large hospitals over a 2-year period[399] and in 27% of children hospitalized for gastroenteritis in Spain.[185]

Noroviruses have been associated with increased morbidity and mortality in patients with an underlying illness such as cardiovascular disease or who are immunosuppressed or receiving cancer chemotherapy.[62,191,390] In a review of hospitalization and emergency room visits in the United States from July 2002 to December 2013, over 51% of the norovirus illnesses occurred in 37% of patients with a chronic medical condition who were hospitalized for gastroenteritis.[623]

Origin and Spread of Epidemics

Noroviruses are the single most important cause of nonbacterial gastroenteritis outbreaks. In an analysis of 233 nonbacterial gastroenteritis outbreaks reported to the Centers for Disease Control and Prevention (CDC) between July 1997 and June 2000, 217 (93%) were associated with noroviruses.[162] In a larger survey of 3,714 nonbacterial gastroenteritis outbreaks that occurred in Europe between 1995 and 2000, 85% were associated with norovirus.[359] A review of 666 norovirus outbreak reports from multiple countries linked 362 (54%) of these to foodborne illness, 174 (26%) to person-to-person transmission, 70 (11%) to water contamination, and 60 (9%) to environmental exposure.[389] Noroviruses are estimated to cause as many as 47% to 96% of acute gastroenteritis outbreaks in pediatric populations and 5% to 36% of sporadic cases.[157]

Norovirus outbreaks characteristically occur in settings that facilitate rapid person-to-person spread or single-source exposure to contaminated food, water, or surfaces. These settings include hospitals, long-term care facilities, camps (recreational and evacuee), recreational areas, schools, universities, daycare centers, cruise ships, stadiums, retirement centers, restaurants, social events with catered meals, families, the military, prisons, and community events. Outbreaks can vary in size, involving small family groups to hundreds of individuals.[240,660] Outbreaks can be prolonged, with recurring sharp peaks, and the modes of transmission can vary within an outbreak.[7,129] While norovirus infection occurs year-round, a seasonal pattern of occurrence (typically peaking in cooler months of the year) has been described that varies according to the climate of the region.[92,416,502] Food service and cooler months were risk factors for higher attack rates within outbreaks.[389]

Noroviruses are the leading cause of foodborne illness in the United States (followed by *Salmonella* (nontyphoidal), *Clostridium perfringens*, *Campylobacter* spp., and *Staphylococcus aureus*), accounting for approximately 26% of all reported outbreaks.[517] An analysis of 8,271 foodborne outbreaks reported to the CDC (1991–2000) showed that norovirus outbreaks were often larger than bacterial outbreaks (median persons affected: 25 vs. 15), with 10% of the affected individuals seeking medical care and 1% being hospitalized.[643] In a study of waterborne outbreaks in Finland, 18 (64%) of 28 outbreaks evaluated were associated with

norovirus.[391] Bivalve mollusks (such as oysters and mussels) are an important cause of foodborne norovirus outbreaks.[291,356,370,395,414,639] In fact, a recent review of foodborne norovirus outbreaks identified shellfish and seafood as the most common foods implicated, followed by lettuce and raspberries.[210]

Noroviruses have been documented as important agents of gastroenteritis in military populations in different areas of the world.[19,68,225,354,393,495,593,633] Norovirus illness can be severe in troops who may already be physically stressed.[132] Large-scale outbreaks of gastroenteritis have been attributed to noroviruses on ships such as aircraft carriers on which hundreds of crew members became ill.[61,117,459,530]

Although the majority of traveler's diarrhea has been attributed to enterotoxigenic *Escherichia coli*,[55] prevalence rates ranging from 10% to 65% have been associated with norovirus.[538] The global distribution of diverse norovirus strains and limited use of diagnostic confirmation suggest that norovirus illnesses have been underestimated in traveler's diarrhea.[37,538] Norovirus transmission during airplane travel[290,592] in addition to that on recreational cruise ships[620,642] illustrates the potential ease with which strains can be spread globally.

Prevalence and Seroepidemiology

Norovirus has been estimated to cause a fifth of all acute gastroenteritis illnesses, consistent with its widespread distribution in the human population.[5] In a review of studies that incorporated norovirus diagnostic confirmation in approximately 190,000 patients, the overall prevalence of norovirus in individuals with acute gastroenteritis was 18%.[5] Norovirus prevalence rates in this report were 24%, 20%, and 17% in cases of acute gastroenteritis in the community, outpatient, and inpatient settings, respectively.[5] The prevalence of norovirus in pediatric populations has been evaluated in a birth cohort of 1,457 children in a multinational study (MAL-ED).[504] Approximately 89% of children had evidence of a norovirus infection by 2 years of age, and 22.7% of the diarrheal stools were norovirus positive.[504] The prevalence of antibody to the GII viruses appears to be greater than that of the GI viruses in most studies, likely reflecting the

predominance of circulating GII strains.[504,615] In Finnish infants and children, aged 0 to 14 years, the antibody prevalence against GII.4 noroviruses reached 91.2% in children above 5 years of age.[442]

The incidence of norovirus gastroenteritis has been estimated in several community-based studies. In the United States, an enhanced surveillance study of acute gastroenteritis (that included pathogen identification with diagnostic assays) in a single state (Georgia) estimated that norovirus was the predominant cause of acute gastroenteritis, accounting for 6,500 (16%) and 640 (12%) per 100,000 person-years of community and outpatient acute gastroenteritis episodes, respectively.[203] In the Netherlands, 18% of the community cases of gastroenteritis over a single winter season and at least 5% of gastroenteritis cases that resulted in a visit to a physician were associated with norovirus infection.[304] Furthermore, a 1-year prospective population-based cohort study showed that noroviruses were the single most important cause of gastroenteritis overall in nearly all age groups in the Netherlands.[131] In Germany, the incidence of norovirus gastroenteritis in the community requiring medical attention was reported as 626 cases/100,000 person-years, making it the predominant known cause of acute gastroenteritis in that country.[266] In England, the community incidence of norovirus gastroenteritis was 4.5 cases/100 person-years, corresponding to approximately 2 million episodes per year.[474] In a community cohort study in the United Kingdom over a 1-year period (2007–2008), noroviruses were the most common organism detected, with incidence rates of 47 community cases per 1,000 person-years.[568] In China, the incidence was estimated to be 15.6/100 children/year among children less than 5 years of age.[672]

Genetic Diversity of Virus

Molecular epidemiologic studies have demonstrated a marked genetic diversity among circulating noroviruses.[613] Genetic typing of circulating strains has proven to be a useful tool in elucidating the source and spread of outbreaks,[312,621] and regional data sharing networks have been established in several areas of the world.[613] A dual genotyping system that identifies both the VP1 and NS7^{Pol} has been developed to track the emergence of recombinant strains in the population.[311] The VP1 system is defined by the amino acid sequence identities of complete VP1 capsid proteins, which

presumably would correlate with the antigenic specificity.[107,311,671] Classification of the VP1 shows the division of the genus *Norovirus* into 10 major phylogenetic genogroups, designated GI through GX, with two additional "nonassigned" (NA) genogroups pending (Table 4.5). Genogroups I, II, and III are further subdivided into 9, 26, and 2 genotypes, respectively. To facilitate global tracking of emerging norovirus strains, online genotyping tools are available that can identify the VP1 and Pol genotype when interrogated with full or partial genomic sequences.[312]

Genotypes are defined based on the complete VP1 sequence.[107]

Large-scale molecular epidemiologic studies have given insight into the role of norovirus genotypes, variants, and recombinants.[613] The GII noroviruses, particularly those of the GII.4 cluster, are the predominant viruses detected, and this distribution reflects the epidemiologic pattern observed in most other parts of the world.[613] Major shifts in the predominant circulating GII.4 variant can occur.[77,174,338,535] Different norovirus genotypes, such as GII.17, can emerge and displace the predominant GII.4 variant in a population for a period of time, but it is not clear whether such displacements are permanent.[232] Sequence analysis of the GII.4 noroviruses that emerged on a global level in the early 2000s identified the presence of an amino acid insertion in the VP1 P2 domain, suggesting a possible change in the antigenic or receptor recognition phenotype.[135] Further evolution in the GII.4 cluster was described,[77] and several studies have examined the possibly unique propensity of this genotype to undergo genetic (and antigenic) drift.[337,461] Genetic variation has been detected in other regions of the genome such as the emergence of the "GGIIb-pol" polymerase type that was found in norovirus strains in combination with several different VP1 genotypes.[493] Additional reports of unique polymerase sequences have led to the conclusion that recombination is a driving mechanism of norovirus evolution.[76,181,366] There is epidemiological evidence that disease with GII.4 may be more severe.[78,133,234] Epidemiological data indicate a higher association of GI noroviruses with environmental outbreaks (such as waterborne and shellfish) as compared to GII, which was more prevalent in health care settings and in outbreaks occurring in cooler months.[389]

Evidence for mixed norovirus infections within the same individual or within the same outbreak has been reported in many epidemiologic studies.[667] In addition, a marked genotypic diversity among norovirus strains has been documented in pediatric patients.[173,208,292,386,677] The presence of diverse norovirus sequences in shellfish and environmental samples is common,[616] suggesting another potential source for mixed infection. Such diverse and mixed infections likely enable recombination between norovirus RNA genomes, a possibility suggested from sequence analyses of naturally occurring noroviruses in several species.[76] Immunocompromised individuals with chronic norovirus infection can be superinfected with a different norovirus and sustain a prolonged mixed infection.[73] Viral RNA populations

are genetically heterogenous, especially during chronic infection, which further drives evolution of new strains.[75,619] Infection of feline kidney cells with two distinct recombinant FCV strains bearing different fluorescent markers has demonstrated that coinfection of the same cell can readily occur, further supporting the potential for recombination of RNA genomes during replication.[2]

CLINICAL FEATURES

Viral gastroenteritis is generally considered to be mild and self-limiting, although the illness can be incapacitating during the symptomatic phase that usually lasts 24 to 48 hours[496] (Fig. 4.13). Illness induced by the noroviruses can be sufficiently severe to require medical intervention, with an increased risk for life-threatening dehydration at both ends of the age spectra (See *Morbidity and Mortality*). Immunocompromised patients with norovirus infection are at increased risk for morbidity and mortality, and an increasing number of reports have linked norovirus to chronic gastroenteritis in patients undergoing transplantation or chemotherapy[191] (see *Treatment*).

CLINICAL COURSE OF NOROVIRUS ILLNESS

EXPOSURE

fecal-oral transmission via:

- Person-to-person contact
- Contaminated food or water
- Contaminated surfaces or fomites
- Droplets (vomitus)

INCUBATION PERIOD

characteristically short:

24–48 hours

ACUTE SIGNS / SYMPTOMS

one or more:
(average duration 48 hours)

- Diarrhea
- Vomiting
- Abdominal cramps
- Nausea
- Fever
- Malaise
- Headache
- Myalgia
- Anorexia

OUTCOME

characteristically self-limiting, risk increased in:

- Infants
- Young Children
- Elderly
- Immunocompromised

FIGURE 4.13 Clinical course of norovirus gastroenteritis. Norovirus disease is characterized by a short incubation period and acute onset. Symptoms and signs vary, but vomiting and diarrhea are common manifestations of disease. In otherwise healthy individuals, illness is characteristically self-limiting without serious sequelae. Risk factors for severe disease include young and old age, a compromised immune system, or a debilitating underlying illness or condition.

Based on volunteer studies with human NV, the incubation period is short, ranging from 10 to 51 hours, with a mean of 24 hours.[25,56,140,141,555,656] This brief incubation period is consistent with the pattern of illness in outbreak investigations.[324] The incubation period recorded in 22 naturally occurring outbreaks of NV gastroenteritis was between 24 and 48 hours in 20 of the outbreaks, and the range was from 4 to 77 hours.[258] The incubation period of experimentally induced Snow Mountain virus illness ranged from 19 to 41 hours, with a mean of 27 hours.[144] Acute illness usually lasts about 24 to 48 hours.

A transient malabsorption of fat, D-xylose, and lactose is observed during experimentally induced NV illness.[56,520] Levels of small intestinal brush-border enzymes (trehalase and alkaline phosphatase) were significantly decreased when compared with baseline and convalescent-phase values, whereas adenylate cyclase activity in the jejunum was not elevated following NV or Hawaii virus-induced illness.[4,331] Gastric secretion of hydrochloric acid, pepsin, and intrinsic factor did not appear to be altered during NV illness.[398] Elevation of serum transaminase levels was reported in four pediatric patients at approximately 2 weeks following acute illness.[606]

Of 16 volunteers who developed illness following Norwalk or Hawaii virus infection, 14 developed transient lymphopenia.[143] This was attributed to a redistribution of circulating lymphocytes to the site of viral infection in the small intestine. The lymphocytes remaining in the circulation responded normally or exhibited an exaggerated response to mitogenic stimuli.

A marked delay in gastric emptying was observed in infected volunteers

who became ill and developed the typical jejunal mucosal lesion.[398] It has been proposed that abnormal gastric motor function is responsible for the nausea and vomiting associated with these viral agents[398]; however, the mechanisms of illness are not clear. An analysis of epithelial barrier and secretion function in norovirus-positive human duodenal biopsy tissue showed that tight junction proteins occludin, claudin-4, and claudin-5 were reduced and anion secretion was stimulated.[604] In addition, a comparison of asymptomatic and symptomatically infected human volunteers identified increased serum cytokines in symptomatic patients only, while viral RNA levels and shedding were similar.[433] Thus, norovirus diarrhea could result from one or more of the following mechanisms: loss of epithelial barrier integrity, secretory pathway dysfunction, and immune system hyperactivation.

Clinical manifestations observed in 31 volunteers experimentally infected with noroviruses who became ill included the following: fever above 99.4°F (45%), diarrhea (81%), vomiting (65%), abdominal discomfort (68%), anorexia (90%), headache (81%), and myalgias (58%).[656] The illnesses were characteristically mild and usually lasted 24 to 48 hours; however, one volunteer was given parenteral fluid because he vomited 20 times within a 24-hour period. The number of clinical signs and symptoms can vary among volunteers receiving the same inoculum.[140] Illnesses induced by the Hawaii, Montgomery County, and Snow Mountain viruses in volunteers cannot be distinguished clinically from those caused by NV.[144,656] Subclinical infections with Norwalk or Hawaii virus have been observed under experimental as well as natural conditions.

Clinical manifestations observed in 38 outbreaks associated with NV included the following (expressed as the median percentage of patients): nausea (79%), vomiting (69%), diarrhea (66%), abdominal cramps (30%), headache (22%), fever (subjective) (37%), chills (32%), myalgias (26%), and sore throat (18%).[258] Bloody stools were not reported. Vomiting occurred more frequently than diarrhea in children, whereas in adults, the reverse was observed. The duration of illness in 28 outbreaks ranged from 2 hours to several days, with a mean or median of between 12 and 60 hours in 26 of the 28 outbreaks. In 6 outbreaks, illness lasted more than 3 days in up to 15% of the affected individuals. The attack rates did not differ significantly with age or sex in 6 outbreaks in which this was analyzed.[258]

A 2-year study in children (≤5 years of age) compared the severity of acute diarrheal episodes caused by noroviruses with rotaviruses in hospital emergency and outpatient settings; most cases for both viruses ranged from moderate to severe, although illness was overall less severe for norovirus-infected individuals.[446] The clinical course of norovirus illness in preterm infants has been reported to include a distended abdomen and symptoms such as apnea or a sepsis-like appearance: vomiting was not a predominant symptom in these patients.[18,467] Noroviruses have been reported as associated with the following rare conditions or sequelae[496]: convulsions,[1,93] seizures,[42,106,229,279] encephalitis/encephalopathy,[241,284,531] intestinal perforation,[465,611,641] transient liver dysfunction,[420] and necrotizing enterocolitis.[559] Noroviruses have been associated with enteropathy in certain immunocompromised patients.[215,655] However, its role in inflammatory bowel disease remains unclear with studies ranging from no effect to exacerbation of disease.[28,273,470]

The determinants of susceptibility and resistance to norovirus disease are clearly complex (See *Immunity*). Expression of HBGAs ABH and Lewis carbohydrate antigens in the intestinal epithelium is considered a genetic susceptibility factor for human norovirus infection.[254,594] These glycans can serve as norovirus attachment factors (see *Mechanisms of Attachment*, Table 4.3), and their synthesis is controlled by enzymes that are products of alleles at the ABO, FUT2, and FUT3 loci. Individuals with two mutated FUT2 alleles, who are therefore devoid of H-type antigens on their gut and other mucosal epithelial cells, are called nonsecretors. Human volunteer studies previously identified that the secretor status of an individual were a major correlate in susceptibility to infection with NV.[341] On oral challenge with NV, only secretor individuals with H-type 1 antigens were susceptible to infection, whereas nonsecretors were resistant. This was confirmed in a retrospective analysis of volunteers.[236] However, variation exists among the noroviruses in their recognition of host cell carbohydrates.[322] For example, infection in volunteers challenged with GII Snow Mountain virus (unlike those challenged with NV) showed no correlation between ABH secretor status and susceptibility.[340]

DIAGNOSIS

Differential

An analysis of the common features of 38 NV outbreaks indicates that a provisional diagnosis of illness by the noroviruses can be made during an outbreak if the following criteria are met: (a) bacterial or parasitic pathogens are not detected, (b) vomiting occurs in more than 50% of cases, (c) the mean or median duration of illness ranges from 12 to 60 hours, and (d) the incubation period is 24 to 48 hours.[257] These so-called Kaplan criteria were found to be highly (99%) specific and moderately (68%) sensitive for the provisional diagnosis of a norovirus outbreak when re-evaluated with samples confirmed as norovirus positive.[608] Suspected foodborne illness presents as abdominal cramps, diarrhea (more common in adults), fever, headache, nausea, and vomiting (more common in children).[564]

Differential diagnosis of sporadic norovirus illness in individual patients is difficult, due to shared clinical features with a wide range of enteric pathogens and disease syndromes (see *Clinical Features*). Laboratory diagnosis is required to confirm etiology, but empiric treatment of symptoms should not be delayed due to the rapid progression of dehydration.[564]

Laboratory

Reverse Transcriptase Polymerase Chain Reaction

Currently, RT-PCR is the most widely used technique for detection of noroviruses.[624] With this method, noroviruses can be detected in clinical specimens (feces is preferred because it contains highest quantity of virus) and contaminated food, water, or fomites. The application of real-time quantitative (q) RT-PCR has gained widespread use because it allows rapid detection as well as comparison of viral RNA levels.[251,472,605] The choice of primers is important, because considerable genetic diversity exists among circulating strains.[624,659,676] The application of RT-PCR to amplify partial or complete genomes, coupled with sequence analysis of the amplicons, has been used extensively to detect and characterize noroviruses in various outbreaks.[72,119,461,614] Norovirus identification is included in multiplex PCR–based assays (several commercially available) that detect a wide array of

enteric pathogens, and these are an important advance in managing and treating infectious gastroenteritis.[49,108] The association of norovirus with an outbreak requires a limited number of specimens.[147]

Immunoassays

Immunoassays for the detection of noroviruses in clinical specimens are commercially available.[646] These assays characteristically utilize hyperimmune sera and monoclonal antibodies generated against recombinant norovirus antigens. Point of care assays that quickly identify norovirus antigen in stool are in development that can distinguish between viral and bacterial gastroenteritis in a clinical setting, and informing the use of antibiotics.[137,369,587]

Immunoassays that use recombinant proteins (such as rVLPs) as antigen to detect serological responses are specific, sensitive, and efficient for detecting infection with the human caliciviruses and have been used in several large-scale seroepidemiologic studies (see *Prevalence and Seroepidemiology*). The Norwalk rVLP ELISA has been shown to detect broadly reactive antibody responses in volunteers given NV, Hawaii virus, or Snow Mountain virus, although the maximal response was observed in volunteers challenged with the NV.[189,192,409,601] Thus, it is difficult to identify conclusively the antigenic type of an infecting norovirus strain by serologic analysis because of shared cross-reactive antigens.[45,441] The demonstration of an antibody response in 50% or more of the individuals involved (or examined) in an outbreak to a calicivirus antigen is strong evidence linking the virus with the outbreak.[258] Newer approaches to detect antibodies include noninvasive assays that utilize saliva to measure norovirus-specific IgA.[24,475,570]

PREVENTION AND CONTROL

Treatment

Noroviruses characteristically induce a mild, self-limited gastroenteritis that normally resolves without complications.[56,139–141,247,555,656] As noted,

hospitalization for severe dehydration, although rare, can occur with norovirus gastroenteritis. Oral fluid and electrolyte replacement therapy is usually sufficient to replace fluid loss.[14,15,122] Oral rehydration therapy should not be administered to patients with depressed consciousness because of the possibility of fluid aspiration. Parenteral administration of fluids may be necessary, however, if severe vomiting or diarrhea occurs.

Oral administration of bismuth subsalicylate after onset of symptoms significantly reduced the severity and duration of abdominal cramps during experimentally induced norovirus illness in adults.[555] In addition, the median duration of gastrointestinal symptoms was reduced from 20 to 14 hours. The number, weight, and water content of stools, as well as the extent of virus excretion, were not significantly affected by treatment. The use of various medications for symptomatic treatment of acute diarrhea in infants and young children (aged 1 month to 5 years) was reviewed: bismuth subsalicylate, loperamide, anticholinergic agents, adsorbents, or *Lactobacillus*-containing compounds were not recommended by the American Academy of Pediatrics, and, in addition, the use of opiates as well as opiate and atropine combination drugs was contraindicated.[14,15]

A need for norovirus-targeted therapy has been recognized in the management of immunocompromised patients with chronic norovirus infection.[271] Treatment protocols implemented for other pathogens have been evaluated in a small number of individuals with norovirus disease, with varying success.[430] Improvement in chronic norovirus diarrhea has been reported in immunocompromised patients following reduction in immunosuppressive therapy (IST) drugs; however, careful monitoring of these patients is required.[62] The effect of exclusion diets, enteral and intravenous immunoglobulins, breast milk, immunosuppressants, ribavirin, and nitazoxanide has also been examined in this patient population with differing efficacies.[71]

Efforts are in progress to develop antiviral drugs to target specific stages of the norovirus life cycle, but their safety and clinical efficacy have not been established.[589] The selection of drug-resistant viruses during treatment will be a continuing challenge,[293] and it is likely that a combined therapy approach will be needed.[16] Improvements in tools for high-throughput drug screening,[483,634] structure-guided drug development,[126,165] and innovative

inhibitors[145] are in development. Ideally, drugs or host immune modulators (such as IFN-lambda or TLR agonists) will be identified that would protect against diverse norovirus genotypes.[155,437,497]

Vaccines

Recognition of the disease burden and economic impact of noroviruses has informed research to develop a vaccine.[361,487] As noted earlier, improved surveillance in concert with diagnostic confirmation has allowed more accurate assessment of morbidity and mortality (see *Morbidity and Mortality*). Globally, norovirus incurs billions of dollars each year in direct health care system costs ($4.2 billion US) and even more in indirect societal costs ($60.3 billion US).[43] A vaccine would be of special importance to infants and young children, health care workers, food handlers, college students, military personnel, nursing home residents, and individuals in various institutional settings. Although norovirus gastroenteritis tends to be a mild illness, a reduction in diarrheal episodes may be especially important in the debilitated, malnourished infant, because it has been suggested that repeated diarrheal episodes may be a precipitating factor in the development of malnutrition through sequential damage to the intestinal mucosa.[387,504] The impact of norovirus infection on normal gastrointestinal microbiota or underlying disease conditions when elucidated may provide additional avenues to support norovirus immunoprophylaxis (see *Norovirus-Microbiota Interactions*).

A vaccine for the control of norovirus gastroenteritis is not yet available, but a number of vaccine candidates are in development.[116,294,365] Various routes of administration, formulations, and expression systems for rVLPs (or subunit forms) are under investigation.[36,40,63,151,161,196,224,278,514,565,566,569,573] Two-phase I/II trials have shown that norovirus rVLPs are safe and provide some protection against illness at the doses, routes, and adjuvants tested. In the first trial, NV (GI.1) rVLPs were administered by an intranasal route followed by oral challenge with infectious NV.[22] The second trial evaluated a bivalent formulation comprised of NV(GI.1) and a GII.4 consensus rVLP administered by intramuscular injection, followed by challenge with infectious GII.4 norovirus.[50] Although both trials showed some evidence for

protective immunity, larger placebo-controlled phase III trials will be needed to establish the efficacy of these vaccines. A phase I trial of an adenovirus-vectored norovirus vaccine administered orally in tablet form was also recently completed with promising results and will likely progress further in clinical trials.[281] Because noroviruses are antigenically diverse, additional work will be needed to determine the number of antigenic components required to provide protection against a broad range of norovirus antigenic types and variants.

Infection Control

Specific methods are not available for the prevention of norovirus infection and illness. Outbreak management generally focuses on containment by the prevention of spread to other areas by ill or exposed individuals, frequent handwashing, and effective environmental decontamination.[39] Shedding can occur beyond the resolution of symptoms as well as in the prodromal stage of infection,[184] presenting challenges to infection control.

The noroviruses are generally resistant to detergent or ethanol-based cleaning of environmental surfaces and fomites and require additional chemical disinfection.[41,146] Reliance on the use of alcohol-based hand sanitizers over handwashing has been reported to actually increase the risk of norovirus transmission and infection in patient care settings.[57,628] Effective disinfectants have been reported to include hypochlorite at 5,000 ppm (domestic bleach is ~5% sodium hypochlorite and can be used as a 10% solution), hydrogen peroxide–based cleaners, and phenolic-based cleaners.[41] Inactivation has been difficult to evaluate in the absence of *in vitro* infectivity assays, and surrogates for human noroviruses have been employed, with variable success.[114] However, recent advances should facilitate this analysis.[380] The poor disinfecting properties of alcohols and the efficacious properties of chlorine against human norovirus have recently been verified in an *in vitro* infectivity assay in human enteroids.[118]

Special care must be given to the hygienic processing of food in view of the frequent occurrence of foodborne outbreaks.[69] Depuration of oysters does not adequately clear tissues of NV,[216] and recent studies have shown that certain norovirus genotypes (such as GI) bind more avidly to HBGA-like glycans in oyster tissues.[321,370] Leafy greens such as lettuce may also bear

HBGA-like ligands that bind norovirus.[175] Precaution must be taken to prevent contamination of oyster beds and farm fields with feces, vomitus, or sewage treatment plant effluent. Measures that increase the purity of drinking water or swimming pool water should also decrease the frequency of outbreaks.[352] Various technological processes are under development to inactivate noroviruses in agricultural food products and shellfish prior to market.[223,285,307,329,412,491]

PERSPECTIVE

The past few years have seen remarkable progress in the calicivirus field, but in particular, major advances were made in our understanding of noroviruses. Chiefly among them was the discovery of two human norovirus culture systems, human intestinal enteroid cultures and transformed human B-cell lines (e.g., BJAB). Admittedly, improvements need to be made in several aspects of both systems to realize the full potential of these culture models. Nevertheless, since this lack of a cell culture model has been hampering progress in the field for decades, these initial steps are vital to spur the many new discoveries in the future that will undoubtedly follow. Furthermore, the MNV model with its many tools continues to reveal fascinating new biology about these viruses. Among them was the discovery of the first norovirus proteinaceous receptor CD300lf, an Ig-like lipid-binding protein, whose presence regulates the cellular tropism of MNVs. Study with MNV also uncovered for the first time that tuft cells, specialized chemosensory cells in the intestinal epithelium, are infected by a virus and that these cells can provide an immunoprivileged location for long-term viral persistence in the intestine. Studies with both human and MNVs also demonstrated an intricate interplay of these enteric viruses with the microbiota. Thus, in addition to host factors, viral biology and pathogenesis are also impacted by members of other kingdoms of life, highlighting the need to broaden our reductionist approaches, if we want to fully understand these emerging viruses. Advances in genomic technologies continue to uncover additional genetic diversity in the calicivirus family, leading to the recent description of six new calicivirus genera. Individual members of these genera hold the potential for additional animal and cell culture models to increase the versatility of existing tools and models in the field. Combining the enormous technical advances being made

in other scientific fields with the calicivirus knowledge and tools from the past decades promises additional scientific breakthroughs in the field as well as effective ways to treat and prevent their infections in the near future.

- Virus Assembly

Perspectives

The *Togaviridae* are simple enveloped plus-strand RNA viruses that are spherical in appearance and contribute significantly to human disease. Although they were originally classified together with several groups of viruses predominantly transmitted by insects, more recent analyses have defined them into a distinct family with two genera: the alphaviruses and the rubiviruses.[165] The alphavirus genus is by far the larger of the two with about 31 recognized members, while the *Rubivirus* genus is composed of a single member, rubella virus. Virus classification into each group is determined by genome organization and nucleotide homologies. The alphaviruses are responsible for a variety of human and animal diseases, involving encephalitis, arthritis, fever, rash, and arthralgia, and are transmitted primarily by arthropod vectors. Viruses such as chikungunya (CHIKV) and Venezuelan equine encephalitis virus (VEEV) have been responsible for recent human outbreaks and have raised awareness of the significance and potential threat of alphaviruses to human health. Rubella virus is a common childhood illness for which an effective vaccine is available. However, in the absence of immunity, the virus can induce severe congenital defects in the fetus of infected women.

Sindbis virus (SINV), the type member of the alphavirus genus, has been extensively studied in large part due to its facile growth in cell culture and its ability to cause mild or inapparent illness in humans. The virus has an 11.7-kb RNA genome that is capped at its 5′ end and contains a poly (A) tract at its 3′ terminus.[255] Virions have a spherical icosahedral arrangement of proteins that has facilitated their structural analysis. The detailed knowledge of the viral life cycle, which is the focus of this chapter, has been exploited for the development of alphavirus gene expression vectors. Many members of this virus group have been studied for their role in pathogenesis. Rubella virus, as expected from its classification, shares a number of properties with the alphaviruses, yet has several important distinctions that are highlighted throughout the chapter.

CLASSIFICATION OF VIRUSES WITHIN THE *TOGAVIRIDAE* FAMILY

Viruses transmitted by arthropods have been referred to as arboviruses. It was

originally observed by electron microscopy that many arboviruses had a similar morphological appearance that resembled a Roman cloak (in Latin, *toga*), hence the name togaviruses. Originally, the family *Togaviridae* consisted of Group A (alphaviruses) and Group B (flaviviruses); however, the genera rubiviruses and pestiviruses were later added based on their similar physical properties but despite their lack of arthropod transmission. With the development of sequencing, it became apparent that the original joint classification for these viruses was in error. The togaviruses have nonstructural or replication proteins encoded at the 5′ end of their genome RNA, while the 3′ end encoded the proteins that constitute the virus particle or virion. In the togaviruses, these structural proteins are translated from a subgenomic mRNA that derives from, and is coterminal with, the 3′ end of the genome.[215,255]

The larger of the two genera within togaviruses, the alphaviruses, has been classified into several antigenically related complexes.[207] Most phylogenetic analyses support this classification, but several recent additions add complexity to the organization. The alphaviruses have a worldwide geographic distribution, including the continent of Antarctica. The alphaviruses have classically been described as either Old World or New World viruses, depending on their distribution, and it is likely that several transoceanic exchanges have occurred.[207] Most alphaviruses are transmitted by arthropod vectors that probably control their geographic dispersal. However, the identification of the salmonid viruses, salmon pancreas disease virus, and sleeping disease virus (infecting rainbow trout) presents examples of alphaviruses for which arthropod transmission is unlikely.[299] These salmonid viruses appear to have diverged from the Old World to New World lineages early in alphavirus evolution, with no present-day close relatives. Another identified alphavirus, southern elephant seal virus, has been isolated from the louse *Lepidophthirus macrorhini*.[148] This isolation demonstrates not only that alphaviruses can be transmitted by lice but also that they can infect marine mammals, and a recent report suggests a marine origin for the alphaviruses.[50] However, the recent isolation of insect-specific alphaviruses such as Eilat virus, which are unable to replicate in vertebrate cells, suggests a potentially ancestral alphavirus.[182]

Although the alphaviruses and rubella virus have been classified within the same family, the evolutionary relationship between them is obscure.[52]

They have a similar genome organization, and their virions share physical similarities, yet their replication and assembly strategies are sufficiently diverse to question whether they arose from a direct ancestor.

VIRION STRUCTURE

Structure of Mature Virion

The structure of the alphavirus virion has been extensively studied, and numerous high-resolution structural studies now provide an atomic view of the virion. Although a variety of biophysical methods were used to elaborate the alphavirus structure, work that has advanced the field the most has come from cryoelectron microscopy (cryo-EM) and image reconstruction techniques.[27,28,89,90,277,278] The virion is 70 nm in diameter, with a molecular mass of 52 × 10^6 Da and a density of 1.22 g per cc. It is composed of repeating units of the E1 and E2 transmembrane glycoproteins, the capsid protein (C, sometimes referred to as the nucleocapsid protein), a host-derived lipid bilayer, and a single molecule of genome RNA. The protein components of the virion are arranged as a T = 4 icosahedral lattice, with 240 copies of each subunit.[28,198,201] These subunits interact with one another to form a rigid structure across the membrane in a one-to-one relationship between glycoproteins E2 and C. Smaller amounts of another membrane-associated protein, 6K, are also found in the virus particle.[64,157] It has been discovered that another small protein, the TransFrame (TF) protein, is found in substoichiometric amounts in the virion.[46] The lipid bilayer is derived from the host plasma membrane and is enriched in cholesterol and sphingolipid, molecules that are required for entry and budding.[110] Inside the bilayer, the C surrounds the genome RNA and forms an icosahedral shell. Thus, the alphaviruses are composed of multiple organized shells of molecules that effectively protect and deliver the viral RNA to susceptible host cells.

Cryo-EM has been extensively used to study the structure of alphaviruses, including SINV,[198] Semliki Forest virus (SFV),[273] Ross River virus (RRV),[28] VEEV,[196,308] Western equine encephalitis virus (WEEV),[238] Eastern equine encephalitis virus (EEEV),[91] Aura virus,[306] CHIKV,[260] and Barmah Forest virus (BFV).[120] The most recent studies with SINV are the

most advanced, with a resolution of 3.5 Å reported for these viruses.[27] The surface view of the virion, seen in Figure 5.1 for SINV, reveals a spherical particle with spike protrusions rising 100 Å from the lipid membrane surface. The icosahedral nature of the particle results in an ordered distribution of the petal-like spikes. The asymmetric unit, which is shaded in green in Figure 5.1A, contains four E1–E2 heterodimers. Each spike consists of three heterodimers of E1 and E2 glycoproteins. A total of 80 spikes reside on icosahedral threefold (solid black triangle in Fig. 5.1A) and quasi-threefold axes (open white triangle in Fig. 5.1A). Earlier biochemical studies established the nature of the heterodimer, and this relationship has been confirmed by cryo-EM reconstructions[312] and by x-ray crystallography.[142,279] Although the protein lattice occupies a substantial surface area, small openings are present in the virion that reveals the underlying lipid bilayer. These openings are most pronounced at the twofold axes but can also be found at the fivefold axes and around the base of each spike.

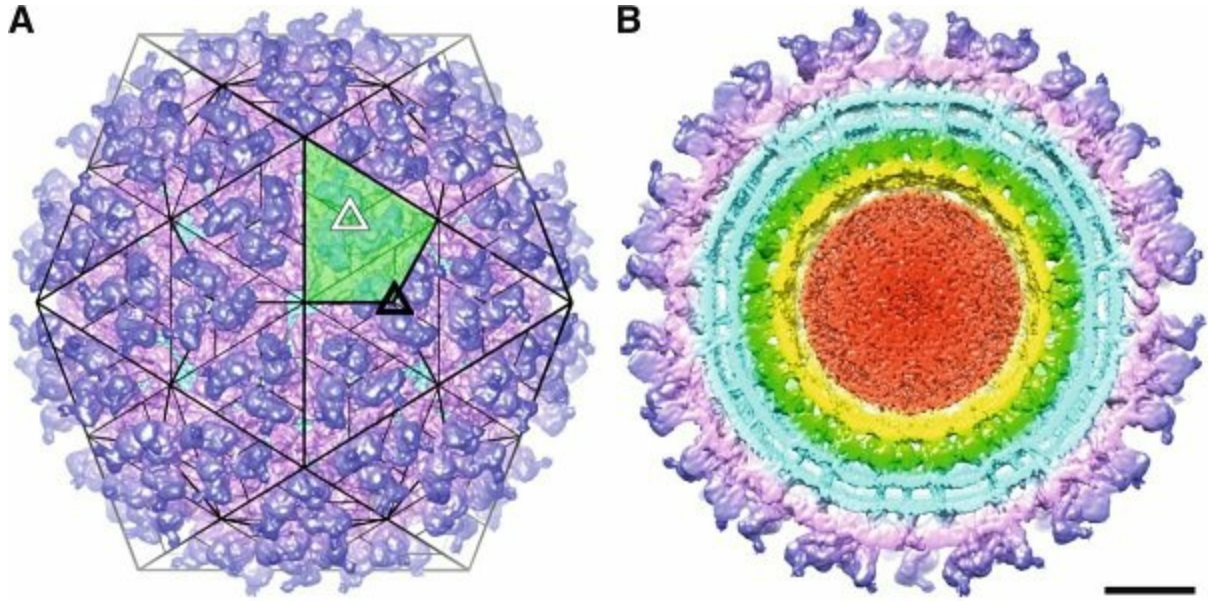

FIGURE 5.1 Structure of an alphavirus determined using cryo-EM. **A:** Surface-shaded view of Sindbis virus as determined by cryo-EM at 7.0 Å. The trimeric petal-shaped spikes are visible, with *solid triangles* representing the threefold axes and *white triangles* representing quasi-threefold axes. One of the asymmetric units is highlighted by *green shading*. **B:** The same view as shown

in **(A)** but with the front half of the reconstructed structure removed. The outer layer containing spikes is shown in *blue*, while the underlying skirt density is in *magenta*. Crossing the lipid bilayer (*cyan*) reveals the ordered capsid protein (*green*; residues 114–264), a disordered region containing a mix of protein and RNA (*yellow*), and a region containing the remainder of the RNA genome (*red*). The transmembrane densities of E1 and E2 are seen spanning the outer and inner leaflets of the lipid bilayer (*cyan*). (Reprinted from Tang J, Jose J, Chipman P, et al. Molecular links between the E2 envelope glycoprotein and nucleocapsid core in Sindbis virus. *J Mol Biol* 2011;414(3):442–459, copyright 2011 with permission from Elsevier.)

The transmembrane components of the two glycoproteins are clearly seen in the cryo-EM reconstructions (Fig. 5.1B). The shape of density demonstrates that each transmembrane segment traverses the bilayer as a helix, although the E1 transmembrane domain is better represented by two alpha helices separated by a two–amino acid kink.[308] The E1 glycoprotein has 5 amino acid residues that penetrate across to the inner side of the membrane (cdE1), while E2 has 33 amino acids (cdE2) that interact with the nucleocapsid core.[146,149,262,308] This interaction is observed in cryo-EM reconstructions and demonstrates that each E2 molecule makes specific contacts with each capsid protein. The nucleocapsid core has a T = 4 arrangement of capsid protein, with the C-terminal protease domain forming pentameric and hexameric projections that appear as capsomeres on the surface of nucleocapsid cores (shown in green in Fig. 5.1B). The genome RNA does not appear to assume regular symmetry within the nucleocapsid core and is not ordered in the reconstructions (red in Fig. 5.1B).

Structure of Immature Virion

The structure of the immature virus containing an uncleaved precursor to E2, called PE2 or p62, has also been solved using cryo-EM.[45,200] Mutant versions of both SINV and SFV were used for independent structure determinations

resulting in similar structures. The extra density corresponding to the small protein E3 was found predominantly between the petals of the spike resulting in a dual-lobed petal. At a resolution of 25 Å, no apparent differences were found in the skirt or other regions of the spike and suggest that following cleavage of PE2 and release of E3, no significant conformational changes occur in the virus structure. These results have been further validated by a 6.8 Å cryo-EM structure of an immature CHIKV virus-like particle.[304] Slight differences were observed in the transmembrane helices and the radius of the spikes when compared with mature particles. The immature form of the virus has been proposed to stabilize the fusion protein as it transits the mildly acidic environment of the Golgi.[152,154,281] At some point in the transit of the particle post-Golgi, the pE2 precursor protein is cleaved by furin; however, the processed E3 remains bound to the particle.[269]

The Structural Proteins of the Virion

The proteins that constitute the alphavirus virion are synthesized as a polyprotein from a subgenomic RNA and are shown in Figure 5.2. The structures of the three major virion proteins have been determined by x-ray crystallography to high resolution. The capsid protein functions to encapsidate the genome RNA and forms a T = 4 icosahedron prior to release from the cell. The 264–amino acid capsid protein of SINV was crystallized, although the N-terminal 105 residues have been absent in the final structures.[30] It was suggested that the highly basic N-terminal domain was susceptible to proteases and degraded during crystal growth. A similar observation was made for the SFV capsid protein.[29] The C-terminal residues 114 to 264 of the SINV capsid protein form a chymotrypsin-like fold with the ultimate residue tryptophan 264 bound in the active site protease pocket. The fold contains two Greek key β−barrel domains that bring the catalytic triad of Ser215, His141, and Asp163 into juxtaposition for activity.[83] This structure substantiated biochemical and genetic data that proposed that the capsid protein had an autocatalytic serine protease activity.[10,84,166] The atomic structure of the capsid protein was used to generate a “pseudoatomic” resolution structure of the alphavirus nucleocapsid core (Fig. 5.3C) by fitting its coordinates into the cryo-EM density.[166,177,222] This was accomplished and suggested that the missing residues of the N-terminus would point inward from the core surface and interact with the negatively charged viral RNA.

The recent 4.4 Å cryo-EM structure of EEEV provides support for the earlier fitted structures and provides additional insight into the position of the N-terminal residues 82 to 112 (Fig. 5.4) that were implicated in genome RNA binding.[91]

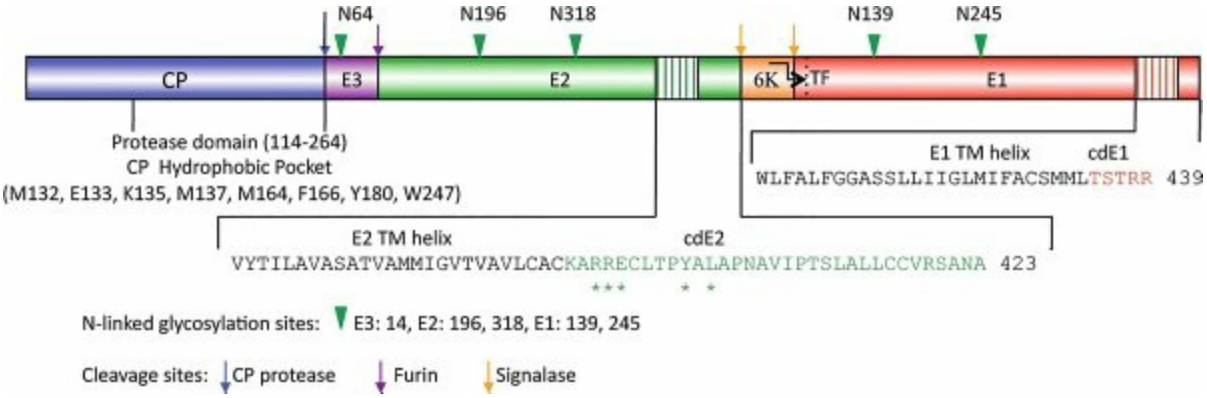

FIGURE 5.2 A schematic of the Sindbis virus structural polyprotein. The individual proteins are color-coded with protease cleavage sites indicated by an *arrow*. N-linked glycosylation sites are shown by *green arrowheads*. The amino acids that constitute the transmembrane and cytoplasmic domains of both E1 and E2 are shown. *Asterisks* indicate residues of cdE2 that interact with the capsid protein. The TF protein is identified by the *bent arrow* followed by the *dotted line* crossing E1.

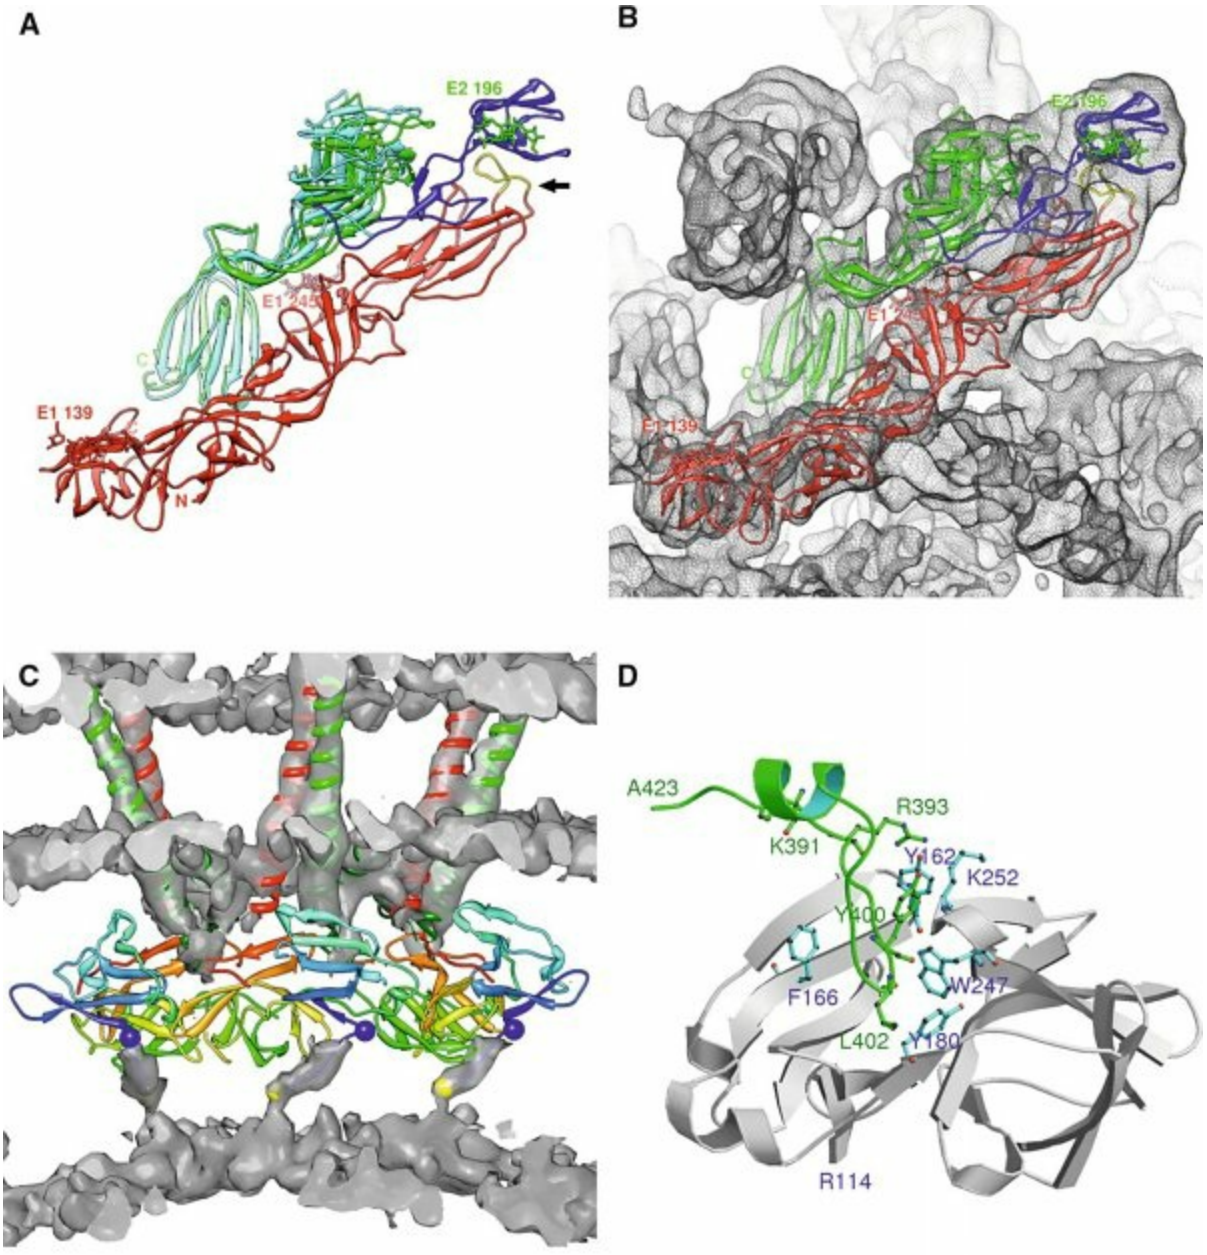

FIGURE 5.3 Pseudoatomic representation of the Sindbis virus structural proteins based on the 7.0 Å cryo-EM reconstruction. **A:** The structure of E1 and E2 of Sindbis virus. E1 is shown in *red*. The A and C domains of E2 are shown in two colors with one representing the structure from the crystal structure (*cyan*) and the one obtained by fitting the crystal structure into the cryo-EM map (*green*). The B domain of E2 (*blue*) is a homology-modeled structure derived from the chikungunya crystal structure. The

arrow points to the E1 fusion peptide (*yellow*). **B:** Same as in **(A)** but fitted into the cryo-EM density (*gray mesh*). **C:** Cross section of the fitted cryo-EM structure showing the transmembrane helices of E1 (*red*) and E2 (*green*) and the underlying N-terminal protease domain of the capsid protein (residues 114–264). Below capsid residue 114 (*blue ball*), the remaining N-terminal residues of the capsid are not identified but must interact with the underlying genome RNA. Additional EM density is shown in *gray*. **D:** Interactions between the capsid protein and the cdE2. The residues that constitute cdE2 (amino acids 391–423) were modeled based on the cryo-EM density and are shown as they interact with the hydrophobic pocket of the capsid protein. Residues of the capsid that have been shown as important in this interaction, F166, Y180, and W247, are highlighted. (Reprinted from Tang J, Jose J, Chipman P, et al. Molecular links between the E2 envelope glycoprotein and nucleocapsid core in Sindbis virus. *J Mol Biol* 2011;414(3):442–459, copyright 2011 with permission from Elsevier.)

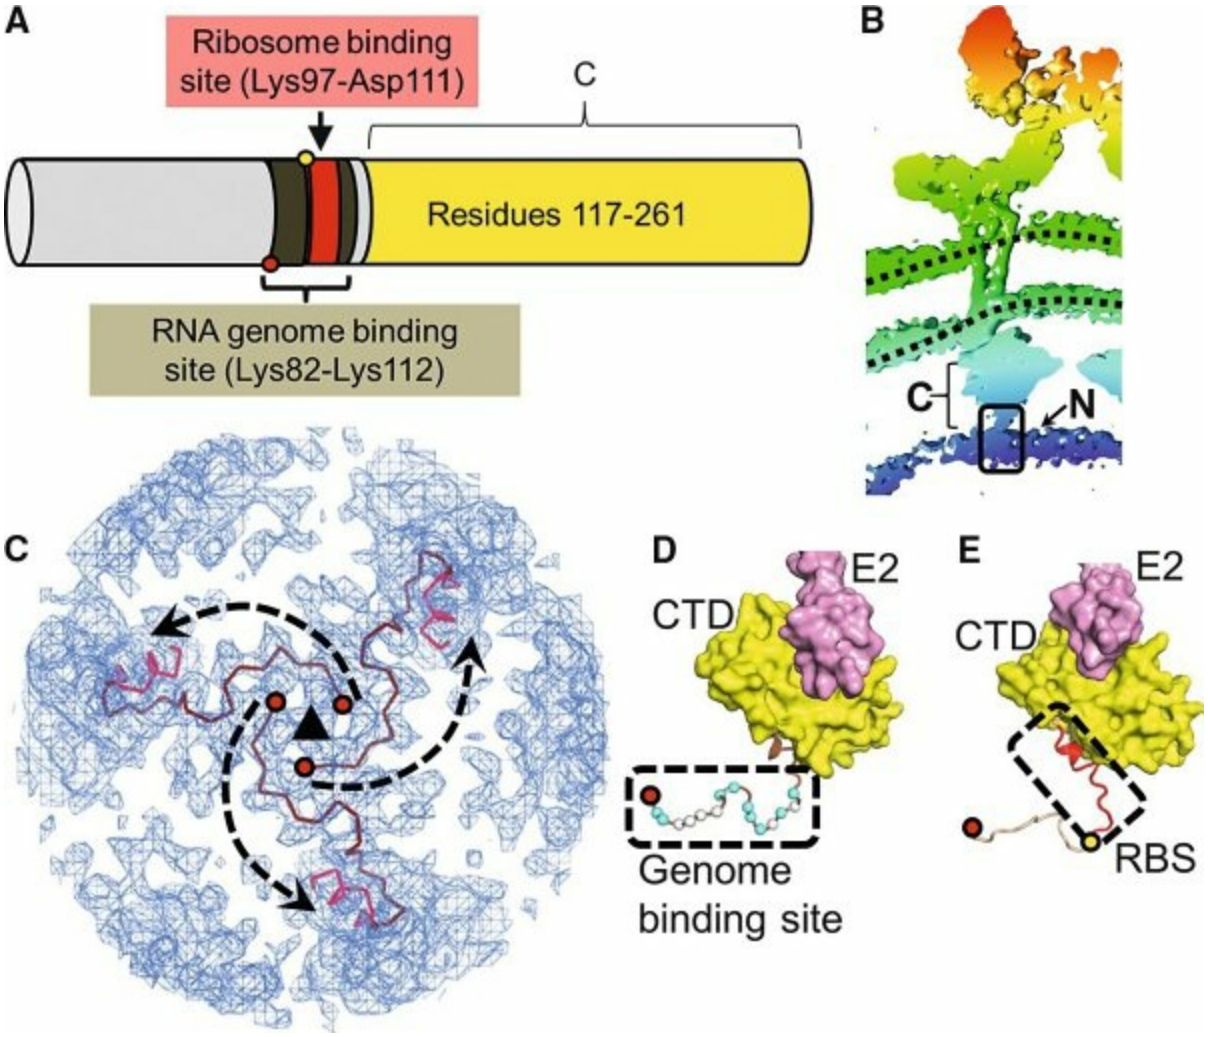

FIGURE 5.4 Structure/topology of the alphavirus capsid protein. **A:** Schematic representation of the EEEV capsid protein with the N-terminal disordered domain (residues 1–81) shown in *gray* and the C-terminal serine protease domain (residues 117–261) shown in *yellow*. The putative RNA genome–binding and ribosome-binding sites (residues 82–112) are shown between the N and C domains. **B:** Cross-sectional density of the 4.4 Å EEEV reconstruction showing a set of E1–E2–C proteins radially colored with the outer tip of E2 shown in *red* and the inner capsid/RNA genome shown in *blue*. The *dashed lines* represent the inner and outer lipid bilayer head groups. **C:** The genome RNA-binding sequence is shown by the *brown* chain with residue 82 represented by the *red circle* at the

radius of the capsid. **D:** A surface-shaded representation of the C-terminal domain of the capsid is shown in *yellow* with the E2 glycoprotein bound in the hydrophobic pocket of the capsid. On the other side (facing RNA genome) of the capsid C-terminal domain are the residues (82–112) of the RNA-binding site. **E:** As in **(D)**, except the ribosome-binding site is highlighted (residues 97–111), and residue Lys97 is shown with a *yellow circle*. The E1 protein functions as a class II fusion machine to promote the joining of viral and cellular membranes under conditions of low pH. The structure of the prefusion form of the E1 molecule from SFV was solved using x-ray crystallography.[137,297] The structure of the E1 ectodomain (residues 1–383) is shown in Figure 5.3A and B and contains three β−barrel domains. Domain I, the so-called central domain, links domains II and III. The extended domain II contains at its distal end the fusion peptide, a short loop of hydrophobic amino acids that promotes insertion of the protein into the target membrane. Domain III has an Ig-like fold and connects at its C-terminus with the transmembrane domain of the protein.

The structure of E1 is remarkably similar to the flavivirus E protein.[214,259] Unlike the alphaviruses, the flavivirus E protein functions both in receptor attachment and in membrane fusion. In the alphaviruses, these two activities are carried out by proteins E2 and E1, respectively. In the flaviviruses, the E protein is oriented roughly parallel to the lipid membrane, and it was anticipated that E1 might assume a similar orientation in the alphavirus virion.[123] This was essentially verified once the E1 atomic structure was fitted into the cryo-EM density. This fitting was accomplished for both SFV and SINV and recently for CHIKV.[137,142,206,279] Furthermore, for SINV, the two sites of E1 glycosylation were mapped onto the cryo-EM structure, and these sites at Asn139 and Asn245 were used as positional

markers to fix the position of E1 in the virion.[206] E1 lies at an angle of approximately 50 degrees relative to the surface of the membrane (Fig. 5.3B), and it forms an icosahedral lattice constituting the region that has been referred to as the skirt.[137,206] The crystallographic E1 dimer, which is a back-to-back dimer as opposed to a face-to-face dimer seen in the flaviviruses, is essentially preserved in the arrangement of E1 in the virion. The interface residues that make contact in the crystallographic dimer are presumably those that are important for forming the icosahedral lattice in the virion.

Although E1 constitutes the skirt region of the alphavirus surface, the majority of the protruding spike is composed of the E2 molecule. E2 constitutes the petals that make up the spike and covers the distal end of the E1 molecule that points outward. E2 serves to engage cell surface receptor molecules required for entry of the virion into the cell. The crystal structure of E2 together with both E1 and E3 for CHIKV was solved and reveals a three-immunoglobulin domain protein.[279] Domain B is located at the outermost point of the spike and contains the residues that have been implicated in receptor binding and as well as those involved in binding neutralizing antibodies. Domain B exhibits mobility in the context of the spike and was absent from the intact SINV E1–E2 trimer structure done at low pH. At the other end of the protein, located closest to the viral membrane is the C-terminal domain C. The N-terminal domain A (residues 1–132 in SINV) is the central bridge of E2, and connections are made to the B domain by the β−ribbon connector. The β−ribbon connector is flanked by a pair of well-conserved histidine residues, with E2 residue His170 shown to function as an acid switch to release the connector and B domain under acidic conditions. While E3 does not directly contact E1, its contact with the β−ribbon connector holds it in place to prevent movement of the B domain while the virus exits the cell in an immature state. The furin cleavage of the p62 to release E3, therefore, releases the clamp holding the B domain and activating the complex for pH-triggered fusion. E1 and E2 have extensive contacts with each other promoting the spike architecture (Fig. 5.3A, B). A recent high-resolution 3.5 Å cryo-EM reconstruction of SINV revealed the existence of a hydrophobic pocket that was occupied by a 20-Å-long linear molecule.[27] This pocket, similar to one seen in a lower-resolution structure of VEEV,[308] lies above the lipid membrane and is bound by conserved amino acids (Fig. 5.5). It has been hypothesized that this pocket stabilizes the

glycoprotein interactions, and when exposed to low pH, several conserved histidines may be protonated and cause the release of this “pocket factor” facilitating the resulting low pH-induced conformational changes.

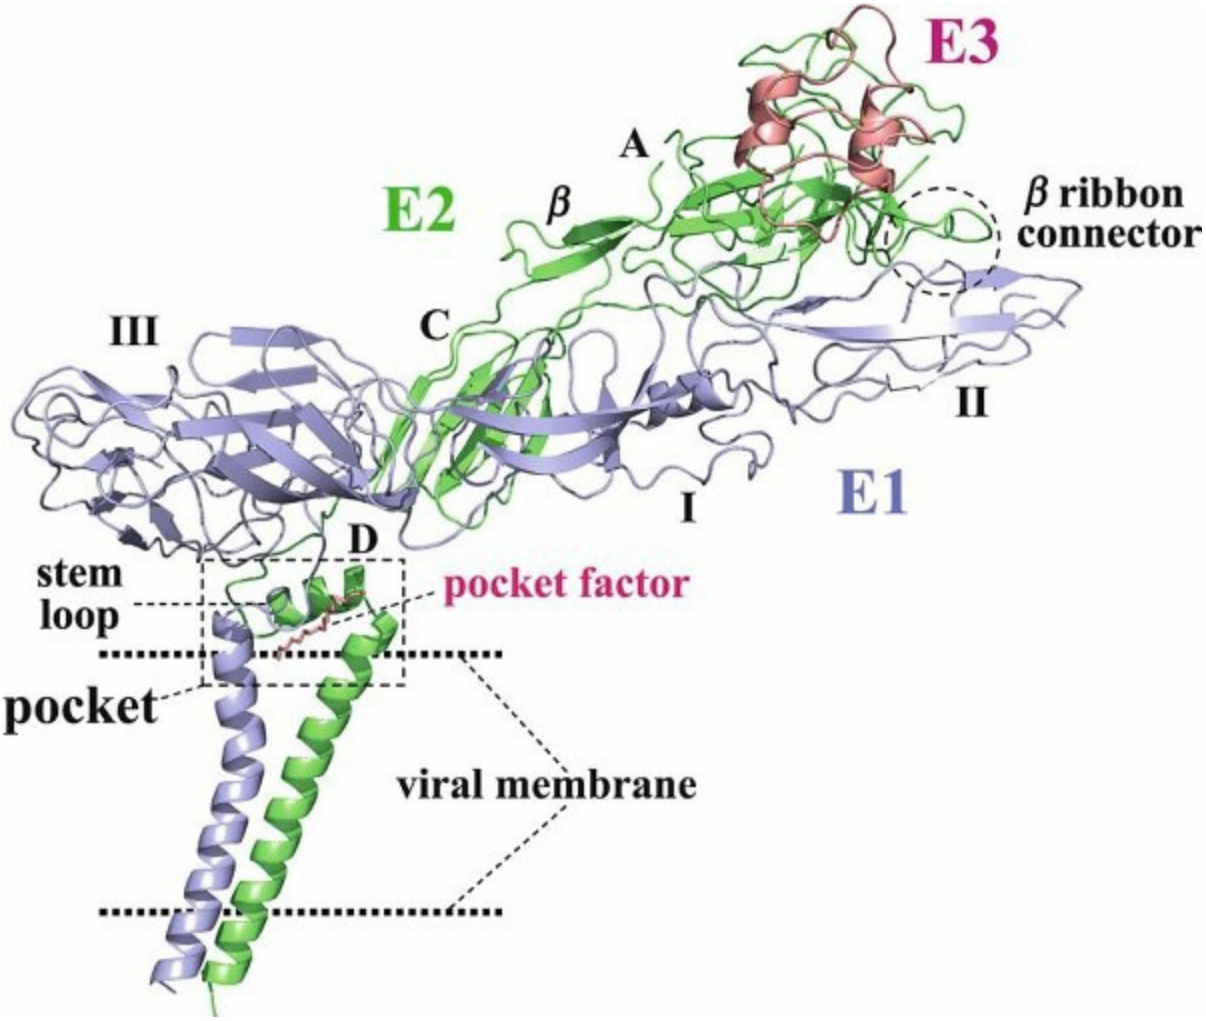

FIGURE 5.5 The C-*α* backbone of the 3.5 Å cryo-EM structure of SINV showing E1/E2/E3 glycoproteins. The atomic model of the glycoproteins was built directly from the cryo-EM density. The *dashed box* shows the location of the hydrophobic pocket that is occupied by an extended lipid molecule (*red*). It is suggested that the collapse of the pocket upon acidification results in ejection of the pocket factor and the ability of the glycoproteins to undergo movement necessary for fusion. (Reprinted from Chen L, Wang M,

Zhu D, et al. Implication for alphavirus host-cell entry and assembly indicated by a 3.5 Å resolution cryo-EM structure. *Nat Commun* 2018;9(1):5326, copyright 2018 with permission from Springer Nature.)

In addition to the three major structural proteins identified by cryo-EM in the virion, two small transmembrane proteins are present in substoichiometric amounts and can be identified using purified virus and mass spectrometry. The existence of the 6K protein in the virion has been well established, but more recently the TF protein (~8 kDa) has also been found within SFV particles.[46] Given the low abundance and presumably random distribution of these small transmembrane proteins, they have not been detected using high-resolution cryo-EM, and their membrane architecture has to date prevented x-ray crystal structures. Whether the TF and 6K proteins exist as oligomers is also unknown.

GENOME STRUCTURE AND ORGANIZATION

The *Togavirus* genome resides on a positive strand RNA that contains a 5′ terminal 7-methylguanosine and a 3′ terminus that is polyadenylated (Fig. 5.6). The alphavirus genome, represented in Figure 5.6 by the type virus SINV, is approximately 11.7 kb in length, while rubella virus is nearly 2 kb shorter at 9.8 kb.[38,255] The genomes segregate their replication and virion proteins coding regions into two segments with the replication region mapping to the 5′ two-thirds and the structural region mapping to the 3′ one-third. Limited nucleotide homology exists between genomes in the two genera, although there are several sequences in both translated and nontranslated regions (NTRs) that do have homology; however, most evidence suggests that their replication and assembly strategies are quite different.[38] The nonstructural or replication proteins are translated from the genome RNA, whereas the structural or virion proteins are translated from a subgenomic mRNA.[190] In SINV, the 5′ NTR is 59 nucleotides, about average for the alphaviruses, while the 3′ NTR is also close to the average in length at

322 nucleotides.

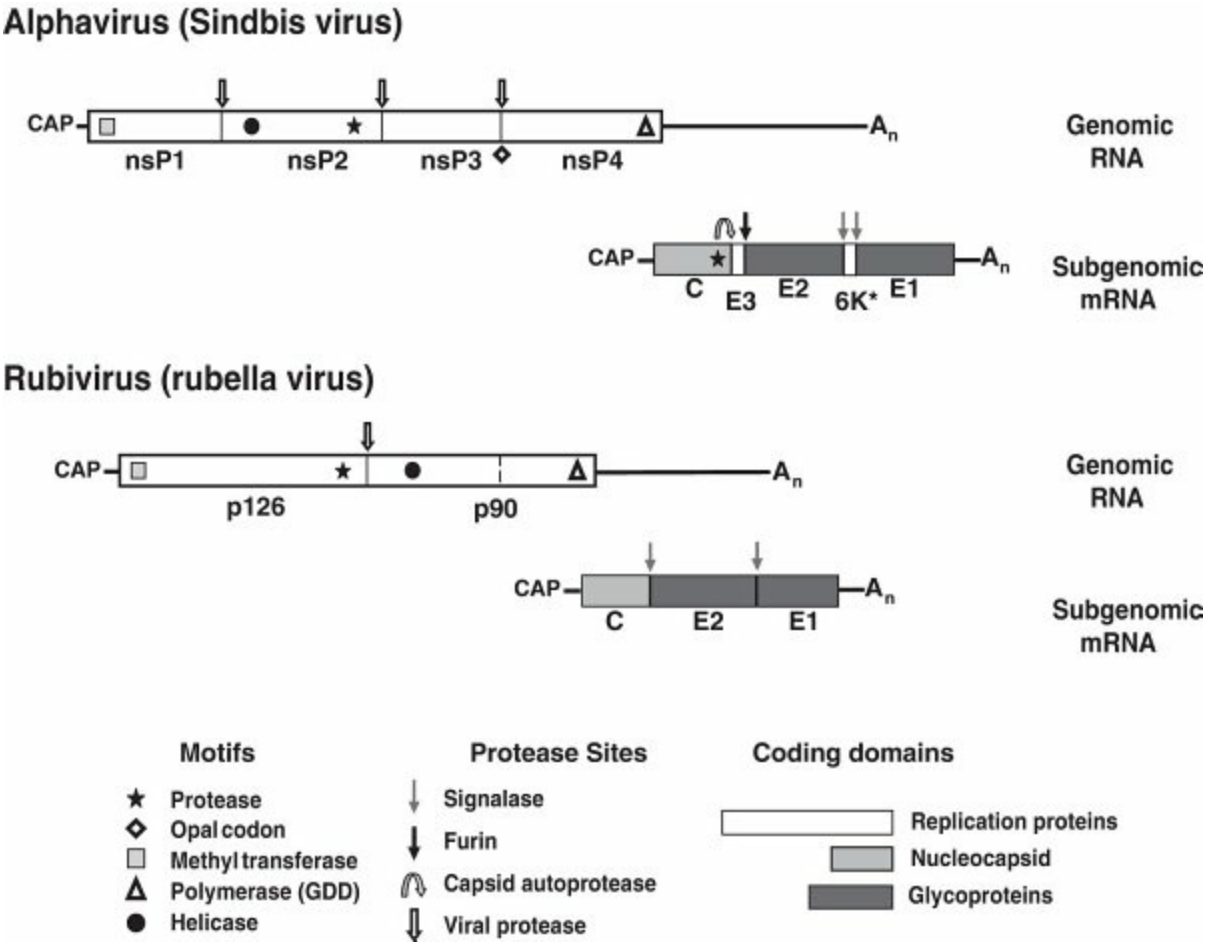

FIGURE 5.6 The genomes of SINV and rubella virus. Nontranslated regions are shown by the *solid line*, and translated regions are shown in *boxes*. *Open boxes* indicate replication proteins and *shaded boxes* represent structural or virion proteins. Motifs and cleavage sites are indicated according to the scheme. The subgenomic mRNAs are not shown to scale with the genomic RNAs.

Using comparative genome analyses and functional genetic studies of defective interfering (DI) particles and viruses, four conserved regions (conserved sequence element [CSE]) of the alphavirus genome were

identified as cis-acting elements important for replication.[141] Two conserved regions are found near the 5′ end of the genome, one is found in the junction region between nonstructural and structural genes, and one is found at the 3′ end immediately preceding the poly (A). Three presumably similar functioning CSEs can also be found in the rubella genome.[38] In the alphaviruses, each CSE has been shown to interact in a host-dependent manner, suggesting that host factors may play a role in their function.[43,122,185,186] It has been shown that a U-rich region in the 3′ NTR of SINV contains elements responsible for viral RNA stability and that the cellular HuR protein binds this region decreasing the rate of cell-mediated decay of the genome RNA.[250] In addition, studies have shown that host proteins bind to the 3′ end of the minus-strand RNA of SINV, and in one case, the protein was identified as the mosquito homolog to the La protein.[193–195]

ALPHAVIRUS REPLICATION

Mechanism of Attachment and Receptors

Alphaviruses display an extremely broad host range, both in terms of susceptible animal species and in terms of cells in culture. This broad host range has prompted speculation as to the nature of the receptor with two hypotheses proposed to explain this phenomenon.[256] In the first, the virus E2 glycoprotein contains multiple receptor-binding sites so distinct cellular receptors can bind the viral surface protein. The second hypothesis proposes that the virus uses a ubiquitous receptor that is highly conserved across species, including both mammals and mosquitoes. Data exist to support each model, and it is likely that a combination of the two is the true strategy for alphavirus attachment to the cell.

The variety of molecules that have been implicated for SINV argues for multiple distinct receptor-binding sites on E2.[256] The use of the laminin receptor with its high conservation across species suggests that it might serve as a receptor in multiple cell types and multiple host species.[285] However, the picture remains obscure for SINV because laminin receptor functions in baby hamster kidney cells but not in chicken embryo fibroblasts, where a 63-kDa

protein has been implicated.[288] In mouse neuroblastoma cells, proteins of 74 and 110 kDa have been reported as possible SINV cellular receptors.[288] DC-SIGN and L-SIGN, C-type lectins that bind mannose-enriched carbohydrates, have also been implicated as receptors of alphaviruses that have been produced in mosquito cells.[116] Studies using a genome-wide RNAi screen in Drosophila cells identified the natural resistance-associated macrophage protein (NRAMP) as a cellular receptor functioning to permit SINV infection.[220] Likewise, NRAMP2, the vertebrate homolog, is allowed for SINV, but not RRV, entry into mammalian cells. This finding raises the possibility that a family of related conserved multipass membrane proteins may serve as receptors for other alphaviruses. However, it has recently been shown using a genome-wide CRISPR–Cas9 screen for host factors involved in CHIKV infection that a membrane adhesion protein, Mxra8, functions as a cellular receptor for CHIKV, RRV, and other related arthritogenic alphaviruses.[309] The virus did bind to Mxra8, and antibodies against the protein were able to block CHIKV infection validating this protein as an authentic alphavirus receptor. A cryo-EM structure of CHIKV bound to Mxra8 reveals the binding of the receptor into a cleft formed by neighboring E1–E2 heterodimers within a spike and engaging a neighboring spike.

Natural isolates of EEEV utilize cell surface heparan sulfate as an attachment receptor.[65] This use of heparan sulfate may direct tropism of EEEV and promote enhanced neurovirulence. In contrast, passage of several other alphaviruses in culture leads to the accumulation of adaptive mutations, some of which introduce basic amino acids in their E2 glycoprotein.[19,21,22,117] This increase of positively charged amino acids in E2 leads to high-efficiency attachment to cells through heparan sulfate molecules. The importance of this interaction was demonstrated genetically by the generation of a Chinese hamster ovary cell line using retroviral insertional mutagenesis that was deficient in the expression of heparan sulfate and chondroitin sulfate.[104] These cells were resistant to SINV infection and defective in binding virus. The substitution of a single residue on the E2 glycoprotein of RRV was sufficient to permit heparan sulfate binding, and this attachment was mapped using cryo-EM to the distal tip of the spike.[94,307] The binding of heparan sulfate does not result in conformational changes in the virion, nor does it enhance the fusion process.[247,307] Therefore, it likely serves simply as a mechanism to attach the particle to the cell surface so an

efficient interaction with the entry receptor can occur. In contrast to what is observed in cell culture with SINV, infection of mice results in the development of large-plaque viral mutants with a reduced affinity for heparan sulfate and a greater viremia.[22] However, given these diverse observations, the utilization of heparan sulfate and its role in pathogenesis among the different alphaviruses requires further investigation. This model in which viruses first use a low affinity ubiquitous cell surface molecule to attach to the cell so that a more limited two-dimensional search for the entry receptor is likely employed by many of the alphaviruses.

Mechanisms of Entry, Membrane Fusion, and Uncoating

Following attachment to cells and engagement with an entry receptor, alphaviruses proceed via the endocytic pathway to gain access to the cell interior (Fig. 5.7).[36,95,162] Structural and biochemical experiments demonstrate that binding of RRV to heparan sulfate does not induce conformational changes in the virion.[307] However, other receptors may induce conformational changes in the particle that might mediate entry such as the reduction of disulfide bonds to disrupt protein–protein interactions.[1,11,199,230] Despite these suggestions that disulfide exchange may play a role in alphavirus entry, the use of thiol-blocking reagents failed to show a significant inhibition of infection.[75] However, it is clear that the attachment of SINV to cells results in the exposure of new epitopes defined by monoclonal antibodies and suggests that protein rearrangements occur following receptor engagement.[47,170] Similar observations have been made using purified virus and treatment with heat, pH, and reducing agents.[169] In addition, the recent observations on the role of virion and protein dynamics in the flavivirus life cycle suggest that other structurally related viruses might employ particle dynamics to sense their environment as they search for an entry receptor.[121] In addition to the role of thiol exchange reactions that have been proposed to play a role in alphavirus entry, there has even been a suggestion that cell penetration may occur at the cell surface in the absence of fusion by conformational rearrangements in the envelope glycoproteins.[1,199] However, it has been fairly well established that membrane fusion triggered by an exposure to acidic conditions is the gateway for the release of genome

RNA into the cytoplasm (Fig. 5.8). Finally, a virus receptor may not need to induce a conformational change in the virion to function as a receptor and for the particle to gain entry.

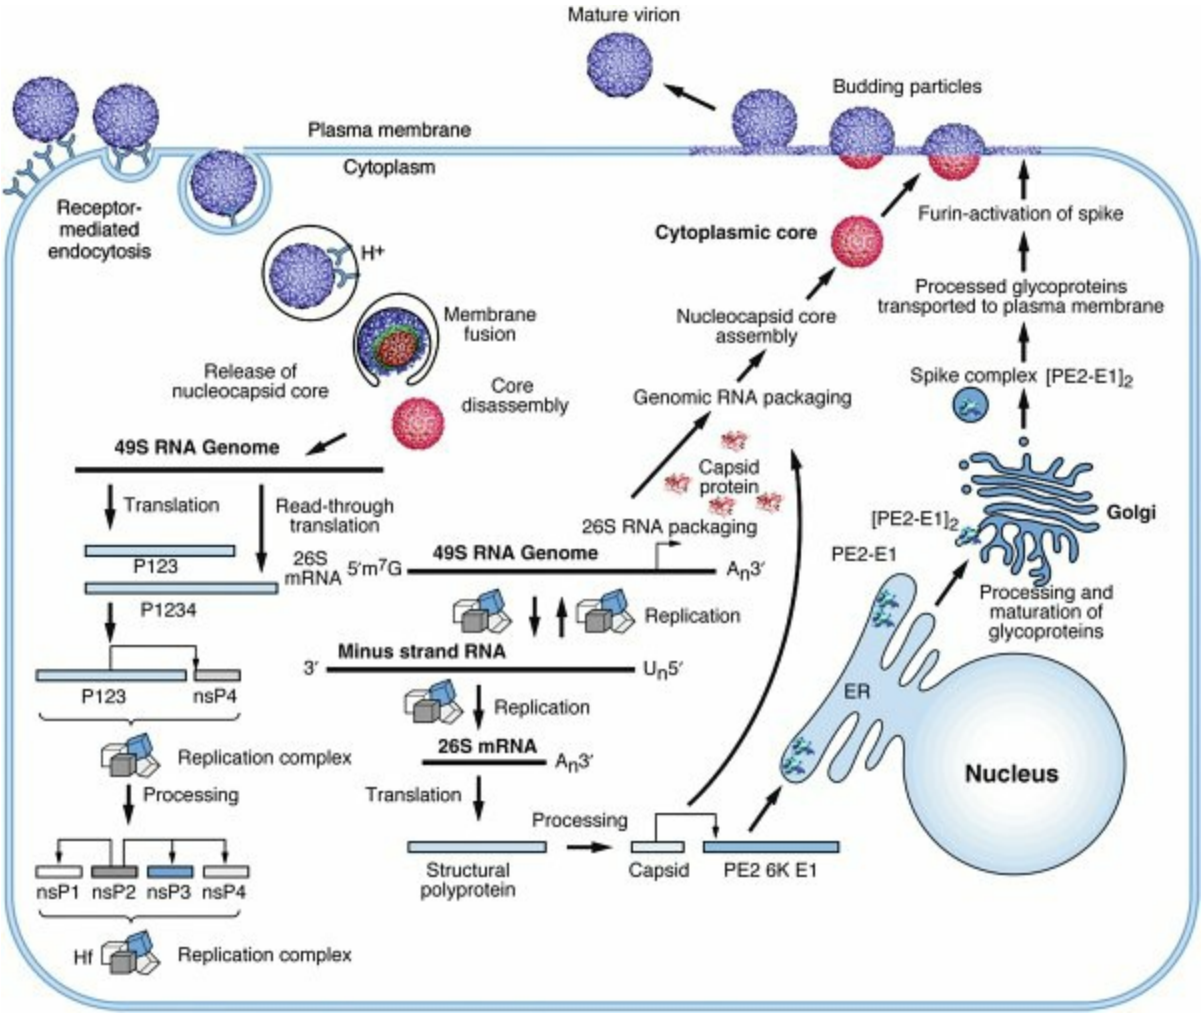

FIGURE 5.7 Life cycle of an alphavirus. The start of the life cycle is shown on the *left* with the attachment of a virion to the cellular receptor. Following fusion of the viral envelope, disassembly of the core, and release of the genome RNA, replication proteins are translated and processed (*bottom left*). These proteins enable the replication of the input genome RNA (*bottom center*) and translation of the subgenomic mRNA into structural proteins. Cytoplasmic assembly of genome RNA and capsid produces the

nucleocapsid core that associates with processed glycoproteins (*right*) at the plasma membrane resulting in budding. Scale varies.

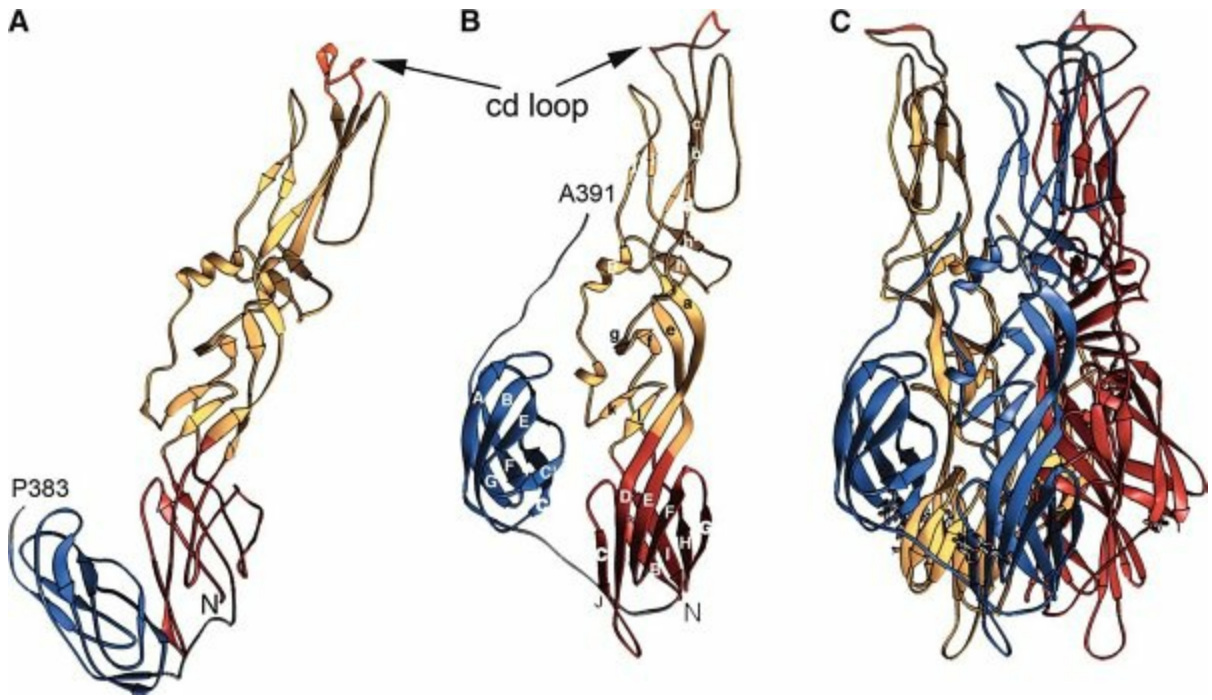

FIGURE 5.8 Postfusion structure of the Semliki Forest virus E1 protein. **Panels A** and **B** represent the neutral and low pH forms of the soluble E1 ectodomain lacking amino acid residues 392 to 438, respectively. The orientation of the protein presents the fusion loop (cd loop) toward the target membrane (*top*). This rearrangement would occur after E1 has undergone trimerization as shown in **panel C**. (This figure was modified using an image kindly provided courtesy of Dr. Felix Rey.[137])

Receptor-bound viruses undergo endocytosis into coated vesicles using a clathrin-dependent pathway. This pathway was demonstrated by DeTulleo and Kirchhausen using dominant-negative mutants of dynamin to block the formation of clathrin-coated pits and prevent entry of SFV and SINV.[36] The vesicles are subsequently acidified, providing the trigger for fusion between viral and cellular membranes. Acid-induced fusion is supported by numerous

studies but most convincingly by the use of lysosomotropic weak bases that raise the pH of endocytic vesicles and prevent entry of alphaviruses.[75,96] Although it has been argued that viral RNA replication might also be affected by the acidification, pseudotyped viruses containing alphavirus envelope proteins are also inhibited in entry by this treatment.[41,97,237] Entry is aided by several host proteins in the endosomal pathway, with TSPAN9 being one that functions in the early endosome to make it more permissive for membrane fusion.[252]

The role of the alphavirus E1 and E2 glycoproteins in the entry process has been firmly established (Figs. 5.8 and 5.9). In the presence of acidic pH, the E1–E2 heterodimer is destabilized and the two proteins dissociate.[281,283] The dissociation of the proteins results in the exposure of the fusion peptide that is found on the distal tip of E1.[4,72,85,137] The fusion peptide of E1 inserts into the target membrane in a cholesterol-dependent manner followed by the trimerization of E1.[4,71,111,187,205,282] A large conformational change in E1 results in domain III and the stem anchor region of the protein packing against domain II, resulting in the viral and target membranes being brought into close opposition (Fig. 5.8).[74] A set of E1 trimers, possibly resembling what has been seen in liposomes, results in membrane deformation and promotes membrane mixing.[72] Finally, a fusion pore will form as the two membranes complete the process, and the nucleocapsid core will be released into the cytoplasm (Fig. 5.9).

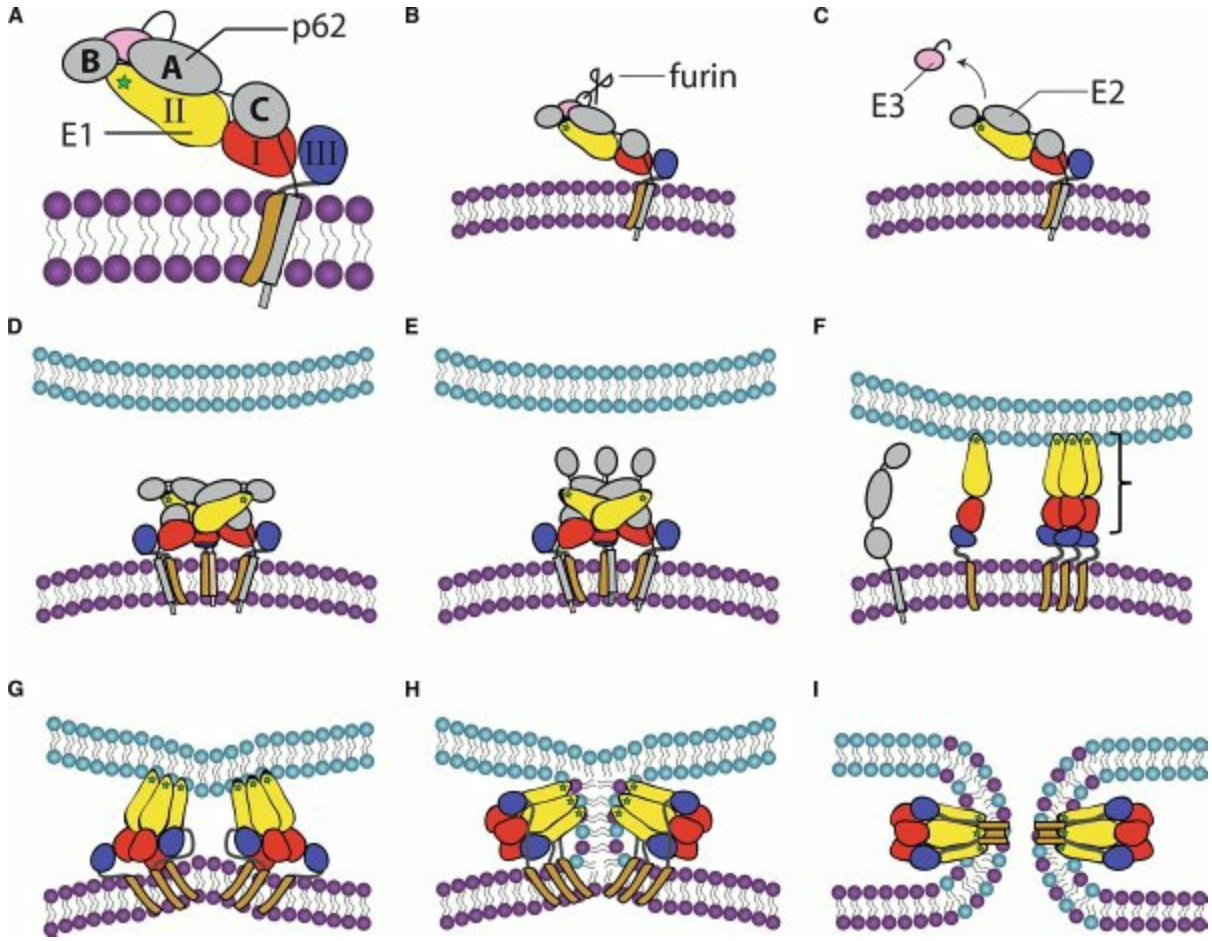

FIGURE 5.9 Model of alphavirus fusion. **A:** The immature p62/E1 (p62 = pE2) heterodimer is shown with E2 domains **(A)**, **(B)**, and **(C)** shown in *gray*, E3 in *pink*, and E1 domains I, II, and III in *red*, *yellow*, and *blue*, respectively, covering the E1 fusion peptide (*star*). **B:** Cleavage of p62 by host furin, although it remains bound protecting E1 in the low pH of the trans-Golgi. **C:** E3 may be released depending on pH conditions as the virus is secreted from the cell. **D:** The mature form of the E2/E1 trimer of heterodimers. **E:** At low pH, domain B of E2 rearranges to expose the E1 fusion loop. **F:** Low pH releases E2 from the heterodimer, and E1 inserts into the target membrane. **G:** Fold-back process by which domain III and the stem region move toward the fusion loop. **H:** Folding of domain III and the stem region against domain II of the trimer pulls the transmembrane domains toward one another distorting the viral

membrane and initiating hemifusion of viral and target membranes. **I:** Close opposition of the fusion peptides and transmembrane domains resolve into the fusion pore. (This figure was kindly provided courtesy of Margaret K from Nature: Felix AR. Virus membrane-fusion proteins: more than one way to make a hairpin. Nat Rev Microbiol 2006;4(1):67–76. Copyright © 2006 Springer Nature.)

Lescar et al.[137] recognized that the structural features of the alphavirus E1 and flavivirus E proteins were distinct from the structures of other previously identified fusion proteins, such as HA from influenza, and proposed that they represented a novel class of fusion machines. They termed these class II membrane fusion proteins and elaborated several distinguishing features that separated the two classes. Class II fusion proteins are predominantly composed of β-strands, contain an internal fusion peptide, and have a companion protein that stabilized the structure; this companion protein forms an activated metastable structure following proteolytic processing of a precursor protein. In the alphaviruses, PE2 is proteolytically activated by cleavage to generate E3 and E2, with E2 and E1 forming a stable heterodimer.[152,153] Mutagenesis experiments have provided insight into the fusion process and the residues that play regulatory and supporting roles in this process. As predicted, a pH-sensitive histidine residue in E1 (SFV H3) appears to regulate the low pH-dependent folding of E1 that is required for fusion.[212] Several other well-conserved histidines in E1 were evaluated and found unable to influence the activity. Kielian and colleagues also found that a salt bridge is formed within domain II of the E1 trimer core, which appears critical for stabilizing the homotrimer fusion intermediate.[150] These have been supported by computational analyses of the envelope proteins undergoing a low pH transition.[305]

Biochemical experiments with SFV have defined the requirements and steps in the alphavirus fusion process. Kielian et al. demonstrated a strict dependence on cholesterol for fusion.[111,156,205] This requirement has been narrowed down to the sterol 3β hydroxyl group in cholesterol.[31,174,280,301] A mutant was isolated (named *srf-3* for sterol requirement in function) that was

cholesterol independent and had an amino acid substitution of a proline to serine at E1 residue 226. This mutation did not affect fusion with normal membranes but significantly enhanced fusion to cholesterol-free membranes.[25,271] In mosquito cells, the *srf-3* mutant grew better than wild-type virus.[5] The importance of this region of E1, which lies in the ij loop, for alphavirus fusion was further demonstrated by mutation of a conserved histidine at position 230 to alanine with the resulting virus particles being noninfectious but capable of proceeding through E1 homotrimer formation under low pH conditions and suggesting a late step in fusion.[24] However, the exact role of cholesterol to promote fusion is not known. The structure of the postfusion form of E1 has been determined using x-ray crystallography.[72–74] This was accomplished using a soluble form of the E1 ectodomain known as E1* following exposure to low pH in the presence of liposomes and solubilization with detergents. The structure of this homotrimer reveals the movement of domain III by 37 Å toward the fusion peptide and target membrane (Fig. 5.8)[74] and is similar to changes that are induced by class I fusion protein activation.[112] Importantly, the addition of exogenous domain III can inhibit fusion by binding to E1 and preventing fold-back of the endogenous domain III.[145] A complete picture of the virion during the fusion process is not available, despite several attempts using cryo-EM to examine these steps.[45,62,81,199]

Following the fusion of the viral and cellular membranes, the nucleocapsid core is released into the cytoplasm. The stability of that core is not known, but uncoating has been suggested to require the interaction of the core with ribosomes. This is based on several reports that suggest that ribosomal RNA competes for a site on the capsid protein and that displacement of this site results in disassembly.[243,244,295] This site has been identified in SINV capsid protein between residues 94 and 105 and coincides with a predicted site for genome RNA binding.[298] It has also been suggested that the core might be primed for uncoating by exposure to low pH, which causes the core to become unstable.[293,296] This exposure to low pH could occur in the endosome because both E1 and 6K have been proposed to have ion channel properties.[155,167,294] However, studies using preformed cores microinjected into naïve cells demonstrated that these cores do uncoat presumably devoid of conditions of low pH.[248] Whether these cores interact with ribosomes to promote disassembly and release of genome RNA remains

to be shown.

Translation and the Role of Viral-Encoded Replication Proteins

The genome RNA serves as a messenger RNA for the synthesis of the nonstructural or replication proteins (Fig. 5.6). These are produced by two polyproteins that originate translation at nucleotide 60 in SINV.[258] The smaller but more abundant polyprotein P123 terminates translation at an opal codon following 1897 amino acids. Readthrough of the opal codon occurs with a low frequency (~10%–20%) and results in the production of the larger P1234 polyprotein. Not all alphaviruses have a termination codon to control the production of the two polyproteins, but mutagenesis of the opal codon in SINV adversely affects replication.[144] Processing of the polyproteins occurs through the action of a virus-encoded protease located within the nonstructural protein 2 (nsP2).[37,87,88] The processing of the polyprotein to generate precursor and end product nsPs is believed to regulate the synthesis of viral RNAs.[34,136,240] Translation of the structural polyprotein proceeds through a subgenomic mRNA that is initiated near the coding region for the C-terminus of P1234. The subgenomic mRNA is 3′ coterminal with the genome RNA and is produced later in the infection.[258]

Initial studies of the replication proteins used temperature-sensitive mutants that were conditional lethal for viral replication. These studies established complementation groups and identified specific functions of the replication proteins.[254] Four complementation groups were identified, and these correlated with the four nsPs. Once sequence information was available, motifs were identified that verified function and permitted phylogenetic relationships between other virus families to be established. This resulted in the suggestion of an alphavirus-like superfamily that contained RNA virus members from several plant families and argued for an evolutionary relationship between them.[3,257]

The nsPs are multifunctional proteins with some of their activities shown in Table 5.1. However, it is likely that additional unknown activities exist. Guanine-7-methyltransferase and guanylyltransferase activities necessary for mRNA and genome RNA capping have been shown to reside within nsP1.[126,171,172] This capping activity is distinct from cellular capping

enzymes in substrate preference.[6] Several genetic studies have confirmed the identity of amino acids critical for the methyltransferase function, but the domain required for guanylyltransferase activity has not be identified and may flank the conserved methyltransferase domain.[8,221] A ts mutant that mapped to Ala348 of nsP1 in SINV demonstrated a role of the protein in minus-strand RNA synthesis.[82] A defect in minus-strand synthesis has also been seen with mutations in nsP4, and some of these have been complemented with changes in nsP1 at residues 349 and 374, suggesting sites for nsP1 and nsP4 interaction.[42] nsP1 is the only alphavirus nonstructural protein that has been shown to be membrane associated.[127,202] The membrane association has been suggested to occur by a palmitoylated cysteine at residue 420 (in SINV).[7,126] Mutations that disrupt palmitoylation did not alter the distribution of replication complexes and show only modest reductions in growth. However, nsP1 can still bind to membranes through a patch of positively charged and hydrophobic amino acids between residues 245 and 264.[9] Nuclear magnetic resonance spectroscopy of a corresponding peptide suggests that this sequence can form an amphipathic α-helix that can interact with liposomes.[128] This membrane anchoring of the replication complex associated with nsP1 is probably required for efficient replicase activity.

TABLE 5.1 Translation products of alphaviruses (sindbis virus)

Protein	Size (aa)	Function
Nonstructural proteins		
nsP1	540	Methyltransferase and guanylyltransferase; anchors replicase complex to membranes
nsP2	807	NTPase, helicase, RNA triphosphatase, protease responsible for processing of nonstructural polyprotein
nsP3	556	Phosphoprotein important for initiation of RNA synthesis; contains macro domain and SH3-binding regions with ADP-ribosyl–binding/hydrolase activities, zinc-binding oligomerization domain
nsP4	610	RNA-dependent RNA polymerase (RdRp), terminal transferase
Structural proteins		
Capsid	264	Encapsidates genomic RNA to form nucleocapsid core; carboxyl domain is an autocatalytic serine protease
E3	64	N-terminal domain is uncleaved leader peptide for E2; E3+E2 = pE2
E2	423	Presents the major neutralizing epitopes and is responsible for receptor binding
6K	55	Leader peptide for E1, enhances particle release, putative ion channel
TF	70	TransFrame protein, putative ion channel, enhances particle infectivity, expression prevents synthesis of E1
E1	439	Responsible for membrane fusion activity

The largest of the replication proteins is nsP2, with a length of about 800 amino acids. The N-terminal half of the protein has helicase, nucleoside triphosphatase, and RNA triphosphatase activities,[76,77,217] while the C-terminal half contains a novel cysteine protease domain and a nonfunctional methyltransferase domain.[253,272] The structure for the C-terminal two domains of the VEEV nsP2 was solved by Watowich and colleagues using x-ray crystallography (Fig. 5.10).[228] The structure shows that the active site of the protease is positioned close to the interface between the two domains. Although related to proteases papain and cathepsin X, the fold of the nsP2 protease domain appears to be unique and a new form of cysteine protease structure. Although having a similar tertiary structure with known methyltransferases such as FtsJ, the SAM substrate binding site is very different in backbone alignment and sequence, arguing against any methyltransferase activity. However, by mapping several previously identified *ts* mutants affected in RNA synthesis onto the C-terminal domain, it was suggested that the domain functions as an RNA-binding scaffold that regulates protease activity and RNA synthesis.[227,228] The structure of the N-terminal helicase domain from CHIKV has been solved by Law and colleagues and reveals a unique fold for its N-terminal region followed by a superfamily 1 RNA helicase domain.[131]

representing residues N468 to S787. The catalytic dyad residues, C477 and H546, are found in the N-terminal protease domain (*top*), while the methyltransferase-like domain (*bottom*) constitutes the C-terminal domain. (This figure was generated in PyMol using the PDB coordinates 2HWK from Russo and colleagues[228] and was kindly provided courtesy of Dr. Joyce Jose.)

The nsP2 protein has a nuclear localization sequence that results in 50% of the protein reaching the nucleus,[216,217] and it has been reported that nsP2 of VEEV undergoes both nuclear import as well as export.[175] Abrogation of the signal results in a slightly defective virus, but at least in SFV, the mutant has lost neuropathogenesis, arguing for a role of nsP2 in host interactions.[216] Studies have identified a role for nsP2 from the Old World alphaviruses in the induction of cytopathic effects and the establishment of persistent infections, and this is discussed later in the chapter.[39,54] Experiments have also provided a link between nsP2 and the host response, resulting in shutoff of minus-strand RNA synthesis.[66,233] Genetic studies identified conditional lethal mutations demonstrating RNA-defective phenotypes that implicated nsP2 in the regulation of minus-strand synthesis and in the initiation of subgenomic RNA synthesis.[82] Furthermore, the role of the protease activity to regulate the temporal control of RNA synthesis has been well established and is described later.[34,136]

The function of the nsP3 protein remains obscure, although genetic analyses indicate that it plays a role in RNA synthesis and neurovirulence.[2,130,267,287] The protein is highly conserved among alphaviruses at its N-terminus, while the C-terminal 200 amino acids are rich in serine and threonine residues. The protein is phosphorylated on serines and threonine, although this modification is not required for replication and its function in the virus life cycle is not known.[129,130,143,203,274,275] The protein has a weak affinity for membranes and will associate with them when expressed in the absence of the other nsPs.[274] A crystal structure of both the CHIKV and VEEV N-terminal 160 residues of nsP3 confirmed previous suggestions that this region contains a macro domain (the VEEV structure is shown in Fig. 5.11).[158,239] These domains function as ADP-ribose binding

modules and have also been shown capable of single-strand RNA binding.[2] The exact function(s) of the macro domain awaits additional studies. While the C-terminal end of nsP3 is not well conserved, a proline-rich sequence found in most alphaviruses was identified as a target site for Src-homology 3 domain containing proteins amphiphysin-1 and amphiphysin-2.[183] Disruption of the binding sequence by mutation or reduction of amphiphysin-2 by RNAi reduced replication in both SINV and SFV. It is unclear how this interaction influences RNA replication; however, the amphiphysins have been implicated as membrane-binding proteins, endocytosis, and membrane trafficking, and the virus may usurp these functions to facilitate RNA synthesis. Furthermore, the C-terminus of nsP3 has been shown to bind to FXR and G3BP that help facilitate formation of viral replication complexes.[115]

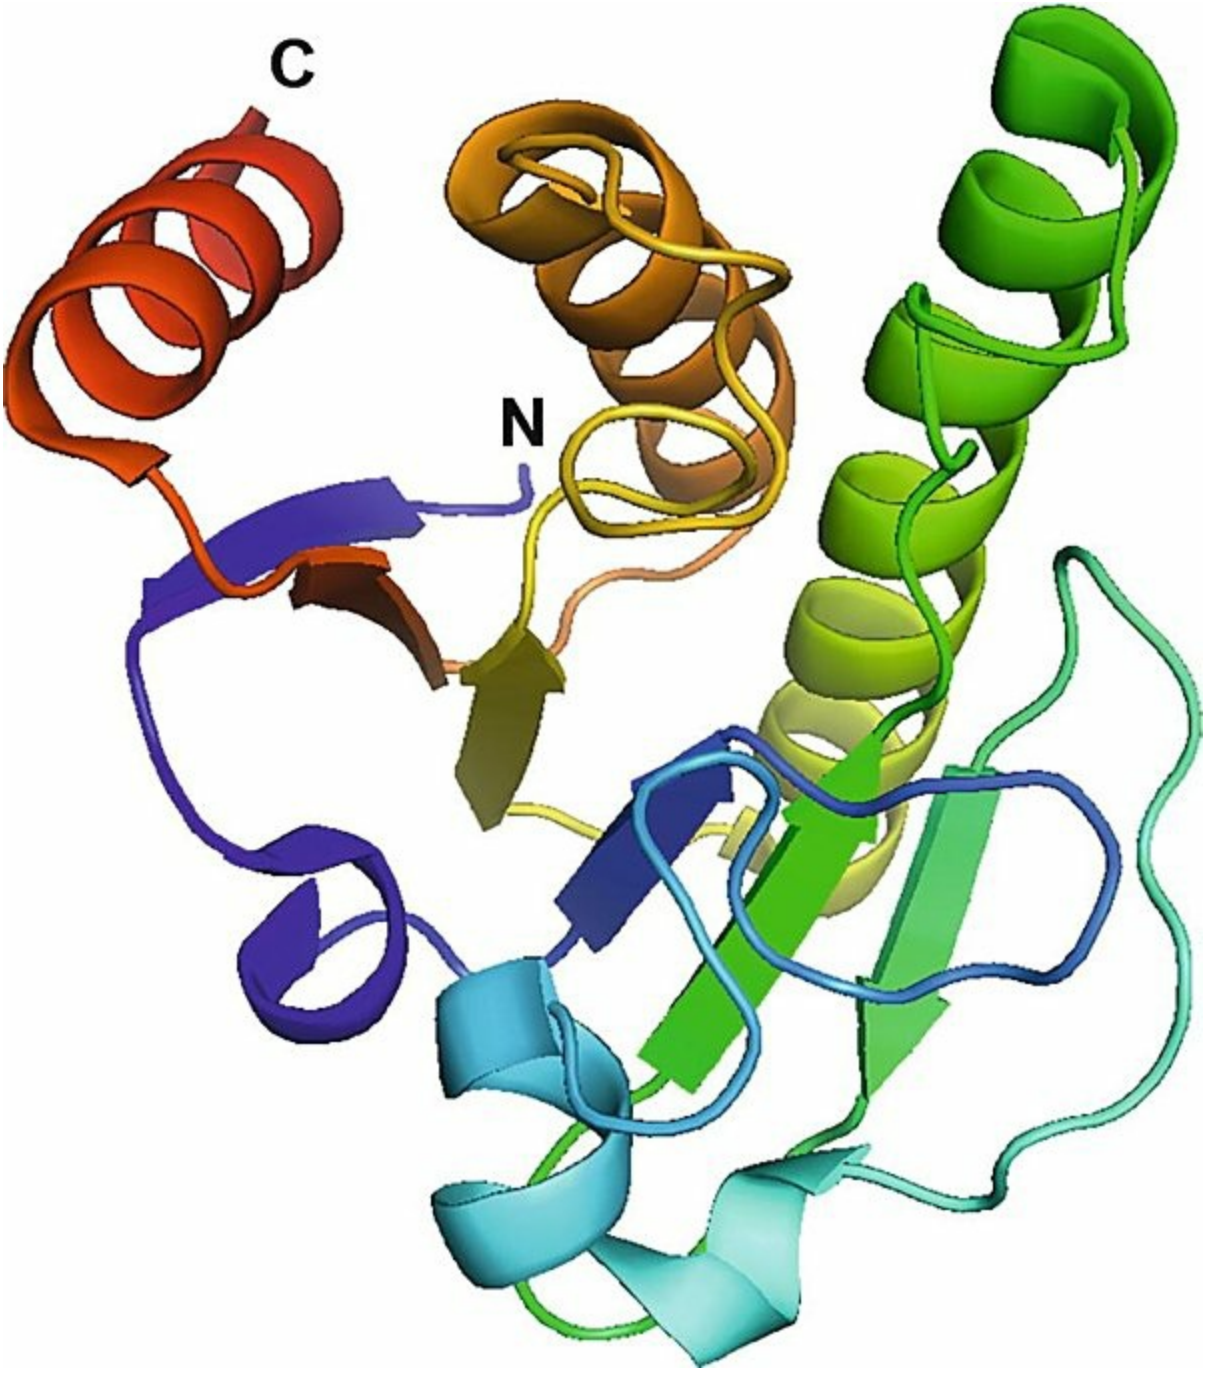

FIGURE 5.11 Structure of the Venezuelan equine encephalitis virus nsP3 macro domain. A ribbon diagram showing the nsP3 macro domain colored from *blue* (N-terminus) through *red* (C-terminus) representing residues A1 to E160. The structure consists of a six-stranded β-sheet ringed by three α-helices. (This figure was generated in PyMol using the PDB coordinates 3GQE from Malet

and colleagues[76] and was kindly provided courtesy of Dr. Joyce Jose.)

The core of the virus replication complex is the RNA-dependent RNA polymerase (RdRp) that maps to nsP4.[82,119] Interestingly, because of the opal codon in SINV, synthesis of P123 is significantly greater than the level of P1234, and thus, nsP4 levels are lower than that of the other nsPs. Furthermore, modifications that increase the synthesis of nsP4, such as the removal of the opal termination codon, result in reduced virus replication.[144] The majority of the protein from the C-terminus constitutes the RdRp domain based on homology with other polymerases and predicted secondary structures.[107] A short region exists at the N-terminus that lacks a counterpart in other viral polymerases, and it has been suggested that it might be a binding domain for the other nsPs. The N-terminus of nsP4 also contains a conserved tyrosine residue, and this serves to make the protein unstable in infected cells.[35,241] de Groot et al.[35] examined the degradation of nsP4 and showed that it was degraded by the N-end rule pathway. It has been suggested that free nsP4 is rapidly degraded, whereas nsP4 that is a component of replicase complexes is protected and relatively stable. Thus, it was not a surprise that attempts to express the full-length nsP4 in heterologous systems were initially unsuccessful. However, expression of nsP4 lacking the first 97 amino acids was successful, and this truncated nsP4 displayed a terminal adenylyltransferase activity.[266] This terminal transferase activity was suggested to play a role in the maintenance of the poly (A) tract at the 3′ end of positive strand RNAs. The nsP4 protein was subsequently expressed as an N-terminal SUMO fusion protein that was cleaved after purification, and nsP4 was shown to possess *de novo* minus-strand synthesis activity that was dependent on the correct 3′ end of positive strand template.[223] Proteomic studies have been used to identify host proteins that might interact with nsP4 during virus infection.[32] In this study, the authors demonstrated a total of 29 host proteins were associated with nsP4 in a temporally regulated pattern. Among the proteins identified, two proteins known as GTPase-activating protein SH3-domain–binding proteins 1 and 2 (G3BP1 and G3BP2) were also shown to interact with nsP2 and nsP3.[32] However, the role of these proteins is unclear, and they may function to

reduce the pool of RNAs available for translation by recruiting the viral RNA to the stress granule pathway.

Transcription and Replication of Genomic Nucleic Acid

Alphavirus-infected cells produce three species of RNAs: genome plus-strand RNA, complementary minus-strand RNA, and subgenomic mRNA. The synthesis of these three species is tightly regulated by the availability of specific nsPs (Fig. 5.12).[34,134,136] Replication is initiated on the cytoplasmic surface of endosomes and lysosomes on structures termed cytopathic vacuoles.[61] All four nsPs can be found associated with each other and within these vacuoles.[125] In elegant studies by DeGroot et al.,[34] it was shown that proteolytic site selection controlled the processing of the nsPs and determined the components of the replicase complex. This was accomplished by assessing cleavage site preferences and determining which enzymes (nsP2 or its precursors) could affect processing. Additional studies by the Sawicki laboratory using temperature-sensitive mutants established the biochemical nature of the replicase complex.[15,232,234] In complementary work, the Rice laboratory carried out *in vivo* replication studies using nsPs expressed in a vaccinia vector to discern the functional complexes.[134–136] Despite earlier problems, they were successful in developing a system for template-dependent initiation of SINV.[133]

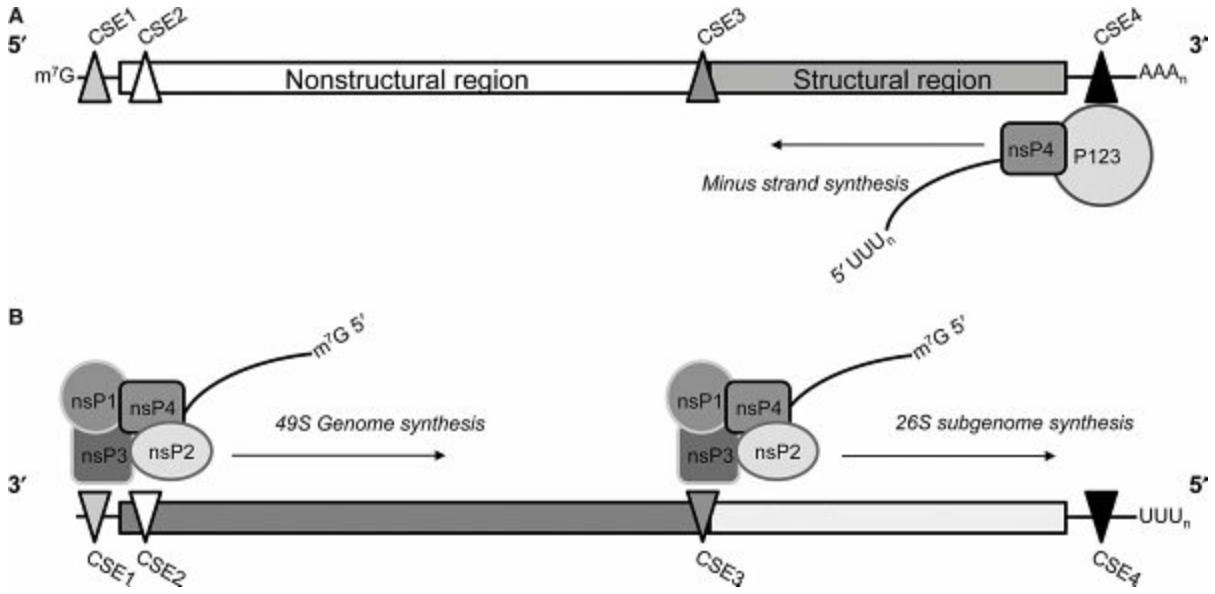

FIGURE 5.12 The conserved sequence elements (CSE) and nonstructural proteins involved in alphavirus genome replication. **A:** A schematic of minus-strand synthesis from a plus-strand template. A protein complex composed of P123 and nsP4, and presumably host proteins (not shown) initiate synthesis of the minus strand from the 3′ end of the genome. CSE4, a 19nt element, is found just upstream of the poly **(A)** tract. CSE4 is thought to act as a promoter for minus-strand synthesis, perhaps via a cyclization event with CSE2, a 51nt element located within the nsP1 coding region (not shown). **B:** A schematic of full-length 49S genomic and 26S subgenomic RNA syntheses from a minus-strand template. An accumulation of P123 allows processing of P123 polyproteins in *trans* into the individual nonstructural proteins. Presumably, the altered conformation of the replicase complex shifts template preference to the minus strand. CSE1, composed of the first 44nt of the 5′ genome, act as a promoter for synthesis of full-length 49S genomic RNA from a minus-strand template, perhaps in conjunction with CSE2. Fully processed replicase complexes also associate on the CSE3 element, which spans the 3′ end of the nsP4 coding sequence and the junction region between the nonstructural

and structural genes. These CSE3-associated replicase complexes efficiently transcribe the 26S subgenomic message. Note that a replicase complex composed of nsP1, P23, and nsp4 may also be capable of plus-strand synthesis (not shown). (This figure was kindly provided courtesy of Jonathan Snyder.)

RNA replication begins with the initiation of minus-strand synthesis. This event requires the 3′ CSE and host proteins/factors.[56,70,122] *In vitro* studies using polymerase extracts suggest the poly (A) tract may not serve as template for the initiation of minus-strand synthesis, although the details of this initiation event are not known.[86] Minus-strand synthesis requires P123 or P23 and nsP4, but a cleavage-defective P1234 is not functional.[134–136] Similarly, in the vaccinia system, expression of the individual nsPs was not sufficient for complex formation and minus-strand synthesis. As minus-strand synthesis continues, nsPs continue to be translated, and concentrations of the protease precursors increase. Cleavage at the nsP1–nsP2 and nsP2–nsP3 junctions results in the switch over to plus-strand synthesis presumably by a change in the conformation and composition of the replicase complex (Fig. 5.12). Synthesis of minus strands by the replicase requires continuous protein synthesis, and it has been suggested that nsP2 engages the host response by using the RNase L–dependent pathway to inhibit host cell translation.[79,233] As with most plus-strand RNA viruses, synthesis is asymmetric with minus-strand synthesis about 2% to 5% the level of plus-strand genome RNA.[286]

Although the viral protein composition of the minus and plus-strand replicases is known, the role of host proteins in the complex is not. From studies with the CSEs, host cell–dependent effects were observed, and several host proteins were shown to bind to the conserved RNA elements.[56,193–195] Furthermore, Fayzulin and Frolov[43] showed that although the 51 nt CSE is dispensable in mammalian cells, in mosquito cells mutations have a deleterious effect. Interestingly, adaptive mutations occur in the 5′ NTR, as well as in nsP2 and nsP3, suggesting their involvement in CSE function. Frolov et al.,[56] using chimeric templates and trans-competition experiments, showed that the 5′ NTR is a component of the promoter for not only plus-strand synthesis but also minus-strand synthesis. From these data,

they proposed a model for the initiation of minus-strand RNA synthesis that requires the 5′ and 3′ ends of the genome RNA to be brought together. This would be accomplished using components of the host translational machinery, which is involved in cap and poly (A) binding. Despite the attractiveness of the model, the lack of a purified reconstituted system for RNA synthesis has hampered progress in understanding alphavirus RNA replication.

The synthesis of the subgenomic mRNA is controlled by a minimal promoter element that spans from −19 to +5 relative to the start of mRNA synthesis. A larger fragment from −98 to +14 provides three- to sixfold more activity and constitutes the fully active promoter. As with the 5′ and 3′ CSEs, the subgenomic promoter appears to interact with host factors as mutations in the promoter have differential effects, depending on replication in vertebrate versus invertebrate hosts.[98,99,300] This promoter has been extensively employed in gene expression and replicon studies using alphaviruses, including the use of multiple tandem promoters.[20,57,59]

Perhaps the most informative studies on alphavirus replication in recent years have emerged using advanced imaging techniques.[55,106,163,164,311] These approaches have shed light on the spatial and temporal assembly of replication complexes. Most intriguing is the observation that membrane-derived structures competent for RNA synthesis appear to form initially at the plasma membrane (Fig. 5.13). Studies from both SFV and SINV demonstrate the membrane invaginations referred to as spherules first accumulate on the plasma membrane and are later internalized using the actin–myosin network.[60] These structures appear to contain all of the nonstructural proteins as well as double-stranded RNA but are devoid of any structural proteins. Structures known as cytopathic vacuoles type 1 and type 2 (CPV1 and CPV2) were previously described to contain the replication proteins and viral glycoproteins, respectively. The role of CPV2 appears to guide the glycoproteins to the site of budding; however, the role of CPV1 for RNA synthesis is not as clear. CPV1 structures form later in RNA replication, probably as a result of spherule recruitment from the plasma membrane, but it has been suggested that they may not be the major site for viral RNA synthesis at least in mammalian cells.[60]

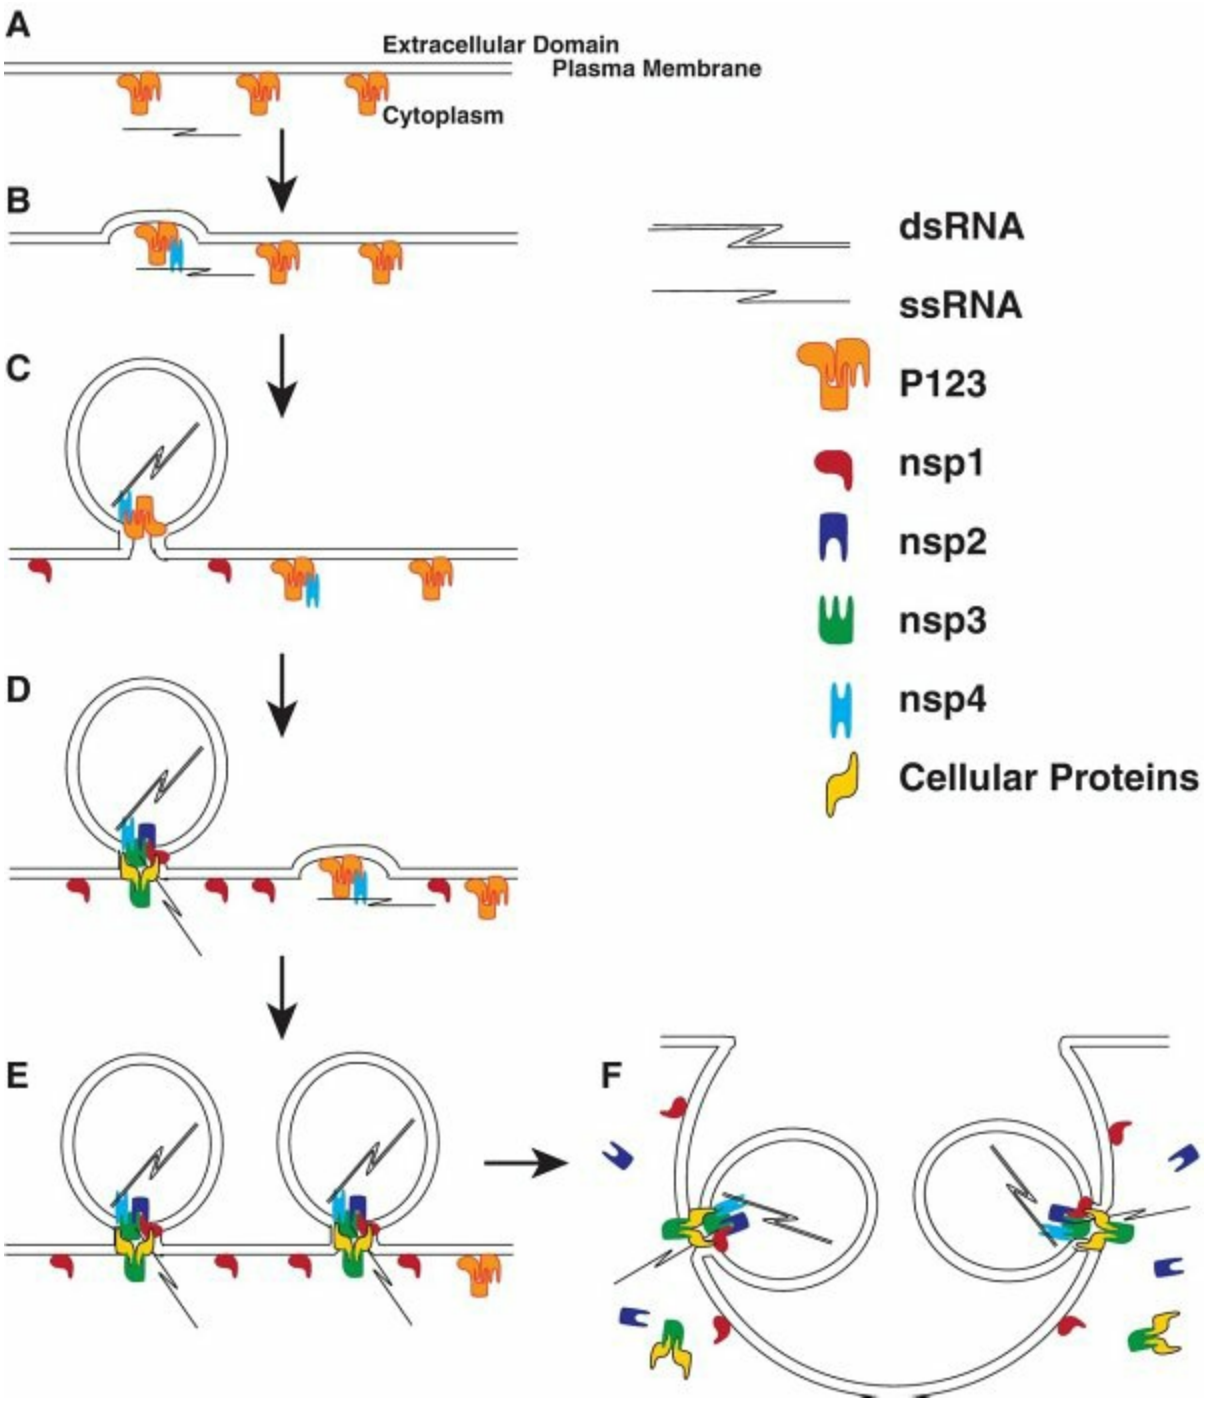

FIGURE 5.13 Assembly of alphavirus replication complexes. **A:** Replication complexes consisting of P123 and genome RNA are found at the plasma membrane; **(B)** with the addition of nsP4, the RdRp, synthesis of dsRNA occurs **(C)** along with the formation of membrane spherules. Upon processing of P123 **(D)**, replication

complexes switch to the synthesis of genomic and subgenomic RNA. As replication continues **(E and F)**, free nsP1, nsP2, and nsP3 are found, with the latter protein associating with specific host proteins and nsP1 remaining membrane associated. At latter stages, multiple spherules coalesce into CPV1 within the cytoplasm. (This figure was adapted by Thomas Edwards and R.J.K. with permission from Drs. Elena Frolova and Ilya Frolov. Assembly of Nucleocapsid Core, Glycoprotein Synthesis, and Processing

The subgenomic RNA, which is made at approximately three times the level of the genomic RNA, is translated to produce the structural or virion proteins.[213] The order of translation is capsid-PE2(E3+E2)-6K-E1 (Fig. 5.6). Translation of the structural polyprotein is enhanced due to the presence of a hairpin secondary structure in the subgenomic mRNA between residues 77 and 139.[59] The polyprotein is processed by host and viral proteases to generate the authentic structural proteins that will end up in the virion, and the membrane topology of the glycoproteins is shown in Figure 5.12. The capsid protein is translated first and is released by proteolysis immediately after the ribosome clears the junction between it and PE2. The capsid functions as an autoprotease, and sequence and mutational analyses suggested that the C-terminal domain of the capsid contained a serine-like protease.[10,83] This hypothesis was confirmed by the x-ray crystal structure of the C-terminal domain from SINV.[30] The protein has a chymotrypsin-like fold, with His141, Asp163, and Ser215 forming the catalytic triad. Interestingly, the C-terminal residue, Trp264, remains in the active site pocket and presumably prevents transcleavage by the protease. With the self-cleavage of the capsid protein, the new N-terminus of the polyprotein now

contains a signal sequence for translocation of the PE2 sequence across the ER membrane.[67] Additional signal sequences are present at the C-terminus of E2, permitting translocation of 6K, and at the C-terminus of 6K, permitting translocation of E1 (Fig. 5.14). The expression of TF protein, which contains the first 43 amino acids of 6K, contains a stop codon that prevents the synthesis of E1. Proteins E1, E2, 6K, and TF are transmembrane proteins, while E3 is released from most alphavirus particles following cleavage of its PE2 precursor.[92,208,209,226] SFV retains the cleaved E3 with the virion; however, it is unclear whether it has a postcleavage function.[312]

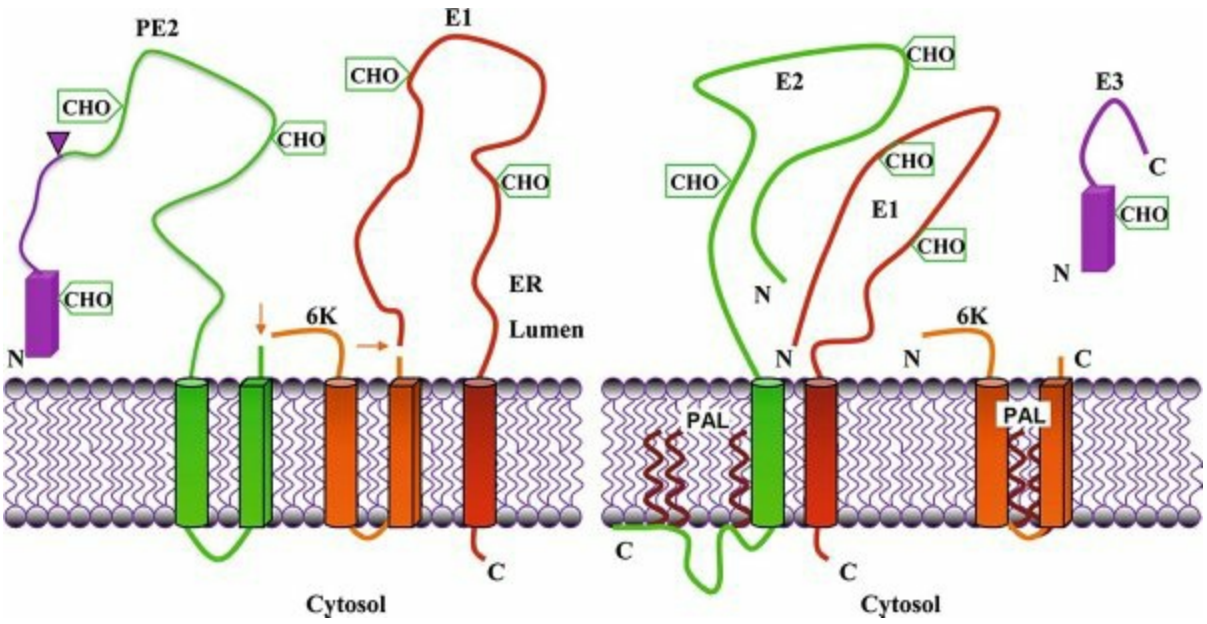

FIGURE 5.14 Schematic model for the configuration of the E1 and E2 glycoproteins in the membrane. **Left:**Configuration of the glycoproteins after signalase cleavage of 6K and E1 but before cleavage of PE2. **Right:**Configuration of glycoproteins after the maturation cleavage of PE2 into E3 and E2. Note the *dark red jagged lines* on the cytoplasmic side of E2 and 6K that represent palmitoylation sites (PAL). Glycosylation sites are indicated by CHO. Signal sequences are indicated as colored rectangular blocks. Stop-transfer sequences are indicated as colored cylinders. The shape of the polypeptides does not imply their native configuration.

Following autoproteolysis, the capsid protein transiently associates with the ribosome, and assembly into a core particle appears to be both rapid and efficient, with no observed intermediates.[249,270] A specific "packaging sequence" has been identified in the genome RNA in SINV that promotes encapsidation of RNA into the assembling core.[290] In SINV, this sequence has been identified as nucleotides 945 to 1,076, and attempts to identify the nature of the recognition element have met with limited success. However, there is conservation of structural and functional components of packaging signal across diverse alphaviruses.[114] The packaging sequence on the genome RNA is recognized by residues 81 to 113 in the capsid protein.[69,289] A deletion of residues 97 to 106 results in a failure to efficiently package genome RNA, although cores still form with heterologous RNA incorporated.[191] Although most alphaviruses package their genomes with high efficiency, Aura virus has been described as an alphavirus that packages its subgenomic mRNA as well.[224,225] The development of alphaviruses as gene expression vectors has prompted much investigation into the packaging requirements, and in VEEV, packaging has been shown to require expression of nsP123, although the mechanism and the generality of this requirement have not been shown.[276]

Although *in vitro* systems for core assembly have been described, the stepwise assembly process has not been clearly elaborated.[263–265,291,292] The capsid protein requires the addition of nucleic acid to initiate the assembly process, and in the presence of full-length wild-type protein, assembly proceeds rapidly. Using a truncated capsid protein, the initial step appears to involve a protein dimer complexed with RNA.[263–265] Cores are found in the cytoplasm and attached to membranes, probably through their interaction with E2. Cytoplasmic cores have a well-defined size and T = 4 icosahedral symmetry, similar to *in vitro* assembled cores, but not identical to the well-ordered T = 4 symmetry in cores found within virus particles.[176,197] However, the symmetry of the core does not necessarily dictate the symmetry of the virion, and it is likely that the icosahedral architecture of the glycoprotein scaffold is the driving force behind the strict T = 4 organization of alphavirus.[197] This is supported by the observation from Forsell et al.,[51]

who produced a SFV capsid protein with a deletion in residues 40 to 118. This mutant was unable to assemble cores, but virus particles were produced that had the expected T = 4 symmetry.

In parallel with the formation of the nucleocapsid in the cytoplasm, the envelope proteins that were translocated into the ER are processed and undergo posttranslational modifications. High mannose chains are added to all potential N-linked glycosylation sites, and the oligosaccharide chains are trimmed depending on the availability of the site.[236] Palmitoylation occurs at several sites in E2 and 6K/TF.[18,64] In a set of elegant studies, Brown et al. showed that E1 and PE2 undergo a complex series of folding intermediates.[23,118,178,179] These intermediates require chaperones and disulfide bond formation and exchange. The E1 and E2 glycoproteins form a heterodimer in the ER, but it is not known whether higher-order oligomerization takes place here.[312] Oligomerization of PE2 and E1 is also a requirement for the transport of the glycoproteins, but the presence of the CP is not required.[68,154] It has been shown that PE2 oligomerizes with a partially folded intermediate of E1 and that this oligomerization is sufficient for the proteins to exit the ER. After the heterodimer reaches the trans-Golgi network, but prior to arrival at the plasma membrane, PE2 is cleaved by furin.[33] This cleavage is required for virion entry and fusion activation in new cells, although revertants can be readily isolated that suppress the requirement for cleavage.[93,209] The E3 protein can be retained on the virion postrelease depending upon the pH of the media.[245]

Virion Budding

The final stage of the virus life cycle is the effective interaction between the capsid protein and the glycoproteins to promote virus budding. Thin-section electron microscopy of infected cells has shown a clustering of nucleocapsid cores at the plasma membrane at sites of budding, but it is likely that the interaction occurs earlier, perhaps in the vicinity of CPV2.[251] All evidence suggests that a proper interaction between the cores and glycoprotein spikes is required for budding.[106,164] When the glycoproteins have been expressed in the absence of the capsid protein, virus-like particles have not been observed. In SFV, virions have been shown to bud from specific sites in polarized cells,[219] and virus has been reported to bud intracellularly in insect cells.[173]

There also appears to be a requirement for cholesterol in the membrane to support budding,[156,161] and host cell lipid metabolism has also been implicated.[184] Several systems have been reported that show the exogenously produced capsid cores can be introduced into naïve cells expressing the viral glycoproteins and particles can be released, suggesting that RNA synthesis is not required for budding.[248]

The interaction between the capsid protein and the envelope glycoproteins has been extensively investigated with most of the available data coming from molecular genetic and structural studies.[262] X-ray crystallography of the capsid protein identified a hydrophobic pocket that was occupied by the amino terminal arm of a neighboring capsid protein. The nature of the arm residues bound in the hydrophobic pocket suggested that a tyr-ala-leu motif found in the cytoplasmic domain of the E2 glycoprotein might function in a similar manner and bind into the capsid protein pocket.[132,246] Residues of the E2 cytoplasmic domain were shown to be important for the interaction with the tyrosine found in the hydrophobic pocket of the capsid protein, which is conserved in the alphaviruses.[105,192,261,262,310] E2 peptides have also been used to inhibit budding, suggesting residues involved in process and similar peptides were shown to bind to capsids.[168] In addition, cryo-EM studies have shown that the cytoplasmic domain of E2 clearly extends down into the core to the site of the hydrophobic pocket.[27,262] As was mentioned previously, deletions that disrupt the accumulation of nucleocapsid cores do not prevent budding because lateral interaction between the glycoproteins appear to be the driving force as long as capsid interactions do occur.[27]

The 6K protein, which has been estimated at 5 to 10 molecules per virion, has been implicated in the budding process and in the formation of virions.[63,64] Removal of 6K from the genome of SFV did not influence the formation of the E1–E2 heterodimer or its transport to the cell surface, but it did reduce budding.[63,64] Other studies have shown that mutations in 6K can influence glycoprotein trafficking and virion assembly.[231] E2 and 6K appear to interact as mutations in 6K can be suppressed by mutations in E2, and chimeric viruses containing a SINV glycoprotein and a RRV 6K are highly defective for virus formation.[303] Recently, it has been shown that a frame shift occurs at a low frequency during translation of the region encoding 6K

resulting in the production of the TF protein shown in Figure 5.15. The TF protein shares 47 amino acids with 6K and contains the transmembrane domain that has been implicated in channel formation. The remaining 23 residues are unique to TF, and end in a termination codon with no E1 is produced from this polyprotein. Preliminary data suggest that TF also has a role in virus replication and is incorporated into the virion, but whether its function(s) overlaps with 6K is not yet known.

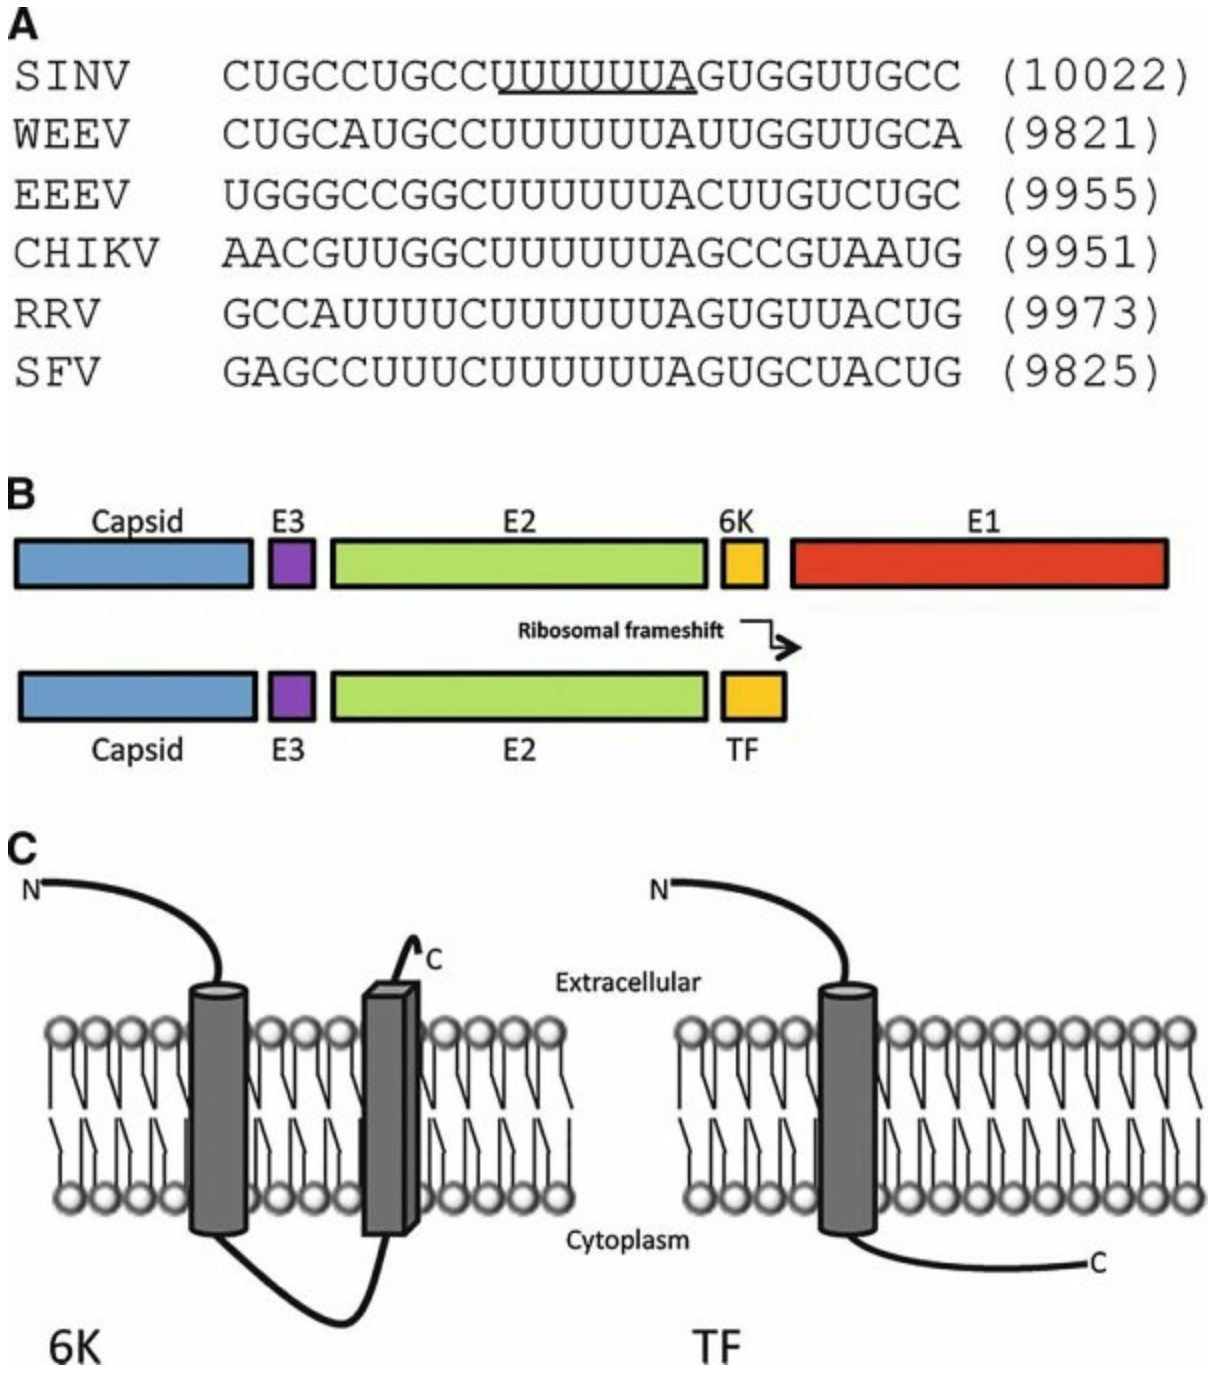

FIGURE 5.15 Ribosomal frame shifting during translation of the 26S subgenomic RNA yields a newly described protein, TF. **A:** Sequence alignment of various alphaviruses demonstrates the conservation of a putative slippery site motif within the 6K gene (underlined for SINV). The coordinate of the first nucleotide of the slippery site is indicated in parentheses for each virus. **B:** The

typical protein products obtained from normal translation of the 26S subgenomic RNA (*top*) and the protein products obtained in the case of a frame shift event (*bottom*). Note that the amino terminal region of the 6K and TF proteins shares the same sequence. **C:** A model of the putative membrane topology of the mature 6K and TF proteins. The N- and C-termini are denoted. 6K (*left*) contains both a transmembrane anchor (*cylindrical*) and a membrane spanning region that acts as the signal sequence for E1 (*rectangular*). TF contains only the transmembrane anchor (*cylindrical*); the frameshift event prevents production of the E1 signal sequence. (This figure was kindly provided courtesy of Jonathan Snyder.)

Effects on the Host Cell

Alphaviruses have a wide host range and must interact with a variety of cellular receptors, either ubiquitous or unrelated molecules. Because the nature of these receptors is largely unknown, equally unknown is the signaling that such molecules might engage in following virion attachment and early steps in entry. Clearly, the response of most vertebrate cells to viral infection is distinct from the response of invertebrate cells. However, in both cases, there appears to be a balance between the needs of the virus to effectively propagate and the needs of the host to control virus infection and dissemination. Host macromolecular synthesis is inhibited in vertebrate cells shortly after infection. Host protein synthesis is shut off at 3 hours after infection, although virus protein translation continues unabated. This has been an intensive area of investigation, and four mechanisms for shutoff have been proposed: (a) an altered intracellular environment such as K^+ concentration that would favor viral translation, (b) direct competition for translational machinery, (c) inhibition of cellular translation by the capsid protein, and (d) inhibition of translation by one of the nonstructural proteins. The development and use of replicon systems that contain only the cis-acting replication signals and the coding region for replication proteins suggested that the structural proteins were not responsible for translational shutoff.[58]

Furthermore, studies investigating the establishment of persistence identified changes in SINV nsP2, at Pro726 to serine, which reduced cytopathic effects of the virus.[54] A variety of studies suggest that alphavirus infection promotes the double-stranded RNA-activated protein kinase (PKR)–dependent and PKR-independent pathways to reduce host cell translation.[229] Mutations in nsP2 suggest that the shutoff of host cell transcription and translation are distinct events and strongly influence the decreased production of a α/β interferon.[78] However, the role of nsP2 in host cell shutoff appears to function only in the Old World alphaviruses. It has been shown that in VEEV and other New World alphaviruses that a region of the capsid protein encompassing residues 33 to 68 and not nsP2 is responsible for transcriptional shutoff and cytopathogenicity.[66] This region of the VEEV capsid protein has also been shown to be responsible for nuclear trafficking of the protein to the nucleus.[12,13,113]

Most infections by alphaviruses of vertebrate cells in culture lead to the induction of apoptosis.[139] Apoptosis of infected neurons is a major determinant of neurovirulence, as demonstrated for SINV.[138] In contrast, mosquito cells can undergo a variety of effects from persistent infections to cell death caused by necrosis.[108] It has also been possible to establish persistent infection of vertebrate cells using DI particles, followed by genetic changes to the helper virus in nsP2.[39]An alternative method was used by selecting for replicons that were noncytopathic to BHK cells, and again, amino acid substitutions were detected in the coding region for nsP2,[54] suggesting a major role for this protein in modulating the virus–host interaction.

A number of antiviral proteins produced in infected cells have been described for the alphaviruses. A small hydrophobic peptide of 3,200 Da was shown to be produced in persistently infected mosquito cells, and this peptide could activate an antiviral state. This peptide induced the synthesis of a 55-kDa protein and inhibited the replication of alphavirus RNA. The rat zinc-finger antiviral protein (ZAP), originally identified as a retrovirus resistance protein, was shown to inhibit multiple alphaviruses.[17] This protein inhibited viral translation by binding to viral mRNA, although its exact mechanism of action is not known.[80] It is likely that many additional proteins, such as interferon-stimulated genes, will demonstrate direct antiviral activity and

might be exploited to control alphavirus infection.

Defective Interfering Genomes and Replicon Systems

Defective interfering genomes replicate and are packaged in the presence of helper virus and retain all cis-acting sequences necessary for RNA replication. Several alphavirus DI genomes have been molecularly characterized, and all retain the 3′ CSE that was previously described. The 5′ end of the DI genomes was found to be more heterogenous, with the 5′ CSE, cellular tRNA sequences, or the 5′ 142 nucleotides from the subgenomic mRNA located at the 5′ end of the DI RNA. The study of DI genomes provided a powerful genetic tool to identify the location and function of required cis-acting sequence elements.[141] The development of DI genomes for genetic purposes gave way to the construction of replicons, which supported RNA replication but were incapable of infection of new cells because they lacked the structural proteins.[140,302] The structural proteins could be supplied by additional helper RNAs so that the replicons could be packaged and used to efficiently infect target cells.[20]

The alphavirus replicon has become a standard gene expression system. The system has proven useful for examining protein expression in heterogenous systems and the development of vaccines.[235] SINV, SFV, and VEEV replicons have been widely used and can allow for targeting to specific cells.[147] By introducing a mutation in nsP2 that renders the replicon noncytopathic, continuous replication in the absence of cell death can occur for SINV. For VEEV, mutations in the 5′ NTR and nsP3 were also required for persistent infection by the replicon.[204] Multiple subgenomic promoters can be employed for the expression of several proteins of interest in a regulated fashion. To further reduce the chance of recombination between replicon and helper RNAs to generate an infectious genome, tricomponent replicon systems have been developed that can produce at least 1,000 packaged replicons per cell.[44]

RUBIVIRUS REPLICATION

Virion Structure and Entry

Although once considered a close cousin of the alphaviruses, molecular analyses of rubella virus have revealed significant differences.[52] Whereas rubella virions are similar to alphaviruses in protein composition and morphology, the particles have yet to yield to high-resolution structural analysis, and it is unlikely that the particles share the property of icosahedral symmetry with the alphaviruses. The rubella virion is composed of three structural proteins that share the same name as alphaviruses yet differ in amino acid sequence.[38] The virions are pleomorphic in shape and are around 60 to 70 nm in diameter.[16,159] The two type I envelope glycoproteins, E1 and E2, form heterodimers and have 13 and 7 amino acids on their inner cytoplasmic face. All three structural proteins are membrane associated with the C-terminus of the capsid containing the signal sequence for E2.[188–190] The structural proteins are cleaved by signal peptidase, with the signal sequence for E1 present at the C-terminus of E2.[100,101] The capsid protein is a phosphoprotein of 293 or 300 amino acids, depending on which AUG codon is used to initiate the polyprotein.[53]

Rubella virus is restricted to growth in humans and is not transmitted by insects, as are the alphaviruses. However, the virus can replicate in a wide range of mammalian cell types and can infect experimental animals producing subclinical results. Thus, like alphaviruses, a ubiquitous cellular receptor may function in entry, although none has yet been identified. The virus also appears to enter through a receptor-mediated endocytosis pathway with membrane fusion promoted by an acidified endosome,[109] and a class II fusion mechanism is expected.

Transcription, Translation, and Genome Replication

The placement of rubella virus in the family *Togaviridae* implies a common genome structure and replication strategy. Complete nucleotide sequences are available for several strains of rubella virus.[52,210] The 9,762 nucleotide genome RNA contains a 5′ terminal 7-methylguanosine and a 3′ terminus that is polyadenylated.[190,284] The genomes of rubiviruses and alphaviruses are compared in Figure 5.6. The replication proteins P150 and P90 are encoded

by the genome RNA, whereas the structural proteins are derived from the subgenomic mRNA. Although there is no amino acid sequence homology among the structural proteins, limited homologies do exist within the replication proteins. The construction of a rubella virus cDNA clone from which infectious RNA could be generated permitted molecular genetic studies on the virus that were, up until then, quite limited.[211,284]

Three species of RNA are synthesized in infected cells: complementary minus-strand RNA, genome RNA, and subgenomic mRNA. On infection, the genome RNA is translated into a 200-kDa polyprotein that is cleaved by a virus-encoded protease.[49] Unlike its alphavirus counterpart, the rubella enzyme is a metalloprotease that contains zinc-binding domains, and it cleaves P200 *in trans*. Virus replication complexes can be found in association with cellular membranes. Virus-specific vacuoles have been identified and colocalize with lysosomal markers, similar to those found for alphaviruses.[124] There is a close association between these replication complexes, identified with antibodies to P150, and ER and Golgi membranes, presumably to facilitate translation and packaging of genome RNAs.[218]

Attempts to identify cellular proteins that might participate in RNA replication have focused on proteins that bind to the 5′ and 3′ NTRs. A 5′ stem-loop structure predicted to form on the plus-strand RNA was shown to bind to the La autoantigen. Several cellular proteins were shown to bind to the 3′ NTR.[180,181] One of these proteins was identified as calreticulin, although decreased binding of calreticulin did not correlate with reduced virus replication.[242] The nonstructural protein P90 has been shown to bind to the retinoblastoma protein Rb through an Rb-binding motif.[14] Mutation of this motif reduces virus replication, but it is unclear whether the defect is related to a reduction in binding.[48]

The capsid protein has also been implicated in RNA replication. It has been shown to complement a replication defect resulting from a deletion of 169 amino acids from P150.[268] Exactly how this might function is not known, but the amino terminal 88 residues of the capsid were sufficient for complementation, and these might function by binding to RNA. In addition, the capsid protein has been shown to influence the replication of rubella replicons,[26] although once again the mechanism is not known. The capsid protein has also been shown to bind to mitochondrial matrix protein p32 and

the proapoptotic protein Bax.[103] The function of capsid in binding these proteins is to prevent apoptosis and enhance RNA replication.

Virus Assembly

A packaging signal has been located between nucleotides 347 and 375 of the genome RNA, and it interacts with capsid residues 28 to 56. Phosphorylation of the capsid protein occurs and has been suggested to act as a regulatory mechanism to prevent binding of nonviral RNAs to the capsid.[151] With the retention of the capsid protein signal sequence at its C-terminus, the capsid remains associated with the ER membrane. This association may be important for ensuring close connectivity with the envelope glycoproteins through their transmembrane domains. Glycoproteins E1 and E2 are believed to have functions similar to their alphavirus counterparts, although rubella virions bud into the Golgi.[102] Indeed the crystal structure of rubella E1 protein revealed it to be a class II fusion protein with a metal binding site not seen in the alphavirus or flavivirus fusion proteins.[40] Virions undergo a maturation step after Golgi budding that may release the capsid signal sequence because morphological changes occur in the core of the virion.[218] The structure of the mature rubella virions using electron tomography revealed a helical particle that lacks the icosahedral symmetry present in the alphaviruses.[160]

PERSPECTIVES

Our knowledge of togaviruses has grown dramatically thanks in large part to the ability to genetically manipulate these relatively “simple” plus-strand RNA viruses. Insights into alphaviruses have been obtained more quickly than for rubella virus due to their greater replication efficiency in cultured cells and their well-organized virions. Structural studies of the alphaviruses have progressed rapidly leveraging the icosahedral nature of the virus particles and the ability to obtain large quantities of homogeneous preparations. The ability to express capsid proteins in heterologous systems has facilitated both structural and biochemical studies of capsid structure and its assembly pathway. The structure determinations of the native and postfusion forms of the E1 protein have provided exceptional insights into the

entry process and the structure of the virion. The atomic structure of the E1 and E2 heterodimer in both a low pH and neutral form has provided insight into the sequential entry process employed by these viruses. Structures of the replication proteins are coming slowly but beginning to provide greater insight into the replication process.

Significant gaps still persist in understanding the replication process of the togaviruses. The ability to reconstitute purified and functional replication complexes will be an important milestone to decipher RNA replication. In contrast, significant progress has been made in understanding the cellular response to viral infection and the recruitment of cellular proteins to promote or inhibit the virus replication complex. Systems-level studies to evaluate the total cellular environment altered in virus infection are beginning to yield a comprehensive picture of how the virus perturbs and subjugates the cell. The use of advanced and real-time optical imaging as well as electron tomography promises to provide a temporal and spatial view of virus infection. However, most studies continue to rely on standard cell culture systems, and it will be important to verify what occurs in more natural target cells such as neurons.

With the growing knowledge of togaviruses, their utility in gene expression and gene therapy continues to be exploited and expanded. Future directions that will further benefit this system will be in understanding the nature of the cellular receptors and the structure of the E2 protein that is involved in binding these receptors. With this knowledge, newly designed alphavirus vectors will be engineered to specifically and efficiently target the replicon to cells and tissues of interest.

Perspective

INTRODUCTION

The genus *Alphavirus* in the family *Togaviridae* includes 31 species that can be classified antigenically or genetically into at least 8 complexes (Table 6.1). Alphaviruses are geographically restricted in their distributions and have been found on all continents and on many islands, as well as in marine mammals. In nature, most alphaviruses are zoonotic arthropod-borne (arbo) viruses that cycle between invertebrate insect vectors and vertebrate hosts. For most alphaviruses, the vectors are mosquitoes, but other hematophagous arthropods, such as lice or mites, are vectors for a few. The vertebrate hosts are mostly wild mammals or birds, and birds, but fish are hosts for some aquatic alphaviruses. In general, the pathogenic alphaviruses are divided into the viruses that cause human disease characterized by rash and arthritis, primarily found originally in the Old World (OW), and viruses that cause encephalitis, primarily found in the New World (NW). For many

alphaviruses, no human or veterinary disease has been recognized. Larger mammals, such as humans and horses, that tend to develop severe or fatal disease are often dead-end hosts unimportant to the enzootic/endemic virus transmission cycles, but can be important for sustaining epidemics.

TABLE 6.1 Alphaviruses, abbreviations, biologic features, and association with disease

Virus (Abbreviation)[a]	Antigenic Complex	Principal Vertebrate Reservoir Host	Geographic Distribution	Human Disease	Animal Disease
Aura virus (AURAV)	WEE	Unknown	S. America		
Barmah Forest virus (BFV)	BF	Birds	Australia	Fever, arthritis, rash	
Bebaru virus (BEBV)	SF	Unknown	Asia		
Cabassou virus (CABV)	VEE	Unknown	French Guiana		
Chikungunya virus (CHIKV)	SF	Primates	Africa, SE Asia, Philippines, Indonesia	Fever, arthritis, rash	
Eastern equine encephalitis virus (EEEV)	EEE	Birds, possibly reptiles	S. Amer., Caribbean	Fever, encephalitis	Horse, pheasant, emu, pigeon, turkey
Eilat virus (EILV)	None described	None	Israel, S. America	None (replication defective)	None (replication defective)
Everglades virus (EVEV)	VEE	Mammals	Florida	Fever, encephalitis	
Fort Morgan virus (FMV)	WEE	Birds	Colorado		
Getah virus (GETV)	SF	Mammals	Asia	Fever	Horse
Highlands J virus (HJV)	WEE	Birds	N. America		Horse, turkey, emu, pheasant, duck, crane
Madariaga virus (MADV)	EEE	S. America, Caribbean	S. America	Fever, encephalitis	Horse
Mayaro virus (MAYV)	SF	Mammals	S. America	Fever, arthritis, rash	
Middelburg virus (MIDV)	MID	Unknown	Africa		
Mosso das Pedras virus /78V3531 (MDPV)	VEE	Mammals	S. Amer.		
Mucambo virus (MUCV)	VEE	Mammals	S. Amer., Caribbean		
Ndumu virus (NDUV)	NDU	Unknown	Africa		
O'nyong-nyong virus (ONNV)	SF	Unknown	East Africa	Fever, arthritis, rash	
Pixuna virus (PIXV)	VEE	Mammals	Brazil		
Rio Negro virus/AG80 (RNV)	VEE	Mammals	Argentina		
Ross River virus (RRV)	SF	Mammals	Australia, S. Pacific	Fever, arthritis, rash	
Salmonid alphavirus (SAV)	None described	Fish	North Atlantic		Trout, salmon
Semliki Forest virus (SFV)	SF	Unknown	Africa	Fever, encephalitis	Horse
Sindbis virus (SINV)	WEE	Birds	Australia, Africa, N. Europe, Middle East	Fever, arthritis, rash	
Southern elephant seal virus (SESV)	None described	Seals	Antarctica		
Tonate virus (TONV)	VEE	Birds	S. Amer.	Fever, encephalitis	
Trocara virus (TROV)	WEE	Unknown	S. Amer.		
Una virus (UNAV)	SF	Unknown	S. Amer., Trinidad		Horse
Venezuelan equine encephalitis virus (VEEV)	VEE	Mammals	S. Amer., N. Amer.	Fever, encephalitis	Horse
Western equine encephalitis virus (WEEV)	WEE	Birds, mammals	N. Amer., S. Amer.	Fever, encephalitis	Horse, emu
Whataroa virus (WHATV)	WEE	Birds	New Zealand, Australia		

[a] All are also considered species by the International Committee on Taxonomy of Viruses.

HISTORY

Records of diseases almost certainly due to alphaviruses date to the 18th and

19th centuries when epidemics of fatal encephalitis in horses in the northeastern United States (USA) and outbreaks of arthritis in Southeast Asia were recognized and recorded. The first clear report of epidemic encephalitis comes from the summer of 1831 when 75 horses died in Massachusetts.[372] Over the next 100 years, several local outbreaks of encephalitis in horses were noted along the Atlantic seaboard of the United States and in the pampas regions of South America.[838] However, the first alphavirus to be cultured was western equine encephalitis virus (WEEV). This virus was isolated in 1930 from the central nervous system (CNS) tissues of two horses involved in an epidemic of equine encephalitis in the San Joaquin Valley of California.[639] The eastern equine encephalitis virus (EEEV) was isolated from the brains of affected horses in New Jersey and Virginia in 1933.[106] Both diseases occurred in summertime epidemics, suggesting an arthropod vector, and in 1933, Kelser showed WEEV transmission by mosquitoes.[478] In 1936, an epizootic of equine encephalitis occurred in the Guajira region of Venezuela, and the virus isolated was not neutralized by antisera against EEEV or WEEV and was designated Venezuelan equine encephalitis virus (VEEV).[512]

Summertime epidemics of polyarthritis were recognized in Australia and New Guinea in 1928,[220,698] and subsequent outbreaks of polyarthritis were reported in Northern Europe, Africa, and Southeast Asia.[895] It is likely, of course, that the alphavirus-induced arthritic diseases are much older than these dates but were not clearly described or differentiated from more prevalent infections in these regions, such as dengue. This is considered to be particularly true of outbreaks of chikungunya virus (CHIKV) infection that have occurred in India and Southeast Asia over the last 200 years[141,971] and probably also in the Americas.[370] Viruses associated with epidemic polyarthritis were eventually isolated, both from mosquitoes collected in the areas of human disease and later from humans. The first of these viruses was isolated in 1952 from a pool of *Culex* spp. mosquitoes collected near Sindbis, Egypt.[963] However, it was many years before Sindbis virus (SINV) was linked to human disease.[604]

The first clear association of an alphavirus with arthritic disease came in 1953 when CHIKV was isolated in present-day Tanzania from the blood of people with severe arthritis.[820] During the next several years, a number of

viruses causing arthritis, often accompanied by a rash, were isolated in Africa, Australia, and South America.[156,654,1083] These viruses were added to the growing list of arboviruses, defined by the World Health Organization in 1967 as "viruses which are maintained in nature principally, or to an important extent, through biological transmission between susceptible vertebrate hosts by haematophagous arthropods; they multiply and produce viremia in the vertebrates, multiply in the tissues of arthropods, and are passed on to new vertebrates by the bites of arthropods after a period of extrinsic incubation."

In 1954, arboviruses were divided by Casals and Brown into three serologic groups A, B, and C, based on cross-reactivity in hemagglutination inhibition (HI) and complement fixation (CF) tests. EEE, WEE, and VEE viruses constituted the group A arboviruses. A second cross-reacting set, including dengue, St. Louis encephalitis, and yellow fever viruses, constituted the group B arboviruses, and the nonreactive viruses were designated group C. As viruses became classified on the fundamental properties of the virion and the genome, the group A viruses became the *Alphavirus* genus within the *Togaviridae* family of enveloped RNA viruses.

INFECTIOUS AGENTS

Alphaviruses are enveloped plus-strand RNA viruses with icosahedral symmetry (Fig. 6.1). The virions are *ca.* 70 nm in diameter and sensitive to ether and detergent. Cryoelectron microscopy structures are available for many.[508,606,890,1106,1107,1109] The RNA is contained within a capsid formed by a single protein arranged as an icosahedron with T = 4 symmetry. The nucleocapsid is enclosed in a lipid envelope derived from the host cell plasma membrane that contains the viral-encoded glycoproteins, E1 and E2. These proteins form heterodimers that are grouped as trimers to form 80 knobs on the virion surface. Glycoproteins are arranged such that 240 copies of each cytoplasmic E2 tail interact with 240 copies of capsid protein.[169]

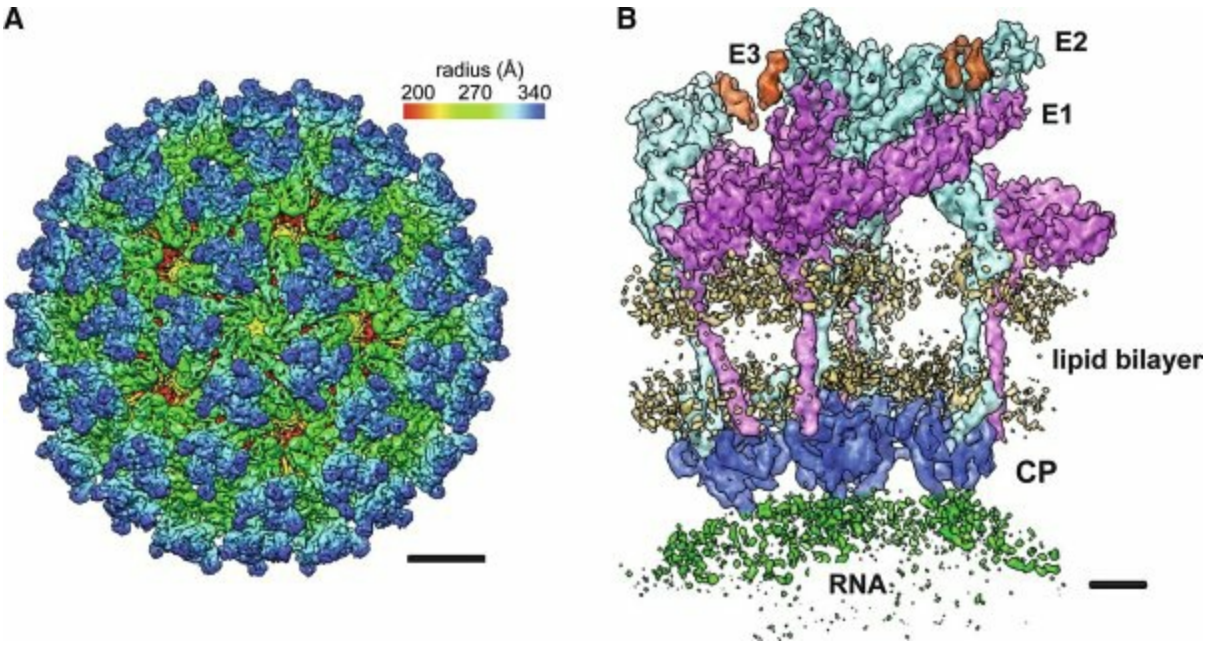

FIGURE 6.1 Three-dimensional reconstruction of the VEEV virion. **A:** Radially colored 3D reconstruction of VEEV showing the E1 basal triangle (*green*) and E2 central protrusion (*blue*) for each spike. Scale bar: 10 nm. **B:** One asymmetric unit of the virus containing four unique copies of E1 (*magenta*), E2 (*cyan*), E3 (*orange*), and capsid (CP, *blue*). The cryo-EM densities for the viral membrane (*yellow*) and genomic RNA (*green*) are also displayed at slightly lower isosurface threshold. (Courtesy of Wah Chiu and reproduced with permission from Zhang R, Hryc CF, Cong Y, et al. 4.4 Å cryo-EM structure of an enveloped alphavirus Venezuelan equine encephalitis virus. EMBO J 2011;30(18):3854–3863.)

The 42-49S genome is composed of a single-strand, nonsegmented, capped, and polyadenylated message-sense RNA that is infectious. Complete genomic sequences are available for representatives of all currently known alphavirus species. The genomes are 11 to 12 kb in size and have two open reading frames organized with the nonstructural proteins (nsPs) at the 5′ end and the structural proteins at the 3′ end. The nsPs are translated as a polyprotein from genomic RNA, and the structural proteins are translated as a

polyprotein from a subgenomic RNA.[943] Four nsPs are sequentially processed to replicate the viral genomic RNA and produce the subgenomic RNA (covered in chapter on Togaviruses). nsP1 has methyl- and guanylyl transferase capping activities, anchors the replication complex to membranes, and initiates minus-strand synthesis.[21,22,525,1042] nsP2 has N-terminal helicase, NTPase and RNA triphosphatase, and C-terminal protease activities.[323,472,633,808,1022] nsP3 is a phosphoprotein that interacts with viral and cellular proteins to regulate replication and is a major determinant of cell-type–specific replication, host range, and virulence.[328,533,741,780] The N-terminal macrodomain is highly conserved in alphaviruses and binds and removes ADP-ribose from proteins,[326,627] while the intrinsically disordered hypervariable domain provides a hub for at least three different host protein families.[332] nsP4 is the RNA-dependent RNA polymerase.[856]

Five potential structural proteins (C, E3, E2, 6K, and E1) are encoded in the subgenomic RNA, and an additional transframe protein (TF) is produced by -1 ribosomal frameshifting within the 6K coding region extending into E1.[177,265,779] The N-terminal portion of C is basic and binds the viral genomic RNA, while the more conserved C-terminal portion proteolytically cleaves C from the nascent chain, interacts with other copies of C to form the nucleocapsid, and binds the cytoplasmic tail of E2 for virion assembly and budding.[587,612,722,921,926,959,1107,1110]

E3 is a small cysteine-rich glycoprotein that serves as a signal sequence for pE2 (the E2 precursor composed of E3 and E2), mediates proper folding of E2, and is necessary for pE2 to heterodimerize with E1 for transport to the cell surface.[572,734] As part of the pE2-E1 heterodimer, E3 prevents premature activation of E1 in the secretory pathway.[443,1013,1035] E3 is cleaved from E2 by furin in the trans-Golgi, remains associated with the spike under acidic conditions, and needs to be shed when virions bud from the cell surface for particles to be infectious.[910,1105]

The E2 glycoprotein is a transmembrane protein that has two or three N-linked carbohydrates and contains the most important epitopes for neutralizing antibody. E2 is organized into three immunoglobulin ectodomains (A, B, and C) and a subdomain (D) (Fig. 6.2). Domain A (residues 1–132) is at the center and top of the heterotrimer and has receptor and neutralizing antibody–binding sites. Domain B is at the spike tip and

probably interacts with cellular receptors, and C is toward the viral membrane.[558,1018,1032] Subdomain D connects C with the transmembrane helix.[168,1107] The intracytoplasmic portion interacts with the capsid and has a second stretch of hydrophobic amino acids and myristoylation sites that tether it to the inner surface of the membrane.

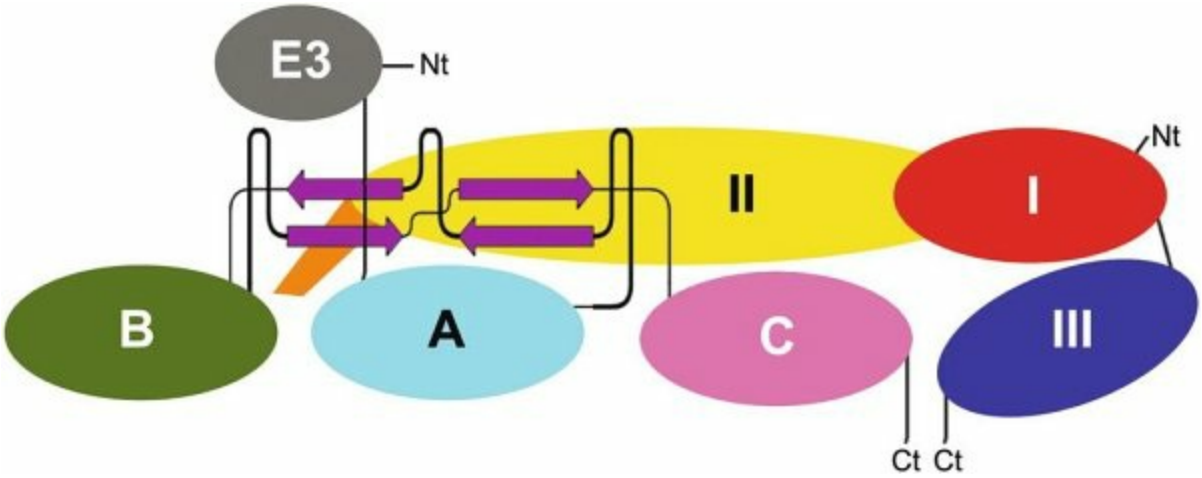

FIGURE 6.2 Domain structure of the glycoprotein spike. Schematic diagram of the E1pE2 heterodimer drawn "untwisted" to show the domains positioned with respect to one another and their connectivity. Domains of E1 (I, red; II, yellow; III, blue; fusion loop, orange) and pE2 (A, cyan; B, dark green; C, pink; E3, gray) are shown. Ct, C-terminus. (Courtesy of Felix Rey and reproduced with permission from Voss JE, Vaney MC, Duquerroy S, et al. Glycoprotein organization of Chikungunya virus particles revealed by X-ray crystallography. Nature 2010;468(7324):709–712.)

The E1 protein has one or two N-linked carbohydrates, a short (one or two residues) intracytoplasmic tail, and a positionally conserved internal hydrophobic stretch of amino acids in the N-terminal portion that serves as the fusion peptide for virion entry into the cell. E1 is organized into three β-sheet–rich domains (I, II, and III) similar to the flavivirus E protein with the internal fusion loop at the tip of domain II[311] (Fig. 6.2). 6K is the signal peptide for E1, is cleaved from E1 and E2 by signalase, and has

characteristics of a viroporin. TF has the same N-terminus as 6K, is palmitoylated, is important for virus virulence, and regulates virus budding with small amounts incorporated into virions.[265,779,922]

Propagation and Assay in Tissue Culture

Initial isolations of alphaviruses were accomplished by intracerebral inoculation into suckling mice, a host very susceptible to infection with most alphaviruses. Many alphaviruses can also be isolated and propagated efficiently in primary chicken embryo fibroblasts (CEF) and in a wide variety of continuous mammalian cell lines such as human epithelial (HeLa, MRC5) cells, baby hamster kidney (BHK) cells, monkey kidney (Vero) cells, and mouse fibroblast and neuroblastoma cells (Fig. 6.3).

FIGURE 6.3 Effects of Sindbis virus infection on vertebrate cells. **A:** Cytopathic effects (CPE) of rounding, shrinkage, and cytoplasmic blebbing in BHK cells infected at a low multiplicity (arrowheads). **B:** Electron micrograph of an infected BHK cell showing chromosomal condensation and cytopathic vacuoles.

Most alphaviruses will form plaques on susceptible mammalian or avian cells under an agar overlay. Mosquito cell lines also support replication, but often without overt cytopathic effect (CPE).[777,939] The first plaque assay of an animal virus was performed using WEEV on CEF cells,[231] and plaque assay remains a convenient and sensitive way to quantify infectious virus. Plaque size has been used to differentiate strains and is determined by the type of overlay used, by relative virus binding to negatively charged sulfated polysaccharides present in the overlay, and by replication efficiency.[111,125,954] Plaque size is sometimes, but not always, associated with virulence differences among virus strains.[1039]

Biological Characteristics

Hemagglutination

Alphaviruses can hemagglutinate avian (e.g., goose, chicken) erythrocytes,[839] and hemagglutination has been used as a method for quantifying virus and HI for measuring antiviral antibody. Hemagglutination requires prior exposure of the virus to acidic pH, is dependent primarily on the E1 glycoprotein, and reflects binding of the fusion domain of the E1 glycoprotein to lipids in the erythrocyte membrane.[159,1016,1069] E2 also participates in hemagglutination because some monoclonal antibodies (mAbs) specific for E2 also have HI activity.[90,785] The HI test is not currently in common use but has been helpful for determining antigenic relationships among alphaviruses and in screening diverse animal sera for antibodies where its cross-reactivity can be advantageous.[137]

Cellular Receptors

Binding of virus to the cell surface and entry into the cell is a multistep process that is dependent on virus glycoproteins E1 and E2, cell-surface molecules, low pH in the endosome, and fusion of membrane lipids. Variations in any of these components will affect the efficiency of infection and the likelihood that any particular cell will become infected. Virus-specific attachment to cells is primarily a function of the E2 glycoprotein. The important role for E2 in initiating virus–cell interaction is evidenced by the ability of anti-E2 mAbs to inhibit binding to cells,[125] of anti-idiotypic antibodies to E2-specific mAbs to recognize putative virus receptors on cells,[1043] and of amino acid changes in E2 to alter virus binding to cells of different types.[230,539]

Identification of specific alphavirus receptors has been difficult and complicated by experimental use of virus strains that are adapted to replicate in tissue culture.[500] Because each alphavirus infects a wide range of hosts, often including birds, mammals, and insects, they must use either an evolutionarily well-conserved cell-surface molecule or multiple molecules as receptors. Specificity in infection is generally maximal for oral infection of even closely related mosquitoes, suggesting a role for processes beyond binding to proteins on the apical surface of midgut cells. None of the alphavirus receptors identified to date appears to be used exclusively, suggesting the possibility of several receptors. Alternatively, alphaviruses may use attachment molecule–receptor–coreceptor combinations to achieve wide host range and the specific tropisms observed *in vivo*.

The first alphavirus receptor to be identified was the major histocompatibility complex (MHC) class I molecule receptor for Semliki Forest virus (SFV) on mouse and human cells.[391] However, cells lacking MHC molecules can still be infected with SFV.[710] The high-affinity laminin receptor is a receptor for SINV on BHK cells and a potential receptor for SINV and VEEV on C6/36 mosquito cells.[581,1040] Again, this molecule appears to account for only a portion of the total virus interaction with the cells studied and does not contribute to SINV binding to avian cells.[1040] Ross River virus (RRV) uses the $\alpha_1\beta_1$-integrin on HeLa cells for binding.[523] SINV and VEEV can use natural resistance–associated macrophage protein (NRAMP) for binding to insect and mammalian cells,[816] and adhesion molecule Mxra8 improves binding of CHIKV, o'nyong-nyong virus (ONNV),

RRV, and Mayaro virus (MAYV) to mouse fibroblasts.[1108] The type of cell in which the virus is grown can also influence initial virus–receptor interactions. For instance, SINV grown in mosquito cells is enriched in high-mannose carbohydrates that bind the C-type lectins DC-SIGN and L-SIGN on the surface of dendritic cells (DCs).[499]

Heparan sulfate (HS), a ubiquitously expressed glycosaminoglycan, is an important initial binding molecule for many alphaviruses. Interaction with HS, a highly sulfated, negatively charged molecule, probably explains the effects of ionic strength and charge on the attachment of virus to cells.[610,752] Use of HS is selected by virus passage in vertebrate cells. However, wild-type strains of EEEV bind HS, so this property is not exclusively determined by passage in tissue culture.[298] For these viruses, addition of heparin or lactoferrin, treatment of cells with heparinase, or use of cells deficient in HS decreases binding to cells and plaque formation. The heparin-binding domain of the E2 glycoprotein is on domain A and overlaps a neutralizing epitope (Fig. 6.2). Changes toward more positively charged amino acids in the region around E2-70 increase the efficiency of attachment to cells in tissue culture.[79,126,500]

Entry requires interaction with the cell membrane followed by a conformational change in the trimer of E1–E2 heterodimers.[389,505,897,912,1075] This conformational change is generally induced by low pH in the endosome, but entry may also occur at the plasma membrane.[930,1017] At neutral pH, the E1 fusion peptide is protected in the virion heterotrimer by domain B of E2 and this association is stabilized by E3.[558,1032] When exposed to acidic pH, E1 dissociates from E2 and forms stable E1 homotrimers in the presence of cholesterol-containing membranes.[140,1102] During this conformational change, the fusion peptide is exposed and inserted into the outer leaflet of the endosomal membrane lipid bilayer.[108,311] E1 folds back to bring the viral and endosomal membranes together, promoting fusion. Efficient fusion with the cell membrane to initiate infection is dependent on cellular factors including presence of a membrane potential, cholesterol, sphingolipid, and tetraspanin TSPAN9.[390,694,718]

Effects on Vertebrate Cells

Alphaviruses replicate rapidly in most vertebrate cell lines with the release of

progeny virus typically within 4 to 6 hours after infection. At the time of virus entry, there is an increase in permeability perhaps due to pore formation by the E1, 6K, and/or TF proteins.[602,1067,1068] Insertion of newly synthesized glycoproteins into the plasma membrane for virion budding renders infected cells capable of ATP-dependent polykaryocyte formation upon exposure to acid pH.[479] Infection causes extensive CPE in a variety of cell lines characterized by cell rounding, shrinkage, and cytoplasmic blebbing (Fig. 6.3A) with the death of infected cells within 24 to 48 hours.[552,777] Alphavirus-induced CPE has been linked to shutoff of host cell transcription and translation, endoplasmic reticulum (ER) stress, the unfolded protein response, and induction of apoptosis.[28,56,303,316,433,552,700] The ability of alphaviruses to induce cell death, combined with the ability to express heterologous genes, has led to their development as potential oncolytic agents.[421,776,830,994]

Shutoff of host cell functions by OW viruses (e.g., SINV, SFV, CHIKV) differs from that of NW viruses (e.g., VEEV, EEEV).[304] Transcription of cellular mRNAs including antiviral response genes is inhibited by nsP2 from OW viruses and by capsid from NW viruses.[18,42,302,303,320] nsP2 of OW viruses translocates to the nucleus[740] and induces degradation of RPB1, the catalytic subunit of RNA polymerase II to shut off cellular transcription.[24] Mutations at nsP2 P726 that impair this function result in viruses that replicate less well and are less cytopathic.[23,290] Capsid of NW viruses inhibits nuclear import by forming a complex with the nuclear export receptor CRM1 and the nuclear import receptor importin-α/β.[41]

Several factors probably contribute in cell type–specific ways to shut off host cell translation.[144] One important factor is activation of RNA-dependent protein kinase (PKR) by interaction with double-stranded RNA (dsRNA) or capsid that results in phosphorylation of eIF2α, which inhibits translation of genomic viral RNA for the nonstructural polyprotein and host mRNAs without affecting translation of viral 26S subgenomic RNA for the structural proteins.[18,255,1026] In many alphaviruses, escape from eIF2α phosphorylation for subgenomic RNA translation is due to the presence of a hairpin loop structure downstream of the initiation codon that allows the 40S ribosome to initiate translation in the absence of eIF2 and eIF4.[144,222,647,850,911,1025]

The apoptotic process in virus-infected cell lines is associated with

blebbing of the plasma membrane, condensation of nuclear chromatin, and formation of apoptotic bodies (Fig. 6.3B). Viral proteins are concentrated in the surface blebs from which budding continues to occur.[511,817] This process does not hamper, and may enhance, virus replication because inhibition of apoptosis usually decreases virus yield.[548,561,860]

The mechanism(s) by which alphaviruses induce apoptosis can involve both intrinsic and extrinsic pathways and likely differs with virus and type of target cell.[458,510] Apoptosis of cultured cells can be initiated at the endosomal membrane during SINV fusion resulting in activation of membrane-bound sphingomyelinases that release ceramide, an efficient inducer of cellular apoptosis.[444,445,449] SFV-induced apoptosis requires accumulation of viral RNA and is independent of p53.[317,956,1015] Cellular caspases are activated with cleavage of caspase-3 substrates and fragmentation of chromosomal DNA.[1011] Other events in alphavirus-induced cell death often include early activation of poly(ADP-ribose) polymerase-1,[684,730] activation of proapoptotic Bcl-2 family member proteins Bad or Bak,[657] loss of mitochondrial membrane integrity, and release of cytochrome c.[66,1015]

Apoptotic death is accelerated by glycoprotein-induced ER stress,[66] sphingomyelinase deficiency,[692] low levels of extracellular Ca^{++},[1011] expression of Bax,[700] and activation of Bid.[1015] Alphavirus-induced apoptosis can be slowed or prevented by expression of ceramidase,[444] altered Ras signaling,[448,502] expression of p21WAF1/CIP1,[418] expression of Bcl-2 family member and interacting proteins,[337,552,555,561,657,672,700,860,1012,1015] expression of the ER stress protective protein Parkin,[700] mutation of nsP2,[303,700] phosphorylation of protein kinase C-delta (PKCδ),[1115] inhibition of constitutive expression of NF-κB,[564] and caspase inhibition.[686,852,1015] Apoptotic cell death is delayed by the cell type–specific induction of autophagy.[458,486,511]

Autophagy serves for lysosomal degradation of damaged cellular organelles and also for defense against intracellular pathogens.[207,553] Autophagy can be activated by viral stimulation of cellular pattern recognition receptors or cytokines such as IFNγ and can serve to deliver viral nucleic acids to endosomal toll-like receptors (TLRs) to amplify innate responses.[950] Autophagy delays neuronal cell death and facilitates SINV

clearance through a selective process by which the adaptor protein p62, along with other selective factors in the autophagy pathway, targets nucleocapsids for delivery to autophagosomes.[541,719,720,951] CHIKV-induced autophagy promotes virus replication in HEK293 cells and mouse embryo fibroblasts (MEFs).[458,511]

Alphavirus-induced vertebrate cell death can also occur by caspase-independent, nonapoptotic mechanisms. Alphaviruses efficiently shut down protein, rRNA, and mRNA synthesis in infected cells,[303,327,621,675] deplete nicotinamide adenine dinucleotide (NAD) and energy stores,[240,1011] and induce dysfunction of Na^+K^+ATPase causing loss of membrane potential and changes in intracellular cation concentrations.[67,1014] Genome replication without structural protein synthesis can also induce cell death.[1015] For Old World viruses, expression of nsP2 alone is cytotoxic, and this property can be separated from its protease activity and the effects of nsP2 on host transcription.[226,287,303,304,327,617,742,956]

Although immature neurons die by apoptosis, mature neurons are more resistant to apoptotic cell death.[316,379] This resistance is due to an intrinsic ability to suppress virus replication.[153,871,1027] Mature motor neurons, infected by virulent strains of virus, die by a necrotic process and are not protected from death by Bcl-2 family proteins.[379,483] Autophagic clearance of viral proteins may promote neuronal survival.[719]

Persistent infection can occasionally be established in mammalian cell cultures. Mouse fibroblasts producing interferon (IFN), or BHK cells with a high concentration of defective interfering particles, can establish SINV-persistent infection.[427,1064] Infection with SINV or SINV replicons (incomplete genomes that retain replicative ability) that have mutations in the C-terminal methyltransferase-like domain of nsP2 results in reduced viral RNA synthesis, decreased CPE, and persistent infection in some vertebrate cell lines.[11,226,287,288,617,742] Persistent infection can also be established if the cell infected is resistant to virus-induced apoptosis.[117,552,1010,1027]

Effects on Invertebrate Cells

Studies of alphavirus infection of cell lines derived from *Aedes albopictus* (e.g., C6/36, U4.4) and *Aedes aegypti* (e.g., Aag2) mosquito larvae

demonstrate fundamental differences in alphavirus replication between vertebrate and invertebrate cells. The time course of virus replication is similar, but there is only a modest effect on host gene expression,[278,853] and persistent noncytopathic infection, or death by a nonapoptotic process,[473] is more common than in vertebrate cells. Infection of mosquito cells does not lead to host cell transcriptional and translational shutoff as seen in vertebrate cells, and this is probably the main factor permitting persistent infection of mosquitoes *in vivo* as well as mosquito cells *in vitro*.[327] Interaction of the nsP3 hypervariable C-terminal domain with SH3-containing domain proteins is particularly important for replication.[636] In culture, virion maturation is often observed within vesicular structures with virion release by exocytosis rather than at the plasma membrane,[640,941] while in polarized cells of the mosquito midgut digestive and salivary gland acinar cells, in vivo maturation generally occurs via budding from the plasma membrane, often in a directed manner.[224,1059]

Virions produced by mosquito cells are relatively deficient in cholesterol (mosquitoes are auxotrophs for cholesterol, which is derived in the adult stage from blood feeding) compared to virions produced by vertebrate cells and have detectable differences in structure and glycosylation of the envelope proteins that can affect infection.[366,386,417,689,931] Recent studies have shown that several alphaviruses produced by mosquito cells are denser than some populations from vertebrate cells, and contain components of the small subunit of the host cell ribosome. These “heavy” virions are more infectious for vertebrate cells than their less dense counterparts from vertebrate cells. However, the “light” particles are more infectious for mosquitoes and induce a stronger innate response in the vector.[600]

The uncloned lines derived from *Ae. albopictus* larvae contain many types of cells with properties representative of different mosquito tissues. Lytic infection occurs in some clones that support high levels of virus replication,[640,984] while persistent infection is associated with a short period of relatively high virus replication followed by a decrease in virus production and in the numbers of cells in the culture that are producing virus.[200,668,669] The decrease in virus production is not associated with activation of the signal transducer and activator of transcription (STAT), immune deficiency (IMD), or toll insect innate response pathways but is associated with decreased processing of the nonstructural polyprotein and expression of the

protease inhibitor TEPII.[278,668] However, in *Ae. aegypti* infection, SINV up-regulation of the IMD pathway is dependent on the mosquito microbiome.[62] Transcriptional analysis of persistently infected cells shows an increase in mRNAs associated with vesicle formation and the Notch signaling pathway.[668] Lytic infection can also be induced by viruses engineered to express death-inducing insect proteins such as reaper or Michelob_x.[1038] Insect-specific viruses present in U4.4 cells (and lines from other mosquito species), but not in C6/36 *Ae. albopictus*–derived cell lines, may also affect infection with alphaviruses.[1063] Studies expressing the proapoptotic gene reaper from a SINV vector suggest that apoptosis is also important for controlling alphavirus infection of mosquitoes.[716]

RNAi is an important insect defense mechanism, and modulation of viral replication in mosquito cells is due in large part to the RNAi pathway. SFV infection of U4.4 or Aag2 cells leads to production of viral RNAs derived from replicative dsRNA that are unevenly distributed across the genome and variable in efficiency for mediating antiviral RNAi.[909] This RNAi signal can spread from cell-to-cell and inhibit replication.[46] The RNAi pathway is defective in C6/36 cells,[97] but the IMD, and not the toll innate response pathway, can suppress SINV replication in these cells.[52] The small interfering RNA (siRNA) pathway is regarded as the principal antialphaviral pathway, and CHIKV nsP2 and nsP3 appear to exhibit RNAi suppressor activity.[615] Knockdown of virus-specific PIWI-interacting RNA (piRNA) pathway components in *Ae. aegypti* cells to reduce CHIKV-specific RNAs does not affect CHIKV replication, suggesting that this pathway is not critical to modulating viral replication. However, knockdown of the helicase Spindle-E (SpnE), essential to the piRNA pathway in *Drosophila melanogaster*, increases CHIKV and SFV replication in *Ae. aegypti cells* independent of the siRNA and piRNA pathways. This suggests a small RNA-independent antiviral function for SpnE.[1021] In addition, *Ae. aegypti* microRNAs appear to modulate CHIKV infection of mosquito cells.[227]

Superinfection Exclusion

Vertebrate and invertebrate cells infected with one alphavirus often cannot be productively infected with the same, or a closely related, alphavirus at a later time. Exclusion is established after translation of the nsP genes of the first

virus to enter. The superinfecting genome can be translated, but not replicated[940] possibly due to the presence of the transacting nsP2 protease that prematurely cleaves the replicase polyprotein required for minus-strand synthesis.[474] Experimental coinfection of *Ae. aegypti* by CHIKV and the often cocirculating dengue-2 and Zika flaviviruses does not appear to be less efficient than single-virus infection.[824]

Antigenic Composition

All alphaviruses are related and share common antigenic sites, as revealed by HI and CF tests with polyclonal immune sera[137] and by cytotoxic T-cell lysis of infected cells.[568,670] Antigenic cross-reactivities may confer some cross protection and interfere with sequential alphavirus immunizations.[136,218,344,568,619] These cross-reactivities formed the basis for the original classification into the group A arboviruses (later the alphaviruses) and continue to be a valuable means for initial identification and classification of alphaviruses.[137] Closely related viruses within a serogroup form a complex. Seven broad antigenic complexes have been identified within the alphavirus serogroup: Barmah Forest (BF), EEE, Middelburg (MID), Ndumu (NDU), SF, VEE, and WEE.[524,767,990] However, several more recently discovered alphaviruses have not been extensively characterized antigenically, so their classification into new complexes is based on extrapolation from sequences alone; examples include Trocara,[990] Eilat,[685] and Tai Forest[398] (Table 6.1). The BF, EEE, MID, and NDU complexes each contain only a single virus, while the SF, VEE, and WEE complexes include several viruses. Viruses within each complex can be subtyped using reactivity with mAbs, kinetic HI, or neutralization assays.[128]

Antibodies to E1 are more likely to cross-react with other alphaviruses than are antibodies to E2.[90,424,1094] This is consistent with the documented greater sequence conservation in the E1 protein. Competitive binding assays using mAbs have identified approximately seven epitopes on the E1 glycoproteins of SINV, SFV, WEEV, and VEEV.[90,424,632,814,867] Most E1 epitopes are not exposed on the virion surface but are present on the surface of infected cells or on acid-exposed virions.[19,399,632,867] These transitional epitopes map to domain III in a region buried at the spike interfaces (Fig. 6.4).[1032] The *in vitro* biologic activities of antibodies to E1 include HI,

neutralization of virus infectivity, and inhibition of fusion.[19,90,424,867] Neutralizing epitopes map to domains I, II, and III.[558]

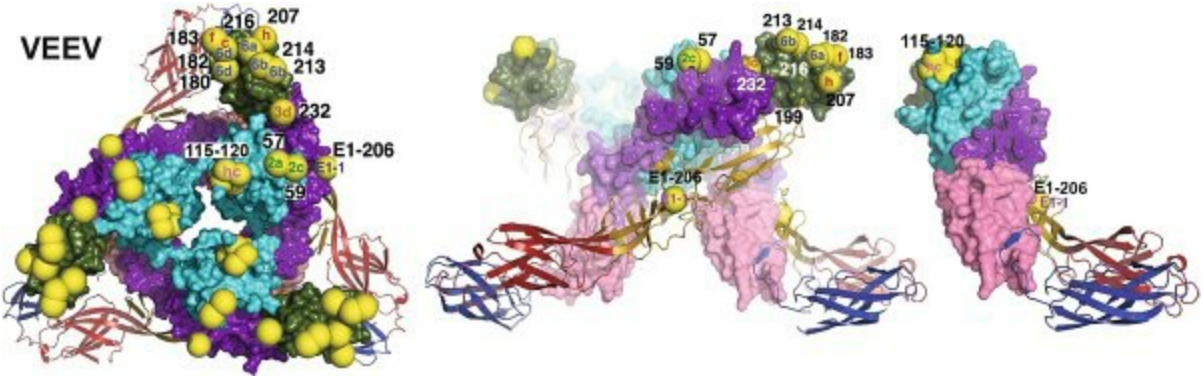

FIGURE 6.4 Neutralization escape mutations and positions affecting host range and tissue tropism mapped on the VEEV spike. Neutralizing antibody escape mutations displayed as yellow spheres on the spike with epitope written in the spheres. E1 is shown in ribbons and E2 in surface rendering using the colors defined in Figure 6.2. The **left panel** shows a top-down view of the spike, the **middle panel** shows the spike from the side, and the **right panel** shows the far right dimer from the middle panel. Nature 2010;468(7324):709–712.).

Antibodies to E2 are usually alphavirus specific, but can be cross-reactive and block multiple steps in the replication cycle including both entry and egress through cross-linking of neighboring spikes.[276] Competitive binding assays using mAbs identify 4 to 5 epitopes on the E2 glycoproteins of SINV, SFV, RRV, and VEEV.[90,482,632,714,814] *In vitro* biologic activities of antibodies to E2 include HI, neutralization of virus infectivity, and blocking of virus binding to the cell surface.[814] Many anti-E2 mAbs have both neutralizing and HI activities suggesting that these functions overlap. Neutralization-escape mutants, naturally occurring variants, λgt11 expression

libraries, site-directed mutagenesis of cDNAs, and recombinant viruses have been used to identify amino acids contributing to the various epitopes on E2 and have identified two major neutralizing sites[868,935,1044] that have been mapped onto domain B of the crystal structure of the E1–E2 heterodimer and trimerized spike[558,1032] (Fig. 6.4). This is an exposed hydrophilic region that often includes an N-linked carbohydrate. There are linear, as well as conformational, determinants in this region because these mAbs frequently react in Western blots and recognize λ-fusion proteins, and antibodies to peptides from this region are protective against challenge.[1044]

The second neutralizing epitope on E2 appears to be primarily conformational and is in domain A (Fig. 6.4). This region is responsible for binding to HS and is obscured if pE2 is not cleaved.[1032] Visualization by cryoelectron microscopy of the binding of HS and mAbs to this epitope on SINV and RRV identifies the domain A knob on the glycoprotein spike.[913,1106]

Monoclonal antibodies against EEEV that bind to E2 domains A or B can protect mice and nonhuman primates when administered passively.[107,196,488,916,1050] One CHIKV mAb that bridges domains A and B prevents entry by interfering with movement of the B domain away from the E1 fusion loop.[576] Other mAbs bind a footprint that spans different domains on adjacent E2 proteins[447] or bind the E2 proteins in the plasma membrane to prevent budding by inducing coalescence leaving nucleocapsids accumulating in the cytosol to activate Fc receptors.[446]

Evolution and Phylogeny

Alphaviruses, which replicate in arthropods, birds, reptiles, fish, and mammals, derive from a single unknown protoalphavirus within the alphavirus superfamily of viruses. Viruses in this superfamily, including many RNA plant viruses, have a similar genetic organization and replicase proteins with homologous conserved motifs, but diverse coat proteins.[507] Amino acids important in secondary structure (e.g., cysteines and those close to one another in adjacent β-sheets and α-helices) have been conserved for the glycoproteins E1, E2, and E3, consistent with a similar conserved three-dimensional structure of the virion.[270] Highly conserved regions in the nsP1 and nsP4 genes have allowed for the development of primers to detect a

broad range of alphaviruses by RT-PCR.[247,314,357] The most variable regions of the open reading frames are in the C-terminus of nsP3 (hypervariable domain) and the N-terminus of C.[270] Sequence information from the entire genome generally groups the viruses similarly to that derived by antigenic analysis (Fig. 6.5) and has detected at least one ancient recombination event.[368] Criteria for species demarcation of alphaviruses combine genetic, ecological, and antigenic information. Species generally have distinct transmission cycles and differ by more than 23% at the nucleotide level and 10% in amino acid sequence when E1 genes are compared.

generated from a conserved region of envelope protein gene nucleotide sequences (2184 nt) using the GTR+I+G substitution model and maximum likelihood method. *Red color* indicates location in the Old World; *green* indicates New World. Parentheses indicate major subtypes; *asterisks* indicates unclassified virus. *Black lines and labels* indicate alphavirus complexes based on antigenic and/or genetic similarities. Abbreviations: EEE, eastern equine encephalitis; VEE, Venezuelan equine encephalitis; WEE, western equine encephalitis. (Courtesy of Rubing Chen.)

The origin of the alphaviruses is unclear. Partial genome sequencing has suggested origins both in the Americas and in the Old World.[333,535,767,1054] Recently, comparison of whole genome sequences from all known alphaviruses has suggested an origin from an ancestor of the louse-borne aquatic alphaviruses[270] (Fig. 6.5). However, the discovery of geographically diverse "insect-specific" alphaviruses,[398,685,986] which infect mosquitoes but are fundamentally defective for replication in vertebrates, suggests that they may represent the ancestral alphaviruses. All of these scenarios require repeated movement across the globe to explain the current virus distributions.

Like other RNA viruses, alphaviruses undergo genetic change primarily by accumulation of point mutations in the genomic RNA, but deletions and duplications also occur, especially in the C-terminal hypervariable domain of the nsP3 gene and the highly variable 3′-untranslated region (UTR).[3,167,268] Mutation occurs at a rate that is slower ($1–7 \times 10^{-4}$ substitutions/nucleotide/year) than is estimated for some other RNA viruses,[120,179] presumably because "tradeoff" fitness must be maintained in both insect vectors and vertebrate hosts.[183] Recombination between alphaviruses can be demonstrated *in vitro*, but is infrequent and usually puts the chimeric virus at a replicative disadvantage.[120,179] However, successful recombination has occurred at least occasionally in nature as evidence by the fact that WEEV is the result of an ancient recombination between EEE- and SIN-like viruses (Fig. 6.5) at the junction of E3 and capsid.[27,270,368,513]

Alphaviruses replicate in and are transmitted horizontally by a wide range

of invertebrate, primarily mosquito, species. However, each virus usually has a principal or preferred vector for the enzootic cycle. Most alphaviruses can infect a variety of vertebrates, but have birds, mammals, or fish as their primary amplifying and reservoir hosts (Table 6.1). The specific invertebrate vector and vertebrate host used by an alphavirus typically contribute significantly to determining the enzootic geographic distribution of that virus. Experiments modeling evolution *in vitro* show that fewer mutations accumulate if replication alternates between vertebrate and invertebrate cells, but diversity, fitness, and adaptability are greater with serial passage in a single host system.[185,186,189,343,1049] Experiments employing *in vivo* passage show that serial passage in mosquitoes increases mosquito infection efficiency and passage in vertebrates produces higher viremias in vertebrates, but alternately passaged viruses do not change fitness.[185]

It is hypothesized that host mobility influences alphavirus genetic diversity and evolution in a given geographic region.[179,1053] Viruses using avian enzootic hosts (e.g., EEEV, WEEV, SINV) extend over wide geographic regions and evolve as a few highly conserved genotypes, while viruses using mammalian enzootic hosts with a more limited range of dispersal (e.g., RRV, enzootic VEEV, enzootic CHIKV) evolve within multiple geographically restricted genotypes.[166,599,842] However, human-amplified lineages of CHIKV and equine-amplified strains of VEEV have the opportunity to spread even more rapidly and extensively than do avian-amplified alphaviruses.[1048]

Some strains of alphaviruses associated with epidemics or epizootics are antigenically and biologically distinguishable from enzootic strains. Phylogenetic evidence indicates that, at least for VEEV and some strains of WEEV, the virulent epizootic strains evolve by mutation from avirulent viruses being maintained in the enzootic cycle.[31,82,770,806] For CHIKV, several human-amplified lineages have been evolving independent of the enzootic, African lineages for several years to many decades.[1050]

PATHOGENESIS AND PATHOLOGY IN VERTEBRATES

Excellent and well-studied model systems exist for several alphaviruses, and much of our detailed knowledge about alphavirus pathogenesis comes from investigations in mice. Information from these models will be combined where appropriate with information from studies of humans with alphavirus-induced disease to deduce the pathogenesis of infection. Specifics will be covered in sections on the individual viruses.

Entry

The primary mode of alphavirus transmission to vertebrates is through the bite of an infected insect, most often a mosquito. Mosquitoes salivate during feeding and deposit virus-infected saliva mainly extravascularly.[1006] Saliva virus titers are highest early after the mosquito is infected and sometimes decline, along with transmission rates, after 1 to 2 weeks, but mosquitoes remain infected for life.[642,1023] The high-mannose glycans on virus from mosquitoes inhibit induction of IFN by myeloid DCs,[885] and proteins in saliva further facilitate transmission by skewing the host cellular immune response toward Th2 cytokines.[977]

Sites of Primary Replication

The initial sites of virus replication vary with the virus and host. Mice have received the most extensive study. After subcutaneous inoculation, viruses may infect skeletal muscle or fibroblasts at the local site (e.g., EEEV, WEEV, SFV, RRV, SINV, and Getah virus) or be taken up by and infect Langerhans cells in the skin (e.g., VEEV)[354,404,571,671] (Fig. 6.6). Langerhans cells and DCs transport virus to lymph nodes draining the site of inoculation that also may become infected.[298,596] *In vitro*, human DCs are susceptible to infection with VEEV, but not to infection with CHIKV or EEEV,[296,699,865,929] so the importance of DC infection after mosquito inoculation is likely to differ with the infecting virus.

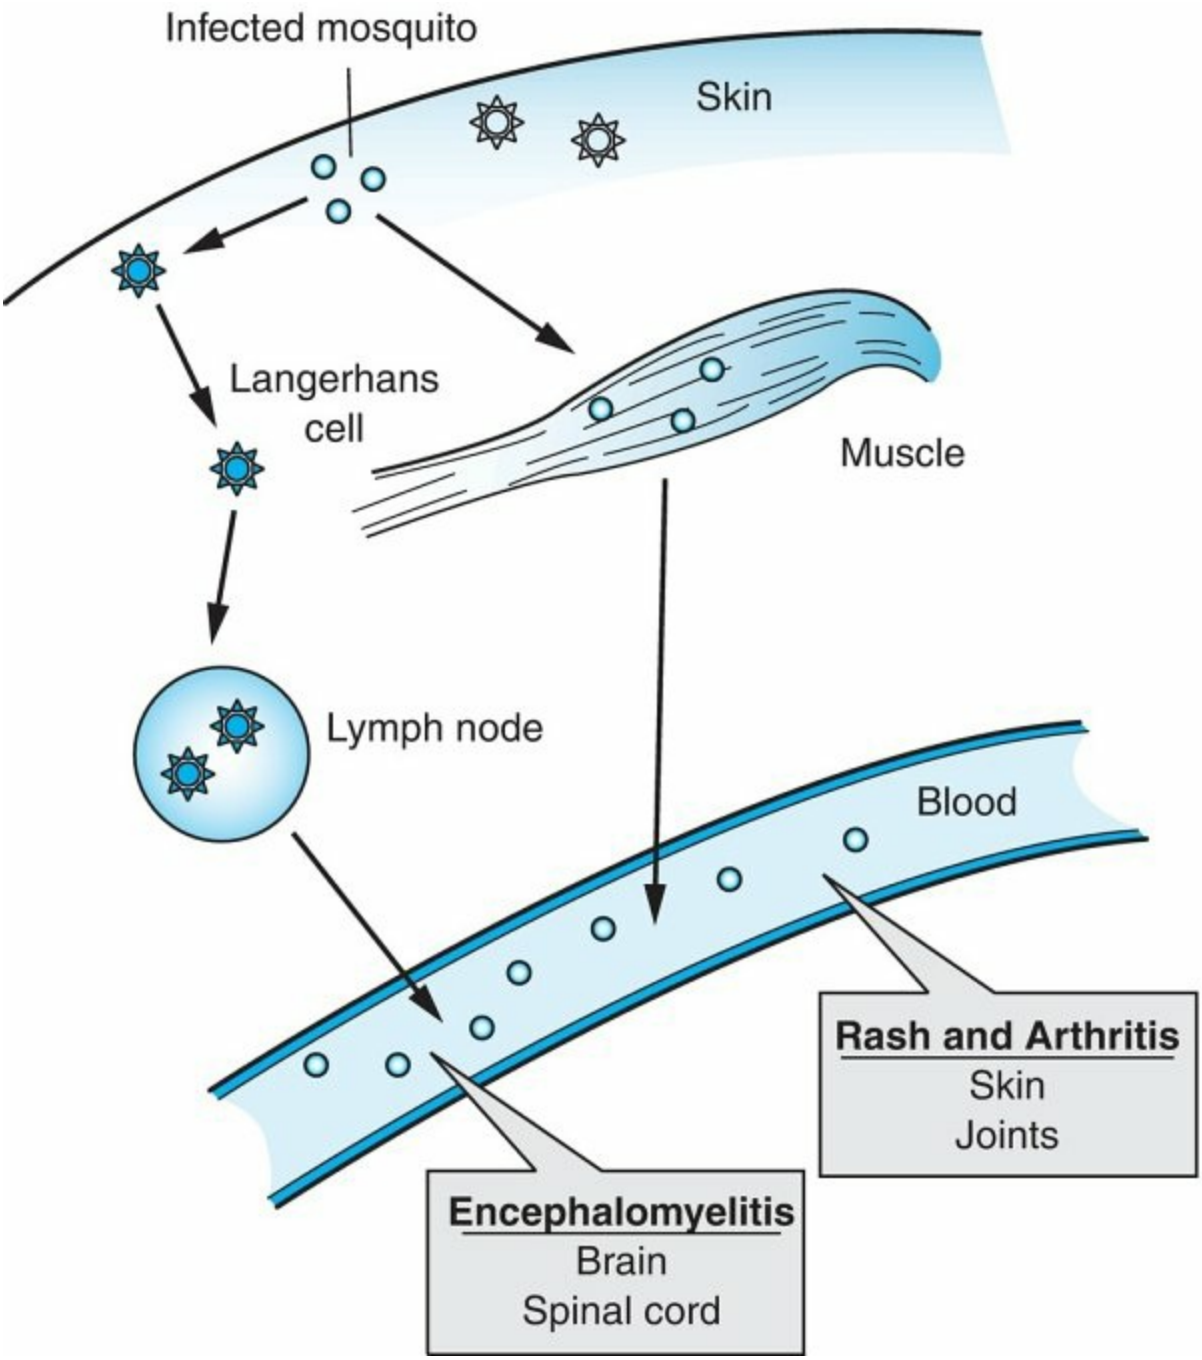

FIGURE 6.6 Basic steps in alphavirus infection of vertebrates. Virus is delivered extravascularly by an infected mosquito and infects local muscle cells or Langerhans cells in the skin. Langerhans cells can carry virus to local lymph nodes where further replication may occur. Virus is delivered to the blood and spreads to target tissues such as skin, joints, and the central nervous

system, in addition to distant muscle and lymphatic tissue.

Spread

Alphaviruses induce a substantial plasma viremia in their amplifying hosts and in hosts susceptible to disease (Fig. 6.7). The ability to mount and sustain a viremia is dependent on the continued efficient production of virus, delivery of virus into the vascular system, and slow clearance from the blood. Animal studies have shown that small-plaque viruses are generally less virulent because they are cleared more rapidly from the circulation than are large-plaque viruses.[436,440,763] This phenomenon is related to the ability of small-plaque viruses to bind HS and thus to be rapidly removed from the circulation by the highly sulfated glycosaminoglycans in the liver.[126] An exception is VEEV, where naturally small-plaque variants produce higher viremia titers in equids, allowing for epizootic amplification.[102] Ability to invade target organs is dependent in part on the duration and height of the viremia, but also on other characteristics of the virus important for tissue invasion.[593]

FIGURE 6.7 Schematic diagram of the pathogenesis of alphavirus-induced disease. Viremia may be accompanied by production of interferon and other proinflammatory cytokines and fever. Virus then spreads through the blood to other target tissues. As the immune response is induced, the viremia is terminated, but fever is renewed with appearance of a mononuclear inflammatory response in the infected tissue. In infections that lead to rash and arthritis, joint pain usually appears early after infection and prior to the appearance of the rash.

Cell and Tissue Tropism

Viruses that replicate initially in skeletal muscle and lymph nodes near the site of inoculation often spread through the bloodstream to more distant skeletal muscles and other lymphatic tissues. In addition, cardiac myocytes, osteoblasts, brain and spinal cord neurons, and brown fat cells are secondary sites of replication for many alphaviruses in mice (Fig. 6.6).[12,571,652,673] RRV and Getah virus cause polymyositis[404,878]; EEEV, WEEV, SFV, and SINV cause encephalitis[57,298,432,571,1030]; RRV and CHIKV cause arthritis[294,661,1111]; and VEEV causes lymphoid depletion and encephalitis.[319,441,1036]

In humans, the skin is a target for alphaviruses that cause a rash,[284,412,520,604] the joints for alphaviruses that cause arthritis,[283,407,661] muscle for alphaviruses that cause myalgia,[723] and the nervous system for alphaviruses that cause encephalitis.[301,901] RRV and SINV have been recovered from skin biopsies.[519,520,604] RRV replicates in skin basal epidermal and eccrine duct epithelial cells.[284] Human synovial cells support RRV infection *in vitro*[459] and RRV RNA is detected in synovial biopsy specimens.[923] Joint fluid taken from humans with acute arthritis has not yielded infectious virus, but viral antigen and RNA can be detected in fibroblasts and macrophages and these cells support RRV and CHIKV replication *in vitro*.[407,459,526]

The mechanism by which encephalitic alphaviruses enter the CNS is not

entirely clear. Neuroinvasiveness is a component of virulence that varies between viruses, virus strains, and route of inoculation.[229] Murine studies have shown infection or transport by cerebrovascular endothelial cells,[485,737,924] choroid plexus epithelial cells,[571] olfactory neurons,[127,162,749,823,975,1029] and peripheral nerves.[188] Once within the CNS, virus can spread from cell to cell or through the cerebrospinal fluid (CSF).[431,711,975] For most encephalitic alphaviruses, the targeted cell within the CNS is the neuron[432,571,711] where cellular protein synthesis is suppressed[985] and damage can be severe and irreversible. In mice that recover from neuronal infection, infectious virus is cleared, but viral RNA persists.[278,549,638,1008] SFV, RRV, and VEEV can also cause persistent infection of microglial and oligodendroglial cells leading to demyelination.[122,196,279,878]

Immune Responses

Innate Responses

Early responses to alphavirus infection include production of cytokines and chemokines and activation of natural killer (NK) cells.[338] Type I (α/β) IFN is induced *in vivo* by many, but not all, alphavirus infections of experimental animals[298,313,439,889,991] and humans[407,832,865,1045] (Fig. 6.7). The amount of IFN produced by infected tissues is usually linked to the level of virus replication, and IFN production continues if virus is not cleared.[118,277,363,407,439,865] IFN rapidly appears in serum, and levels are diminished by splenectomy or failure to replicate in hematopoietic cells, suggesting that lymphoid tissue is one important source.[298,439,504,506]

Different cell systems have been used to determine the mechanisms by which alphaviruses induce and control synthesis of IFN in response to infection. Viruses vary in their ability to induce IFN production by different types of cells,[763,865,889] and the cellular sources of IFN probably differ with time after infection. In tissue culture cell lines, IFN production, shutoff of host protein synthesis, and CPE are controlled by nsP2 (SINV, SFV) or C (VEEV, EEEV).[18,104,288,303,304] In these cells, shutoff of host gene expression suppresses antiviral responses.[18,104,304,1096] Alphaviruses can also interfere

with IFN signaling by decreasing JAK activation and STAT phosphorylation and nuclear translocation.[289,904,905]

The primary source of early IFN *in vivo* may be plasmacytoid DCs for some alphaviruses,[898] but not for others.[865] SFV induction of IFN by myeloid DCs requires fusion and IFN regulatory factor (IRF)-3, but not replication, and is independent of MyD88.[403] For SINV and RRV, N-linked glycans on E2 are important determinants of IFN production by DCs.[886]

In cells other than DCs, induction of IFN and IFN-stimulated genes (ISGs) requires viral entry and RNA synthesis.[74,1078] Data from *ts* mutants suggest that formation of dsRNA is the necessary step in replication for IFN induction. NsP1/nsP2 cleavage affects IRF3 activation and IFN induction by SINV without affecting shutoff of host transcription or translation.[194] Viruses with mutations in the protease domain of nsP2, which cannot process the nonstructural polyprotein to initiate plus-strand RNA synthesis, do not induce IFN.[367,609] In infected or transfected fibroblasts and epithelial cells, dsRNA and higher-ordered RNA structures convert host cell RNA into 5′-ppp dsRNA to activate MDA5 and PKR, important intracellular sensors of alphavirus infection,[65,696] and stimulate phosphorylation of IRF3[751,872] and formation of the IRF3/CBP/p300 transcriptional activation complex for induction of immediate early IFNs.[74] This process is independent of mTOR pathway activation.[211] Virulent strains of EEEV do not induce IFN after fibroblast infection, while attenuated strains do, potentially associated with differences in binding to HS.[300]

Production of IFN often follows the initial release of virus from infected cells by 2 to 3 hours[406] and for some but not all alphavirus strains is regulated by whether host protein synthesis is shut off before IFN can be synthesized.[104,119,1078] The ability of CHIKV to induce IFN mRNA and protein is cell type dependent.[865] Primary human monocytes infected by CHIKV produce IFN-α, IL-6, and IL-12.[396] Replication in primary human fibroblasts is controlled by TLR signaling with production of IFN-β mRNA, but no protein because the mRNA is not translated.[397,1078]

IFN is an important part of the host response to alphavirus infection and virus replication is generally sensitive to its effects.[16,191,208,439,545,659,835,885,929,1103] Mutations associated with altered

sensitivity to antiviral activities of IFN have been mapped to the 5′ UTR, nsP1, and nsP2,[288,455,819,933,1079] and this variation in sensitivity may or may not correlate with virulence.[32,91,210,425,933,1096]

Animals can be protected from lethal infection if treated with type I IFN or IFN-inducers before or soon after infection.[16,439,461,584,772,879] Animals unable to respond to IFN due to deletions of the *α*-chain of the IFN receptor or crucial IFN signaling molecules develop more severe disease than wild-type mice.[16,124,191,193,258,277,346,825,834,865,870,884,933,1079] Furthermore, absence of an IFN response allows virus replication in cells previously resistant to infection.[277,833,834,995] IFN appears to primarily limit virus replication early while the adaptive immune response is being induced (Fig. 6.7). Roles for several ISGs have been identified with effects on entry, genome translation, replication complex formation, structural protein synthesis, and morphogenesis.[84,275,970]

Antiviral proteins PKR and RNase L have a limited role in the IFN-induced antiviral response *in vitro* and *in vivo*.[836] However, activation of PKR improves the stability of IFN mRNA,[65,872] and RNase L–deficient fibroblasts fail to shut off minus-strand RNA synthesis or form stable replication complexes and establish persistent infection suggesting a role for RNase L in regulating viral RNA synthesis.[857] Several IFN-induced proteins have been demonstrated, often through overexpression studies, to inhibit alphavirus replication *in vitro*, and through studies of transgenic or knockout mice *in vivo*. Transgenic expression of MxA, a large cytoplasmic GTPase, in IFN-*α*/*β* receptor-deficient mice results in decreased SFV replication by preventing accumulation of genomic and subgenomic RNA and provides some protection against fatal disease.[387,531] Zinc finger antiviral protein (ZAP/PARP13) is an RNA-binding protein that blocks translation of incoming viral genomic RNA[84,358] by binding to specific viral mRNA sequences, interaction with the host DEAD box helicase p72, and degradation by the RNA-processing exosome.[84,165,359,481,536,597,1103] Viperin (Rsad2) is a conserved multifunctional protein that can bind Fe-S clusters and associates with the cytosolic face of the ER and lipid droplets to inhibit the replication of many viruses.[388,883,967,1103] The large form of 2′-5′-oligoadenylate synthetase (OAS3) is associated with ribosomes and blocks early stages of replication independent of RNase L.[105] Tetherin (Bst2) is a transmembrane

protein that blocks alphavirus release from the plasma membrane.[455,717] Tetherin-deficient mice have increased viral loads and decreased inflammatory responses suggesting an additional regulatory role for this ISG.[603] ISG15 is an ubiquitin-like molecule that exerts its antiviral effect by conjugating proteins, and ISG15-deficient mice have increased mortality with increased levels of proinflammatory cytokines.[310,544,545,1070] ISG20 is a nuclear DEDD family 3′-5′ exonuclease that inhibits alphavirus replication by increasing expression of antiviral ISGs such as IFN-induced protein with tetratricopeptide repeats (IFITs).[1065,1103] IFIT1 (ISG56) is a cytoplasmic protein that inhibits translation by binding 5′-ppp or incompletely capped (cap 0) viral RNAs and components of the eIF3 translation initiation complex.[7,260,517,750] IFIT1-deficient mice have increased susceptibility to infection, but virulent alphaviruses with a secondary structural motif in the 5′ UTR escape IFIT1 binding and function.[425,802] IFN-induced transmembrane protein (IFITM)-3 is present in early endosomes and blocks pH-dependent virus fusion required for entry, and deficiency leads to increased viral load in tissues.[759,1072]

IFN may also contribute to alphavirus-induced disease. Fever during the viremic phase of infection, as is seen with CHIKV and RRV, is probably a response to the IFN induced early after infection (Fig. 6.7). It has been postulated that the rapidly fatal disease induced by alphaviruses in newborn mice may be due to the production of large amounts of IFN and proinflammatory cytokines.[991] Acute phase responses induced by alphaviruses prior to the virus-specific adaptive immune response often reflect the extent of virus replication and include up-regulation of TLR expression and increased production of tumor necrosis factor (TNF), interleukin (IL)-1 and IL-6, as well as IFN-α/β.[345,623,865,991,1071] Adult mice deficient in IL-1β have reduced mortality after CNS infection with a neurovirulent strain of SINV, suggesting that cytokine production may also contribute to disease.[560]

Virus-Specific Adaptive Responses

Both cellular and humoral immune responses are induced by infection[275] (Fig. 6.7). In experimentally infected adult mice, antiviral IgM is usually detected in serum within 3 to 4 days after infection.[347,585,725,878] The cellular

immune response, manifested by the presence of virus-reactive lymphocytes in draining lymph nodes and blood and the infiltration of mononuclear cells into infected tissues, also appears within 3 to 4 days after infection.[350,620] These responses appear later (7–10 days after infection) in neonatal mice.[889] Both play a role in recovery from infection and protection against reinfection.

Humoral immunity

Virus-specific IgM antibody is detectable very early in human disease, which often provides a means for rapid diagnosis of infection when it is short-lived or when seroconversion is detected, but it can also persist for many months after recovery.[92,129,133,142,148,355,407,519,605,695] Appearance of antibody correlates with cessation of viremia (Fig. 6.7). Virus-specific IgA also appears early in infection, but declines rapidly.[147] IgG antibody is present in serum after 7 to 14 days and is maintained at relatively high levels for years.[131,220] Many lines of evidence support the hypothesis that recovery from alphavirus infection is dependent in large part on the antibody response and that either IgM or IgG is sufficient.[118,351,585,697,761] Rapidity of antibody synthesis within the CNS is predictive of outcome from encephalitis in both mice and humans. Those without evidence of early antibody synthesis are most likely to die.[70,129] Antibody in the periphery can neutralize virus infectivity and promote virus clearance by the reticuloendothelial system in conjunction with complement.

The most extensive experimental studies to define the relevant antibody specificities and the mechanisms of antibody-mediated recovery and protection have been done using VEEV, SFV, CHIKV, and SINV infection of mice. Passive transfer of antibody before or after infection is protective. Both neutralizing and nonneutralizing mAbs against multiple epitopes on the E1, E2, and E3 glycoproteins can protect against alphavirus challenge and promote recovery.[88,89,107,356,424,488,613,632,732,934,1094]

Treatment of immune-deficient mice persistently infected with SINV or SFV with antiviral antibody clears infectious virus from the CNS without causing neurologic damage.[29,551] Similarly, antibody clears CHIKV from the joints of infected mice.[382,383,761] E2-specific mAbs can down-regulate intracellular virus replication *in vivo* and *in vitro* by a nonlytic mechanism.[551,1010] Antibody against an N-terminal peptide of VEEV E2 that

is not neutralizing can limit virus replication *in vivo*,[423] and a nonneutralizing mAb to SFV E2 can limit virus replication *in vitro*.[89] Anti-E3 mAbs inhibit production of VEEV.[732] Anti-E1 mAbs may also be able to alter intracellular virus replication.[158]

In vitro studies show that the process by which antibody alters intracellular virus replication requires bivalent antibody, but does not require the Fc portion of the MAb, complement, or other cells.[551,1010] However, the effects of antibody are amplified by treatment of infected cells with IFN-α.[208] Soon after antibody binding, virion budding from the plasma membrane is inhibited.[209] *In vivo* studies also show that IFN and antibody act synergistically to promote recovery and that germ-line IgM as well as IgG is effective, but the mechanisms by which these systems interact have not been identified.[124,190,697]

Clearance of infectious virus is rapid, while the decline in viral RNA occurs more slowly.[549,551,638] After recovery from encephalitis or arthritis, viral RNA often remains detectable in murine tissues for life. Therefore, one consequence of a nonlytic mechanism for clearance of virus from tissue is that the virus genome is not completely eliminated if the originally infected cells survive.[549,551,1008] This leads to a need for long-term control of virus replication that is accomplished in part by infiltration and maintenance of antibody-producing B cells in the CNS.[348,637,638,1008]

Antibody also is important for protection from infection.[656] Inactivated or replication-defective vaccines protect against EEEV, VEEV, and WEEV.[245,781,783] Delivered before or shortly after infection, passive transfer of antibody can protect from acute disease, but may predispose to late disease.[351,490,877]

Cellular immunity

Alphavirus infection induces virus-specific lymphoproliferative, cytokine, and cytotoxic T-cell responses.[2,350] After epidermal virus inoculation, Langerhans cells increase expression of MHC class II antigens and accessory and costimulatory molecules that enhance activation of naïve T cells.[453] The mononuclear inflammatory process in response to alphavirus infection is immunologically specific and includes infiltration of NK cells, $CD4^+$ and

$CD8^+$ T lymphocytes, B cells, and macrophages.[428,620,638,646,658] Relative proportions of these mononuclear cells vary with the time after infection.[428,638,646] T cells play a role in virus clearance and in protection from challenge.[242,1100] Cytokines and chemokines increased in plasma during acute disease include IL-4, IL-6, IL-10, IL-12, IL-13, IFN*γ*, CCL2, and CXCL10.[407,1045] Mice lacking the ability to produce antibody can clear infectious virus from some populations of neurons through production of IFN*γ*,[85,109] and IFN*γ* down-regulates SINV replication in mature neurons *in vitro* through a JAK-/STAT-dependent mechanism.[116,117] Viral RNA levels in the CNS of SINV-infected mice decrease more rapidly when $CD8^+$ T cells are present.[489] In animals infected with virulent strains of virus, cellular immune responses contribute to tissue damage and fatal disease and can be modulated by regulatory T cells.[340,490,514, 515, 516,542,608,683,822] Humans with persistent symptoms have prolonged elevations of IFN, cytokines, and chemokines indicating ongoing immune activation.[175,407,866]

Pathological Changes

Encephalomyelitis

Pathological changes in the CNS of humans with fatal neurologic disease and mice with experimentally induced encephalomyelitis begin with perivascular infiltration of mononuclear and polymorphonuclear inflammatory cells.[620,646,703] Adhesion molecules (e.g., ICAM-1, VCAM-1) are up-regulated on endothelial cells, and integrins LFA-1 and VLA-4 are important mediators of mononuclear cell entry.[429,915,925] This phase of infection may include extravasation of red blood cells and endothelial cell swelling and hyperplasia.[703] Lymphocytes and monocytes move from the perivascular regions to areas of the parenchyma with virus-infected neurons. This inflammatory process is accompanied by gliosis and evidence of inflammatory and glial cell apoptosis.[301]

Neonatal mice and human infants may die with widespread virus-induced neuronal cell death before the inflammatory process, a manifestation of the cellular immune response, can be initiated.[674] Immature neurons die by an apoptotic process,[556] while death of mature neurons may be characterized by

cytoplasmic swelling, vacuolation, membrane breakdown, and cellular degeneration suggesting necrosis.[301,379,674] Demyelination has been described as a consequence of EEEV and WEEV infection in humans[68,702,703] and of WEEV, RRV, and SFV infection of mice, probably as a result of infection of oligodendrocytes.[122,648,880]

Reticuloendothelial Infection

The pathology of VEE in horses includes cellular depletion of bone marrow, spleen, and lymph node tissue and pancreatic necrosis.[496] Small mammals also develop widespread infection of reticuloendothelial system tissues and may develop fatal ileal necrosis.[51,331,1036]

Arthritis

In CHIKV- and RRV-induced arthritis, there is hyperplasia of the synovial lining, vascular proliferation, and mononuclear cell infiltration.[407,923] Synovial fluid contains increased protein, $CD4^+$ T lymphocytes, activated NK cells and macrophages, and increased levels of monocyte chemotactic protein (MCP)-1/CCL2, IL-6, and IL-8.[182,283,407] Evidence of persistent human infection as a cause of chronic arthritis includes the presence of RRV RNA 5 weeks after onset of symptoms[923] and CHIKV antigen and RNA in synovial macrophages 18 months after acute disease.[407]

Rash

Skin biopsies taken from patients with RRV-induced rash show perivascular infiltration of lymphocytes (primarily $CD8^+$ T cells) and monocytes without evidence of immune complex deposition.[284]

Release and Transmission

A common feature of alphaviruses is their transmission by insects and maintenance in a natural cycle of replication in vertebrate and invertebrate hosts. Arthropod vectors become infected by feeding on a viremic host, are able to transmit the virus 2 to 10 days later (extrinsic incubation), and remain persistently infected. Maintenance of this cycle requires an amplifying host

that develops a viremia of sufficient magnitude to infect feeding mosquitoes. For many alphaviruses, humans and horses are dead-end hosts unable to infect mosquitoes efficiently due to insufficient viremia. However, human–mosquito–human transmission has been important in epidemics of RRV-, ONNV-, and CHIKV-induced polyarthritis,[586,845,973] and equid–mosquito–equid transmission is important in epizootics of VEE.[810,948]

Other modes of transmission are occasionally important. Horses infected with VEEV may shed virus in nasal, eye, and mouth secretions as well as in urine and milk resulting in the potential for respiratory and oral route.[151,496] CHIKV can also be transmitted through oral secretions from animals with hemorrhagic manifestations[299] and during childbirth.[1052] Aerosol transmission of VEEV, CHIKV, and MAYV has occurred in laboratory settings,[151,464,543,971,981] and aerosolized VEEV has been developed as an agent of biological warfare.[896] EEEV persists in the feather follicles of infected pheasants, and transmission among penned pheasants can occur through feather picking and cannibalism.[854] Person-to-person transmission has not been reported.[543,810]

Veterinary Correlates and Animal Models

WEEV, EEEV, and VEEV, the first alphaviruses to be cultured, came to the attention of virologists because they caused fatal disease in horses and these viruses remain important equine pathogens.[106,219,639] EEEV and WEEV cause encephalitis in horses, while VEEV causes severe respiratory disease associated with leukopenia; encephalitis occurs with some epizootic strains. Getah virus causes an urticarial rash and hind leg edema in horses.[690] WEEV, EEEV, and Highlands J virus (HJV) cause disease in domesticated birds such as chickens, pigeons, pheasants, turkeys, and emus,[54,203,263,273,583,1009] and EEEV causes fatal disease in swine.[243] The alphaviruses associated with arthritis in humans have not been recognized as important causes of disease in animals or birds.

Good small animal models have been developed for many alphaviruses. In mice, alphaviruses generally infect lymphatic tissue, muscle, brown fat, brain, and spinal cord, but the extent and relative importance of infection at these sites differ among these viruses. For instance, RRV and Getah virus cause primarily myositis, VEEV causes reticuloendothelial infection, and

WEEV and EEEV cause encephalitis with neurons as the main target cells.[12,643,673] In mice infected with relatively avirulent strains of SFV, RRV, and VEEV, the acute encephalitic phase is accompanied by infection of oligodendroglial cells and demyelination.[122,880] For all alphaviruses, fatal disease in immunocompetent mice is usually associated with CNS infection even if encephalitis is not a manifestation of the human infection. For instance, SINV and SFV infections of mice are studied as models for acute viral encephalitis although these viruses usually cause fever, arthritis, or rash, and rarely CNS disease, in humans.[10,431,598,614,1007] Specifics of these animal model systems are discussed with the individual viruses.

Virulence

Virulence is a measure of the ability of the virus to cause fatal or severe disease. For most alphaviruses, this usually reflects the severity of neurologic disease, but disease in other organs can also reflect viral virulence. Outcome is influenced by characteristics of both the host and the virus. An early virus determinant of virulence is induction of IFN and susceptibility to IFN-mediated inhibition of replication. Viruses that induce IFN and are susceptible to IFN are generally attenuated.[16,119,194,288,300,905,933,1079] Most alphaviruses show an age-dependent susceptibility to disease.[12,98,363,673,711,878] Resistance increases with maturation and is associated with decreased virus replication in tissues at the site of virus inoculation and in target tissues (e.g., brain) and not with changes in induction of IFN or the ability of infected mice to mount a virus-specific immune response[347,354,673] although older mice increase ISG12 while young mice do not.[528] Avirulent alphavirus strains may replicate poorly even in newborn animals, while virulent strains can usually replicate well and cause disease in adult as well as newborn animals. The ability of a virus strain to cause fatal disease or a particular complication of infection is also often dependent on the genetic background of the host,[225,514,936,975,1001] but the genetic determinants of susceptibility are just beginning to be identified.[514,976]

For encephalitic alphaviruses, another viral determinant of virulence is their ability to enter the CNS efficiently (neuroinvasiveness). Many alphavirus strains can cause fatal disease after intracerebral or intranasal

inoculation, but not after subcutaneous or intraperitoneal inoculation, while others cause fatal disease after peripheral inoculation as well. The duration of viremia often correlates with virulence with virulent strains having slower clearance and sustaining longer viremias than avirulent strains.[437,438,440] Peripheral replication, viremia, neuroinvasiveness, and neurotropism (ability to replicate in CNS cells) all contribute to virulence.

The viral determinants of virulence have been most extensively studied in murine models for SINV, SFV, RRV, CHIKV, and VEEV infections. Viruses with altered virulence have been selected after chemical mutagenesis,[64,113] by passage in tissue culture,[75,202,484,554,964] by passage in mice,[351,629,964] by isolation of mAb escape mutants[1034] or plaque variants,[436] and by manipulation of cDNA virus clones. Nucleotide and amino acid changes affecting virulence have been mapped to the 5′ UTR, nsP1, nsP2, nsP3, E1, and E2, particularly the receptor-binding regions of the A and B domains[1032] (Fig. 6.4). Specifics are covered in the sections dealing with each of these viruses.

Persistence

There is substantial evidence that alphaviruses can persist after appearance of an immune response and clearance of infectious virus from the circulation and from tissue.[550] An active inflammatory process is present in CNS tissue from human cases of progressive WEEV months to years after resolution of acute encephalitis.[701,703] Viral RNA and proteins can be detected in the nervous system long after recovery of mice from SINV- or SFV-induced encephalitis and in the joints of humans and mice with CHIKV- and RRV-induced arthritis.[225,353,383,407,485,550,638,923,1008] It is postulated that this persistence of RNA is due to failure of the virus or the immune system to eliminate infected cells. Interestingly, passive antibody protection predisposes to transmission persistent infection and the late onset of progressive disease.[490,877]

Congenital Infection

Alphaviruses can be transmitted transplacentally. This has been documented in mice for RRV, SFV, VEEV, and Getah virus[1,38,641,932] and in humans for

RRV, WEEV, VEEV, and CHIKV.[5,285,467,891,988] In mice, the virus infects the placenta where it is able to persist and spread to the fetus despite the development of maternal antibody. The outcome of fetal infection is dependent on the timing of infection relative to transfer of maternal antiviral IgG to the fetus. Fetuses are protected if transfer occurs prior to infection, but transfer of antibody after fetal infection does not mediate recovery.[641] In monkeys, congenital infection with VEEV induces malformations of the brain and eye.[575] In humans, no abnormalities were observed in infants infected with RRV at 11 to 19 weeks' gestation; however, earlier infection may lead to fetal death.[5] Epidemics of VEE are associated with increases in spontaneous abortion.[810,1057] No effect on pregnancy outcome was identified during the CHIKV outbreak on Réunion Island,[285] although perinatal infection rates have approached 50% in Latin America.[988]

PATHOGENESIS AND PATHOLOGY IN MOSQUITOES

The ability of alphaviruses to infect mosquitoes efficiently with dissemination to and replication in the salivary glands is essential for maintaining the natural cycle of transmission. Not all mosquitoes taking a blood meal from a viremic host will become infected, and not all infected mosquitoes develop disseminated infections required for transmission. Many alphaviruses preferentially infect a narrow range of mosquito species, and this host specificity plays an important role in determining the geographic distribution of the virus. Even within a species, strains of mosquitoes may vary in susceptibility to infection. *Ae. albopictus* collected from different geographic regions show differences in susceptibility to infection with CHIKV and in the amount of virus produced after infection.[972] Field and laboratory populations of *Culex tarsalis* differ in susceptibility to WEEV.[413] These differences may reflect geographic genetic variation or differences in the microbiome composition, which can affect innate immune activity and responses as well as susceptibility and transmission. Strains of virus also differ in their abilities to infect mosquitoes, and laboratory-adapted strains may establish infection relatively inefficiently.[676,875,876,1019,1023]

The extrinsic incubation period, or time between taking an infected blood meal and ability to transmit infection, is dependent on the rapidity of virus replication and dissemination to the salivary glands. This period is relatively short (2–7 days) for alphaviruses compared to other arboviruses.[228,875]

Entry and Sites of Primary Replication

Posterior midgut epithelial cells are the initial sites of infection,[100,677,753,873,1059] and infection is facilitated when virus in the serum is concentrated next to these cells as the blood meal clots (Fig. 6.8).[1061] Susceptibility of mosquitoes to alphavirus infection is determined in large part by the ability of the virus to infect midgut epithelial cells.[413,487,875] Changes both in the virus and vector can affect this interaction.[1090] WEEV rapidly fuses with microvillar membrane preparations from *Cx. tarsalis* mosquitoes, and both WEEV and CHIKV bind better to membranes from susceptible mosquitoes than to membranes from refractory mosquitoes[413,666] consistent with a role for viral structural proteins as determinants of vector specificity, midgut infection, and dissemination.[753,1000,1020,1023] Natural mutations in both the E2 and E1 proteins of CHIKV increase initial infection of *Ae. albopictus* midgut cells to permit more efficient transmission by this invasive species.[998,999] nsP3, a determinant of vector transmission by ONNV, the only alphavirus transmitted by *Anopheles* mosquitoes, is sufficient to confer CHIKV infection competence for these mosquitoes.[676,858]

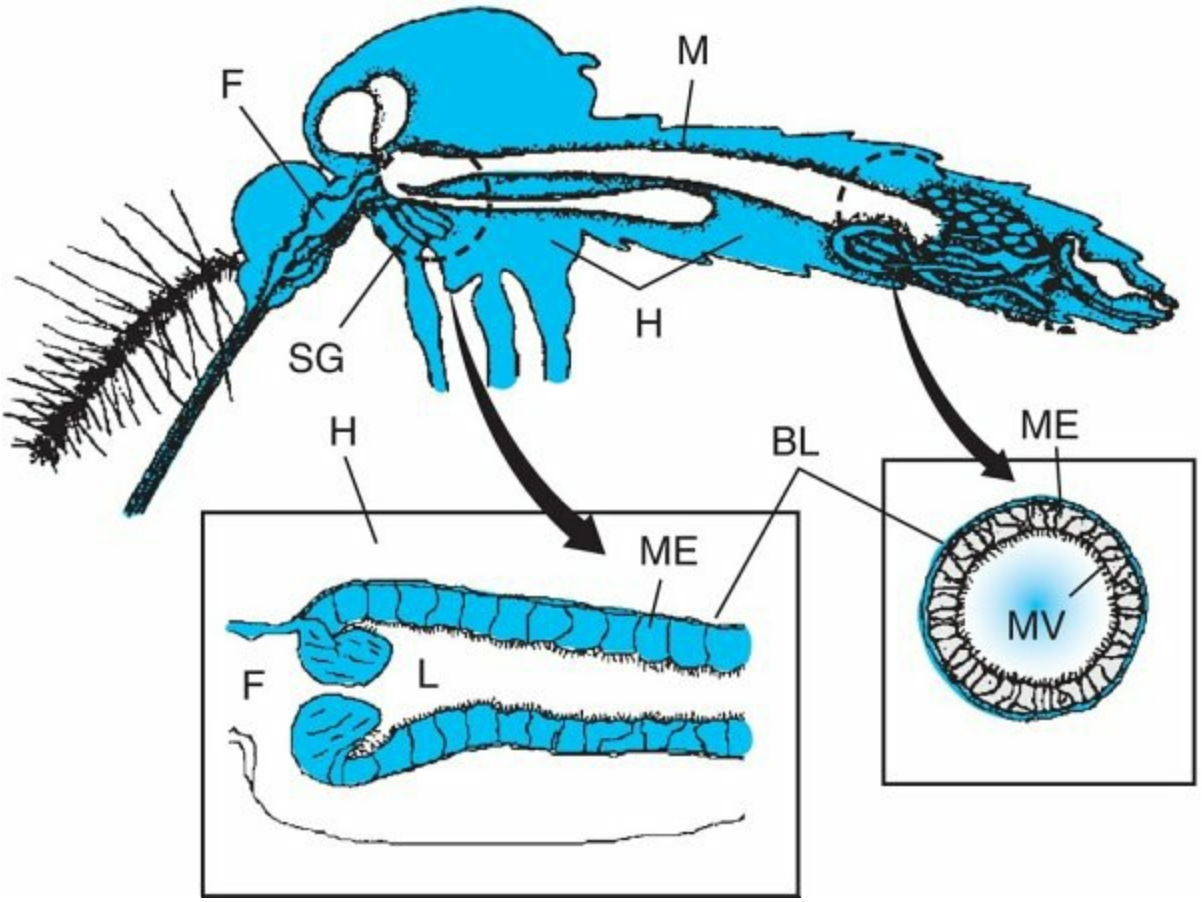

FIGURE 6.8 Diagram of mosquito internal anatomy showing the essential sites for alphavirus infection. BL, basal lamina; L, lumen; F. foregut; M, midgut; ME, midgut epithelium; MV, microvilli or brush border; SG, salivary gland. (Adapted from Weaver SC, Scott TW, Lorenz LH, Lerdthusnee K, Romoser WS. Togavirus-associated pathologic changes in the midgut of a natural mosquito vector. J Virol 1988;62(6):2083–2090.)

Receptors for mosquito infection by alphaviruses remain enigmatic. The high-affinity laminin receptor A can serve as a receptor for VEEV and SINV on the surface of C6/36 larval *Ae. albopictus* cells,[581,1040] and proteins of 60 and 38 kDa have been identified as putative receptors for CHIKV on brush-border membranes from *Ae. aegypti*.[666] However, the roles of these proteins remain unclear because their distribution does not explain alphavirus–vector specificity. The recently identified cell adhesion molecule Mxra8, which

serves as a receptor for arthritogenic, but not encephalitic alphavirus infection of vertebrate cells, does not appear to have a mosquito ortholog.[1108]

Host cell membrane cholesterol levels affect the efficiency of alphavirus entry.[579] Mosquitoes, like other insects, do not synthesize cholesterol and obtain sterols needed for reproduction and development from dietary blood. Cholesterol-independent mutants of SFV replicate better than parental SFV in cholesterol-depleted C6/36 cells and in adult *Ae. albopictus* mosquitoes.[20]

Replication in midgut epithelial cells is regulated by the RNAi innate antiviral response that is triggered by virus-derived dsRNA and siRNAs.[138,476,487,678] RNAi affects infection rate of the midgut, intensity of infection, and virus dissemination to secondary tissues and is probably an important determinant of vector competence, which depends on modulating virus replication to allow the vector to survive for transmission.[476,487] In addition to small RNAs, CHIKV-infected mosquitoes generate a viral-derived DNA (vDNA) that is essential for viral tolerance and survival.[321]

Spread

For the mosquito to become capable of transmission after a viremic blood meal, virus must disseminate from the midgut into the hemocoel to reach the salivary glands via the hemolymph.[875] Virus buds primarily from the basolateral surface of the infected midgut epithelial cells and accumulates next to the basal lamina,[875] a layered structure composed of mucopolysaccharide that acts as a barrier to hemocoel entry. Dissemination of SINV from the midgut of *Ae. aegypti* mosquitoes is dependent on expression of endosomal proteins UNC93A and synaptic vesicle-2.[139] Replication of ONNV in *Anopheles gambiae* is controlled by expression of heat shock protein cognate 70B.[902,903] Although the basal lamina surrounding the midgut appears to be a major barrier to dissemination, it is degraded by matrix metalloproteinases during blood meal digestion, probably providing an opportunity for virus escape into the hemocoel.[223] Infected midgut epithelial cells can degenerate and slough into the lumen 36 to 48 hours after infection, and this process may facilitate penetration of the virus into the hemocoel.[875,1060]

Infection of salivary gland acinar cells requires that the virus again

traverse a basal lamina, a process that may depend on hemolymph titer and replication in adjacent organs such as the fat body, an important site for virus amplification.[1047,1059] Other organs may or may not become infected. In addition to the midgut, EEEV infects the fat body, muscle, and salivary glands without involving the nervous system or the ovarioles,[873,1059] while VEEV infects the nervous system[1047] and SINV infects respiratory tissue.[96]

Once salivary gland infection is established, virus matures by budding into apical cavities or randomly into vesicles, basolaterally and apically. This process may be associated with cytopathic changes in the salivary glands.[642] The rapidity of virus replication and dissemination to the salivary glands is dependent on the ambient temperature and can be as short as 2 to 3 days for EEEV[875] or CHIKV.[228] Higher temperatures may accelerate the alphavirus transmission cycle in warm months,[795,1003] although WEEV transmission by *Cx. tarsalis* can decrease with temperatures greater than 30°C.[796] In general, virus content of an individual mosquito reaches a peak within 4 to 7 days after infection.[642,875] Some tissues (e.g., fat body) produce large amounts of virus, while others (e.g., head ganglia) produce small amounts and others (e.g., ovarioles and malpighian tubules) remain virus-negative.[640]

Vector competence for alphaviruses is also dependent on the microbiome[34,62] and the introduction of endosymbiotic *Wolbachia* bacteria into *Ae. aegypti* and *Ae. albopictus* decreases vector competence for CHIKV[25,655,667]; conversely, CHIKV infection alters the microbiome diversity in *Ae. albopictus*.[1114] In a *Drosophila* cell culture model, a comparable effect of *Wolbachia* on SFV infection involves early inhibition of viral genome replication without a role for the bacterial transcriptional response of the insect cell small RNA pathways.[778]

For transovarial transmission to occur, virus must be able to infect oocytes early in development. Failure to infect ovarioles precludes efficient transovarial transmission of most alphaviruses.[96,213,873,1047] However, the presence of RRV and CHIKV in field-caught male mosquitoes suggests that vertical transmission can occur.[565,784,978] Eggs can also be infected after they have been fertilized. Low levels of vertical transmission have been documented in the laboratory for RRV in *Aedes vigilax*, for SINV in *Aedes australis*, and for CHIKV in *Ae. aegypti* and *Ae. albopictus*,[174,616,721] and venereal transmission of the latter has also been reported.[616] Vertical

transmission in nature has been reported for RRV, SINV, and WEEV.[213,291,565] However, reports of the persistence of CHIKV RNA without the presence of infectious virus after putative vertical transmission underscore the need to perform infectious assays rather than relying on RT-PCR alone.[1088]

Pathology, Persistence, and Host Response

Although generally considered to be benign for the invertebrate vector, alphavirus infection may generate CPEs in the vector midgut and can reduce survival and reproductive capacity.[874,875] The IMD pathway of innate immunity can be activated by infection to decrease virus replication.[52] Suppression of the RNAi response increases virus replication and mosquito mortality after infection.[180,476] Mosquitoes generally remain infected and infectious for life,[642,875] although WEEV transmission efficiency decreases with time after peaking about 7 to 10 days after oral infection.[796] In the fat body and salivary glands, EEEV infection is persistent, although titers decline after the acute phase of infection, decreasing efficiency of transmission.[873,1059]

ALPHAVIRUSES ASSOCIATED PRIMARILY WITH ENCEPHALITIS

Eastern Equine Encephalitis

EEE was first recognized as a disease of horses in the northeastern United States. In the summer of 1831, more than 75 horses died in 3 coastal counties of Massachusetts.[372] Between 1845 and 1912, epizootics were recorded on Long Island, in North Carolina, New Jersey, Florida, Maryland, and Virginia.[372,875] The virus responsible for EEE was first isolated in 1933 from the brains of affected horses in New Jersey and Virginia during a widespread outbreak that also involved coastal areas of Delaware and Maryland.[106] A South American virus originally considered a subtype of EEEV, but recently reclassified to the species *Madariaga virus* (MADV), was first isolated in 1936 from a horse in Argentina.[838] Although human EEE was suspected

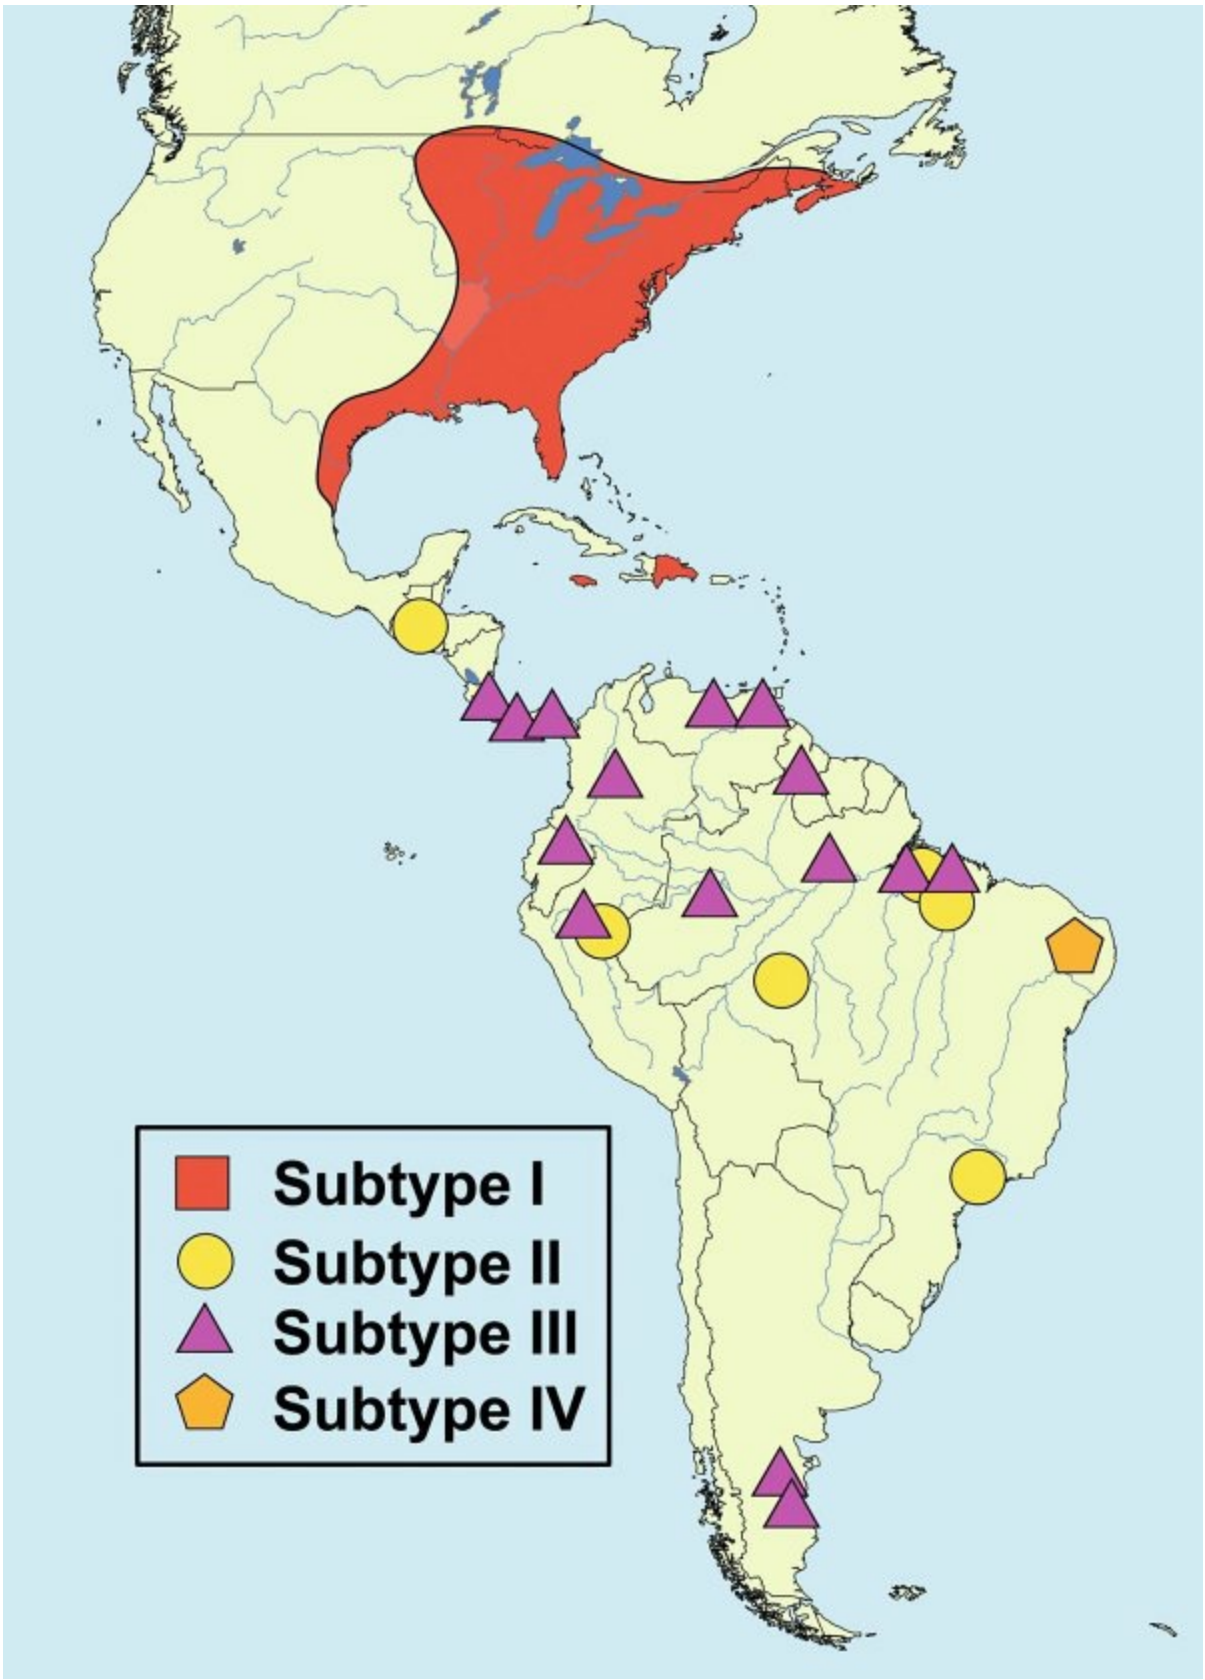
earlier, it was not demonstrated until 1938 when an outbreak in the northeastern United States resulted in 30 cases of fatal encephalitis in children living in the same areas as equine cases. At that time, EEEV was isolated from the CNS of humans, as well as from pigeons and pheasants.[273,1062]

Based on seasonality, location of cases near salt-marsh areas, lack of evidence of transmission from horse-to-horse through contact, short period of equine viremia, and geographic distribution of cases, it was postulated that insects transmitted infection and that birds were likely to be the reservoir hosts.[966] The first arthropod isolates were actually from chicken mites and lice that can transmit infection only inefficiently.[234,875] Transmission of EEEV by *Aedes sollicitans* in the laboratory was accomplished in 1934,[635] and subsequently multiple *Aedes* species were shown to be competent vectors. However, recovery of EEEV from naturally infected mosquitoes did not occur until 1949 with isolates from *Mansonia perturbans* in Georgia[415] and *Culiseta melanura* in Louisiana.[157] Subsequent work showing the competence of *Cs. melanura* and a consistent association between infected birds and the isolation of virus from this vector has led to the current understanding that *Cs. melanura* is the primary enzootic vector for North American EEEV (NA-EEEV) strains.[35,197,538,875] However, in some Gulf Coast regions, *Culex* mosquitoes are considered the primary enzootic vectors.[195]

Epidemiology

NA-EEEV causes localized outbreaks of equine, pheasant, and human encephalitis in the summer. NA-EEEV is enzootic in North America from Maine southward along the Atlantic seaboard and Gulf Coast to Texas, in the Caribbean, and in Central America[312] (Fig. 6.9). Inland foci exist in the Great Lakes region and have extended to South Dakota and Quebec.[170,567] In the northeastern United States, the primary enzootic cycle is maintained in shaded swamps where the vector is the ornithophilic mosquito *Cs. melanura*[35,875] (Fig. 6.10). Modeling suggests that in Florida, transmission is associated with tree plantations and cardinal abundance.[251,477] In most locations, birds are the primary reservoir host and many species are susceptible to infection.[495] The amplifying species for NA-EEEV are wading

birds, migratory passerine songbirds, and starlings.[197,250,503,625] Young birds are probably important for virus amplification because they are more susceptible to infection, have a prolonged viremia, and are less defensive toward mosquitoes.[197] In addition to occasional mammalian blood feeding by *Cs. melanura*,[650] multiple mosquito species, such as *Coquillettidia perturbans*, Ae. (*Ochlerotatus) canadensis*, and various *Aedes* species, may serve as bridge vectors for transmission to susceptible mammals.[35,195,645,875] In temperate areas, the virus is probably periodically reintroduced from subtropical areas of year-round transmission by migratory viremic birds or wind-borne infected mosquitoes.[881,1056,1077,1099] Reptiles and amphibians with viremias that are prolonged and persist through hibernation may maintain the virus focally.[86,195,335,1076] There is no convincing evidence for overwintering in mosquitoes and ovarioles are not involved after experimental EEEV infection of *Cs. melanura*.[873]



Subtype I
Subtype II
Subtype III
Subtype IV

FIGURE 6.9 Geographic distribution of EEEV. The map shows the locations for isolation of NA-EEEV (subtype I) and the three SA-EEEV lineages (subtypes I, II, and III; now Madariaga virus). (From Weaver SC, Powers AM, Brault AC, Barrett AD. Molecular epidemiological studies of veterinary arboviral encephalitides. Vet J 1999;157(2):123–138.)

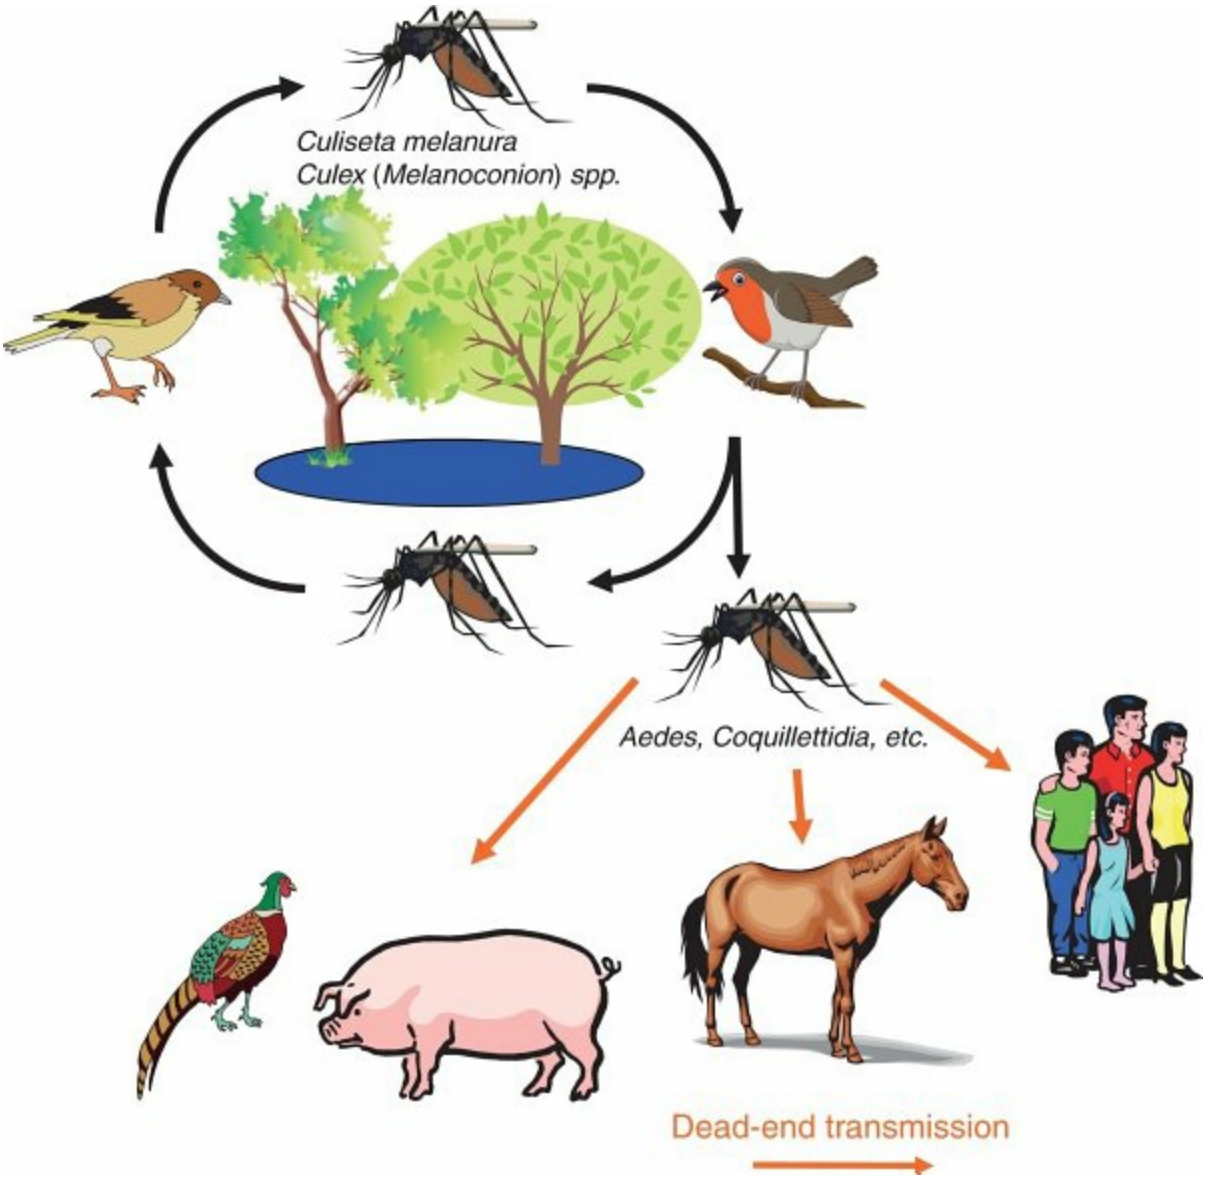


FIGURE 6.10 Enzootic transmission cycle of EEEV in North America. This is an example of an alphavirus that uses a species of

mosquito with different host preferences to bridge from the enzootic avian-ornithophilic mosquito (*Culiseta melanura*) cycle to infect mammals such as humans and horses. In Alabama, *Culex* (*Melanoconion*) spp. mosquitoes with broader host feeding patterns serve as enzootic EEEV vector, as they do for the closely related Madariaga virus in Central and South America, where rodents may also serve as enzootic hosts in addition to birds. Similar mechanisms are operative in transmission of Sindbis virus to humans.

MADV, originally comprising three antigenic South American subtypes of EEEV (SA-EEEV), is enzootic in Central and South America including the Amazon Basin (Fig. 6.9).[155] In South and Central America, the enzootic cycle is maintained in moist forests where *Culex* (*Melanoconion*) spp. appear to be the primary vectors.[875,1005] Forest-dwelling rodents, bats, and marsupials are frequently infected and may provide a reservoir, but these transmission cycles are not well characterized.[36,875]

Morbidity and mortality

EEEV is the most virulent of the encephalitic alphaviruses with a high mortality due to encephalitis. Most cases are associated with exposure to wooded areas adjacent to swamps and marshes[128] with more cases in males than females.[259,567] Children under 10 years of age are most susceptible[259] with 1 in 8 infections resulting in encephalitis compared to 1 in 23 for adults.[322] The case-fatality rate was 60% to 70% in earlier studies and 30% to 50% in more recent studies, with the highest rates in children and the elderly[246,680,660,682,683] Most strains of MADV appear to be much less virulent, but lineage III viruses can cause fever and encephalitis.[17,87,146,155,217,837]

Origin and spread of epidemics

In the northern part of the North American range, human and equine cases of EEE occur between July and October, while in the southern region, cases can

occur throughout the year.[775] In the Caribbean, outbreaks appear to be linked to virus introduction by southbound migratory songbirds.[875] In North America, human and equine cases usually occur near hardwood freshwater swamps maintaining enzootic transmission among passerine birds. Outbreaks are initiated when the virus spreads from the enzootic cycle involving ornithophilic mosquitoes into mosquito populations that feed on a wider variety of hosts (Fig. 6.10). Multiple species of mosquitoes with catholic feeding habits have been implicated as potential bridge vectors in different regions.[35,195,645,712,851,875]

Cases of equine encephalitis are usually the first indication of an outbreak. In the absence of equid immunization, epizootics appear approximately every 5 to 10 years and are associated with heavy rainfall and warmer water temperatures that increase the populations of enzootic and epizootic mosquito vectors.[547] Many epidemics have occurred in Massachusetts and surrounding states,[259,567] but the largest recorded outbreak occurred in 1947 in Louisiana and Texas with 14,344 cases of equine encephalitis and 11,722 horse deaths. The virus is widespread, but since 1955, only an average of 8 cases of EEE have been diagnosed in humans each year[567] (Fig. 6.11). Recently, outbreaks and enzootic EEEV activity have been detected as far north as Vermont, Maine, and Nova Scotia, suggesting a northward expansion.[78,567,580,859] As of late October, 2019, more than 30 human EEE cases were reported in the United States, the most in over 50 years (https://www.cdc.gov/easternequineencephalitis/index.html).

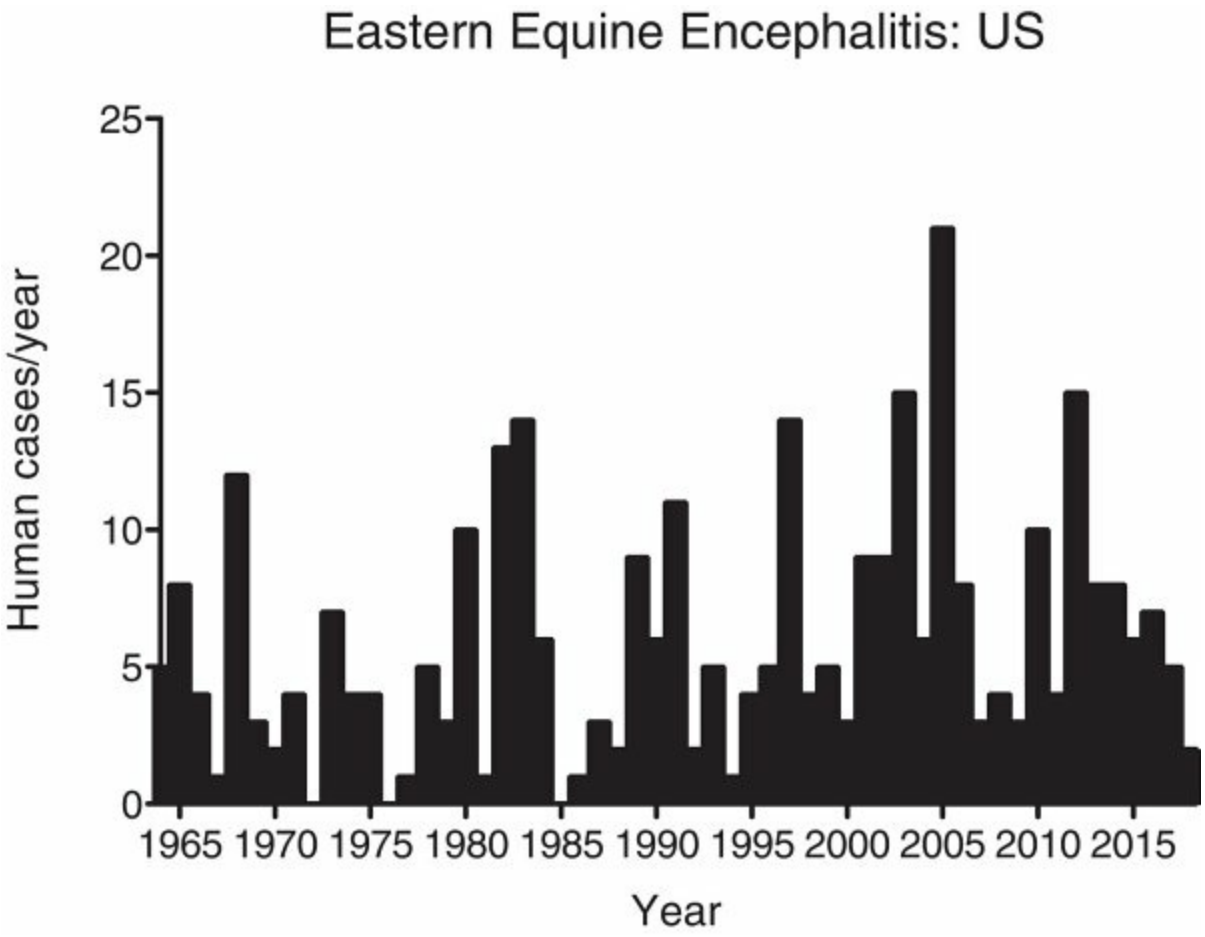

FIGURE 6.11 Numbers of human cases of eastern equine encephalitis reported annually in the United States since 1964. Based on data from the Centers for Disease Control and Prevention.

Molecular epidemiology

Antigenic differences between EEEV and MADV (formerly SA-EEEV) have long been recognized,[150] and the viruses can be distinguished by reactivity with mAbs to the E1 glycoprotein,[815] as well as by neutralization assays.[101] Based on their sequence divergence as well as ecologic and pathogenesis differences, the three SA-EEEV lineages were recently classified as a different alphavirus species, MADV.[37] Sequence comparisons indicate that EEEV/MADV has evolved independently in North and South America for thousands of years or longer reaching 23% to 24% nucleotide and 9% to 11%

amino acid sequence divergence.[37] There is one lineage of EEEV and three lineages of MADV: on the coasts of South and Central America (originally EEEV lineage II), in the Amazon Basin (lineage III), and in Brazil (lineage IV)[101,1056] (Fig. 6.9). Isolates of EEEV are highly conserved, differing over a large geographic range and nearly 100 years by less than 3% in nucleotide sequence consistent with birds as highly mobile vertebrate reservoir hosts. The calculated annual nucleotide substitution rates are 2.1×10^{-4} for MADV and 2.7×10^{4} for EEEV.[101,1056] EEEV enzootic in Florida appears to be the source of frequent introductions into the northeastern United States.[957] The two main lineages of MADV (II and III) exhibit 17% to 21% nucleotide divergence and 3% to 5% amino acid divergence and are evolving at a slower rate (1.2×10^{-4} substitutions/nt/year).[37] MADV lineages appear to be evolving locally, consistent with small mammals as the reservoir hosts.[37,1053,1056] The recent detection of MADV in Haiti suggests a possible expansion in its geographic range.[87]

Clinical Disease and Pathology

Illness caused by infection with EEEV may consist of 1 to 2 weeks of fever, chills, malaise, and myalgias followed by recovery. In cases of encephalitis, these prodromal symptoms are followed by the fulminant onset of increased headache, vomiting, restlessness, irritability, seizures, obtundation, and coma.[206,254,259,901] Meningismus is frequent, and focal signs including cranial nerve palsies and hemipareses are not uncommon.[206,775] Hyponatremia due to inappropriate secretion of antidiuretic hormone is a common complication, and edema of the face and extremities has been noted.[206,254] Death typically occurs 2 to 10 days after onset of encephalitis.

CSF examination shows increased pressure and white cell counts ranging from 10 to 2,000/μL. Polymorphonuclear leukocytes are often abundant early in disease with a shift to mononuclear cells over the first few days of illness.[206,900] The presence of red blood cells or xanthochromia is not uncommon.[775] CSF protein levels are increased, while glucose is low to normal.[254,775] EEG findings are relatively nonspecific, usually showing slowing.[206] CT scans may be normal or show only edema.[206,775] Magnetic resonance imaging (MRI) scans are more often abnormal with focal lesions most commonly observed in the thalamus, basal ganglia, and brainstem.[206]

Poor outcome is predicted by high CSF white cell count or severe hyponatremia, but not by the size of the radiographic lesions.[206] Recovery is more likely in individuals who have a long (5–7 days) prodrome and do not develop coma.[775,900] Sequelae, including paralysis, seizures, and cognitive deficits, are common, with 35% to 80% of survivors, particularly children, having significant long-term neurological impairment.[206,254,259]

Histopathology on fatal cases demonstrates a diffuse meningoencephalitis with edema, widespread neuronal destruction, perivascular cuffing with polymorphonuclear as well as mononuclear leukocytes, and vasculitis with vessel occlusion in the cortex, basal ganglia, and brainstem. The spinal cord is frequently spared.[254,274,937] Virus antigen is localized to neurons and neuronal death is marked by cytoplasmic swelling and nuclear pyknosis.[301,901] Apoptotic glial and inflammatory cells are frequently found in the regions of affected neurons.[254,301]

Veterinary Correlates, Host Range, and Animal Models

EEEV is an important cause of disease in horses, pheasants, emus, and turkeys and can also cause encephalitis in penguins, sheep, deer, dogs, seals, and pigs.[69,203,273,360,583,618,854,962] Horses develop signs of depression, progressive incoordination, seizures, and prostration. The case-fatality rate is 80% to 90%. Most survivors are left with neurologic sequelae.[875] Birds vary in their susceptibility, with some species developing disease, while many others show no morbidity or mortality despite a prolonged viremia.[495,583] Chickens, turkeys, emus, and whooping cranes often develop fatal viscerotropic disease with multifocal necrosis in the heart, kidney, and pancreas and lymphoid depletion in the thymus, spleen, and bursa.[203,360,1009] Pheasants develop encephalitis with 50% to 70% mortality, while penguins develop nonfatal encephalitis.[583,854]

Laboratory studies of macaques, marmosets, mice, guinea pigs, and hamsters generally confirm the neurovirulence of EEEV for mammals.[106,274,571,725,823,937,1030,1095] Peripheral replication is in fibroblasts, skeletal muscle, and osteoblasts, while macrophages are resistant to infection due to restriction by hematopoietic cell–specific miRNA 142-3p.[992,1030]

Macaques and marmosets develop encephalitis, while New World *Aotus* owl monkeys develop viremia without evidence of disease.[248] EEEV can initiate CNS infection in experimental animals by infecting choroid plexus epithelial cells or olfactory neurons.[571,937] Young mice show extensive neuronal damage and rapid death.[1030] Older mice are more resistant to peripheral inoculation, but can develop fatal disease and after intracerebral inoculation develop seizures and die rapidly.[298,571] Guinea pigs develop encephalitis after aerosol exposure to EEEV with neuronal death, inflammation, and vasculitis.[823] Hamsters develop a biphasic fatal illness with hepatitis and lymphatic organ infection followed by encephalitis characterized by extensive vasculitis and microhemorrhages.[725]

Virulence

EEEV is generally more virulent than MADV in humans and most experimental animals.[16,155,875] Construction of chimeric viruses and testing in mice indicate that both structural and nonstructural proteins contribute to virulence.[13] Viruses with a temperature-sensitive, small-plaque phenotype and decreased virulence for mice and hamsters have been selected after chemical mutagenesis.[113] One determinant of the neurovirulence of EEEV is the ability to bind HS. Increased E2 HS binding and miR2142-3p are associated with decreased tropism for lymphoid tissue and production of little IFN leading to increased likelihood of virus spread to the CNS.[297,298,992,993]

Diagnosis, Treatment, and Prevention

Diagnosis is based on virus isolation, detection of RNA, or serology (IgM or seroconversion for IgG). Virus can be isolated from CSF, blood, or CNS tissue by inoculation into newborn mice or a variety of tissue culture cells. Detection and identification of virus in field and clinical samples can also be accomplished through various nucleic acid amplification assays.[529] Antibody is usually measured by enzyme immunoassay (EIA) with detection of IgM in serum and CSF particularly useful.[129,130] Although specific therapies are in development for EEE,[456] currently treatment is supportive.[790]

Infection in mosquito populations can be monitored by virus isolation, by nucleic acid amplification, or by seroconversion of sentinel pheasants or

chickens. This information can be used to guide insecticide spraying to reduce adult and larval mosquito populations and prevent human cases. A formalin-inactivated vaccine (EEEV PE-6) is available for horses and emus and for investigational use in humans to protect laboratory workers. This vaccine does not induce significant neutralizing or anti-E2 antibody to MADV.[944] Experimental vaccines include replicon particles and chimeric viruses and rationally attenuated viruses.[246,729,786,823]

Western Equine Encephalitis

Epizootics of viral encephalitis in horses were described in 1908 in Argentina, and in 1912, 25,000 horses were estimated to have died in the central plains of the United States.[838] In the summer of 1930, a similar epizootic occurred in the San Joaquin Valley of California causing an estimated 6,000 cases of equine encephalitis. During this outbreak, WEEV was isolated from the brains of two affected horses by intraocular inoculation of another horse, and this virus was subsequently used to infect other animals.[639] WEEV was suspected at that time to be a cause of human disease, and in 1938, WEEV was recovered from the brain of a child with fatal encephalitis.[415]

Mosquitoes were implicated in WEEV transmission when it was demonstrated that horses developed a viremia[414] and that experimentally infected *Ae. aegypti* mosquitoes were capable of transmitting the virus to horses.[478] However, it was not until the summer of 1941 during a widespread epidemic in the northern plains of the United States and Canada that the virus was isolated from naturally infected *Cx. tarsalis* mosquitoes.[371] Subsequently, WEEV was isolated from *Cx. tarsalis* in other epizootic sites and recognized to be the principal vector.

Other New-World WEEV Complex Viruses

The WEE complex in the New World includes three viruses in addition to WEEV: HJV, Fort Morgan virus (FMV, including the subtype Buggy Creek), and Aura virus.[132] These viruses have different ecological niches and vary in virulence. Only WEEV is recognized to cause human disease.[128] Viruses in the WEE complex found in the Old World (e.g., SINV and Whataroa virus) are discussed in the section on SINV. WEEV, HJV, and FMV all belong to

the lineage that diverged since recombination between a SIN-like virus and an EEE-like virus.[368] Aura virus is a "prerecombinant" virus (Fig. 6.5).

Highlands J virus

WEEV-like viruses were first isolated in the eastern part of the United States in 1952, and in 1960, the prototype HJV was isolated from a blue jay in Florida.[393] HJV is enzootic on the U.S. East Coast and is maintained in a cycle similar to that of EEEV with *Cs. melanura* the primary vector and migrating birds the primary reservoir. All alphaviruses in the WEEV complex isolated in the eastern United States are strains of HJV.[385] Rates of divergence of WEEV and HJV of 0.1% to 0.2% per year have been estimated.[179] HJV can occasionally cause encephalitis in horses[469] and is a recognized pathogen for a variety of avian species including turkeys, pheasants, partridges, ducks, emus, hawks, and whooping cranes.[26,263,360,1056]

Fort Morgan, Buggy Creek, and Stone Lakes viruses

FMV and its close relatives Buggy Creek virus (BCRV) and Stone Lakes virus have been isolated from cliff swallows, sparrows, and swallow nest bugs.[99,384,411] These viruses are found primarily in the western regions of North America[724,745] and are transmitted to swallows and sparrows that parasitize swallow nests by cimicid swallow nest bugs (*Oeciacus vicarius*).[110,112,135,708] These viruses cause encephalitis in nestling house sparrows, but are not recognized as pathogens for humans.[707]

Aura virus

Aura virus was isolated in 1959 in Brazil from *Culex* (*Melanoconion*) spp. collected near the Aura River and later from *Aedes serratus* in Brazil and Argentina.[154] This virus may be related to the New World "SIN-like" virus that recombined with EEEV to produce WEEV and related postrecombinant viruses.[27,829] It is relatively nonpathogenic for mice and has not been linked to human disease.

Epidemiology

WEEV is widely distributed in the western plains and valleys of the United

States and Canada and in South America. In North America, WEEV is maintained in an endemic cycle involving domestic and passerine birds (particularly finches and sparrows) and *Cx. tarsalis*, a mosquito well-adapted to irrigated agricultural areas.[128] Occasional isolations have been made from *Aedes melanimon* and *Aedes dorsalis*, also competent vectors. There is evidence for a secondary transmission cycle involving *Aedes melanimon* and the blacktail jackrabbit[128,374] in addition to the *Cx. tarsalis*–avian cycle. Increased transmission is associated with greater abundance of *Cx. tarsalis*.[61] Serosurveys and virus isolations provide evidence of natural infection in chickens, pheasants, rodents, rabbits, ungulates, tortoises, and snakes. In some areas of South America, most mosquitoes from which WEEV has been isolated feed primarily on mammals, and antibodies are common in small mammals including rats and rabbits, while in other areas antibodies are found primarily in birds.[894,1056] A survey of horses in the Pantanal region of Brazil found 36% seropositivity for WEEV.[738] Interseasonal persistence can occur in saltwater marshes perhaps by overwintering in adults.[793,794]

Morbidity and mortality

WEEV in the western United States has caused epidemics of encephalitis in humans, horses, and emus, but the case-fatality rate of 3% for humans, 20% to 40% for horses, and 10% for emus is lower than for NA-EEEV. In older children and adults, males are two to three times more likely to develop disease than females.[578] The estimated case-to-infection ratio is 1:58 in children under 5 years and 1:1,150 in adults.[128] Clinically apparent disease is most common in the very young and those over 50.[578] Severe disease, seizures, fatal encephalitis, and significant sequelae are more likely to occur in infants and in young children.[235,501] The case-fatality rate rises to 8% in those over 50.[578] Accidental infections involving aerosolized virus in the laboratory have been reported and WEEV is regarded as a potential bioterrorist threat.[896] The rare occurrence of significant human disease during equine outbreaks of WEE in South America may be related to the feeding habits of the vector or to a lower virulence of South American strains for humans and horses.[205,838]

Origin and spread of epidemics

During the 20th century, large, often widespread, epidemics of equine encephalitis occurred from mid-June to late September in North America with significant spillover into the human population. These outbreaks correlated with regional increases in the population densities of *Cx. tarsalis*.[715] Major epizootics occurred every 2 to 3 years in the United States from 1931 to 1952. In 1941, more than 3,400 human WEE cases were reported in the plains of the western United States and Canada with attack rates of up to 167 cases/100,000 population.[128] During the 1952 epidemic in California's Central Valley, attack rates were 36 cases/100,000 humans and 1,120/100,000 equids.[128] Seroprevalence in humans was 34% in rural areas of California endemic for WEEV in 1960[286] but only 1.3% to 2.6% in similar areas in 1993 to 1995.[791] Beginning in the late 20th century, human cases of WEE steadily declined with the last detected in North America in 1998[77] (Fig. 6.12) and in South America in 2009.[205] This decline does not appear to be due to a decrease in virus virulence or a change in vector competence,[269,792,1104] but WEEV population declines and genetic drift could provide a partial explanation.[77,664] However, recent reverse genetic studies indicate no loss in fitness, suggesting ecologic changes as the explanation for the decline in WEEV circulation.

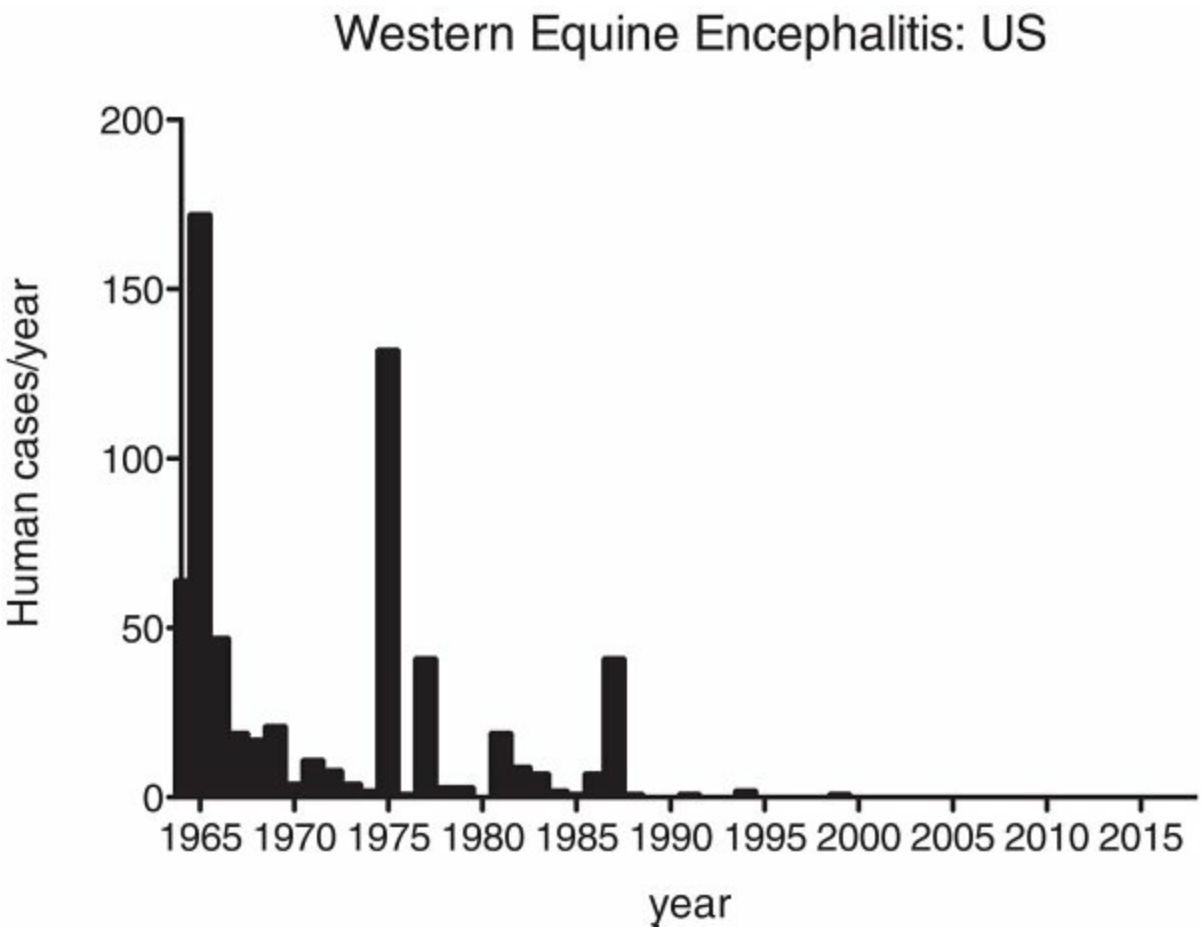

FIGURE 6.12 Numbers of human cases of western equine encephalitis reported annually in the United States since 1964. Based on data from the Centers for Disease Control and Prevention.

In South America, both epizootic (equine-virulent) and enzootic (not associated with disease) strains circulate.[82] Sequence analysis of the viruses found at the initial focus of the 1982 WEE epizootic in Argentina suggested that the enzootic virus was the source of a virulent variant, which emerged by mutation or selection to cause the epizootic. An epizootic vector in South America is *Aedes albifasciatus* and rabbits may serve as an amplifying host.[1056]

Molecular epidemiology

WEEV has three major lineages: one was isolated during the 1982 to 1983 epizootic in Argentina, a second has been sampled in Brazil and Argentina, and a third is widely distributed in the western half of North America.[77,1054,1056] Within California, separately evolving lineages have been identified in the Central Valley and the southern part of the state.[509]

Clinical Features and Pathology

WEEV causes encephalitis with signs and symptoms similar to those of EEE. Transmission can occur by aerosols as well as by mosquitoes.[787] There is a 3- to 5-day prodrome of fever and headache that may progress to restlessness, tremor, irritability, nuchal rigidity, photophobia, altered mental status, and paralysis.[264,501,628] Infants develop rigidity, seizures, and a bulging fontanel.[264,628] Transplacental transmission results in perinatal infection manifesting within the first week of life as fever, failure to feed, and seizures.[628,891] CSF pleocytosis is typical with 100 to 1,500 cells/μL. Neutrophils are present early in disease and mononuclear cells later.[628] In infants less than 1 year of age, approximately 60% of survivors have brain damage, and in some, the disease is progressive.[628,701] Common problems are cognitive deficits associated with quadriplegia, spasticity, recurring seizures, cortical atrophy, ventricular dilation, and intracranial calcification.[235,264,702,927] In older individuals, recovery is typically rapid with remission of signs and symptoms within 5 to 10 days, and sequelae are less common (5%).[264] Increased susceptibility of the very young compared to adults is likely related to the maturation-dependent ability of neurons to respond to IFN and limit virus replication.[153]

Pathology of acute cases of WEE shows leptomeningitis and perivascular cuffing with neutrophils in the earliest cases and lymphocytes, plasma cells, and macrophages at later times. In areas of neuronal degeneration, there is inflammation accompanied by endothelial hyperplasia, petechial hemorrhages, and glial nodules. Lesions are found primarily in the basal ganglia, brainstem, cerebellum, cerebral cortex, and spinal cord with areas of focal necrosis and demyelination in the subcortical white matter and basal ganglia.[264,702,703]

Occasionally in infants and children, there is pathologic evidence of progressive disease consistent with persistent infection.[628,702,703] Individuals

surviving months to years after onset of encephalitis (often with progressive disease) may have cystic lesions, gliosis, and demyelination with areas of active mononuclear inflammation.[702,703]

Veterinary Correlates, Host Range, and Animal Models

WEE was first recognized as a neurologic disease of equids characterized by fever, incoordination, drowsiness, and anorexia leading to prostration, coma, and death in approximately 40% of the affected animals.[219] Emus also develop symptomatic, often fatal, disease characterized by ataxia, paralysis, and tremors.[54] As a part of its enzootic cycle, WEEV infects sparrows, finches, blackbirds, mourning doves, pheasants, cowbirds, swallows, and chickens. The virus can cause fatal disease in sparrows, while chickens, which are often used as sentinels, develop inapparent infection.[797]

Experimentally infected newborn mice die within 48 hours after infection with involvement of skeletal muscle, cartilage, and bone marrow. In weanling mice, brain, heart, lung, and brown fat appear to be the primary target tissues.[12] After intracerebral inoculation, there is infection of the choroid plexus and ependyma with spread to neurons and glial cells in the brain, cerebellum, and brainstem and to motor neurons in the spinal cord.[571] After intranasal inoculation, olfactory neurons are infected with subsequent neuronal spread.[749] After peripheral inoculation, WEEV replicates in skeletal and cardiac muscle cells, causes a necrotizing myocarditis, and occasionally spreads to the CNS.[571,652] Virus is first detected in the cerebral circumventricular organs followed by centripetal spread via the neuronal axis.[748] Hamsters are more susceptible to WEEV-induced disease than mice with high mortality due to encephalitis after intranasal or intraperitoneal inoculation.[461] Neurons are infected and neuropathological changes include perivascular inflammation, microcavitation, and astrocytic hypertrophy.[1112] Cynomolgus and rhesus macaques are susceptible to intranasal and aerosol, as well as intracerebral, infection and develop dose-dependent signs of encephalitis with fever, tremors, and altered consciousness. Pathology shows encephalitis with infection of neurons accompanied by mononuclear inflammation.[787,1095]

Virulence

Variants of WEEV with decreased pathogenicity for mice and hamsters (e.g., B628 clone 15) have been selected by passage on CEF cells.[1112] Large-plaque strains tend to be more virulent than small-plaque strains.[436] Epizootic strains appear to be optimized for viremia and neuroinvasiveness and are generally more virulent for mice and guinea pigs than are enzootic strains.[82,83,375] North American isolates vary substantially in their virulence for mice, but are generally more virulent than South American strains.[269,573,680] Differences in mouse virulence are determined in part by E2 sequence changes.[664]

Diagnosis, Treatment, and Prevention

Diagnosis can be made by detection of WEEV-specific IgM in serum, by IgG seroconversion, or by isolation of virus in mice or cultured cells or by nucleic acid amplification.[129,529] Small molecule screening has identified lead compounds that inhibit WEEV replication and are partially protective in mice.[463,739] An inactivated vaccine is available for horses and as an experimental preparation for laboratory workers.[783] Preclinical studies of approaches to protection include activation of innate immunity,[574] DNA virus vectors expressing IFN or viral proteins, and chimeric alphaviruses.[43,60,305,679,786,953,1092,1093]

Venezuelan Equine Encephalitis

Equine disease was recognized in South America in the 1920s, and a virus (VEEV) was isolated from the brains of encephalitic horses in 1936 during an outbreak of equine encephalitis that may have spread from the central river valleys of Colombia into the Guajira region of Venezuela. This virus was antigenically distinct from the viruses causing equine encephalitis in the eastern and western portions of North America (EEEV and WEEV) and became the third encephalitic alphavirus identified in the Americas.[73,512] Between 1943 and 1980, many VEEV-related viruses, including the prototypic Trinidad donkey (TrD) strain,[782] were isolated in South America, Central America, and southern regions of the United States.[14] The first reported human cases of VEE were in laboratory workers,[151,543] and

subsequently human disease was documented in the general population during equine outbreaks and virus was isolated from ill humans.[782,848,1051]

Studies in Central America during this period indicated an enzootic cycle involving *Culex* (*Melanoconion*) spp. mosquitoes and rodents,[292] and human cases in Colombia in the absence of equine disease also reflected enzootic circulation and spillover.[848] In 1969, an epizootic/epidemic of VEE appeared and spread from Peru or Ecuador and through Central America and into Texas causing human disease and a high mortality in horses.[14] Virus isolations during the epizootic were primarily from *Psorophora confinnis* and *Ae. sollicitans* and Ae. taeniorhynchus mosquitoes and from horses suggesting that the epizootic and enzootic transmission cycles differed.[494,948] The latest major epizootic/epidemic in 1995 involved northern Venezuela and Colombia with an estimated 100,000 human cases.[1057]

Other VEEV Complex Viruses

Using a short-incubation (kinetic) HI test, isolates of viruses related to VEEV were originally classified into subtypes I to IV: VEE (I), Everglades (EVE, II), Mucambo (MUC, III), and Pixuna (PIX, IV).[1098] When Cabassou (CAB) and AG80-663 (Rio Negro, RN) viruses were isolated and shown to be within the VEE antigenic complex, they became subtypes V and VI.[134,218] The VEE subtype I viruses were further subdivided serologically into IAB, IC, ID, IE, and IF (Mosso das Pedras)[134,1051,1098] and the MUC subtype III viruses into IIIA, IIIB (Tonate/Bijou Bridge), IIIC, and IIID.[493,1051] Analysis of the phylogenetic relationships of the VEE complex viruses gained from sequencing led to a recognition of eight distinct species, with the species VEEV now comprising only subtypes IAB, IC, ID, and IE (Table 6.1)[492,631,770] (Fig. 6.13).

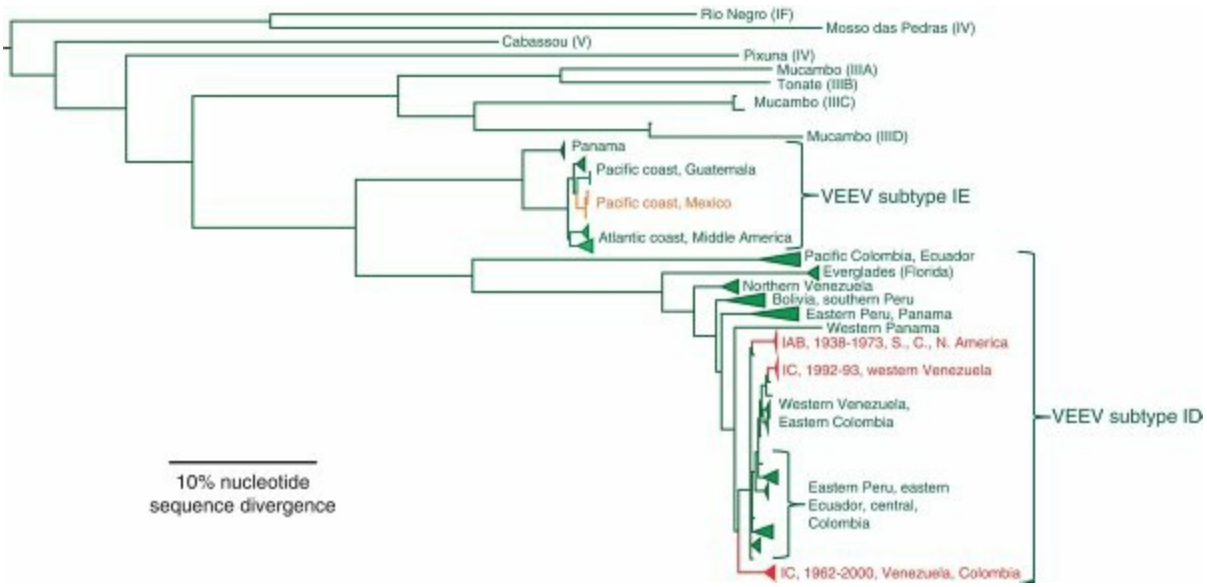

FIGURE 6.13 VEEV phylogenetic tree showing relationships of epizootic (colored *red* and *orange*) and enzootic/endemic strains (colored *green*). Strains are abbreviated with country followed by year of collection. The tree was generated using 817 nt sequences from the PE2 envelope glycoprotein gene using maximum likelihood methods. Courtesy of Naomi Forrester.

1. *Everglades*—EVEV (*subtype II*) was first recognized in southern Florida in the 1960s in persons living near Everglades National Park. Transmission is widespread in Florida with *Cx.* (*Melanoconion*) *cedecei* as the primary vector and cotton rats (*Sigmodon hispidus*) the main vertebrate reservoir.[184,1058] Disease in humans is usually mild.[239]
2. *Mucambo*—MUCV (subtype IIIA) was first isolated (strain BeAn 8) from a Brazilian monkey in 1954.[155] Three clades have been identified with temporally defined clades 1 and 2 from Trinidad and clade 3 from Brazil.[48,50] The virus causes fatal disease in newborn and adult mice after intracerebral, but not peripheral, inoculation. Experimentally inoculated guinea pigs and horses survive infection.[893] More recently, genetically distinct subtype IIIC[862] and IIID[15] VEE complex virus strains, now formally part of the species MUCV, have been identified in eastern Peru. All appear to be maintained in enzootic, sylvatic transmission cycles with direct spillover human infections documented

only for IIIA and IIID.

3. *Tonate*—TONV (subtype IIIB) was first isolated in 1973 from a bird (*Psarocolius decumanus*) captured in French Guiana[218] and subsequently from *Cx.* (*Melanoconion*) *portesi.*[728] The close relative TONV (strain Bijou Bridge) has also been recovered from cliff swallow bugs and birds in North America.[653] Human seropositivity is 11.9% in French Guiana with the highest rates in savannah areas.[955] Infection is most often associated with a mild dengue-like illness, but fatal encephalitis has also been reported in a young child.[410]
4. *Pixuna*—PIXV (subtype IV) was first isolated (BeAr 35645) from *Anopheles* (*Stethomyia*) *nimbus* mosquitoes in Belém, Brazil, in 1961[893] and has also been identified in Argentina.[754,756] There is no evidence that it causes disease in humans or equids.
5. *Cabassou*—CABV (subtype V) was first isolated (strain CaAr508) from mosquitoes in French Guiana in 1974.[218] CABV is not neurovirulent for adult mice or guinea pigs.
6. *Rio Negro*—RNV (subtype VI) was first isolated (strain AG80-663) from *Cx.* (*Melanoconion*) *delpontei* near the Rio Negro in Argentina in 1980.[134] RNV circulates in neotropical regions of Argentina[644,754,756] where it has caused outbreaks of acute febrile illness.[187] Suckling mice die within 2 to 3 days, but adult mice and guinea pigs survive infection.[1340]

Epidemiology

Enzootic VEE complex viruses are involved in perennially active transmission cycles in subtropical and tropical areas of the Americas (e.g., EVE in Florida; VEE ID and IE in Central America; IF Mosso das Pedras, MUCV (IIIA, C, D), PIXV, CABV, and RNV in South America). In enzootic areas, mosquito isolates are primarily from *Culex* (*Melanoconion*) spp. mosquitoes that live in tropical and subtropical swamps and forests throughout the Americas, with larval habitats often associated with aquatic plants and which typically blood-feed at dawn, dusk, and nighttime on a wide variety of rodents, birds, and other vertebrates.[14,262,292,339] Wild birds are susceptible to infection, but mammals, such as cotton rats, spiny rats, other rodents, and sometimes bats, are the most likely reservoir hosts of all but

TONV, as determined by virus isolation, levels of viremia, serology and resistance to disease.[63,143,252,339,361,1051] Although enzootic circulation is typically associated with sylvatic habitats, it also occurs in periurban regions with large numbers of human spillover infections.[14]

Morbidity and mortality

Clinically evident, including fatal, human infection can occur with most, if not all, enzootic, as well as epizootic, VEE complex viruses.[14,239,410,955,1051] Humans living in areas of enzootic transmission have a high prevalence of antibody due to infection associated mostly with undiagnosed mild febrile illnesses, often assumed in the absence of laboratory diagnostics to be dengue.[14,252,339,755,863,955] During epizootics, human attack rates vary widely, but recent epidemic estimates approach 30%.[810] In some outbreaks, most infections are asymptomatic with the apparent-to-inapparent infection ratio estimates as low as 1:11[95,239]; however, attack rates up to 30% during 1995 suggest a much higher rate of symptomatic infection.[810] All ages and both sexes are equally susceptible to infection, but disease manifestations vary with age.[810] Individuals under the age of 15 are more likely to develop fulminant disease with reticuloendothelial infection, lymphoid depletion, and encephalitis. In older children and young adults, a relatively benign influenza-like illness is most common.[239] Individuals over 50 are prone to develop encephalitis, but most recover.[239] The incidence of encephalitis in clinically ill humans is generally less than 5% and the mortality less than 1%.[810] Essentially all deaths occur in children.

Origin and spread of epidemics

Since the 1920s, VEE epizootics/epidemics have occurred at approximately 10- to 20-year intervals in cattle ranching areas of Venezuela, Colombia, Peru, and Ecuador when heavy rainfall leads to increased populations of epizootic mosquito vectors and when herd immunity decreases with equine population turnover.[810] Formalinized vaccines containing residual live virus were probably responsible for initiating all IAB outbreaks since the 1940s, including ones in South and Central America/Texas between 1969 and 1972[494] and another in Peru in 1973.[770,1055] VEE complex viruses causing epizootics are members of subtypes IAB, IC, or IE, while enzootic viruses

include ID, IE, and all other subtypes/species. During 1995, a major IC outbreak occurred in coastal areas of Venezuela and Colombia causing disease in 75,000 to 100,000 people. This region had experienced a similar outbreak in 1962 to 1964. Subtype ID VEEV strains obtained from mosquitoes and sentinel animals in western Venezuela and eastern Colombia when there was no epidemic activity have sequences that are closely related to the predicted epizootic IAB and IC progenitors, indicating that epizootic strains are not maintained in a separate cycle, but rather evolve by mutation from enzootic ID strains[770,806,1057] (Figs. 6.13 and 6.14). Epizootic potential is correlated with positive charge mutations in E2 that increase the level of viremia in equids and may also increase infectivity for the mosquito vector *Aedes* (*Ochlerotatus*) *taeniorhynchus*,[31,103,342] and one of these mutations was shown using reverse genetics to transform a subtype ID enzootic strain to an equine amplification-competent, subtype IC phenotype.[31] During epizootics, horses are an important amplifying species, and susceptible equids provide a means for virus amplification and spread.[948]

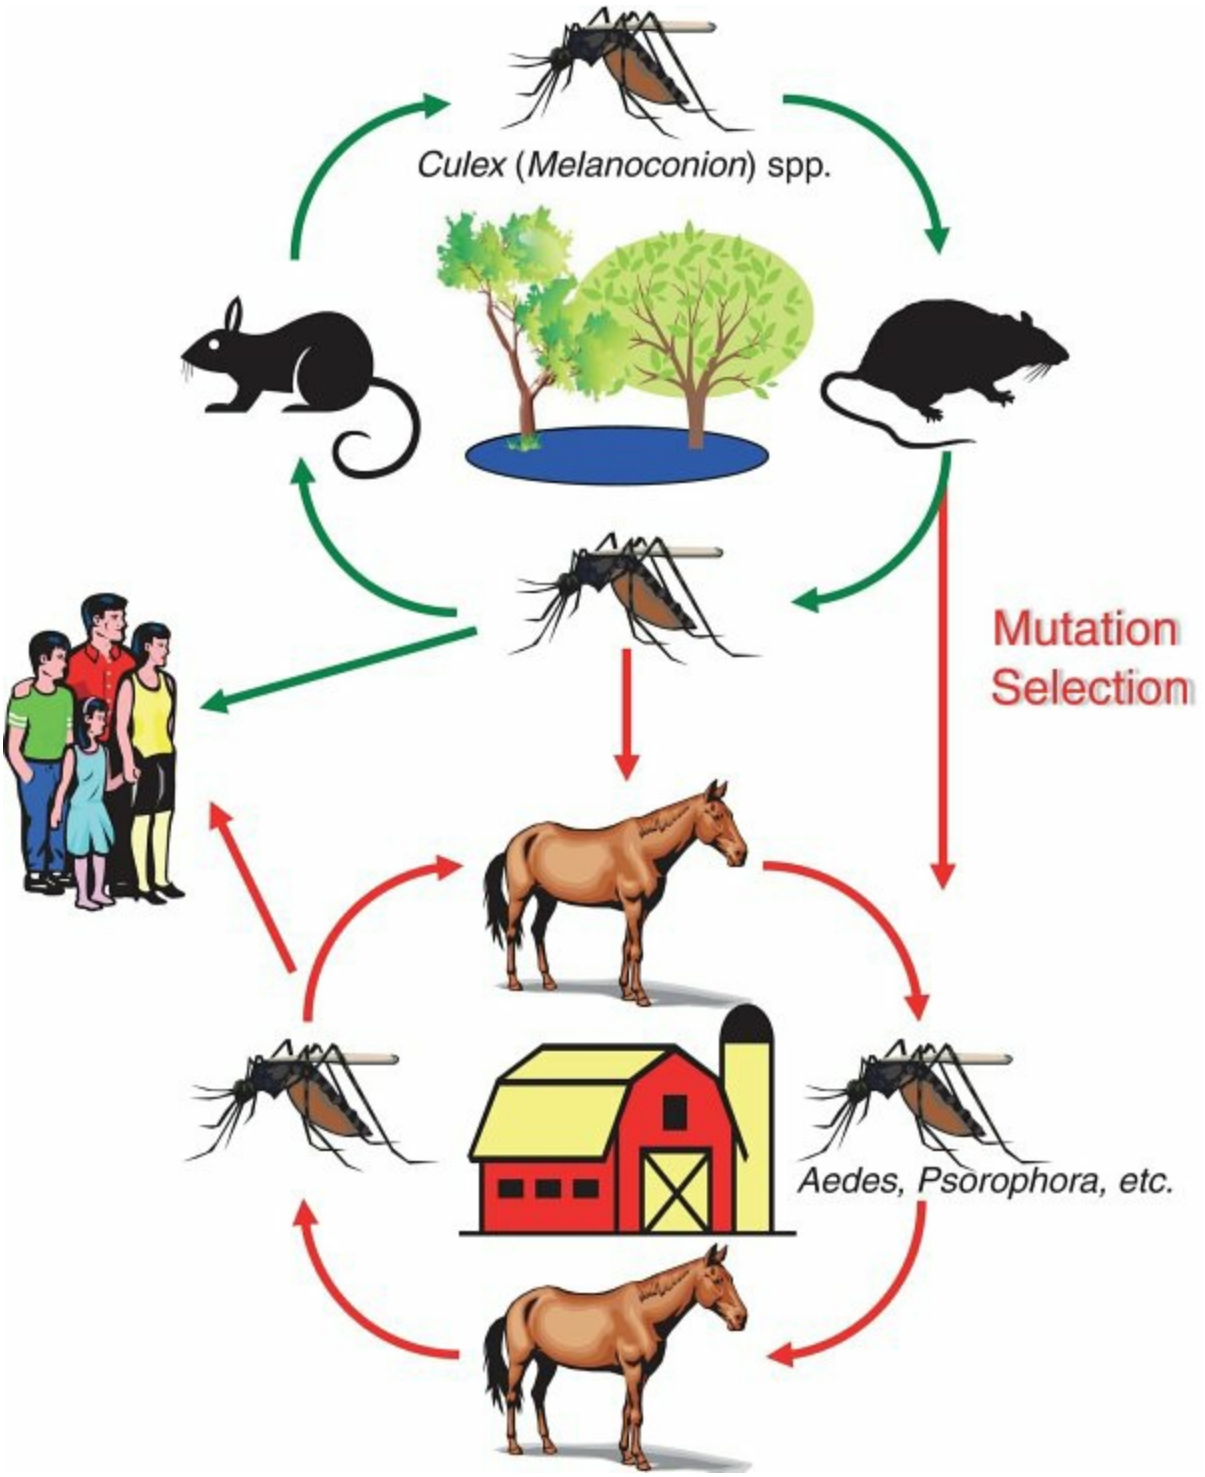

FIGURE 6.14 Enzootic and epidemic/epizootic cycles of VEEV as an example of an alphavirus for which epizootic strains arise by mutation and selection for equine viremia or epizootic vector transmission from the enzootic virus.

Detailed phylogenetic studies have delineated six major lineages of enzootic VEEV including five subtype ID strains and the subtype IE lineage (Fig. 6.13). All epizootic strains from major outbreaks fall into a clade nested within one of these lineages.[1051] Enzootic IE viruses were the source of epizootic IE strains in two recent equine epizootics in Mexico.[705] Interestingly, these epizootic IE strains cause encephalitis in horses with little viremia.[324,840] A substitution in E2 that appeared prior to outbreaks along the Pacific Coast of Mexico appears to have adapted the local enzootic IE strains for more efficient transmission by *Ae. taeniorhynchus*.

During outbreaks, VEEV has been isolated from several species of mosquitoes. Those most incriminated as VEEV vectors include *Ae.* (*Ochlerotatus*) *sollicitans*, *Ae. taeniorhynchus*, *Psorophora columbiae*, and *Psorophora confinnis*.[948,1051] After an epizootic, IC viruses may persist in a natural cycle and serve as a source for subsequent smaller outbreaks.[687]

Molecular epidemiology

Sequence analysis of the VEE complex viruses shows the greatest divergence for the E2 glycoprotein and the C-terminal region of nsP3.[271,631,770] At least five enzootic subtype ID lineages have been identified: Colombia and coastal Ecuador; Panama/Peru; Colombia, western Venezuela, and northern Peru; north central Venezuela; and Peru/Bolivia (Fig. 6.13). All epizootic IAB and IC strains are related to ID strains from Colombia, Venezuela, and Peru.[770,1051] Three distinct geographically separate IE lineages have also been recognized: northwestern Panama, Pacific Coast (Mexico and Guatemala), and Gulf/Caribbean Coast (Mexico and Belize).[706]

Clinical Features and Pathology

Infection with enzootic, as well as epizootic, strains of VEEV can cause significant human disease with the most common signs and symptoms being fever, headache, tremors, prostration, nausea, and vomiting that last 3 to 4 days.[14] Accidental laboratory aerosol infections of young adults with epizootic strains of VEEV caused a febrile illness with the abrupt onset of chills, headache, myalgia, somnolence, vomiting, diarrhea, and pharyngitis 2 to 5 days after exposure without evidence of encephalitis.[151,239,543] Natural epidemic human infection was first described in 1952 in Colombia and

subsequently in Venezuela during the 1962 to 1964 outbreak that resulted in 32,000 human cases and 190 deaths.[239,452] The 1995 outbreak in Colombia caused an estimated 75,000-100,000 human cases, 3,000 with neurologic complications and 300 deaths.[810,1057] The case-fatality rate is 0.7% to 1%. Neurologic disease tends to appear 4 to 10 days after onset of illness with headache and vomiting the most common initial symptoms. Specific neurologic signs include focal or generalized seizures, paresis, behavioral changes, and stupor or coma.[810,1057] Children recovering from encephalitis may be left with neurological deficits, particularly seizure disorders.[546] Fetal abnormalities, spontaneous abortions, and stillbirths may occur with infection during pregnancy.[810,1057]

Laboratory studies often show lymphopenia. Pathology on fatal cases has shown myocarditis, focal centrilobular hepatic necrosis and inflammation, generalized lymphoid depletion, cerebral edema, and vasculitis.[452] Congenitally infected infants show severe neurologic damage with widespread necrosis, hemorrhage, and hypoplasia resulting, in the most severe cases, in hydranencephaly.[1066]

Veterinary Correlates, Host Range, and Animal Models

Enzootic strains of the VEE complex can infect horses, but these infections are typically asymptomatic or cause short-term fever, low-level viremia, and little clinical illness and may immunize horses against infection with epizootic strains (IAB, IC, and IE).[392,1051] Equine disease induced by epizootic strains is characterized by fever, depression, and diarrhea leading to death 6 to 8 days after infection. Viremia persists until death with titers up to 10^8 infectious units/mL blood. Virus can also be recovered from eye washings, nasal washings, and urine. Leukopenia coincides with the viremia and is progressive in fatal cases. In animals that recover, antibody appears approximately 7 days after infection.[496] Pathology on fatal cases shows pancreatic necrosis and cellular depletion in the bone marrow, lymph nodes, and spleen. The brains of horses with signs of neurologic disease show swollen cerebrovascular endothelial cells, edema, extravasation of blood, and leukocytic infiltration into the perivenular spaces.[319,496]

Infection of macaques by aerosol or subcutaneous inoculation with enzootic and epizootic strains of virus elicits a biphasic febrile response—the first phase is coincident with the viremia and the second phase with termination of viremia, that is, the appearance of the immune response[319,651,789] (Fig. 6.7). Leukopenia is common. Symptom signs are usually mild, consisting of anorexia, loose stools, irritability, and occasionally loss of balance, tremor, or myoclonus.[651,937] Examination of tissues shows lymphocyte depletion early, mild hepatitis, myocarditis, and encephalitis. Lesions in the brain are found primarily in the olfactory cortex and basal ganglia and consist of lymphocytic perivascular cuffing and glial nodules.[319]

Experimental infection of small laboratory animals with VEEV produces a variety of disease patterns. After subcutaneous inoculation of guinea pigs, rabbits, or hamsters with virulent strains of VEEV, there is a viremia. Virus replicates in the bone marrow, lymph nodes, spleen, and brain with rapid destruction of myeloid and lymphoid cells in lymph nodes, spleen, thymus, intestinal and conjunctival lymphoid tissue, liver, and bone marrow, damage to the intestinal wall and pancreas, cerebral hemorrhage, and neuronal cell death.[319,441,1036] Death occurs 2 to 4 days after infection and may be associated with ileal necrosis, bacteremia, and endotoxemia.[331] EVEV, MUCV, and PIXV are progressively less virulent.[441]

In addition to myeloid and lymphoid necrosis, susceptible strains of mice develop encephalomyelitis leading to death in 6 to 9 days after infection with the TC-83 vaccine strain, as well as wild-type strains of VEEV.[319,462,582] After subcutaneous inoculation, virus replicates first in DCs or Langerhans cells that migrate to the draining lymph node where virus is amplified[596] (Fig. 6.6). Virus enters the CNS by the olfactory route after respiratory or peripheral inoculation, although cerebral infection can also follow hematogenous seeding of the circumventricular organs.[748] Initial infection is of olfactory epithelium with spread to olfactory neurons and then caudally to all regions of the brain, causing encephalitis and neuronal apoptosis.[162,433,936,937,1029] Virus also infects the pancreas, liver, and teeth. Fatal disease has an immunopathological component dependent on the strain of mouse infected.[161,937] There can also be transplacental transmission of infection.[932]

Virulence

Comparative studies of the virulent TrD and avirulent TC-83 strains of the IAB serotype and construction of recombinant viruses have led to identification of the 5′ UTR (nt 3) and the E2 glycoprotein (residue 120) as important determinants of VEEV virulence for mice.[202,491] Attenuated viruses infect DCs less efficiently and replicate less well in lymphoid tissue and in the CNS than virulent viruses.[596,936] Virulence for guinea pigs is determined by both envelope and nonenvelope genes.[341,766] Determinants of equine virulence are different from determinants of murine virulence, but also lie largely within the E2 glycoprotein.[102,342,770] Changes most frequently associated with acquisition of equine virulence for ID strains are replacement of uncharged residues with Arg at positions 193 and 213 of E2.[31,1037] Acquisition of surface charge changes in E2 is also associated with emergence of epizootic IE strains.[102]

Diagnosis, Treatment, and Prevention

Diagnosis can be made by virus isolation from blood or pharynx[151,543,1057] or by documenting the presence of anti-VEEV IgM or a rise in IgG antibody. HI, CF, neutralization, or EIA tests can be used for serologic diagnosis and nucleic acid amplification for detection of viral RNA. Antibody responses to enzootic versus epizootic strains can be differentiated with an epitope-blocking EIA.[1041]

Treatment is generally supportive, but passive transfer of antibody can protect mice before or up to 24 hours after challenge.[325,420,422] The D-(−) enantiomer of carbodine, an inhibitor of cellular cytidine triphosphate synthetase, and antisense morpholino oligomers suppress VEEV replication *in vitro* and improve the outcome of infected mice.[460,726]

The earliest vaccines developed for horses and laboratory workers were formalin-inactivated preparations.[781,783] These vaccines had repeated problems with residual live virus producing disease and initiating equine-amplified outbreaks and with poor immunogenicity and are no longer in use.[494,770,1055] A live attenuated vaccine (TC-83), developed by serial passage of the virulent TrD strain in guinea pig heart tissue culture cells,[75] is protective for horses and laboratory workers, but 15% to 30% of recipients

develop fever and pharyngeal viral shedding.[758] Therefore, a formalin-inactivated TC-83 vaccine (C-84) was produced.[237] Both the live and inactivated vaccines are immunogenic, but live TC-83 provides better protection against aerosol challenge in hamsters than C-84 and is therefore preferred despite the reactogenicity.[442] To produce a more optimal vaccine, several experimental DNA, inactivated, live attenuated, chimeric, and replicon particle vaccines are at various stages of development.[160,232,233,246,611,727,786,788,821]

A number of measures are effective in controlling outbreaks. These include immunizing equids, limiting equine movements from regions of infection, applying larvacides to mosquito-breeding sites, and spraying insecticides to control adult mosquitoes.[810,948,1051] Protection of human populations relies primarily on personal protection from mosquito bites.

ALPHAVIRUSES ASSOCIATED PRIMARILY WITH RASH AND POLYARTHRITIS

Chikungunya

An outbreak of a crippling arthritic disease of sudden onset was first recorded in the Newala District of Tanzania in 1952.[812] Retrospective case reviews have suggested that CHIKV epidemics in Africa, Asia, and the Americas occurred as early as 1779, but were confused with dengue.[141,370] Because of the severe arthritic symptoms, the disease was given the name of "chikungunya" meaning "to walk bent over" in the Kimakonde language of Mozambique.[407,812] The virus, isolated in 1953 from serum and from *Aedes* spp. and *Culex* spp. mosquitoes, was related to the group A arboviruses (Fig. 6.5).[820] Subsequent epidemics were recognized in the Transvaal of South Africa, Zambia, India, Southeast Asia, and the Philippines. From 2004 to 2007, a large epidemic affected islands in the Indian Ocean and India with spread to SE Asia and Europe,[769,801] and in 2013 and 2014, CHIKV was introduced into the Caribbean and Central and South America.[1050,1052]

Epidemiology

CHIKV causes epidemics of rash and arthritis in India, Southeast Asia, Indonesia, the Philippines, most of sub-Saharan Africa, and Indian Ocean islands with recent extension into southern Europe and the Americas[336,532,803,971] (Fig. 6.15). In Africa, the virus is maintained in cycles similar to that of yellow fever virus. There is a rural cycle involving *Aedes africanus*, *Aedes furcifer*, nonhuman primates, and other mammals and an urban cycle involving *Ae. aegypti* or *Ae. albopictus* and humans.[171,214,996] In rural areas, the disease is endemic with small numbers of cases occurring most years.[214] In urban areas, outbreaks are sporadic and explosive with infection of a large proportion of the susceptible population within a few weeks.[309,736,801,812,813] In Asia, there is no evidence for a sylvatic cycle; rather, urban transmission is by *Ae. aegypti* and suburban rural transmission is by *Ae. albopictus* in a human–mosquito–human cycle.[405,693,768] Laboratory-acquired infections have also been reported.[981]

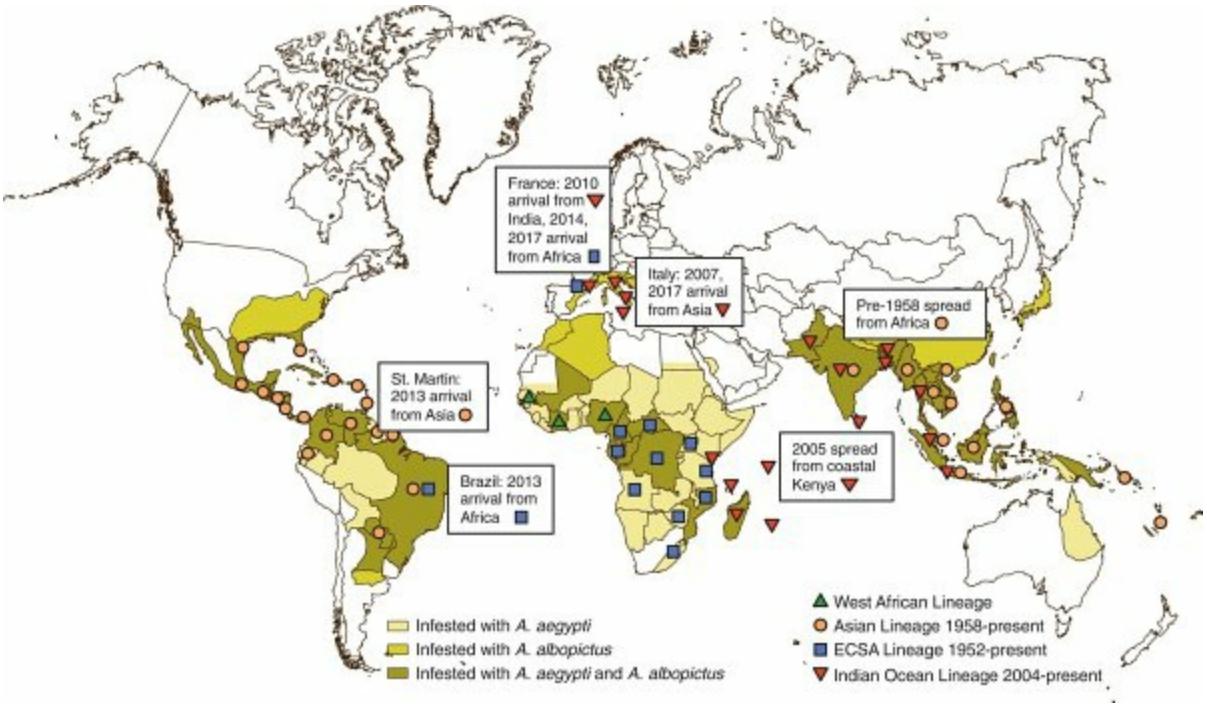

FIGURE 6.15 Time course of worldwide spread and current geographic distribution of lineages of chikungunya virus along with the distribution of the relevant *Aedes aegypti* and *Ae.*

albopictus mosquito vectors. Adapted from reference 805, with permission.

Morbidity and mortality

All ages and both sexes are susceptible and disease is usually self-limiting and rarely life threatening. However, approximately 0.3% of cases are atypical or severe with nephritis, hepatitis, meningoencephalitis, thrombocytopenia, or encephalopathy, and the case-fatality rate has been estimated at 1 in 1,000 with most of the deaths either in neonates infected peripartum, adults with underlying conditions, or the elderly.[152,236,801,811] The epidemic on Réunion Island affected almost 40% of the population (estimated 300,000 cases) and led to an excess of 254 deaths.[309,395,800] Infants infected at birth are susceptible to CNS complications including cerebral edema and hemorrhage resulting in long-term disabilities.[307,988] Musculoskeletal symptoms are recurrent or persistent in approximately 40% of adults and more likely to affect females than males.[928,1086]

Origin and spread of epidemics

CHIKV is believed to have originated in sylvatic, enzootic African transmission cycles involving nonhuman primates and arboreal *Aedes* spp. vectors. However, this cycle was identified after the first epidemics were recognized in the 1950s in Africa and Asia (although outbreaks probably occurred for the past few centuries in both Asia and the Americas following the spread of both CHIKV and *Ae. aegypti* mosquitoes from Africa).[370,1050] After an epidemic, the disease usually disappears from an affected region for years, probably due to herd immunity. An unprecedented series of epidemics began in Kenya in 2004 with spread to Comoros, Réunion Island, the Seychelles, Mauritius, and Mayotte in 2005. This epidemic strain, called the Indian Ocean Lineage (IOL), was derived from one of the two main African enzootic genotypes called the East/Central/South African (ECSA) lineage[470,869] (Fig. 6.16). The same IOL strain subsequently spread from Africa to the Indian subcontinent and then to Southeast Asia with smaller outbreaks in France and Italy following imported cases.[395,733] Some IOL strains increased their ability to be transmitted by *Ae. albopictus*, not

previously implicated in CHIKV transmission, through a series of mutations in the envelope glycoprotein genes.[405,997,1023] Because susceptible urban vectors are widely distributed, travelers provide a source of CHIKV introduction into many other geographic regions.[395,733,799] There is some evidence that virus can be maintained within mosquito populations by low rates of transovarial or venereal transmission.[616,784,978]

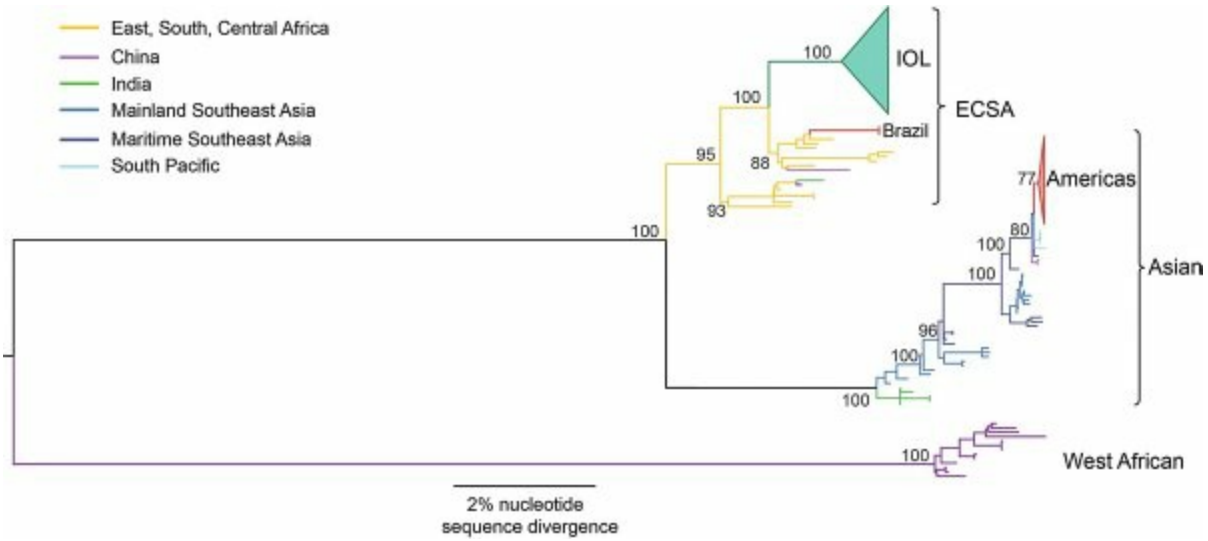

FIGURE 6.16 CHIKV phylogenetic tree derived from nucleotide sequences encoding the two ORFs using Bayesian methods. The major enzootic lineages (West African and East/Central/South African) are shown as well as the two endemic/epidemic lineages that involve human–mosquito transmission cycles in urban settings: Asian and Indian Ocean Lineage (IOL). Endemic/epidemic strains circulating in the Americas from Asian and ECSA lineages are shown in *red*, and legend indicates the geographic locations of other strains. All posterior probability values were 1.0. (Courtesy of Rubing Chen.)

Molecular epidemiology

CHIKV is a member of the SFV complex evolved from an enzootic ancestor in Africa, and the first permanently endemic (human-amplified and *Ae.*

aegypti–transmitted) virus was probably introduced into Asia about a century ago.[1031] Two distinct enzootic lineages exist, transmitted in sylvatic locations among nonhuman primates by arboreal *Aedes* mosquitoes: West African and ECSA[768,769,869] (Fig. 6.16). All extant endemic/epidemic strains analyzed were derived from the latter.[166,373,470,869,1031] Of the two endemic/epidemic lineages, only the IOL has adapted for more efficient transmission by *Ae. albopictus*. The Asian lineage, which was introduced into the Americas in 2013, is constrained by an epistatic interaction between threonine at E1-98 and the adaptive E1-226 alanine-to-valine substitution.[996] The second lineage to reach the Americas, from Angola into Brazil in 2014, is constrained in the same manner by a different epistatic interaction at E2-211, where a threonine residue is required for the effect of E1-226 to be realized,[1000] while isoleucine found in the Brazilian ECSA strain does not allow penetrance of the 226 substitution. Another constraint on this adaptation is the geographic source of *Ae. albopictus*; unlike other populations tested, this species derived from the Democratic Republic of the Congo is not more susceptible to the E1-226V mutant.[1024]

After identification of the E1-A226 mutation, additional *Ae. albopictus*–adaptive mutations were identified in E2, all involving glutamine or glutamic acid substitutions of various amino acids.[998] Structural mapping of these mutations combined with their common derived amino acids allowed for additional *Ae. albopictus*–adaptive mutations, never observed in nature, to be predicted and confirmed experimentally. These results suggested that CHIKV has additional potential for adaptation to this invasive vector species. In addition to having two major epidemic vectors, IOL strains also appear to be more virulent than those of the Asian lineage.[306,1097]

Clinical Features and Pathology

The disease is of sudden onset with an incubation period estimated at 3 to 12 days.[812] No prodrome is recognized and most infections result in disease with children more likely than adults to have mild symptoms.[142,330,809,907,908] Fever rises rapidly to 103°F to 104°F and may be accompanied by a rigor. The onset of fever corresponds to the period of viremia and may be related to the ability of this virus to induce large amounts of type I IFN, IFN pathway genes, and proinflammatory cytokines[175,267,967,968,1045] (Fig. 6.7). Disease

severity and levels of neutralizing antibody are associated with TLR3 polymorphisms.[397] Monocytes are infected and are a source of IFN.[396,967] Virus titers in blood can reach greater than 10^6 PFU/ml and virus load correlates with disease severity and IFN production.[142,175,407,865] Joint pain appears suddenly and can be incapacitating and chronic. Essentially any joint can be involved and pain may be accompanied by swelling and paresthesias.[92,480,691] Headache, conjunctivitis, and gastrointestinal symptoms are common, and in 80%, a maculopapular rash appears 4 to 8 days after the initial illness. The rash may be associated with a second rise in fever (Fig. 6.7), lasts approximately 2 days, and is described as "irritating" or "itchy."[93,812] Meningoencephalitis associated with CNS infection can result in death or permanent disability and is more common with CHIKV than with other alphaviruses causing primarily rash and arthritis.[152,308,630,811,844] In addition, atypical cases with severe disease and increased mortality can develop hepatitis, myocarditis, bullous dermatosis, myelopathy, pneumonia, and diabetes.[176,178,236,416,958,987] Fibroblasts in the skin and joints and satellite cells in the muscle are targets for infection.[191,723] Leukopenia and thrombocytopenia are frequent.[93,175,407,1086]

There are multiple indications of virus persistence after resolution of acute infection. Episodes of joint pain and myalgia and detection of viral RNA and sometimes antigen often continue for many months to years after the original illness.[58,92,204,241,407,820,866,928] Chronic pain is more likely in females and those over 60 years of age with a high viral load during the acute illness.[407,1086] Synovial tissue harbors persistently infected perivascular macrophages, fibroblast hyperplasia, activated NK cells, and $CD4^+$ T cells, but few $CD8^+$ T cells.[407] Cytokines are increased during acute infection, and persistent arthralgia is associated with elevated plasma levels of IL-6 and granulocyte–macrophage colony-stimulating factor.[173,175,691] Joint x-rays are usually normal or show soft tissue swelling without evidence of bone or joint damage, although bone erosion has been reported.[480,605,607] Osteoblasts can be infected and express osteoclast-activating factors such as IL-6 and RANKL.[704] In India, but not Africa, inguinal lymphadenopathy and red swollen ears are also observed as part of the clinical picture.[142]

Animal Models, Host Range, and Virulence

Mice and nonhuman primates can be infected with CHIKV.[365] In wild-type mice, disease severity is age-dependent.[191] Neonatal mice develop fatal disease.[212,681] One- to two-week-old mice survive infection, but develop weight loss, difficulty walking, myositis, foot swelling, tenosynovitis, and vasculitis with virus replication in multiple organs, including the CNS.[280,661,1111] Local inoculation of adult mice causes biphasic foot swelling associated with macrophage and $CD4^+$ T-cell infiltration and production of inflammatory cytokines, particularly TNF, IFNγ, and MCP-1.[275,294,827,969] Virulence is associated with changes in the 3′ UTR, nsP3, and E2.[8,39,329,381,627]

Fibroblasts and macrophages are target cells for CHIKV infection in the periphery, recruited to sites of virus replication and a major source of IFN-α/β.[294,827,865] In the CNS, neurons and astrocytes are target cells with up-regulation of multiple innate response genes.[199,280,681,772] Adult IFN-α/β receptor (IFNAR)-, IRF3-/IRF7-, and STAT1-deficient mice develop fatal disease with replication in macrophages, liver, muscle, joint, and skin fibroblasts; occasional dissemination to the choroid plexus, leptomeninges, and ependyma of the CNS; and features of hemorrhagic shock.[191,295,299,825,864,865] Viperin (Rsad2)-deficient and TLR3-deficient mice survive but have higher viremias, wider virus dissemination, and more joint inflammation than WT mice.[397,967] Infection of pregnant mice does not result in fetal infection.[193]

The adaptive immune response mediates much of the inflammation and is required for clearance of infectious virus.[275] Virus clearance is associated with production of antibody to the E1 and E2 surface glycoproteins.[382,468,585] Antibody-deficient mice develop persistent infection even after infection with an attenuated virus strain.[382] Higher viral loads in TLR3-deficient mice are associated with decreased production of neutralizing antibody to a linear B-cell epitope in E2.[397] Viral RNA persists in joint-associated tissues for months after infection.[382,383]

Adult cynomolgus macaques infected intravenously, subcutaneously, or intradermally develop a dose-dependent viremia, fever, rash, gingival bleeding, liver enzyme elevation, arthritis, and meningoencephalitis with astrocyte activation.[299,426,526] IFN-α/β production correlates with the viremia.

Pathology shows persistent mononuclear cell infiltration into lymphatic tissue, joints, muscle, and liver associated with prolonged presence of CHIKV RNA in macrophages at these sites.[526] Pregnant rhesus macaques infected with enzootic West African and epidemic Indian strains of CHIKV develop viremia, rash, joint swelling, leukopenia, and cytokine increases after infection, but fetuses did not become infected providing further evidence that transplacental transmission is infrequent.[163]

Diagnosis, Treatment, and Prevention

The primary differential diagnoses for CHIK fever are dengue and Zika and, in Africa, ONN fevers. Dengue and Zika overlap the CHIK geographic distribution extensively, but are characterized more by myalgia than arthralgia.[480] ONN is clinically similar, but has geographic overlap only in Africa (Fig. 6.17).[142] Routine laboratory parameters are variable and not particularly helpful in the diagnosis.[769] CHIKV can be isolated from plasma or detected by nucleic acid amplification during the initial fever.[355,451,735,820,965] Detection of IgM antibody provides a means of early diagnosis and can persist for months, particularly in those with persistent symptoms.[92,130,355] In some locations, slight cross-reactions in EIA with other SF complex alphaviruses such as RRV or MAYV must be ruled out.[244]

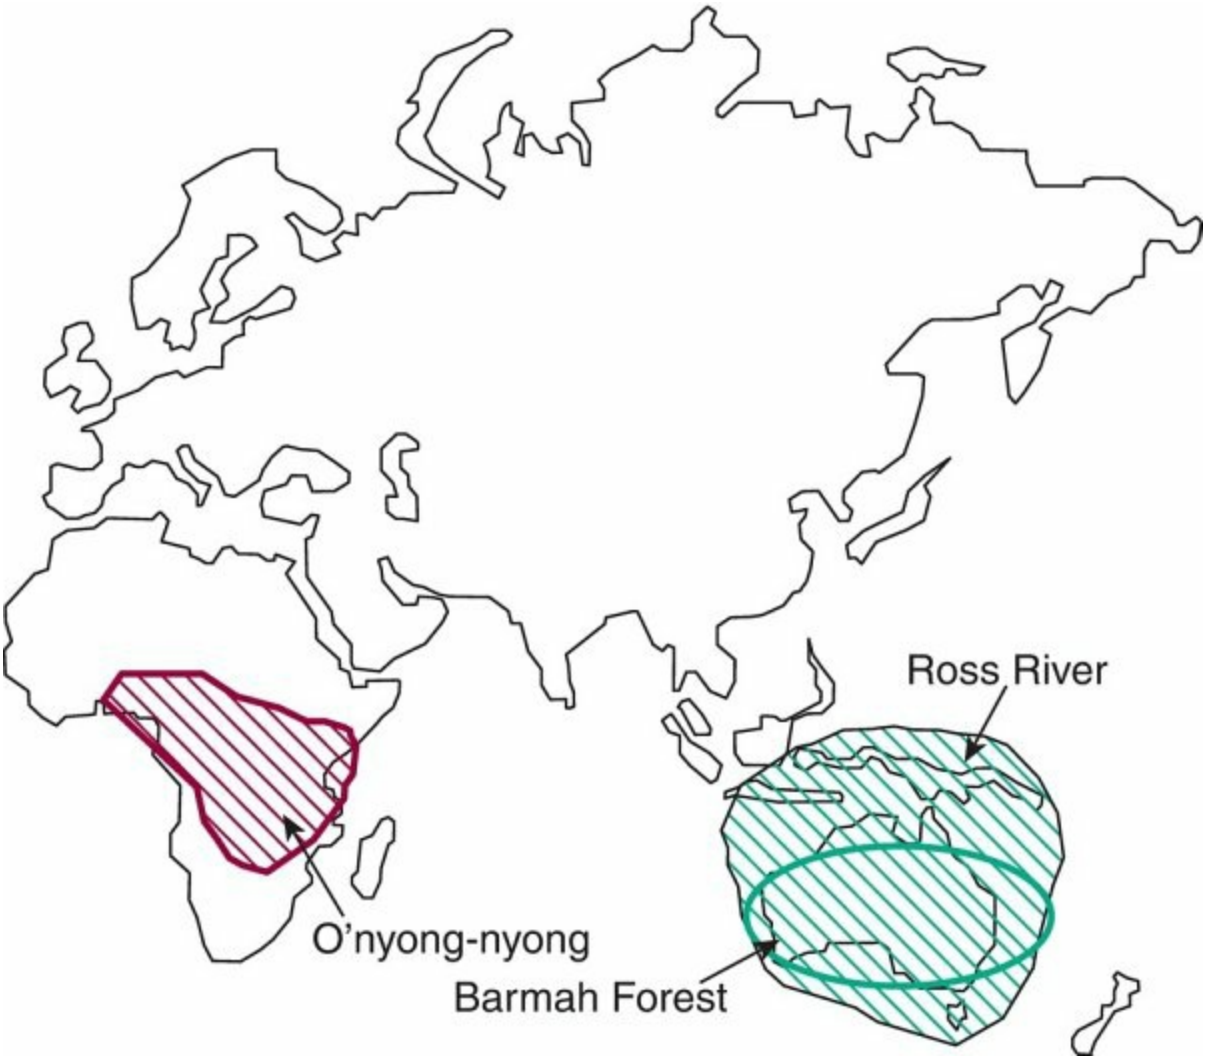

FIGURE 6.17 Geographic distributions of several alphaviruses that cause epidemic polyarthritis and rash: O'nyong-nyong, Barmah Forest, and Ross River viruses.

Treatment is generally symptomatic with anti-inflammatory agents, and in mice, inhibition of IL-1β signaling decreases bone loss and inhibition of MCP-1 synthesis decreases muscle and joint inflammation.[827,1087] Passive transfer of immunoglobulin containing antibody to CHIKV can protect neonatal wild-type mice and IFNAR-/- mice from fatal infection.[192] IFN-α is protective in mice if given prior to infection and activity in peripheral joints is promoted at warm ambient temperatures.[294,774]

A live attenuated vaccine has been developed by passage of a CHIKV

isolate from Thailand in MRC-5 cells.[238,554] This vaccine (strain 181/clone 25) induces long-term production of neutralizing antibody and can be used to protect laboratory workers from infection.[619,769] A formalin-inactivated vaccine can elicit protective immune responses in mice.[294,979] Additional approaches to vaccination include DNA, chimeric and rationally attenuated engineered viruses, and virus-like particles with a measles virus–vectored vaccine recently shown to be safe and immunogenic in a phase 2 human trial.[245,798,805]

O'nyong-Nyong

In 1959, an outbreak of a new disease, originally mistaken for dengue, was reported from northwestern Uganda,[364,895] and it is likely that a similar epidemic occurred in the same region in 1904 to 1906.[895] The name o'nyong-nyong originated from one of the first tribes to be affected, the Acholi, and refers to the painful joints characteristic of the disease.[364] During the 1959 outbreak, ONNV was isolated from the serum of a patient with acute arthritis[1083] and from anopheline mosquitoes.[1084] ONNV is a member of the SF complex and antigenically most closely related to CHIKV from which it is estimated to have diverged at least thousands of years ago.[768,1083] The virus reemerged in southern Uganda in 1996 to 1997 suggesting a 30- to 50-year epidemic cycle.[530] In 1967, Igbo-Ora, now recognized to be a strain of ONNV,[530,768] was isolated from humans in western Nigeria.[654]

Epidemiology

ONNV causes sporadic, widespread outbreaks of fever, rash, and arthritis with high attack rates like CHIKV. The first epidemic recognized originated in northwestern Uganda in 1959 and spread south and east to Kenya, Tanzania, Zaire, Malawi, Mozambique, and Zambia to affect greater than 2 million people.[1085] Another major outbreak occurred in southern Uganda in 1996.[845] More recent evidence of widespread ONNV infection has been documented in West, Central, and East Africa.[80,518,527,557,762,804,960]

The presumed enzootic vector and vertebrate reservoir host for ONNV are unknown. Interepidemic seroconversions and mosquito isolations suggest continuous sporadic transmission in East Africa, and it is possible that

humans or nonhuman primates are the primary reservoir.[530] During outbreaks, ONNV is transmitted principally by *Anopheles funestus* and *An. gambiae* mosquitoes and is the only alphavirus known to be transmitted by anopheline mosquitoes.[595,1084] Human–mosquito–human transmission occurs during epidemics, and spread from one region to another occurs through the movement of infected humans.[845] The most recent outbreak began near swamps and lakes in the rural Rakai district of south central Uganda in 1996. Serosurveys showed infection rates of 45% to 96% in areas of epidemic transmission with the ratio of apparent-to-inapparent infection ranging from 1:4 to 1:24.[557,654,845] All ages and both sexes are equally susceptible.[497] Among domestic animals in the same region, cattle have the highest seroprevalence (40%),[709] but few animals have been studied, so the putative enzootic reservoir is not known.

Clinical Features

The onset of fever is sudden and often accompanied by a rigor. The characteristic syndrome includes joint pains, rash, lymphadenitis, and conjunctivitis. Fever is typically moderate (100°F–101°F) and lasts approximately 5 days. Joint pain most often occurs in the knees, but ankles, elbows, wrists, and fingers can also be affected. The pain usually lasts 6 to 7 days and is severe enough to be immobilizing in 80% to 90% of patients and can persist for up to 3 months. The generalized morbilliform maculopapular rash erupts 4 to 7 days after the onset of symptoms and is similar to that of CHIK. It begins on the face and extends to the trunk and extremities occasionally affecting the palms. Cervical lymphadenopathy distinguishes the disease from CHIK, occurs in approximately half of the patients, and most frequently involves posterior cervical lymph nodes. Leukopenia is common. Fatalities have not been described, but morbidity is substantial.[497,557,654,895]

Diagnosis

The disease is often clinically confused with malaria, measles, dengue, and rubella,[762,895] but also resembles CHIK. Virus can be isolated, or nucleic acid amplified, from blood early in the illness.[80,762,1085] Diagnostic serology includes a positive IgM EIA and neutralizing antibody to ONNV that is more than twofold greater than that to CHIKV.[845] IgM persists for about 60 days

after infection.[497]

Ross River

Epidemics of polyarthritis in Australia probably date from at least 1886, but were first clearly described in towns on the Murrumbidgee River in New South Wales in 1928 and then in troops stationed in the Northern Territory and Queensland during World War II.[378,435,598] Serological studies suggested an alphavirus as the causative agent and RRV (strain T48) was first isolated from *Ae. vigilax* mosquitoes trapped near the Ross River in Queensland in 1959.[378,598] The first human isolate was made in 1971 from the blood of a child with fever.[221] In 1979, RRV spread from Australia to Fiji, Samoa, and the Cook Islands causing an explosive outbreak of tens of thousands of cases of polyarthritis on these Pacific Islands.[378] Virus was first isolated from the serum of patients with polyarthritis during this epidemic.

Epidemiology

RRV is endemic throughout the coastal regions of much of northern and central Australia and epidemic in the rest of Australia, Papua New Guinea, and the Solomon Islands.[818,973] In general, the Wallace and Weber hypothetical lines in the Indo–Australian archipelago that separate the fauna of the Oriental and Australian regions appear also to have separated the geographic distributions of CHIKV and RRV[598] (Fig. 6.17). RRV is the most common mosquito-borne pathogen in Australia with approximately 5,000 cases reported each year, an annual incidence of 14 to 50/100,000 population, and 10-year seroconversion rates of 24% in some areas.[831] Cases are most common in the north and occur primarily in late summer and early autumn with some evidence of an increasing incidence.[378,598,831] Two salt marsh–breeding mosquitoes *Aedes camptorhynchus* and *Ae. vigilax* are probably the major vectors in coastal regions of Australia.[831] In inland areas, the freshwater-breeding mosquito *Culex annulirostris* is the major vector, and in urban areas, *Aedes notoscriptus* appears to be involved in transmission.[831] Both urban and rural cycles of transmission occur. A wide variety of mammals, primarily macropods such as kangaroos and wallabies and potentially pteropid bats, appear to serve as vertebrate hosts for the enzootic cycle, although placental mammals and birds have not been studied

adequately to rule them out as reservoirs.[149,181,378,764,831,938] In urban areas, horses and brushtail opossums are likely involved in transmission.[475]

Morbidity and mortality

Infection rates can be as high as 1:30 during outbreaks.[598] Estimates of apparent-to-inapparent infections range from 1:3 to 1:1.[378,739] Seroprevalence and disease incidence are similar in males and females. Clinically apparent infections are rare in children and the highest incidence of disease is in the 25- to 40-year age group.[378,434]

Origin and spread of epidemics

In Australia, a wide variety of mosquito species is believed to be involved in RRV transmission.[181] Outbreaks are seasonal and have been associated with prolonged inundation of salt marshes due to increased tidal heights or heavy rains during the summer[419,435,598,982,1082] and with a loss of herd immunity in reservoir populations.[149] In arid regions, outbreaks often occur within 2 or 3 weeks of heavy rains suggesting that RRV survives in desiccation-resistant mosquito eggs with vertical transmission.[565] This is further suggested by isolation of RRV from field-caught immature and male *Ae. vigilax* and *Aedes tremulus* mosquitoes.[565]

Epidemic polyarthritis, initiated by a viremic traveler from Australia to Fiji, spread to several South Pacific Islands between 1979 and 1980 in explosive outbreaks similar to urban CHIK with a man–mosquito–man transmission cycle and *Aedes polynesiensis* as the vector.[818,973] Human viremias of greater than 10^6 mosquito ID_{50}/mL have been documented.[973] Cases in travelers suggest that RRV has been reintroduced to Fiji,[498] and serosurveys in American Samoa and French Polynesia indicate ongoing silent circulation.[47,534]

Molecular epidemiology

Strains of RRV originally isolated from the northeastern (Queensland), southeastern (New South Wales), and western regions of Australia are antigenically and genetically distinguishable.[454,842,1089] However, the

northeastern lineage has not been recovered since 1977 and, along with the western lineage, has been replaced by the southeastern lineage.[3,454] This replacement accompanied the appearance of a duplication in the C-terminal hypervariable domain of nsP3 first identified in a strain recovered in 1979 from a patient in Fiji.[3,4] The data suggest genetic divergence and independent evolution of RRV within geographically isolated enzootic foci consistent with mammals as a vertebrate reservoir.[842] However, overall diversity is low, perhaps due to purifying selection.[454] Sequencing of intrahost populations of RRV reveals substantial diversity and evidence of mixed infections.[569]

Clinical Features and Pathology

RRV infection most often induces fever, arthralgia, and rash (Fig. 6.7), but not all patients develop all three signs/symptoms.[380,971] Usually, the illness has a sudden onset after a 7- to 9-day incubation period. Fever is the initial symptom, is low grade, and is typically followed by the onset of pain, swelling, and tenderness in multiple joints. Joint involvement is usually symmetrical and both small and large joints can be affected. Characteristically, the rash appears on the 3rd or 4th day of illness; is maculopapular, nonpruritic, and present on the face, trunk, and extremities with occasional involvement of the palms and soles; and generally lasts 3 to 4 days. Frequent accompanying signs and symptoms include lymphadenopathy, lethargy, headache, myalgias, and photophobia. The average period of incapacity is 6 weeks and symptoms gradually resolve in most affected individuals over 3 to 6 months.[282,376,380,570]

Examination of synovial fluid shows increased protein, $CD4^+$ T lymphocytes, monocytes, and activated macrophages and increased levels of RANKL, TRAP56, TNF, IFNγ, and MCP-1.[164,182,283,563] Cell counts are moderately increased, ranging from 1,500 to 15,000 cells/mm[283]and RRV RNA is present.[923] RRV replicates in osteoblasts and can cause persistent infection of synovial macrophages *in vitro*,[1046] and it is postulated that infection of these cells leads to cytokine production and inflammatory arthritis *in vivo*.[949] For instance, osteoblast infection induces inflammatory cytokine production and increases RANKL relative to its decoy receptor osteoprotegerin favoring osteoclast formation.[164] Serum levels of complement pathway protein long pentraxin 3 are increased.[267]

The skin lesions show mononuclear perivascular inflammation without evidence of immune complex deposition. Most of the infiltrating cells are $CD8^+$ T lymphocytes. RRV antigen is present in the basal epidermal and eccrine duct epithelial cells.[284]

Animal Models and Host Range

Despite its extensive host range, RRV induces clinically evident disease only in humans, mice, and horses.[55,964] The prototype T48 strain has been extensively passaged in mice and virulence is age-dependent.[643,673] In newborn mice, T48 infects cardiac muscle causing myocardial necrosis and death 3 to 4 days after infection.[673,880] One-week-old mice survive and infection of the CNS leads to demyelination and destruction of the internal granule cell layer of the cerebellum.[880] In 2- to 3-week-old mice, RRV causes myositis, arthritis, and weakness with virus replication in muscle, perichondrium, periosteum, bone, and skin.[164,663] Macrophages are prominent components of the disease-inducing inflammatory and virus control processes.[369,563,570,828] Soluble mediators that contribute to disease pathogenesis include complement, pentraxin 3, TNF, IFN-α/β, IFNγ, IL-6, MCP-1, and macrophage inhibitory factor (MIF).[164,369,401,562,563,660,662] Treatment with antibody to IL-6 decreases bone loss.[164] $CD8^+$ T cells contribute to virus clearance from muscle, but not joint tissue,[121,563] and mice deficient in TLR7 signaling have more severe disease, inadequate production of neutralizing antibody, and poor virus clearance.[688] Mice deficient in pentraxin 3 have decreased inflammation and virus replication with improved outcome.[267] Adult mice develop an asymptomatic viremia that persists for 5 to 9 days.[887] In pregnant mice, virus can replicate in the placenta and spread to the fetus.[641]

The less virulent NB5092 strain induces severe myositis and muscle cell death in newborn mice after subcutaneous inoculation.[673] Mice become stiff and unable to move and then gradually regenerate muscle and recover function after virus is cleared.[673] CNS disease is minimal with patchy infection of ependymal cells and ependymitis leading to hydrocephalus. Neurons are only occasionally infected.[643] Brown fat is another important site of virus replication.[673] By 1 week of age, mice no longer develop signs of

disease.[673]

Virulence

To identify determinants of virulence for mice, virulent T48 has been compared to the less virulent NB5092 and DC5692 strains with different passage histories.[253,293] Virulence has been associated primarily with amino acid differences in nsP1 and E2.[465,466,484,629,964,1033,1034] Changes in nsP1 affect disease without affecting virus replication, while changes in E2 usually affect replication. Induction and susceptibility to IFN also influence disease development.[369,562] Of unproven but possible significance is the fact that the epidemic strain of RRV in the Pacific differed from the parent Australian strain by a change from Thr to Ala at E2-219 and a duplication in nsP3.[3,120]

Diagnosis, Treatment, and Prevention

Diagnosis is aided by geographic location and travel history. The differential diagnosis includes rubella, other alphavirus-induced arthritides, and Henoch-Schonlein syndrome.[282] Virus can be recovered from blood early in disease,[818,1092] but most diagnoses are made using serology. The IgM capture EIA is sensitive, but can remain positive for 1 to 2 years after the onset of disease.[148] Neutralization assays can distinguish between viruses in the SF complex.[394]

In mice, treatment with drugs to block NF-κB, MCP-1 synthesis, or IL-1β signaling can decrease inflammation and tissue damage.[563,826,1087] In contrast, treatment to block TNF enhances virus replication, inflammation, and tissue damage.[1101]

Vector control and personal protection against mosquito bites remain the primary means of prevention.[377,980] An aluminum hydroxide–adjuvanted inactivated whole-virus vaccine that protects mice from infection and disease induces neutralizing antibody in humans at levels predicted to be protective and is in phase 3 clinical development.[6,409,1091]

Sindbis

The prototype strain of SINV, AR339, was initially isolated from *Culex*

univittatus mosquitoes collected near Sindbis, Egypt, in 1952.[963] Humans living in the Nile Delta at that time had a seroprevalence of 27%, but no disease was associated with infection.[963] Over the next 25 years, SINV was isolated in Europe, the Middle East, Africa, India, Asia, Australia, and the Philippines from a variety of mosquito and vertebrate species. SINV was first isolated from the blood of febrile humans in Uganda in 1961 and recognized as a cause of rash and arthritis in South Africa in 1963.[604]

Epidemiology

SINV is the most widely distributed of the alphaviruses causing arthritis in man, but is not recognized as a cause of disease in much of its range (Fig. 6.18). The primary sites of recognized SINV-mediated human disease are in Northern Europe (Ockelbo fever in Sweden, Pogosta fever in Finland, and Karelian fever in Russia)[249] and South Africa[467] (Fig. 6.18). In the many other regions where the virus exists, human infection occurs, but results only in subclinical disease, fever, or mild arthralgias. The basic maintenance cycle of SINV is between *Culex* spp. or *Culiseta* spp. mosquitoes and wild birds.[598] In Sweden, the enzootic cycle involves *Culex torrentium*, *Culiseta morsitans*, and passerine birds.[281,402,589,591] In Finland, grouse are an important vertebrate host.[521]

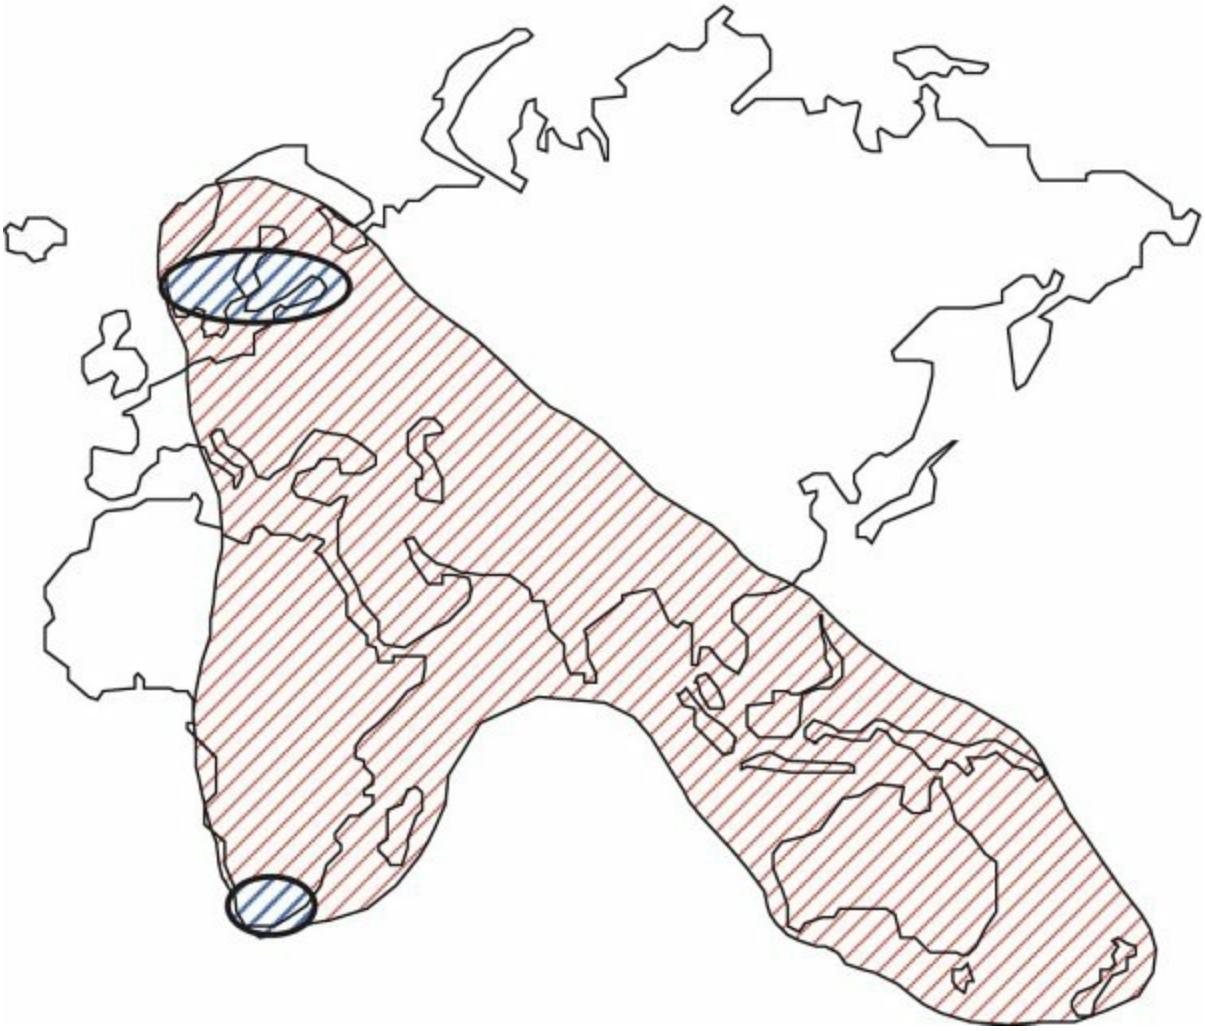

FIGURE 6.18 Geographic distribution of Sindbis virus. Northern Europe and South Africa, regions with significant outbreaks of arthritis and rash disease in humans, are designated in *blue*.

Morbidity and mortality

The age-adjusted prevalence for SINV is 2% to 8% in endemic regions of Northern Europe and 0.1% to 0.2% in neighboring nonendemic areas. Risk is highest between the 60th and 64th parallels and is associated with spending time in the woods or marshland and exposure to mosquito bites.[114,249,521,588,846] The ratio of symptomatic to asymptomatic cases is 1:17 with 45- to 65-year-old females most likely to develop disease.[114]

Origin and spread of epidemics

Spread of SINV from its enzootic cycle between passerine birds and ornithophilic mosquitoes to humans involves bridge vectors with less specialized feeding habits[1004] (Fig. 6.10). In Northern Europe, the primary bridge vector is *Aedes cinereus* and availability of this species may determine the frequency of human infection. Cases begin to appear in late July and continue into the fall. Large outbreaks occur approximately every 7 years, perhaps in association with fluctuating grouse populations.[588,846] During a 2013 Swedish outbreak, *Cs. morsitans* was naturally infected and the SINV strain detected was closely related to recent Finnish SINV isolates.[76] Vertical transmission in mosquitoes can occur.[213] Detection of SINV in mosquito larvae of three species (*Aedes* [*Ochlerotatus*] *communis*, *Aedes* [*Ochlerotatus*] *punctor*, and *Aedes* [*Ochlerotatus*] *diantaeus*) in Sweden also indicates natural transovarial transmission as a maintenance mechanism. In South Africa, cases appear annually, mainly during late summer and early autumn in the central plateau region.[942]

Molecular epidemiology

Antigenic and genetic analyses of strains from different locations indicate the presence of five geographically distributed distinct genotypes: Africa and Europe (I), Australia (II), East Asia (III), Azerbaijan and China (IV), and New Zealand (V, Whataroa).[590,591,841,843,899] Strains isolated in Northern Europe and South Africa, where most SINV-induced disease occurs, are more closely related to each other than to strains isolated in south and central Europe and the Middle East where disease is rare.[457,892] Israeli SINV strains together with those from Saudi Arabia comprise a Middle Eastern clade within genotype I.[53] Patterns of SINV clade distributions are consistent with a major role for migratory birds in dispersal.[590,843]

Clinical Features

The primary clinical manifestations are itching rash, arthritis, fever, and muscle pain.[10,249,519,1007] The rash is distributed diffusely over the trunk and limbs and can affect the palms and soles. Skin lesions have a macular base with central vesicle formation and a pale halo and are occasionally

hemorrhagic.[249,604] Joint pain preferentially affects large joints and may be severe enough to be immobilizing. Macrophages infected with SINV become activated; release MIF, TNF, IL-1β, and IL-6; and express matrix metalloproteinases.[40] Most patients recover within 14 days, but joint pain and muscle stiffness may persist for months to years.[249,362,519,847,1007] In Australia, SINV-induced arthritis and rash are milder and less frequent than RRV-induced disease or SINV-induced disease in Northern Europe and Africa.[598]

Animal Models and Host Range

SINV can infect a wide variety of vertebrates and has been extensively studied in mice as a model for acute encephalomyelitis. In mice, there is an age-dependent susceptibility to fatal encephalitis.[450] In young mice, virus replicates to high titer and spreads rapidly, causing death in 3 to 5 days. In older mice, virus replication is more restricted and mice often recover. After peripheral inoculation, virus replicates in muscle, produces a viremia, and then spreads to the brain and spinal cord where the primary target cells are neurons.[431] The ability of SINV to spread to the CNS and cause fatal disease is dependent on the strain of virus and the genetic background of the mouse.[432,592,593,889,975,1001] C57BL/6 mice are most susceptible to fatal encephalomyelitis after infection with neurovirulent strains, and this is determined in part by a gene on chromosome 2.[975,976,1001] Neuronal death requires host contributions such as glutamate excitotoxicity and T-cell–mediated immunopathology.[198,340,514,515,608,683,822] Mice with deficiencies of IFN signaling, IRF7, or acid sphingomyelinase have increased susceptibility to fatal encephalitis.[124,692,870]

In nonfatal encephalitis, a SINV-specific perivascular mononuclear inflammatory response consisting of T cells and monocytes appears in the CNS within 3 to 4 days after infection followed by entry of antibody-secreting B cells.[638,646] Spread of infection is limited initially by IFN-α/β,[124] and infectious virus is cleared within 7 to 8 days after infection primarily through the effects of antiviral IgM antibody and IFNγ.[85,116,117,352,551,697] Viral RNA persists in the CNS after clearance of infectious virus, and reactivation of infection appears to be prevented by continued presence of T lymphocytes and antibody-secreting B cells within the CNS.[353,550,638,1008]

Virulence

Strains of SINV differing in virulence have been derived from independent isolates from Egypt (AR339), South Africa (SR86), and Israel (SV-Peleg). Variants of AR339 and SV-Peleg differing in virulence have been derived by passage in mice and in tissue culture.[351,592] Virulence is determined primarily by the 5′ UTR, nsP3, and the E2 glycoprotein, but is also influenced by changes in E1, capsid, and the other nsPs.[201,594,624,627,731,926,952] Changes from A to G in nucleotide 5 or 8 in the 5′ UTR decrease recognition by IFIT1 and increase neurovirulence.[229,425,624] The N-terminal nsP3 macrodomain affects efficiency of replication in neurons.[731] Amino acid changes in the E2 glycoprotein alter efficiency of virus entry into the CNS and can enhance neuronal infection.[71,201,539,1002] Neuroinvasion is affected by changes at residues 55 and 190 of E2.[229] A Gln to His change at E2-55 increases efficiency of infection of neurons and is a major determinant of increased virulence in older mice.[539,1002]

Diagnosis, Treatment, and Prevention

The major differential is with other causes of acute rash and arthritis, such as parvovirus B19 and rubella. SINV can be recovered from skin lesions and from blood,[519,520,604] but the diagnosis is most often made by serology. SINV-specific IgM increases during the acute phase of the disease and then tends to decrease slowly for 3 to 4 years independent of persistent symptoms.[695]

Mice can be protected from fatal encephalitis by treatment with drugs that inhibit inflammation and glutamate excitotoxicity.[340,430,608,773] Mice can also be passively protected with antibody, but develop progressive destruction of infected regions of the brain.[490]

Barmah Forest

Barmah Forest virus (BFV) was first isolated in 1974 from *Cx. annulirostris* mosquitoes collected in the BF in the Murray River Valley region of southeastern Australia and soon thereafter in southwest Queensland.[33] It is the only recognized member of the BFV complex and has a unique E2 protein without N-linked glycosylation.[94,508,540] Human disease was first

reported in 1986 with an epidemic of polyarthritis in New South Wales,[94] and BFV was first isolated from the blood of a patient in 1988.[747] The geographic range of BFV is expanding although problems with serologic diagnosis have been identified.[522,983] In 1989, BFV, previously restricted to eastern portions of Australia, was isolated in Western Australia with subsequent outbreaks of human disease.[566]

The vertebrate reservoir host is unknown, but serosurveys suggest that horses and marsupials, particularly brushtail possums, may play a role.[475,566] On the other hand, sequence analysis shows a high degree of sequence identity over the geographic distribution consistent with an avian vertebrate host.[760] Newborn mice are susceptible to experimental infection with virus replication in muscle and brain, but disease is less severe than that induced by RRV.[400] The main mosquito vectors are not well established, but appear to include *Cx. annulirostris*, *Ae. vigilax*, *Ae. notoscriptus*, and *Ae. camptorhynchus*.[434,566] Transmission in coastal areas is influenced by temperature, tides, and socioeconomic factors.[682]

Disease is most common in the 30- to 50-year age group with males and females equally affected.[72] The most common clinical features are fever, lethargy, polyarthritis, and myalgia accompanied by a vesicular rash.[33,72,747] Diagnosis may not be made because the illness is frequently mild and overlaps the clinical spectrum and geographic distribution of RRV and SINV infections (Figs. 6.17 and 6.18). Rash is more prominent in BFV, while arthritis is more prominent in RRV[266] and the serology is distinct.[747] In over half of infected individuals, recovery takes several weeks, with lethargy the most prominent persisting symptom.[72]

Mayaro and Una

MAYV was first isolated in 1954 from febrile forest workers in Trinidad and then from several individuals with fever and frontal headache in the Guamá River area of Brazil.[30,156] The virus is widely distributed in South America,[272,665,974] and evidence of human infection has been obtained in Haiti[537] and Panama[145] suggesting recent spread. Human cases are sporadic and occur primarily in persons with recent contact with humid tropical forests.[989] There are three distinct genotypes. Genotype D contains isolates

from Trinidad and north central South America, genotype L contains isolates from Brazil, and genotype N is represented by a single isolate from eastern Peru.[49,765] The principal mosquito vectors are in the forest-dwelling genus *Haemagogus* and the vertebrate hosts are mammals, mainly nonhuman primates. Airborne transmission to laboratory personnel has also occurred.[464] However, experimentally, MAYV can be transmitted by *Ae. aegypti* and *Ae. albopictus*,[577,914,1080] and human viremia levels suggest the possibility of urban, human-amplified transmission like that exhibited by CHIKV.[577] Recent studies also demonstrate laboratory vector competence by *Anopheles* mosquitoes.[115]

Signs and symptoms of MAYV infection, which, like CHIKV, is usually symptomatic, include fever, headache, arthralgia, myalgia, vomiting, diarrhea, and rash that last 3 to 5 days.[665] The diagnosis can be made by isolation of virus from blood or by serology using an IgM capture EIA or neutralization assay.[130,394]

Una virus is closely related to MAYV and was first isolated from *Psorophora ferox* mosquitoes in the Amazonian region of Brazil in 1959.[154] It is widely distributed in Central and South America.[154,215,216] Vertebrate hosts include nonhuman primates.[215] Una virus is pathogenic for mice, but is not recognized to cause human disease.

OTHER ALPHAVIRUSES

Semliki Forest

SFV was first isolated in 1942 from *Aedes abnormalis* collected in the Semliki Forest (SF) of western Uganda.[917] It is widely distributed in Africa with mosquito (e.g., *Ae. africanus*, *Ae. argenteopunctatus*) isolates documented from Mozambique, Nigeria, and the Central African Republic.[601,614,622] Although SFV is one of the most extensively studied of the alphaviruses and serosurveys indicate that human infection is relatively common,[614,917] it has been linked to human disease on only two occasions. In the first case, reported in 1979, a 26-year-old laboratory worker in Germany with a 1-year history of “purulent bronchitis” working with the Osterrieth

strain of SFV developed fever and headache followed by seizures, coma, and death from encephalitis. SFV was isolated from the CSF and from the brain. No antiviral antibody was detectable at the time the CNS symptoms began, but was detected at the time of death 1 week later.[1081] The history of chronic pulmonary infections and failure to rapidly produce antiviral antibody suggest that this individual had an immunodeficiency disorder involving antibody production. In 1987, SFV was isolated from serum samples of individuals in the Central African Republic with fever, persistent headache, myalgias, and arthralgias.[614]

Animal Models

SFV can cause encephalitis in horses, mice, rats, hamsters, rabbits, and guinea pigs.[45,98,917,1113] Severity and type of disease are dependent on the age of the animal at the time of infection, on the route of inoculation, and on the virulence of the strain of SFV used for infection.[98,354] Mice have been most extensively studied and the strain of inbred mouse infected can also influence outcome.[946]

In newborn and suckling mice, inoculated peripherally virulent and avirulent strains of SFV replicate rapidly and extensively in the muscle, elicit a high-titered viremia, spread to the CNS, and cause death within 2 to 4 days.[256,354,671] Evidence suggests that SFV enters the brain across cerebrovascular endothelial cells.[256,485,924] Once within the CNS, the virus replicates primarily in neurons and spreads rapidly along neural pathways producing neuronal cell death.[711]

In weanling (3–5 weeks old) mice, SFV replicates rapidly, but reaches lower peak titers in muscle, blood, and brain than in younger animals.[354] Virus enters perivascular regions of the brain and initiates foci of infection within the CNS. After intranasal inoculation, virus infects olfactory neurons and then spreads within the CNS.[711] The primary target cells in the brain are neurons that control virus replication more effectively than oligodendrocytes.[45,256,279,485] A mononuclear inflammatory response consisting of T lymphocytes, B lymphocytes, and monocytes is apparent 3 to 4 days after infection, peaks at 2 to 3 weeks, and is mostly resolved by 6 weeks.[658]

Mice infected with virulent strains can be passively protected from fatal encephalitis with immune serum, but then develop a delayed disease associated with persistent infection, inflammation, and neuronal degeneration.[877] Mice that survive infection develop demyelination, accompanied by mild paralysis, 2 to 4 weeks after infection.[172,947] Clearance of infectious virus is complete 7 to 10 days after infection and this clearance is mediated by antibody.[256] Viral RNA and protein persist for months.[225,485] Focal areas of demyelination are found 14 to 21 days after SFV infection and are characterized initially by swelling and vacuolation of oligodendrocytes and loss of myelin sheaths followed by remyelination.[122] Demyelination is macrophage-mediated and appears to be the result of oligodendrocyte infection, the immune response to infection, and induction of an autoimmune response to myelin.[257,648,945] SJL mice have more prolonged inflammatory responses and demyelination after infection compared with other strains of mice.[225,918]

SFV infection of the CNS can also increase the susceptibility of mice to induction of experimental autoimmune encephalomyelitis[649] apparently by damaging the blood–brain barrier, increasing adhesion molecule expression on endothelial cells, and facilitating entry of autoimmune T lymphocytes into the CNS.[924,925]

Virulence

Isolates from mosquitoes collected in 1942 in Bwamba, Uganda,[917] in 1948 in Kumba, Nigeria,[601] and in 1959 in Namacurra, Mozambique,[622] have given rise to a variety of laboratory strains of SFV with differing levels of virulence. The most commonly studied are virulent strains V12, V13, and L10 (Uganda strain independently passaged in mice in Bethesda [V] and London [L]) and avirulent strain A7 (Mozambique strain AR2066 passaged in mice) and its less virulent derivative A7-74.[98] In addition, avirulent strains of L10 have been derived by chemical mutagenesis (e.g., m9).[64] Virulent and avirulent strains differ in their ability to invade and replicate in the CNS of weanling mice and rats after peripheral inoculation, but all strains cause fatal disease in newborn or suckling mice.[45,256,354,671] In 3- to 4-week-old mice, avirulent SFV is restricted in replication and spread in the CNS compared to virulent strains of virus and compared to avirulent strains in younger mice.[713]

This difference in replication is associated with decreased budding of infectious virus and is independent of the host immune response.[256] Mature neurons and pancreatic and myocardial cells can be made more susceptible to avirulent virus by treatment with aurothiolate compounds that induce intracellular membrane proliferation.[256,861] In general, reduced virulence correlates with reduced replication in neurons.[57]

In vitro studies of the differences between virulent and avirulent strains of SFV have shown differential replication in neuronal cells[44] and differences in susceptibility to IFN.[210] Efforts to identify specific nucleotide and amino acid changes important for virulence have utilized comparative sequence analysis and an infectious SFV cDNA clone pSP6-SFV4 derived from the prototype virulent L10 strain. Construction of SFV4/A7 chimeric viruses has shown that determinants of virulence reside in both the structural and nonstructural regions of the genome[961] with changes in E2, nsP2, and nsP3 identified as particularly important.[256,261,315,318,807,849,855]

Other SFV-Related Viruses

The SFV complex includes eight viruses and has representatives in both the Old World (BEBV, CHIKV, GETV, ONNV, RRV, and SFV) and the New World (MAYV and Una virus) (Table 6.1; Fig. 6.5). Southern elephant seal (SES) virus is phylogenetically, but not antigenically, related to SFV. Human disease, when present, is generally characterized by fever that may be accompanied by arthritis and rash. CHIKV, ONNV, RRV, and SFV have been discussed previously.

Getah

Getah virus was first isolated from *Culex* spp. mosquitoes collected in Malaysia in 1955 and causes myositis when inoculated into mice.[404] It is maintained in a cycle similar to Japanese encephalitis virus with transmission by *Culex tritaeniorhynchus* and amplification in domestic pigs.[906] Getah virus is widespread and ranges from Eurasia to Southeast and Far East Asia, Pacific Islands, and Australasia. Disease in humans is limited to fever,[559] but it causes abortion in pigs and is an important pathogen of horses.[59,690,882] The equine disease is characterized by fever, an urticarial rash, and hind leg

edema, but is not life-threatening.[882]

Southern Elephant Seal

SES virus was isolated from lice residing on Southern elephant seals on Macquarie Island, Australia. It is phylogenetically related to SFV, but does not cross-react serologically. No disease has been recognized in infected seals and it is not known whether lice are responsible for transmission.[524]

Salmonid Alphaviruses

Salmonid alphaviruses (SAV), formally multiple subtypes of the species salmon pancreatic disease virus (SPDV), cause sleeping disease in rainbow trout and pancreas disease in farmed Atlantic salmon.[408,1028,1073,1074] SPDV has unusually large E1 and E2 structural glycoproteins and relatively low (30%–34%) homology to other alphaviruses.[1028,1074] Six subtypes have been identified that likely evolved from a wild reservoir.[471,919] Subtypes 1, 4, and 5 are closely related and have been isolated from farms in Britain with pancreas disease. Subtype 3 causes disease on salmon farms in Norway and subtype 2 causes sleeping disease in Europe. Subtype 6 is represented by a single isolate from Ireland. SPDV causes significant disease on fish farms characterized by abnormal swimming behavior and lack of appetite. SPDV replicates in muscle satellite stem cells with frequent generation of deletion mutants and E2 is a determinant of virulence.[81,634,744] Histopathology shows degeneration of the pancreas and of cardiac and skeletal muscles.[626] SPDV is shed in feces and mucus and can be horizontally transmitted.[334] Sea lice can be infected, but their role in transmission is unclear.[743] Subtype 5 SAV RNA sequences have been detected in wild marine fish further suggesting that marine reservoirs exist.[920]

DIAGNOSIS

The differential diagnosis of alphavirus-induced diseases often includes more than one alphavirus in addition to other mosquito-borne febrile viral diseases such as dengue and Zika and West Nile fevers, other rash diseases such as rubella and parvovirus B19, and other causes of encephalitis. IgM capture

EIAs can be used for diagnosis early in disease.[129,130,133] The IgM response is relatively specific for each antigenic complex and is useful even at later times, because IgM persists for at least 2 to 3 weeks after onset of disease.[130] In regions where two or more viruses in a given antigenic complex occur, virus-specific IgM EIAs or neutralization assays may be required to rule out cross-reactions. Virus isolation remains useful, but nucleic acid amplification tests have simplified virus identification in clinical samples.[771] RT-PCR primers have been designed that can amplify the conserved region of all alphaviruses,[247,357,746] as well as alphavirus-specific regions,[529] and are useful for rapid diagnosis.

PREVENTION AND CONTROL

Treatment

There is currently no available specific antiviral treatment for any alphavirus-induced disease, although compound screening and molecular docking studies have identified many potential antiviral therapies for evaluation in animals along with therapeutic monoclonal antibodies, IFN, and immune system activators.[9,123,570] Several neuroprotective drugs can protect mice from fatal encephalomyelitis and supportive treatment can be lifesaving.[349] Symptomatic treatment for arthritis with anti-inflammatory drugs and immune modulators can be beneficial.[570]

Vaccines

Formalin-inactivated vaccines against EEE, WEE, and VEE are available for horses and against EEE for birds. Experimental inactivated vaccines against EEE, WEE, and VEE are also available for laboratory workers exposed to these agents with yearly booster doses required for EEE and WEE.[237] PE-6, the investigational inactivated EEE vaccine for humans, induces good immunoreactivity against the NA-EEEV, but not MADV.[944] Because formalin inactivation of TrD for VEE vaccination was sometimes incomplete, other virus strains and methods of inactivation have been evaluated.[888] An inactivated RRV vaccine was safe and immunogenic in a phase 3 human

trial.[1091] Live attenuated vaccines for VEEV (TC-83) and CHIKV (181/25) have been tested in clinical trials,[554,888] but substantial side effects are common with both. Alternative approaches at various stages of preclinical development for prevention of CHIKV, VEEV, and RRV infection include monoclonal antibodies and DNA, subunit, replicon, virus-like particle, and virus-vectored vaccines.[245,570,888] In both horses and humans, prior vaccination against one alphavirus can interfere with development of neutralizing antibody to subsequent alphavirus vaccines.[136,619,757]

Other

Prevention of infection with most alphaviruses relies primarily on efforts to control mosquito populations with insecticides and elimination of aquatic larval habitats. A variety of means can be used for assessing the need for mosquito abatement. These include monitoring mosquito population densities, seroconversion of sentinel animals, and presence of virus in populations of mosquitoes capable of transmitting virus to humans or domestic animals. Individual use of protective measures, such as mosquito repellents and protective clothing, is important. New methods directed against *Ae. aegypti*, including population reductions based on release of *Wolbachia*-infected or transgenic males to effectively sterilize wild females, or the introduction of *Wolbachia* that interfere with CHIKV transmission, are in widespread trials.[1050]

PERSPECTIVE

The ability to construct full-length cDNA alphavirus clones that can be transcribed into infectious RNA has advanced understanding of the functions of various genes and their importance for replication and virulence in the multiple hosts necessary for maintenance of these viruses in their natural cycles. An understanding of the three-dimensional structures of proteins in the virion has greatly aided interpretation of much of the sequence and virulence data previously acquired. Further sequence information on virulent and avirulent strains, functional and structural analysis of the nonstructural proteins and polyproteins, and assessment of cell-type–specific virus interactions is likely to provide the next level of understanding of virus–host

relationships.

In addition, there is a need for improved approaches to prevention and treatment. There is a particular need for understanding the components of the immune response necessary for noncytolytic virus clearance, protection from reinfection, immunomodulation of disease, mechanisms of chronic arthralgia, and importance of persistent viral RNA in tissues. New and improved vaccines are needed for protection during outbreaks and for laboratory workers. In addition, there is a need for effective antialphaviral drugs, and an understanding of the structure of viral proteins may offer new approaches to therapeutics. These areas have implications for biological defense purposes because many alphaviruses can be transmitted by aerosol and VEEV, EEEV, and WEEV are considered potential agents of biowarfare.[9] Finally, improved, inexpensive, point of care diagnostics are needed so that alphaviruses such as CHIKV, MAYV, and VEEV are not misdiagnosed as dengue and other common infections. This could lead to major improvements in surveillance and control measures, as well as identification of endemic locations suitable for clinical efficacy testing of vaccines and therapeutics.[805]

Perspectives

INTRODUCTION

Yellow fever had been an endemic and emerging disease for centuries when, in 1901, Walter Reed demonstrated that this disease could be experimentally transferred via the filtered serum of an infected individual, the first identification of a human virus. It is now understood that yellow fever virus (YFV) is but one representative of a large family of related positive-strand RNA viruses, the *Flaviviridae* (from the Latin flavus, “yellow”). This family consists of four genera: *Flavivirus*, *Hepacivirus* (from the Greek *hepar*, “liver”), *Pegivirus* (for *pe*rsistent *G*B virus), and *Pestivirus* (from the Latin *pestis*, “plague”).

Family Classification

The *Flaviviridae* exhibit diverse biological properties and limited serological cross-reactivity. Despite this diversity, viruses are classified within the *Flaviviridae* based on similarities in genome organization and shared phylogeny of essential viral replication enzymes. Currently, all members of the *Flaviviridae* share the following common features: (a) enveloped virus particles that are labile to detergents and organic solvents; (b) nonsegmented, positive-strand RNA genomes, 9.4 to 13.0 kb in length, which encode a large open reading frame (ORF); and (c) a common set of virus-encoded replication enzymes: nonstructural (NS) protein 3 (NS3) with serine protease and RNA helicase activities and NS5 (or NS5B) with RNA-dependent RNA polymerase (RdRP) activity. On larger evolutionary scales, the NS3 helicases share phylogenetic similarity to other superfamily 2 "DEx(D/H)" RNA helicases, including those of plant-infecting, positive-strand RNA potyviruses[447]; the NS5/NS5B RdRPs share phylogenetic similarity with a diverse set of "branch 3" positive-strand RNA viruses, including alphaviruses, nodaviruses, tombusviruses, and luteoviruses.[978]

Recent advances in virus discovery and metagenomics have led to profound reorganization and expansion of the *Flaviviridae*, including establishment of a new genus, *Pegivirus*, as well as the identification of new viruses within established genera with expanded host tropism, such as *Hepaciviruses* that infect rodents, bats, and nonhuman primates. All currently recognized members of the *Flaviviridae* are listed in Table 7.1; a molecular phylogeny of the *Flaviviridae*, based on conserved regions of viral RdRPs, is shown in Figure 7.1A. It should be noted that a number of *Flaviviridae* remain to be officially classified at the genus level, such as Tamana bat virus and, at the species level, such as several arthropod-specific flaviviruses. In addition, metagenomic surveys have identified several "flavi-like" viruses with very large (16–23 kb) monopartite genomes as well as "Jingmenviruses" with 10.5- to 11.0-kb multipartite genomes divided among four or five RNA segments that are independently encapsidated.[467,836] Jingmenviruses have been found in arthropod hosts but may be transmitted to humans and other primates, where they can cause febrile illness.[467,952] Although these latter virus groups have not been classified within the *Flaviviridae*, they do encode canonical NS3-like serine proteases/RNA helicases and NS5/NS5B–like RdRPs. Clearly the field is entering an exciting period of comparative studies

and critical evaluation of essential features shared among the *Flaviviridae*.

TABLE 7.1 Taxonomy of the *Flaviviridae*

Taxonomic Unit	Member Species
Genus *Flavivirus*	
Mosquito-borne	*Aroa virus* (AROAV); *Bagaza virus* (BAGV); *Banzi virus* (BANV); *Bouboui virus* (BOUV); *Cacipacore virus* (CPCV); *Dengue virus*, types 1–4 (DENV-1 to DENV-4); *Edge Hill virus* (EHV); *Ilheus virus* (ILHV); *Israel turkey meningoencephalomyelitis virus* (ITV); *Japanese encephalitis virus* (JEV); *Jugra virus* (JUGV); *Kedougou virus* (KEDV); *Kokobera virus* (KOKV); *Koutango virus* (KOUV); *Murray Valley encephalitis virus* (MVEV); *Ntaya virus* (NTAV); *Saboya virus* (SABV); *Saint Louis encephalitis virus* (SLEV); *Sepik virus* (SEPV); *Tembusu virus* (TMUV); *Uganda S virus* (UGSV); *Usutu virus* (USUV); *Wesselsbron virus* (WESSV); *West Nile virus* (WNV); *Yaounde virus* (YAOV); *Yellow fever virus* (YFV); *Zika virus* (ZIKV)
Tick-borne	*Gadgets Gully virus* (GGYV); *Kadam virus* (KADV); *Kyasanur Forest disease virus* (KFDV); *Langat virus* (LGTV); *Louping ill virus* (LIV); *Meaban virus* (MEAV); *Omsk hemorrhagic fever virus* (OHFV); *Powassan virus* (POWV); *Royal Farm virus* (RFV); *Saumarez Reef virus* (SREV); *Tick-borne encephalitis virus* (TBEV-Eur); *Tyuleniy virus* (TYUV)
No known vector	*Apoi virus* (APOIV); *Bukalasa bat virus* (BBV); *Carey Island virus* (CIV); *Cowbone Ridge virus* (CRV); *Dakar bat virus* (DBV); *Entebbe bat virus* (ENTV); *Jutiapa virus* (JUTV); *Modoc virus* (MODV); *Montana myotis leukoencephalitis virus* (MMLV); *Phnom Penh bat virus* (PPBV); *Rio Bravo virus* (RBV); *Sal Vieja virus* (SVV); *San Perlita virus* (SPV); *Yokose virus* (YOKV)
Unclassified	*Aedes flavivirus* (AEFV), *Cell fusing agent virus* (CFAV); *Culex flavivirus* (CXFV); *Spondweni virus* (SPOV); *Tamana bat virus* (TABV), etc.
Genus *Hepacivirus*	*Hepacivirus A* (nonprimate hepacivirus, NHPV); *Hepacivirus B* (GB virusB, GBV-B); *Hepacivirus C* (hepatitis C virus; HCV, genotypes 1–7); *Hepacivirus D* (guereza hepacivirus, GHV); *Hepacivirus E* (rodent hepacivirus E, RHV-E); *Hepacivirus F* (rodent hepacivirus F; RHV-F); *Hepacivirus G* (Norway rat hepacivirus 1, NRHV1); *Hepacivirus H* (Norway rat hepacivirus 2, NRHV2); *Hepacivirus I* (rodent hepacivirus I, RHV-I); *Hepacivirus J* (rodent hepacivirus J, RHV-J); *Hepacivirus K* (bat hepacivirus K, BHV-K); *Hepacivirus L* (bat hepacivirus L, BHV-L); *Hepacivirus M* (bat hepacivirus M, BHV-M); *Hepacivirus N* (bovine hepacivirus N, BoHV)
Genus *Pegivirus*	*Pegivirus A* (simian pegivirus [formerly GB virus A], SPgV); *Pegivirus B* (GB virus-D, GBV-D); Pegivirus C (human pegivirus, HPgV); *Pegivirus D* (Theiler disease–associated virus, TDAV); *Pegivirus E* (equine pegivirus, EPgV); *Pegivirus F* (bat pegivirus F, BPgV-F); *Pegivirus G* (bat pegivirus G, BPgV-G); *Pegivirus H* (human hepegivirus, HHPgV); *Pegivirus I* (bat pegivirus I, BPgV-I); *Pegivirus J* (rodent pegivirus, RPgV); *Pegivirus K* (porcine pegivirus, PPgV)
Genus *Pestivirus*	*Pestivirus A* (bovine viral diarrhea virus 1, BVDV1); *Pestivirus B* (bovine viral diarrhea virus 2, BVDV2); *Pestivirus C* (classical swine fever virus [formerly hog cholera virus], CSFV); *Pestivirus D* (border disease virus, BDV); *Pestivirus E* (pronghorn antelope pestivirus, PAPeV); *Pestivirus F* (porcine pestivirus, PPeV); *Pestivirus G* (giraffe pestivirus, GPeV); *Pestivirus H* (HoBi-like pestivirus, HoBiPeV); *Pestivirus I* (Aydin-like pestivirus, AydinPeV); *Pestivirus J* (rat pestivirus, RPeV); *Pestivirus K* (atypical porcine pestivirus, APPeV)

Virus species and genera currently recognized by the International Committee on Taxonomy of Viruses are shown in italics; common names and abbreviations are shown in parentheses.

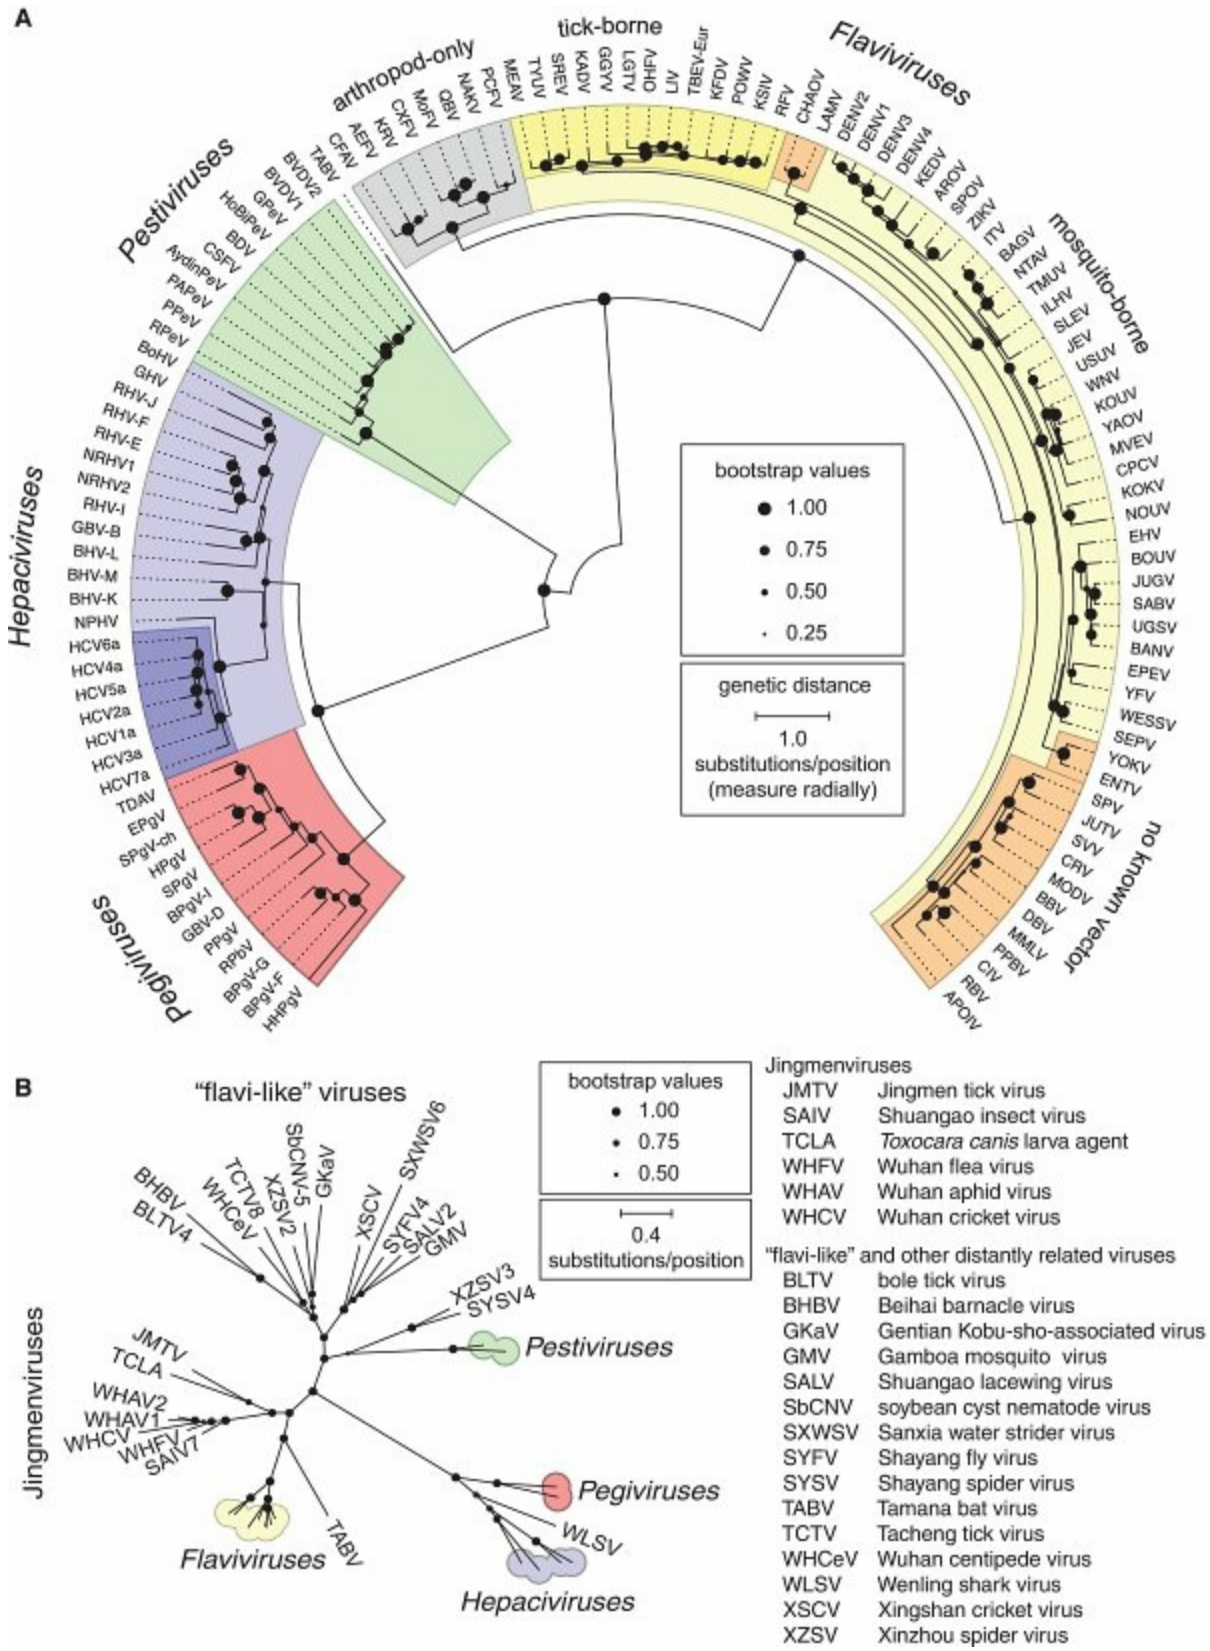

FIGURE 7.1 The family *Flaviviridae*. **A:** Unrooted phylogenetic

tree of all current members of the *Flaviviridae*, based on maximum likelihood alignment of a conserved, 352-aa region of the RdRP domains, constructed by using previously described methodology.[836] Virus names are abbreviated as in Table 7.1 and the text, with clades of interest highlighted by colored arcs. TABV, which has not been officially classified as a *Flaviviridae*, was included as an outgroup. The linear scale bar represents genetic distance along the radial axis; circular scale bars represent bootstrap support values for each node (n = 1,000 iterations). We thank Anderson Brito and Nathan Grubaugh for assistance in sequence alignment and tree construction. **B:** Unrooted phylogenetic tree of unclassified viruses that resemble the *Flaviviridae*, based on maximum likelihood alignment of a conserved region of the RdRP domain, as above. We thank Mang Shi and Eddie Holmes for assistance in sequence alignment and tree construction.

Family Characteristics and Replication Cycle

This chapter is organized around common features of the family *Flaviviridae* life cycle (Fig. 7.2). The enveloped virions are composed of a lipid bilayer with two or more species of envelope (E) glycoprotein surrounding a nucleocapsid, which consists of a single-stranded, positive-sense RNA genome complexed with multiple copies of a small, basic capsid (C) protein. Binding and uptake are believed to involve receptor-mediated endocytosis, although bona fide entry receptors have only been positively identified for a few viruses. For the purposes of this chapter, we define virus entry factors as a general category of cellular molecules that contribute toward productive virus entry; attachment receptors are a subset of entry factors that bind to virus particles, often with low specificity, and thereby increase virus–cell avidity but may not be essential for virus entry; entry receptors are a distinct subset of virus-binding cell surface molecules that target the virus for essential steps in productive virus entry. Following endocytosis, the low pH of the endosome induces fusion of the virion envelope with cellular

membranes. Following uncoating of the nucleocapsid, the RNA genome is released into the cytoplasm. The genome serves three discrete roles within the life cycle: as the messenger RNA (mRNA) for translation of all viral proteins, a template during RNA replication, and the genetic material packaged within new virus particles. The organization of the genome is similar for all genera. Viral proteins are produced as part of a single polyprotein that is cleaved by a combination of host and viral proteases. The structural proteins are encoded in the N-terminal portion of the polyprotein with the NS proteins in the remainder. Sequence motifs characteristic of a serine protease, RNA helicase, and an RdRP are found in similar locations in the polyproteins of all four genera. RNA replication occurs entirely in the cytoplasm in close association with intracellular membranes; the synthesis of a genome-length minus-strand RNA provides the intermediate. Progeny virions assemble by budding into an intracellular membrane compartment, most likely the endoplasmic reticulum (ER), and then transit through the host secretory pathway and are released at the cell surface.

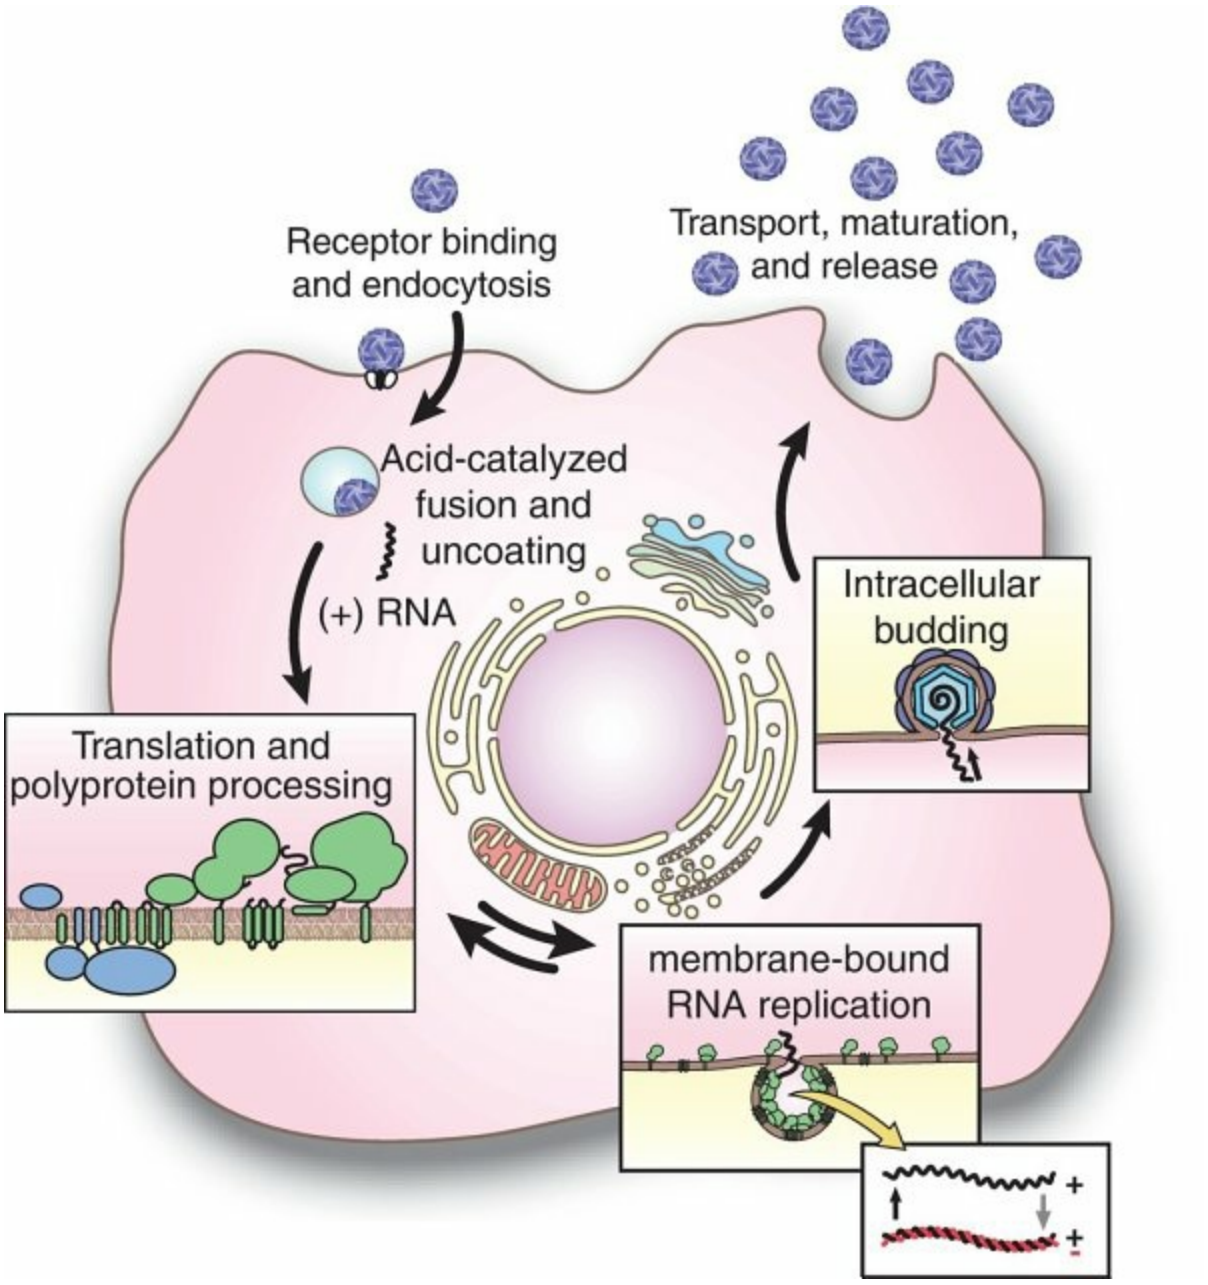

FIGURE 7.2 The life cycle of the *Flaviviridae*. See text for details.

FLAVIVIRUSES

Background and Classification

The *Flavivirus* genus currently includes 56 virus species, many of which are

arthropod-borne human pathogens. Flaviviruses cause a variety of human and animal diseases, including fever, encephalitis, and hemorrhagic fevers. Entities of major global concern include dengue virus (DENV)—with its associated dengue hemorrhagic fever (DHF) and dengue shock syndrome (DSS)—Japanese encephalitis virus (JEV), West Nile virus (WNV), YFV, and Zika virus (ZIKV).[959] Decreases in mosquito control efforts coupled with societal factors (e.g., increased transportation and dense urbanization) have contributed to several significant flavivirus outbreaks, including the reemergence of YFV in Africa and the Americas, reemergence of multiple DENV serotypes in the Americas, the introduction and spread of WNV in North America, and the emergence of ZIKV, notably linked to fetal birth defects, in South and Central America.

Mosquito-borne and tick-borne flaviviruses, although distinct, appear to have evolved via a common ancestral line that diverged from viruses with no known arthropod vector. In addition, several arthropod-specific flaviviruses remain to be taxonomically classified within this genus. Flavivirus species are further categorized into antigenic complexes and subcomplexes based on serological criteria or into genetically related clusters and clades, according to molecular phylogenetics.[131,848] For instance, the JEV serocomplex includes eight virus species that are genetically and antigenically related. DENV, which is both a single virus species and a distinct serogroup, notably circulates as four distinct serotypes. Human antibody responses to one DENV serotype are poorly cross-protective and may even enhance pathogenesis during secondary infections with other DENV serotypes; one explanation for this immunopathology is through antibody-dependent enhancement (ADE) of virus entry into myeloid cells that express antibody Fc receptors.[333,413] Although DENV-specific antibodies can also enhance ZIKV infection in experimental models,[49,120,273,871] preexisting DENV immunity appears to afford partial cross-protection to ZIKV infection in humans.[775]

In 1937, Max Theiler developed a live attenuated yellow fever vaccine by extensive serial passage of a virulent YFV isolate in suckling mouse brain and chick embryo tissues. The resulting virus, YFV-17D, has been successfully used to prevent yellow fever in over 300 million people. Despite this early success, only a limited number of flavivirus vaccines are available, including both inactivated and live attenuated JEV for use in humans, inactivated TBEV for use in humans, and inactivated WNV for use in

animals.[352] Development of effective DENV vaccines that exhibit cross-protection between serotypes remains particularly challenging. One recently approved tetravalent DENV vaccine, Dengvaxia, is based on four chimeric YFV-17D derivatives, each expressing the structural glycoproteins of one DENV serotype. However, Dengvaxia shows limited prophylaxis in DENV-naïve individuals and may enhance disease in natural infections.[773] Therefore, its use is currently limited to people aged 9 to 45 with prior DENV infection and who live in DENV endemic areas.

Structure and Physical Properties of the Virion

Infectious flavivirus particles are lipid enveloped, roughly spherical, and approximately 50 nm in diameter and lack prominent spikes (Fig. 7.3A–C). Viruses sediment between 170S and 210S and have buoyant densities of 1.19 to 1.23 g/cm^3 depending on the lipid composition, which varies by host.[793] The outer shell of the particle is made up of two viral proteins, envelope (E) and membrane (M). The E glycoprotein is the major antigenic determinant of the virion and mediates binding and fusion during virus entry. The M protein is a small proteolytic fragment of the precursor membrane (prM) protein and is produced during virus maturation within the secretory pathway. Removal of the lipid envelope with nonionic detergents reveals discrete nucleocapsids (120–140S; 1.30–1.31 g/cm^3), which consist of a single RNA genome and multiple copies of capsid (C) protein.[422]

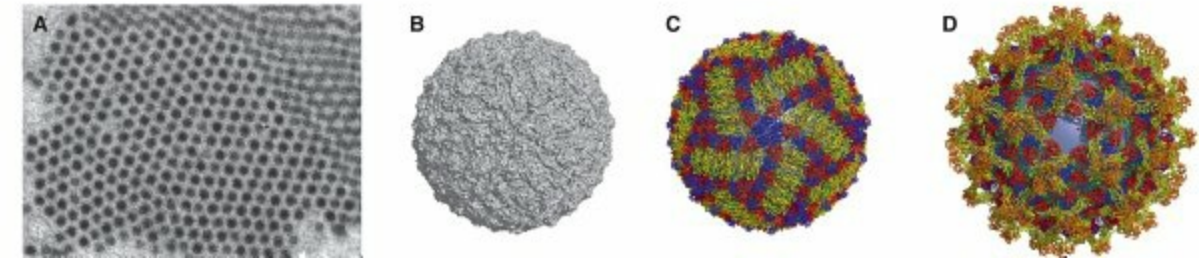

FIGURE 7.3 Flavivirus particles. **A:** Paracrystalline array of SLEV particles in the salivary gland of a *Culex pipiens* mosquito 25 days after blood meal feeding on an infected suckling mouse. (Courtesy of Sylvia G. Whitfield, Frederick A. Murphy, and W. Daniel Sudia.) **B:** Surface view of a symmetrical cryo-EM

reconstruction of mature DENV-2 particles, at 3.5 Å resolution, as rendered from PDB 3J27.[1025] **C:** DENV-2 glycoproteins rendered on the same cryo-EM reconstruction in **panel B**, colored as in Figure 7.5: *red*, E glycoprotein domain I; *yellow*, E domain II; *blue*, E domain III; *green*, E membrane-proximal and transmembrane domains; *orange*, M protein; *slate*, envelope membrane. **D:** Symmetrical cryo-EM reconstruction of immature DENV-1 particles, at 6 Å resolution, as rendered from PDB 4B03.[449] Features are colored as in **panel C** except: *orange*, prM glycoprotein.

Exquisite structural details of immature and mature flavivirus particles have been determined by cryo-electron microscopy and x-ray crystallography. Mature infectious particles display a relatively smooth, dimpled outer surface, with 90 antiparallel E glycoprotein dimers lying flat across the surface of the virion, tightly packed in a "herringbone" array that completely covers the lipid bilayer (Fig. 7.3C).[343] This packing involves two-, three-, and fivefold axes of symmetry, similar to a $T = 3$ icosahedral particle but lacking quasi-equivalence. Beneath this outer protein shell, the membrane-proximal and transmembrane domains of the M and E proteins interact with the membrane in orderly, regular intervals; beneath the lipid envelope, flavivirus nucleocapsids lack discernible symmetry and make intermittent contacts with the glycoprotein transmembrane domains.[908] Despite this seemingly well-ordered structure, flavivirus particles are not rigid, uniformly dimpled golf balls. Antibody neutralization studies have shown that the surface of DENV particles is conformationally dynamic and capable of strain- and temperature-dependent "breathing."[551] Moreover, a subset of flavivirus particles form with fewer than 180 copies of prM–E[908] and, as described below, mature virus particles display variable amounts of uncleaved prM.

Immature virions are larger than mature virions, 60 nm in diameter, and display 60 prominent spikes with icosahedral symmetry (Fig. 7.3D).[343] Each protrusion is composed of three prM–E heterodimers, with prM serving to protect the E fusion peptide against premature fusion during particle

secretion. Within immature particles, the nucleocapsid appears as an asymmetric ovoid, displaced to one side of the virus particle.[908] As immature particles pass through the low pH environment of the *trans*-Golgi network, the 60 $(prM–E)_3$ complexes dissociate and reform as 90 $(prM–E)_2$ complexes, which lie flat against the envelope and give immature particles a smoother appearance.[1016] It is at this point that the trigger for fusion has been set, with E held in a pH-sensitive metastable conformation. Thereafter, prM is cleaved by the Golgi-resident host protease furin, leading to subsequent release of mature virions and free pr fragments. This process is imperfect: some flaviviruses, like DENV, release significant quantities of partially mature and immature particles.[761] Partially mature particles, which retain a mixture of M and uncleaved prM, can undergo attachment and fusion to initiate infection similar to fully mature particles. Released immature particles are incapable of triggering fusion and are noninfectious; however, immature particles opsonized by prM- or E-specific antibodies can infect Fc receptor–bearing cells.[268] The mechanisms of this antibody-dependent fusion are not well understood but may require cleavage of prM in the endosome. Importantly, immature and partially mature particles display envelope membrane and prM–E conformations that are not exposed in mature particles, pleiomorphisms that have significant implications for antibody neutralization, viral entry, and pathogenesis.[202,761]

Flavivirus-producing cells also secrete smaller, noninfectious subviral particles (SVPs), which contain E and M glycoproteins but lack nucleocapsids. SVPs complete the same maturation process as whole virions and can undergo fusion with target membranes; however due to lack of a genome-containing nucleocapsid, they are not infectious. Cells that express only prM and E release structurally similar “recombinant subviral particles” (RSPs), indicating that the viral glycoproteins are sufficient to drive the budding process.[19,810] RSPs are approximately 30 nm in diameter and less dense than infectious virus particles (1.14 g/cm^3). RSPs have a markedly different arrangement of E glycoprotein, with only 30 E dimers lying flat against the surface in a $T = 1$ icosahedral shell rather than the herringbone pattern seen in mature virus particles.[258]

Binding and Entry

Flaviviruses enter target cells through receptor-mediated endocytosis, followed by intracellular membrane fusion. Bona fide flavivirus entry receptors have not been fully identified, although a number of important cellular entry factors have been characterized.[487,761] Binding of E glycoprotein to glycosaminoglycans (GAGs), such as heparan sulfate, can enhance cell surface attachment; however, cell culture–adapted flaviviruses with high affinities for GAGs are attenuated *in vivo*.[585] As mentioned above, ADE can lead to infection of Fc receptor– expressing cells with flavivirus particles opsonized with subneutralizing antibodies, which likely contributes to the pathogenesis of DSS and DHF in people previously exposed to other DENV serotypes.[334]

A number of C-type lectins, which bind mannose-rich glycans and are highly expressed on several myeloid-derived cell types, have been implicated in flavivirus attachment and entry. In particular, the C-type lectin DC-SIGN can function as an attachment receptor for DENV infection of dendritic cells[668,890]; this interaction may be particularly relevant when mosquito-produced virus particles, which display more high-mannose glycans and fewer complex glycans, encounter intradermal dendritic cells. In contrast, WNV preferentially binds DC-SIGNR, a related C-type lectin that is highly expressed on microvascular endothelial cells.[195] The mannose receptor, another C-type lectin, has been implicated in the endocytosis of DENV, JEV, and TBEV.[633] Interestingly, interaction of DENV particles with yet another C-type lectin, CLEC5A, does not mediate viral entry but can trigger the release of proinflammatory cytokines, which may contribute to dengue pathogenesis.[155]

Phosphatidylserine (PtdSer) receptors, which normally mediate recognition and phagocytosis of apoptotic cells, are another important class of flavivirus entry factors.[487,610,761] PtdSer, a phospholipid, is normally sequestered in the inner leaflet of the plasma membrane and membranes of the secretory pathway and only exposed to the extracellular milieu during apoptosis, when it serves as an “eat me” signal. Flaviviruses, which bud into the ER, may acquire envelope membranes enriched for PtdSer. Thus, when the viral envelope is exposed on the surface of immature, partially mature, and breathing flavivirus particles, it can be directly bound by T-cell immunoglobulin–mucin (TIM) proteins, a family of PtdSer receptors expressed on a variety of immune cells. Similarly, Tyro3, Axl, and Mer

(TAM), a distinct family of PtdSer receptor–protein tyrosine kinases, can bind flavivirus particles indirectly via their soluble PtdSer-binding protein ligands Gas6 and ProS.[610] While TIMs and TAMs can contribute to flavivirus entry, they are not essential for virus infection[487]; thus, their specific roles in viral entry and pathogenesis require further study. Finally, the endoplasmic reticulum membrane complex (EMC) reportedly plays an important but undefined role in flavivirus entry, perhaps by modulating the trafficking of host factors needed for viral internalization.[805]

After binding to the appropriate receptor(s), flaviviruses are internalized by clathrin-mediated endocytosis and delivered to early or intermediate endosomes, which mature into late endosomes.[932] Fusion of the viral envelope with the bounding endosomal membranes occurs during endosomal trafficking, although the exact compartment where fusion occurs differs between flaviviruses, perhaps reflecting differences in pH optima.[932] In the acidic environment, E protein dimers dissociate and undergo an irreversible conformational change to become fusogenic trimers.[18,872] In this conformation, the fusion peptide, previously buried within the E homodimer interface, extends away from the viral envelope and inserts into the endosomal membrane (Video 7.1). The lipid composition of target membranes influences the pH threshold and efficiency of flavivirus fusion.[448,873,874,1020] Nevertheless, the flavivirus fusion mechanism is generally very rapid, complete within seconds after exposure to low pH.[149,718,932]

Flavivirus fusion is an active target of antiviral development, with a number of small molecules demonstrating potent virus-specific or broad activity against several flaviviruses.[718] Some of these compounds apparently target a hinge within the E glycoprotein that is needed to induce its conformational change into the fusogenic form. Other compounds may target the rate-limiting steps of trimer formation or fusion peptide extension.[148]

Following *in vitro* dissolution of the viral envelope, viral genomes are immediately accessible for translation, suggesting that capsids can spontaneously uncoat.[448] Indeed, nucleocapsids isolated from virions are unstable in high salt, disassembling into C protein dimers.[422] However, *in vivo*, it appears that postfusion capsid uncoating and genome translation require ubiquitylation of capsid protein.[129]

Genome Structure

As for other positive-strand RNA viruses, flavivirus genomes are infectious once delivered into the cytosol of target cells.[703] Several flavivirus infectious complementary DNA (cDNA) clones and replicons have been constructed, allowing the structure and function of the genome to be dissected via reverse genetics.[35,458,790] Flavivirus genomes consist of a single segment of positive-stranded RNA, approximately 11 kilobases (kb) in length (sedimentation, 42S), with a type 1 5′ cap, $^{m7}GpppA_mN$, and lacking a 3′ poly-A tail (Fig. 7.4).[171,970] The cap serves to initiate translation, stabilize viral RNA, and subvert innate antiviral defenses.[190,283] Genomes encode a single long open reading frame (ORF, ~3,400 codons) flanked by 5′ and 3′ noncoding regions (NCR) of approximately 100 nucleotides (nts) and 400 to 700 nts, respectively (Fig. 7.4A).[675] The NCRs contain *cis*-acting RNA structures and sequences important for viral gene expression, replication, and immune modulation.

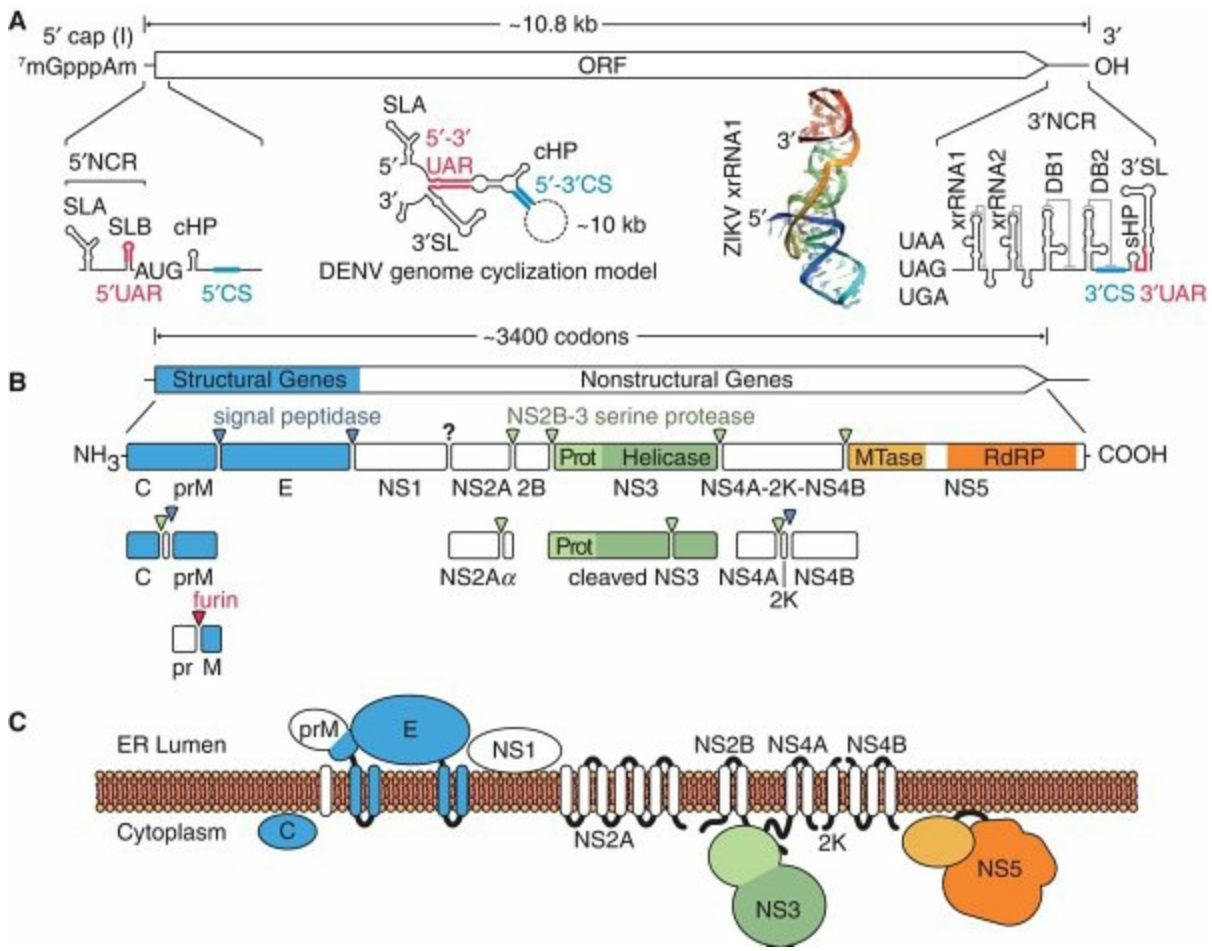

FIGURE 7.4 Flavivirus genome structure and polyprotein expression. **A:** Genome structure and RNA elements. The viral genome is depicted with the structural and nonstructural (NS) coding regions, the 5′ cap, and the 5′ and 3′ noncoding regions (NCR) indicated. Functionally significant RNA structures within the DENV genome are illustrated, with pseudoknot base pairing indicated by *gray lines*. Insets include a model of DENV genome cyclization and the structure of the ZIKV xrRNA1 fragment, colored across the visible spectrum (5′ blue–3′ red), as rendered from PDB 5TPY.[11] **B:** Polyprotein processing and cleavage products. Boxes below the genome indicate precursors and mature proteins generated by the proteolytic processing cascade. Structural proteins are colored *blue*, while NS proteins are white or shaded according to their enzymatic subunits, as indicated. Cleavage sites

for host signal peptidase, the viral NS2B-3 serine protease, furin, and an unknown protease (?) are indicated.

C: Polyprotein membrane topology. The proposed membrane orientation of the flavivirus proteins is shown. The proteins are approximately to scale (areas are proportional to the number of amino acids) and arranged in order (*left* to *right*) of their appearance in the polyprotein.

Flavivirus 5′ and 3′ NCRs are poorly conserved across the genus, with particular divergence between mosquito-borne, tick-borne, and arthropod-specific flaviviruses and flaviviruses with no known vector, likely reflecting adaptation of these RNA structures to specific hosts.[941] Nevertheless, functionally important RNA structures and sequence motifs have been identified, including structurally conserved bifurcated 5′ stem–loop (SL) and large 3′ SL structures. A key unifying feature among flaviviruses is cyclization of their genomes via long-distance base pairing between the 5′ and 3′ ends.[331,538,941]

Because the study of flavivirus 5′ and 3′ NCRs is complicated by their inherent variability, a paucity of rigorously determined RNA structures, and differences in nomenclature, this discussion focuses on DENV, which is the best characterized model of flavivirus 5′ and 3′ NCR structures and genome cyclization. While the details differ between flaviviruses, the fundamental mechanisms elaborated with DENV appear to operate in other mosquito-borne flaviviruses and even extend to flaviviruses with other vector host ranges, despite low sequence similarity.[538,923,941] The DENV 5′SL, frequently termed SL-A, is followed by a small SL-B, just upstream of the translational start site, that includes a sequence termed the 5′ upstream AUG region (5′UAR) (Fig. 7.4A). Shortly within the capsid-coding region is another small SL, termed the capsid-coding region hairpin (cHP), followed by an unstructured 5′ cyclization sequence (5′CS) and additional small SLs.[941]

The DENV 3′ NCR consists of three functionally distinct regions. Region I is the most variable, with deletions and point mutations frequently arising in mosquito-adapted DENV isolates, suggesting that its function is particularly important in vertebrate hosts.[941] Region I typically folds into two SLs, xrRNA1 and xrRNA2 (sometimes called SLI and SLII), the loops of which

can base-pair just downstream of each SL to form two adjacent pseudoknots (Fig. 7.4A). These pseudoknots are tightly packed, essentially threading the RNA backbone through the pseudoknot and rendering this region of flavivirus genomes resistant to the cellular 5′ to 3′ exonuclease XRN1 (inset, Fig. 7.4A).[11,150] Upon XRN1 degradation of the genome, the resulting subgenomic flavivirus RNAs (sfRNAs) have immunomodulatory properties.[856] Region II folds into two conserved dumbbell structures, DB1 and DB2, that also form pseudoknots with downstream adjacent regions. In particular, DB2 base-pairs to the 3′CS, which has complementarity to the 5′CS, while DB1 can base-pair directly to the capsid-coding region. Region II can also tolerate variability, with mutations that stabilize DB1 or destabilize DB2 arising in mosquito-adapted DENV isolates.[196] Region III, the most conserved part of the DENV 3′NCR, consists of a small hairpin (sHP) followed by a large, structurally conserved terminal 3′SL; the base of sHP and 3′SL are formed from the 3′UAR sequence, which has complementarity to the 5′UAR.

The DENV genome exists in a dynamic equilibrium between competing linear and cyclized structures, formed by long-distance base pairing between the 5′ to 3′UAR and 5′ to 3′CS elements (inset, Fig. 7.4A). Mutations that disrupt or favor one conformation frequently select for reversions that restore this equilibrium.[940] The cyclized conformation is critical for RNA replication: SL-A binds the NS5 RdRP domain and positions it to initiate minus-strand synthesis from the 3′ end, held proximal by genome cyclization.[265,266,546,1007] Genome cyclization also alters 5′ and 3′ secondary structures, leading to occlusion of the translation start site. Thus, large-scale genome conformation may regulate the switch from translation to RNA replication. Consistent with this, *in vivo* SHAPE analysis of DENV and ZIKV RNA confirmed that viral genomes are highly structured, containing several conserved structural motifs and transient long-distance base-pairing interactions.[369]

Translation and Proteolytic Processing

The efficiency of genome translation is a primary determinant of flavivirus infectivity.[228] The viruses therefore use several mechanisms to ensure translational competence, including specialized structures within the 5′ and 3′

NCRs. Translation of flavivirus genomes is largely cap-dependent; 2′-O-methylation of the 5′ nucleotide also helps to overcome innate antiviral defenses that down-regulate translation in infected cells.[190] While translation initiates via ribosomal scanning, many mosquito-borne flaviviruses lack a canonical Kozak initiation motif and contain several AUG codons near the correct start site. To help ensure proper AUG selection, DENV uses a small RNA stem–loop embedded within the C gene to induce ribosomal pausing over the authentic initiation codon.[175]

In addition to canonical cap-dependent mechanisms of translation initiation, DENV and ZIKV 5′ NCRs are reported to have internal ribosome entry site (IRES) activity, capable of driving expression of a downstream reporter gene in bicistronic mRNAs within human cells, but not in mosquito cells.[861] Nevertheless, given that flavivirus genomes lacking a 5′ cap have approximately 1,000-fold reduced specific infectivity[764] and that flavivirus cap methylation activity is essential for RNA replication,[214,1034] it appears that flaviviruses are more dependent on cap-mediated translation than on IRES activity. Interestingly, mutations in the 5′ SL-A partially restored replication of a WNV genome containing lethal mutations in the NS5 methyltransferase active site[1024]; it will be interesting to see whether these mutations increase IRES activity. Thus, perhaps flaviviruses encode a proto-IRES, reflecting an evolutionary midpoint between capped and uncapped genomes within the family and allowing flaviviruses to maintain genome translation under conditions of translation-arresting stress in vertebrate cells. Indeed, flavivirus genomes remain efficiently translated even as the translation of host mRNAs is down-regulated during infection.[757,786] This preferential reprogramming of the translational apparatus involves activation of the MAPK-interacting Ser/Thr protein kinase 1, which phosphorylates eIF4E to enhance translation of capped mRNAs.[786] In addition, flaviviruses antagonize the formation of cytosolic RNA stress granules,[94,238,364] which inhibit virus genome translation and replication.[13]

Translation of the single, long ORF produces a large polyprotein that is co- and posttranslationally cleaved into at least 10 proteins (Fig. 7.4B). The N-terminal region of the polyprotein encodes the structural proteins C–prM–E, which are followed by the NS proteins NS1–NS2A–NS2B–NS3–NS4A–2K–NS4B–NS5.[138,765] Host signal peptidase is responsible for cleavages of

C/prM, prM/E, E/NS1, and 2K/NS4B. Please note that dashes are used to refer to uncleaved polyproteins (e.g., NS4A-2K-NS4B) or to protein complexes (e.g., NS2B-3); slashes specifically refer to cleave sites within the polyprotein (e.g. C/prM). A virus-encoded serine protease, NS2B-3, processes at the NS2A/NS2B, NS2B/NS3, NS3/NS4A, NS4A/2K, and NS4B/NS5 junctions. The enzyme responsible for NS1-2A cleavage is presently unknown. The predicted topology of the flavivirus polyprotein is depicted in Figure 7.4C.

Features of the Structural Proteins

Capsid (C) Protein

The capsid (C) protein is a small (~12 kDa), positively charged protein that binds RNA with high affinity and low specificity; its major function is to encapsidate the viral genome within flavivirus particles. C is initially synthesized as an uncleaved C–prM precursor; processing of this intermediate occurs in two steps: cleavage by the viral serine protease on the cytosolic side of the transmembrane domain to release mature C, followed by signal peptidase cleavage on the lumenal side to generate the N-terminus of prM.[544] This coordinated cleavage results from the combination of a fairly short (14–22 aa) signal sequence, a suboptimal signalase cleavage site, and downstream regions of prM and E.[544,875] Mutations that uncouple signal peptidase cleavage from viral serine protease cleavage lead to increased production of empty virus particles.[495,545] Coordinated cleavage therefore serves to delay structural protein processing until the viral serine protease has accumulated and replication is under way, which may limit the release of immunogenic but noninfectious SVPs early in infection. In addition, this delayed cleavage mechanism renders flaviviruses highly dependent on signal peptide complex protein SPCS1.[1026]

Mature C protein folds into a compact dimer with each monomer contributing four alpha helices that enwrap to form a wedge-like core (Fig. 7.5A). The N-terminal approximately 25 aa of C remains unstructured and encodes several basic residues; along with basic residues on the surface of α4, this region is involved in RNA binding.[128] On the opposite surface, α2 displays a hydrophobic surface that mediates membrane association of

C.[128,572]

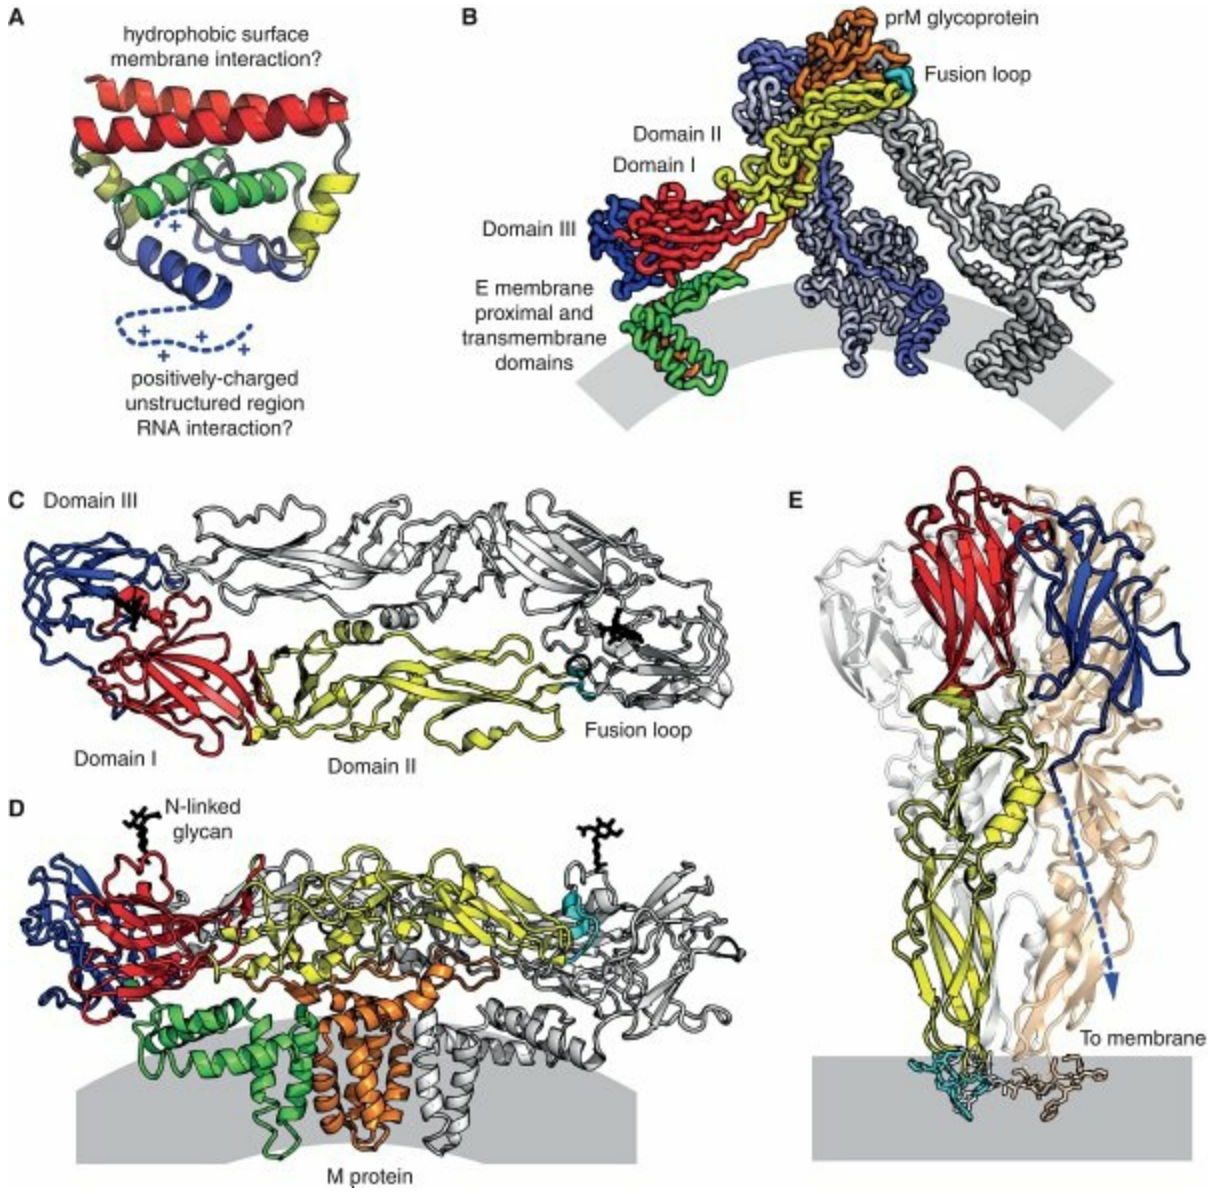

FIGURE 7.5 Flavivirus structural proteins. **A:** Flavivirus C protein structure. The WNV C protein dimer is shown, with helices colored sequentially N-blue, green, yellow, and red. Rendered from PDB 1SFK.[213] **B:** Structure of the trimeric prM–E glycoprotein complex on the surface of immature DENV-1 particles. One E monomer is colored *red* (domain I), *yellow* (domain II), *blue* (domain III), *cyan* (fusion loop), and *green* (membrane-proximal and transmembrane

domains); one prM monomer is colored *orange*. Rendered from biological assembly 2 of PDB 4B03.[449] **C:** The structure of a mature ZIKV E glycoprotein dimer as viewed perpendicular to the lipid bilayer, with one monomer colored as in **(B)**, rendered from PDB 6CO8.[828] For simplicity, the E and M membrane-proximal and transmembrane domains are hidden from view. **D:** The structure of a mature ZIKV E glycoprotein dimer as viewed lateral to the lipid bilayer, colored as in **(B)**, as rendered from PDB 6CO8.[828] **E:** TBEV E protein trimers in their postfusion form, colored as in **(C)**. Rendered from PDB 1URZ.[114]

Despite its compact, well-ordered structure and essential function in virus particle formation, the flavivirus C protein is actually poorly conserved and demonstrates remarkable structural plasticity. YFV C retains its ability to package RNA even after deletion of nearly 40 residues from the N-terminus or 27 residues of the C-terminus; internal deletions of the hydrophobic sequence are less tolerated.[697] The TBEV C protein remains functional even after deletion of 16aa from the central hydrophobic helix, albeit with increased production of empty particles.[436] Mutants containing larger deletions are not viable but can be rescued by second-site changes that increase the hydrophobicity of downstream sequences.[437] WNV tolerates small deletions in hydrophobic helix $\alpha 2$ to various degrees; remarkably, infectivity of the deleted genomes was improved by even larger deletions—up to one-third of the C protein sequence—encompassing all of helix $\alpha 3$.[815] It is not yet clear how C protein dimers are organized within the apparently disordered nucleocapsids, but RNA or DNA can induce isolated C protein dimers to assemble into nucleocapsid-like particles *in vitro*.[422]

Small amounts of flavivirus C protein localize to the ER and to the outer surface of lipid droplets (LDs),[128,799] which are ER-derived cytosolic reservoirs of neutral fatty acids and cholesterol esters. However, a large fraction of C localizes to the nucleus and to the nucleolus in particular.[128,882] Since virus assembly occurs on the cytosolic surface of the ER, the function of nuclear localization is unclear. Nuclear localization (and LD localization)

may serve to sequester C away from replication complexes until it is needed for virus assembly or may simply reflect the fact that clusters of basic residues, which are found in the RNA-binding regions of C, also serve as nuclear localization signals. On the other hand, DENV C can interact with histones and disrupt nucleosomes[182]; it also interacts with nucleolin, which may contribute to virus particle assembly.[44] In addition to these intranuclear interactions, YFV C reportedly inhibits RNA interference (RNAi) via its RNA-binding activity,[800] while the ZIKV C protein can enhance the replication of other RNA viruses without inhibiting RNAi.[934]

Precursor Membrane (prM) Glycoprotein

The glycoprotein precursor of M, prM (~26 kDa), functions as a chaperone for the E glycoprotein. The N-terminal pr region has a unique fold consisting of seven β strands, with six conserved, disulfide-linked cysteines, and one to three N-linked glycosylation sites[507]; prM folds rapidly after synthesis and assists in proper folding of the E glycoprotein.[445] In addition to interactions through their ectodomains, the C-terminal transmembrane domains of prM and E heterodimerize and act as an ER-retention signal for the prM–E complex.[687,689]

A key function of prM is to prevent E from undergoing premature acid-catalyzed fusion as virus particles transit through the secretory pathway.[326,353] In immature particles, the pr region sits at the tip of the E protein, forming the pr–E spike and shielding the fusion peptide from the cellular environment (Fig. 7.5C).[507] The acidity of the *trans*-Golgi compartment induces a global rearrangement of prM–E, exposing the furin cleavage site within prM.[864,1016,1029] After cleavage, the pr peptide remains associated with virus particles until exposure to neutral pH of the extracellular space.[864,1012,1016]

As a structural protein that sets the trigger for flavivirus fusion, prM is a key determinant of flavivirus pathogenesis. Incomplete furin cleavage of prM gives rise to partially mature virus particles that display different epitopes and the PtdSer-rich envelope membrane, which can influence cell entry and tropism.[761] This is particularly apparent for DENV prM, which features suboptimal furin cleavage[761]; indeed, prM-specific antibodies can contribute to ADE in secondary DENV infections.[202] Furthermore, a single point

mutation on the surface of the pr region was reported to contribute to ZIKV pathogenesis in a murine model of microcephaly, although the epidemiological impact of this mutation on human infections is still under debate.[319,1017]

Envelope (E) Glycoprotein

Flavivirus E (~53 kDa) is the prototype class II fusion protein that, unlike class I and III fusion proteins, do not make preformed trimers. E mediates receptor binding and membrane fusion and is the major neutralizing antigen on the surface of flavivirus particles. E contains 12 conserved cysteines that form intramolecular disulfide bonds; it is anchored to the viral envelope by adjacent C-terminal transmembrane anchors; and in some viral species, E is N-glycosylated. Proper folding, ER retention, secretion, and acid stabilization of E is dependent on coexpression with prM.[445]

As originally isolated and crystallized in its prefusion conformation from mature TBEV particles,[760] E folds into an elongated β-sheet–rich structure, forming head-to-tail homodimers that lie parallel to the virus envelope (Fig. 7.5C, D). Each E monomer consists of three domains: DI, which forms an eight-stranded β-barrel; DII, a long, finger-like domain that projects along the virus surface; and DIII, which has an immunoglobulin-like fold. The interfaces between DI and DII and between DI and DIII, which contain conserved histidine residues, act as pH-sensitive hinges.[801] The DI–DII interface also contains a hydrophobic pocket that can accommodate a β-octylglucoside detergent molecule.[641] The fusion peptide is located at the tip of the DII finger, buried in a distinct hydrophobic pocket formed by DI and DIII of the partner monomer; this intermolecular interface is also where pr binds and is a major neutralizing epitope.[788] DIII, which slightly protrudes from the virion surface, is a determinant of host tropism and a target of neutralizing antibodies[241,762]; DIII is therefore postulated to bind receptors, although DIII-specific receptors have not yet been identified. Between the ectodomain of E and the membrane is a short but functionally important stem region composed of two α-helices that lie parallel to the plane of the membrane.[20,1023]

Upon exposure to low pH, the dimer-stabilizing histidine residues in E become protonated, causing E dimers to dissociate into monomeric subunits,

which spontaneously reform as fusogenic trimers.[801] In its postfusion conformation (Fig. 7.5E), E is folded back onto itself, bringing the N-terminal fusion peptide (and target membrane) into proximity with the C-terminal transmembrane domain (and viral envelope).[642] To accomplish this, DII must rotate relative to DI, similar to the displacement of DII seen in crystals of native E protein grown in the presence of β-octylglucoside.[641,642] Furthermore, DIII must rotate and fold back more than 30 Å in relation to DI. Thus, flavivirus fusion is blocked by DIII-specific neutralizing antibodies or soluble, recombinant form of DIII, which inhibit these rearrangements.[520,680] Based on these mechanistic insights into the structure and function of E, a number of small molecules are under development as flavivirus fusion inhibitors and potential antiviral therapies.[148,718]

Features of the Nonstructural Proteins

NS1 Glycoprotein

NS1 (~46 kDa) is a high conserved, homodimeric glycoprotein that is retained within the early secretory pathway and also secreted from flavivirus-infected cells. NS1 has important roles in RNA replication and virus particle assembly; it is also a major humoral antigen, an immunomodulator, and a key determinant of flavivirus pathogenesis.

NS1 is cleaved from E by host signal peptidase; its C-terminus arises via cleavage at the NS1/NS2A junction by an unknown ER-resident host enzyme that requires the eight C-terminal residues of NS1 and an undefined portion of NS2A.[249,250] A report that NS1 has a C-terminal GPI-anchor has not held up to further scrutiny.[958,971] Flaviviruses in the JEV serogroup also express an elongated form of NS1, termed NS1′, which arises through a -1 ribosomal frameshifting event near the NS1-2A junction and terminates approximately 52 codons downstream.[267,596] NS1 contains 2 or 3 N-linked glycosylation sites and 12 conserved cysteines that are disulfide bonded.

Shortly after synthesis, NS1 forms stable homodimers that have an affinity for membranes. X-ray crystallography has revealed that NS1 consists of three domains: a small, N-terminal β-hairpin that interdigitates with the corresponding region of another NS1 monomer, forming a "β-roll" that drives stable dimer formation; a "wing" domain that includes a flexible loop and 2

N-linked glycans; and a long, C-terminal 9-stranded antiparallel *β*-sheet that forms an 18-rung "*β*-ladder" across the dimer interface (Fig. 7.6).[10] The near-planar arrangement of the wings and *β*-ladder render the NS1 dimer relatively flat, presenting one polar "outer" surface that displays epitopes and localized regions of variability, and one extended, hydrophobic "inner" surface that mediates peripheral membrane interaction. Based on this membrane association, purified NS1 can coat liposomes and remodel them into smaller lipoprotein particles.[10] Although it is not yet clear if this membrane rearrangement activity is relevant for the formation flavivirus replication complexes, a recent study has shown that NS1 is essential for the formation of vesicle packets (VPs), which are the sites of viral RNA replication.[726]

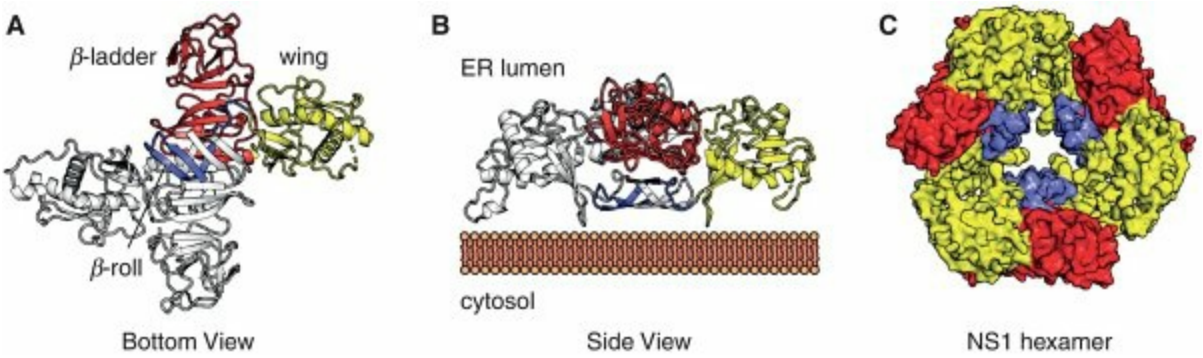

FIGURE 7.6 Flavivirus NS1 glycoprotein. **A:** Top view of ZIKV NS1 dimer, with one monomer colored to highlight the *β*-ladder (*red*), wing (*yellow*), and *β*-roll (*blue*). Rendered from PDB 5K6K.[119] **B:** Side view of ZIKV NS1 dimer, showing the inferred membrane-interaction surface, rendered as in **(A)**. **C:** Model of the ZIKV NS1 hexamer, showing a central hydrophobic channel, rendered as in **(A)**.

Intracellular NS1 dimers are retained in the early secretory pathway and localize to the lumenal side of viral replication vesicles, where they play an essential but enigmatic role at an early stage of RNA replication.[528,576] As RNA synthesis occurs on the cytosolic side of these membranes, NS1 fulfills this essential function, at least in part, via interaction with two polytopic membrane proteins, NS4A and NS4B or the NS4A-2K-NS4B

precursor.[532,726,1010] The intracellular form of NS1 also contributes to virus particle assembly via interactions with prM and E.[809,975]

Secreted NS1 (sNS1) forms soluble, hexameric lipoprotein particles of approximately 10 nm composed of three dimers held together in a barrel configuration surrounding a lipid core (Fig. 7.6C).[10,327] DENV sNS1 was originally identified as a soluble, complement-fixing antigen present at high levels during the acute phase of DENV infections[858,958]; indeed sNS1 is a diagnostic marker of flavivirus infections more broadly. Because of its abundance and multivalent structure, sNS1 is highly antigenic and induces strong humoral immune responses, including complement-fixing antibodies; NS1 can also directly inhibit thrombin and inhibit and/or stimulate components of the complement pathway.[958] While NS1-specific immune complex formation, reduced clotting activity, and complement activation all likely contribute to flavivirus pathogenesis, sNS1 also directly binds to and modulates relevant target cell types. For instance, DENV sNS1 is bound and internalized by hepatocytes, enhancing subsequent infection of these cells.[14] The mechanism whereby a secreted replication protein prepares cells for subsequent infection remains unclear but theoretically could enhance cross-species transmission. In fact, a genetic polymorphism in ZIKV correlates with higher sNS1 levels and increased ZIKV transmission to mosquitoes.[539] DENV sNS1 also binds to the innate immunity pattern recognition receptor TLR4 on the surface of monocytes, triggering release of proinflammatory cytokines, and on the surface of endothelial cells, triggering vascular leakage.[736,958] Surprisingly, sNS1 proteins from different flaviviruses disrupt endothelial barriers in a tissue-specific manner that resembles the tropism of the parental viruses.[736]

A fraction of NS1, presumably in dimeric form, is also expressed on the surface of infected cells via interaction with surface GAGs.[37] Cell surface–expressed NS1 can be recognized by NS1-specific antibodies, and NS1-specific antibodies can protect animals from lethal disease through direct complement-mediated lysis of infected cells, Fcγ R-mediated phagocytosis, or via complement- and Fcγ R-independent mechanisms.[958]

NS2A and NS2B Proteins

NS2A is a small (~22 kDa) polytopic membrane protein with important

functions in RNA replication and virus assembly. While the NS1/2A junction is cleaved by an unidentified ER- resident protease, the NS2A C-terminus is generated by NS2B-3 serine protease cleavage in the cytosol, suggesting that NS2A contains an odd number of transmembrane domains. NS2A contains eight membrane-interacting regions; its membrane topology has been inferred through genetic approaches although NS2A structure still awaits rigorous biochemical determination.[944,987] For some flaviviruses, the viral serine protease also cleaves at an internal site within NS2A to generate a C-terminally truncated form, NS2Aα.[671] Mutations at the YFV NS2Aα cleavage site have minimal effect on RNA replication but block virus particle production; these defects can be suppressed by a second mutation on the surface of the NS3 helicase domain.[459] Additional mutational analyses have identified NS2A residues critical for RNA replication, virus particle assembly, and interaction with NS2B and NS3, although the structure and function of NS2A remains elusive.[500,944,982,983,988]

Several flavivirus NS2A proteins have been reported to inhibit innate immunity. Mutations within the WNV NS2A gene enhance interferon-β promoter–driven transcription and attenuate WNV pathogenesis in mice, implying that the wild-type NS2A may function to inhibit this pathway.[536,542] Consistent with this, expression of DENV-2 NS2A inhibits interferon-β–stimulated gene induction and enhance the replication of an interferon-sensitive reporter virus.[660] Moreover, DENV NS2A inhibits TBK-1, a kinase that integrates input from several innate sensing pathways to phosphorylate IRF3.[191]

NS2B, a small (~14 kDa) membrane-associated protein, is an essential cofactor for the NS2B-3 serine protease activity and anchors this enzyme complex to cellular membranes.[174,251] NS2B's protease cofactor activity resides within a central peptide that intercalates within the fold of the serine protease domain.[242] DENV NS2B can target the human innate immune DNA sensor cGAS for lysosomal degradation, independent of its protease cofactor activity, thereby inhibiting innate immunity.[6] Mutational analysis has also identified determinants of RNA replication and virus particle assembly within the transmembrane domains of NS2B,[504] regions that were also found to interact with the SPCS1, a host-dependency factor for multiple flaviviruses.[573,1026]

NS3 Protein

NS3 is a large (~70 kDa) multifunctional protein, encoding enzymatic activities required for viral gene expression and RNA replication. The N-terminal third of the protein is the catalytic domain of the NS2B-3 serine protease, which has a chymotrypsin-like fold (Fig. 7.7A). X-ray crystallography revealed that the NS2B cofactor contributes one β-strand to an essential β-barrel of this protease fold.[242,563] The NS2B-3 serine protease cleaves substrates containing adjacent basic residues at the NS2A/NS2B, NS2B/NS3, NS3/NS4A, and NS4B/NS5 junctions.[141,142] Secondarily, the NS2B-3 serine protease generates the C-termini of capsid and NS4A proteins via delayed cleavage and cleaves internal sites within NS2A and NS3. DENV NS2B-3 can also cleave the human innate immune adaptor protein STING, inhibiting type I interferon induction.[7] Because NS2B-3 protease activity is essential for flavivirus gene expression, and because protease inhibitors have proven to be useful therapeutics against other viruses including hepatitis C virus (HCV) and human immunodeficiency virus, NS2B-3 is considered to be a high-priority target for antiviral development.[563]

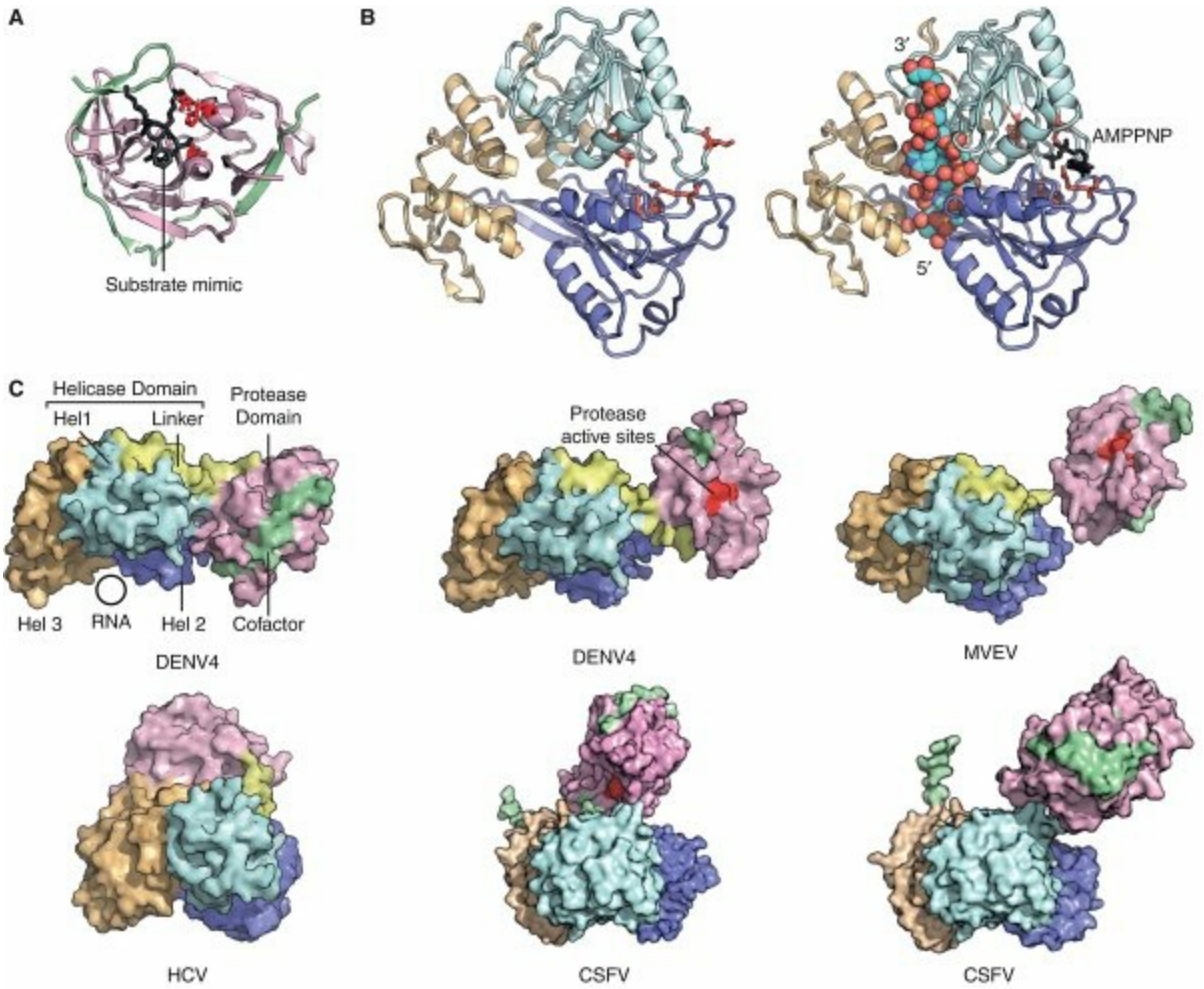

FIGURE 7.7 *Flaviviridae* NS3 proteins. **A:** The structure of the WNV NS2B-3 serine protease domain, with NS2B cofactor peptide (*green*), NS3 protease domain (*pink*), and a substrate-competitive inhibitor (*black*). Active site residues are shown in *red*. Rendered from PDB 2FP7.[242] **B:** Structure of the DENV-4 NS3 helicase domain with (*left*) or without (*right*) bound RNA substrate (*colored spheres*) and ATP analog (*black*). Note the ATPase active site (*red*) becomes structured at the interface of domain I (*cyan*) and domain II (*purple*) upon RNA binding. The RNA is bound within a cleft formed by the first two domains and domain III (*gold*). Rendered from PDBs 2JLQ and 2JLV.[566] **C:** Structural interdomain flexibility within full-length NS3. Shown are two conformations of

full-length DENV-4 NS3 as rendered from PDBs 2VBC[565] and 2WHX[564], respectively; MVEV from PDB 2WV9[34]; HCV from PDB 1CU1[998]; and CSFV from PDB 5MZ4[223]. Helicases were structurally aligned, with molecular surfaces colored as in **panels (A)** and **(B)** and the protease–helicase linker peptide in *yellow*.

As for other members of the *Flaviviridae*, NS3 encodes a C-terminal superfamily 2 nucleoside triphosphatase (NTPase)-RNA helicase.[302] *In vitro*, NS3 has demonstrated RNA-stimulated NTPase and RNA unwinding activities, and mutational analyses confirm that these activities are essential for RNA replication.[597,955,968] However, it is not yet clear what specific role the NTPase–RNA helicase performs in the viral life cycle, nor whether this enzyme unwinds double-stranded replicative intermediates (RI) *in vivo*. The helicase domain also exhibits RNA triphosphatase (RTPase) activity, which is presumed to remove the 5′ γ-phosphate, yielding 5′ dephosphorylated genomes for subsequent capping.[969] The NTPase, RNA helicase, and RTPase activities of NS3 all depend on the Walker B motif, indicating that all three nucleic acid–modifying activities utilize a common active site.[51,67] In addition to its essential but undefined role in RNA replication, the helicase domain of NS3 is also implicated in the assembly of virus particles.[289,459,698] This role in virus assembly appears to be genetically separable from NS3's NTPase–RNA helicase activities[289,698] and may involve recruitment of the ESCRT pathway components to facilitate budding.[135] However, because flavivirus particle assembly is tightly coupled to RNA replication,[421] an additional role for helicase activity in virus assembly has not been formally excluded. In the context of full-length NS2B-3, the helicase also inhibits innate immunity, perhaps by unwinding double-stranded RNAs (dsRNAs).[827]

The NS3 helicase domain consists of three subdomains: two RecA-like subdomains that are conserved among all superfamily 2 helicases and an α-helix–rich C-terminal subdomain that is common to all *Flaviviridae* but structurally distinct between genera.[563,981,990] This latter region, subdomain 3, mediates critical interactions with NS5.[896] The NTP active site resides at the interface of the RecA-like subdomains 1 and 2, while RNA is bound in a

cleft between subdomains 1 and 2 and subdomain 3 (Fig. 7.7).[563,566] Full-length NS3 structures have revealed both structural flexibility and coordination between the serine protease and helicase domains.[563], [564], [565] Thus, the flexible linker region likely plays an important role in coordinating these enzyme activities.

In addition to its enzymatic activities, DENV NS3 can also antagonize innate immunity by binding to the cellular 14-3-3ε protein.[143] Truncated forms of NS3, which result from NS2B-3 serine protease cleavage within the helicase domain, have been observed *in vitro* and *in vivo*.[31,737,904] The role of these cleavages is unclear, although it is possible that the products could have a distinct function. In this regard, replication defects caused by helicase domain mutations can be complemented in *trans*, while serine protease domain activities are required in *cis*.[394,420,541]

NS4A and NS4B Proteins

NS4A (~16 kDa) and NS4B (~27 kDa) are small, polytopic membrane proteins that contribute to RNA replication and subversion of innate immunity. These proteins are initially synthesized as a NS4A-2K-4B precursor that is cleaved by the NS2B-3 serine protease and host signal peptidase; similar to the coordinated processing of C protein, upstream cleavage by NS2B-3 at the NS4A/2K junction is a prerequisite for downstream cleavage by signal peptidase at the 2K/NS4B junction.[522,733] Expression of NS4A, NS4B, or NS4A-2K-4B has differing effects on cellular membranes[782]; thus, the coordinated cleavage of NS4A-2K-4B likely impacts the temporal assembly of membrane-bound replication complexes. In fact, mature NS4A, but not NS4A-2K, induces membrane alterations suggesting that removal of the 2K peptide is important for membrane activity.[634] The regulation of this cleavage is not fully understood, but it is interesting to note that in DENV-infected cells, NS1 selectively interacts with NS4A-2K-4B, but neither with mature NS4A nor NS4B.[726] Furthermore, NS2B-3 cleavage at the YFV NS3/4A and NS4A/2K junctions is highly dependent on DNAJC14, an Hsp40 cochaperone of Hsp70-mediated protein folding and a host factor required for the replication of multiple flaviviruses.[103,1003]

NS4A consists of an approximately 50-aa N-terminal cytosolic region, a transmembrane domain, a lumenal amphipathic helix, and a second

transmembrane domain; a third transmembrane domain, 2K, is removed via NS2B-3 proteolysis.[634] NS4A forms higher-order structures via its first transmembrane domain, which mediates both homo-oligomerization and heterodimerization with NS4B.[496,1040] NS4A localizes to replication complexes and contributes to RNA replication via genetic interaction with NS1.[532,578,966] NS4A can also serve as a cofactor of the NS3 helicase, increasing the efficiency of NTPase activity.[844] Moreover, mutations in NS4A and 2K have been found to confer resistance to a potent inhibitor of flavivirus replication and to overcome superinfection exclusion, further implicating these proteins in RNA replication.[1038,1041]

NS4B consists of an N-terminal lumenal region, two transmembrane domains separated by a long cytoplasmic loop, and a third transmembrane domain that can posttranslationally insert across the membrane.[635,1039] For some flaviviruses, the N-terminal lumenal region is glycosylated on one or two asparagine residues; mutation of these glycosylation sites cause defects in DENV RNA replication.[666] NS4B forms homodimers,[1039] localizes to sites of RNA synthesis,[635] and maintains critical interactions with several other replicase components, including NS1, NS3, and NS4A.[153,1010,1037,1040] The interaction of NS4B with NS3 may serve to enhance helicase activity.[929] The DENV NS1-NS4B complex was shown to interact with MAGT1, a subunit of the N-oligosaccharide transferase (OST) complex, and DENV replication is dependent on MAGT1 oxidoreductase activity.[524] This interaction may explain why OST is essential for the replication of several flaviviruses, independent of OST activity.[524,589,738]

Both NS4A and NS4B can inhibit innate immune activation. The DENV-2 NS4A protein binds mitochondrial antiviral-signaling (MAVS), a mitochondrial innate immune adaptor protein, inhibiting its activation by RIG-I.[348] DENV-1 NS4A also inhibits TBK-1,[191] and several flavivirus NS4B proteins potently antagonize TBK-1 as well as JAK/STAT1 signaling.[191,659,660] In addition, DENV NS4B counteracts innate immunity by dampening integrity of the mitochondria-associated membranes (MAMs) that serve as platforms for innate immune signaling.[152] Finally, WNV NS4A and NS4B expression cause ER stress, inducing an unfolded protein response that down-regulates JAK/STAT signaling through ATF-6.[23,24]

NS5 Protein

NS5 is a large (~103 kDa), highly conserved, and multifunctional protein essential for flavivirus RNA synthesis and capping. The N-terminal domain encodes RNA capping activities, while the C-terminal domain is the viral RdRP. In addition, NS5B modulates host gene expression and antagonizes innate immune activation.

The structure of the capping domain is shown within the context of full-length NS5 (Fig. 7.8A). Flaviviruses modify their genomes with a type 1 5′ RNA cap in a stepwise process: (a) removal of 5′ γ-phosphate from a triphosphorylated RNA substrate, presumably by the RTPase activity of the NS3 helicase domain[969]; (b) addition of a 5′ to 5′ guanosine cap (from GTP) by a guanylyltransferase activity within the NS5 capping domain[231,380]; (c) addition of a methyl group (from S-adenosylmethionine) to the N7 position of the guanylyl cap by NS5's methyltransferase (MTase) activity[231,754]; and (d) methylation at the 2′O position of the +1 nucleotide by a distinct NS5 MTase active site.[231,754] Thus, the capping of nascent viral RNAs requires coordination of the NS5 RdRP domain, the NS3 helicase domain, and the NS5 capping domain.[107] Mutational analyses showed that the cap methylation steps are separable and that N7 methylation is required for viral translation and replication, while 2′-O-methylation allows the virus to avoid innate antiviral defenses.[190,214,454,754,1034]

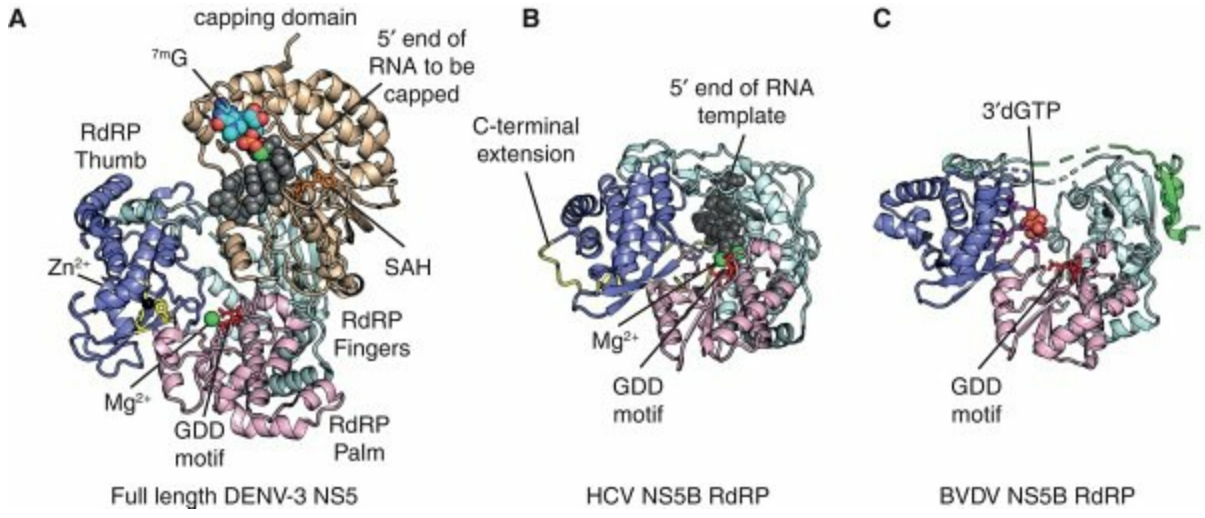

FIGURE 7.8 *Flaviviridae* NS5 and NS5B proteins. **A:** Full-length

DENV-3 NS5 was labeled to highlight the capping domain (*wheat*) and the canonical RdRP fingers (*cyan*), palm (*pink*), and thumb (*blue*) domains. Catalytic Mg^{2+} and structural Zn^{2+} ions are indicated, as is ^{7m}G, the substrate for cap addition, and SAH (S-adenosyl-L-homocysteine), the by-product of the methylation reaction. Rendered from PDB 5DTO.[1028] **B:** The HCV NS5B RdRP is shown with bound template RNA; the HCV-specific C-terminal extension is shown in *yellow*. Rendered from PDB 1NB7.[681] **C:** The BVDV1 NS5B RdRP is shown modeled in the GTP-bound state by rendering PDB 2JCQ[160] and the GTP analog from 2J7W.[999] The pestivirus-specific N-terminal extension is shown in *green*.

The C-terminal domain of NS5 contains conserved RdRP motifs and structurally resembles other RNA polymerases, forming a "right-hand" structure with palm, fingers, and thumb subdomains (Fig. 7.8A).[107,584,999] NS5 RNA polymerase activity has been confirmed with purified, recombinant protein.[2,885] The major product of *in vitro* RdRP reactions is often a self-primed copy-back RNA; however, NS5 can initiate *de novo* RNA synthesis, which likely reflects the authentic mechanism in infected cells.[2,679,1015] This unprimed RNA synthesis requires high concentrations of GTP, which binds within a GTP pocket much like a nascent RNA strand and helps to stabilize the initiating NTP.[107,679]

Structures of full-length NS5 reveal flexibility in the linker between the capping and RdRP domains, with conserved interdomain interfaces and the potential to form functionally relevant homodimers.[107,127,430] NS3 presumably binds to the NS5 linker region in order to coordinate RNA synthesis with capping activities, and plausible models for NS3-NS5 interaction have been proposed, whereby nascent RNAs are modified and capped as they exit the RdRP,[107] very much like the capping assembly line originally described for bluetongue virus, a member of the *Reoviridae*.[878] NS5 does indeed form a complex with NS3 and stimulates its NTPase and

RTPase activities.[188,1006] Cross-linking studies have shown that both proteins bind to the 3′ SL of the viral genome, which, together with genome cyclization, may serve to initiate minus-strand synthesis by 5′ SL-bound NS5.[154]

NS5 has been shown to localize to sites of viral RNA synthesis for only a few flaviviruses.[577,966] This is likely because only a small fraction of NS5 cofractionates biochemically with replicase activity[321,928]; rather, NS5 frequently localizes to the nucleus of flavivirus-infected cells, where it has been proposed to dysregulate gene expression and splicing.[121,198,608] Because the NS5 nuclear localization signals frequently overlap critical structures within the RdRP, it has been challenging to dissect the role of NS5's nuclear localization from its role in viral replication. Nevertheless, at least two groups have identified DENV mutants that replicate well with little or no nuclear NS5 localization.[456,897] In addition, NS5 has been shown to block the Jak/STAT pathway of IFN signaling by a variety of mechanisms.[79,80]

Ultrastructure and Biogenesis of the Flavivirus Replication Organelle

In flavivirus-infected cells, replicase activity is associated with membrane fractions that are enriched for most viral proteins.[167] Upon treatment of these membrane fractions with nonionic detergents, viral RNA and proteins are rendered sensitive to degradation, arguing that membranes are protecting viral components against nucleolytic and proteolytic attack. Consistent with this observation, the flavivirus replication organelle consists of ER membrane invaginations toward the ER lumen,[184,294,399,636,683,966] giving rise to vesicles, which in the case of DENV have an average diameter of about 90 nm (Fig. 7.9). These vesicles are linked to the cytosol via a pore-like opening that has a diameter of around 11 nm (Fig. 7.9H). Thus, the lumen is topologically identical to the cytosol but provides a shielding environment, for example, to limit the access of pattern recognition receptors (PRRs) to viral RNA.[692,927] In 2D sections, these membrane invaginations appear as arrays of vesicles in ER tubes designated VPs.[576,966,972] VPs have been found in all flaviviruses studied thus far, including ZIKV, WNV, and TBEV.[184,294,399,636,683,966] Although several lines of evidence, including metabolic labeling of RNA, *in situ* hybridization, and immunodetection of

dsRNA, suggest that VPs are the site of viral replication,[966,973] firm proof demonstrating *de novo* synthesis of viral RNA in the vesicle lumen is still lacking.

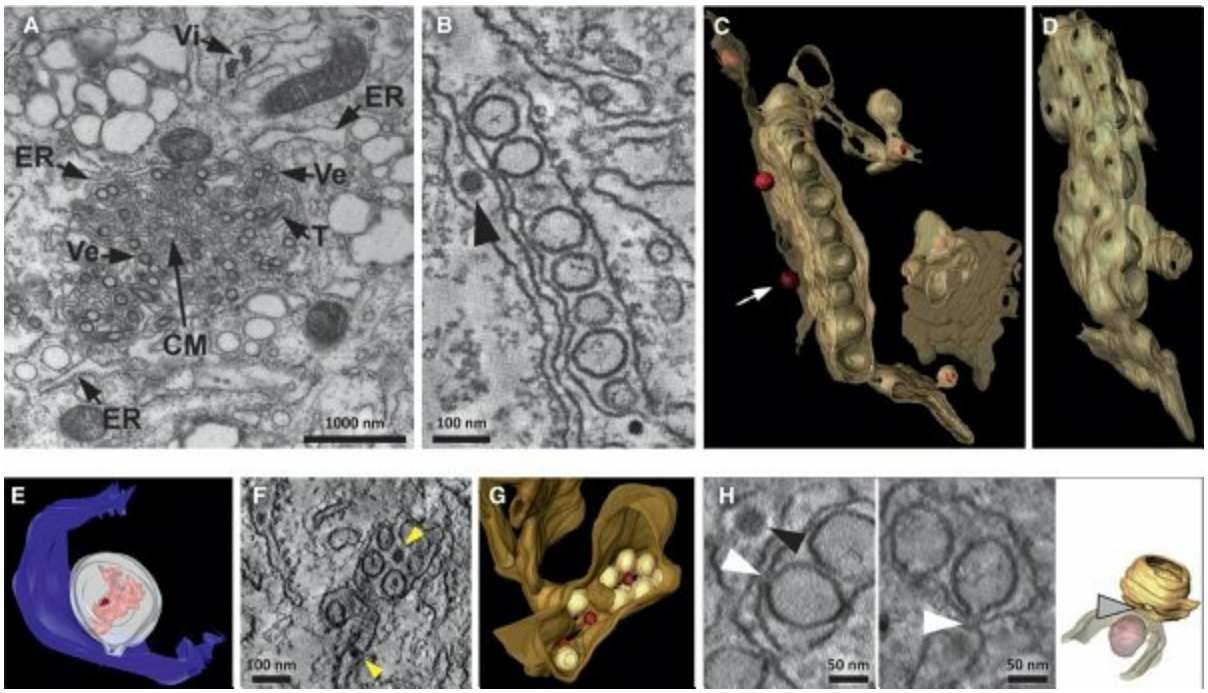

FIGURE 7.9 Flavivirus replication organelles. **A:** Membrane alterations induced in DENV-infected cells. Shown is a thin-section TEM image of DENV-infected, resin-embedded Huh-7 cells fixed at 24-hour postinfection. Ve, virus-induced vesicles; T, membrane tube; CM, convoluted membranes; Vi, clusters of virus particles. **B:** Single tomographic slice (~2 nm thick) showing DENV-induced vesicular invaginations toward the ER lumen. A virus particle (*black arrowhead*) is seen in the ER-proximal nuclear envelope. **C:**3D reconstruction of vesicle packets and cellular membranes in close proximity. Virus particles (*white arrow*) are shown as *red spheres*. **D:** The vesicle-containing ER segment shown in **(C)**, rotated by 90 degrees around the *y*-axis to visualize the vesicle openings. **E:**3D reconstruction of an ER-luminal vesicle in WNV-infected cells. An electron-dense structure assumed to correspond

to viral RNA in the vesicle interior is shown in *red*. **F:** Membrane alterations induced by TBEV infection. The tomographic slice shows several vesicles in the ER lumen in close proximity to newly assembled virus particles residing in the same ER luminal compartment (*yellow arrowheads*). **G:**3D surface rendering of the area in **(F)**, displaying TBEV-associated vesicles (*light yellow*) sharing the ER lumen with TBE virions (*dark red*) and surrounded by ER membranes (*light brown*). **H:** Single slices of tomograms showing DENV-induced vesicles as invaginations of the ER membrane (*white arrowheads*). Note the diffuse electron density at the cytosolic face of the vesicle openings and the tight apposition of vesicle openings to the opposing ER membrane containing a virus particle (*black arrowhead*). A 3D surface rendering of the ER/vesicle continuity (*yellow*) and the tightly apposed ER (*semitransparent*) containing a virus particle (*red*) are shown in the *right panel*. **(Panels (A–D)** and **(H)** were adapted from Welsch S, Miller S, Romero-Brey I, et al. With permission from American Society for Microbiology.)

In addition to VPs, bundled smooth ER membranes, designated as convoluted membranes (CMs), are often found in close proximity to VPs and mitochondria (Fig. 7.9A). At least for WNV (subtype Kunjin), it has been proposed that CMs might be sites of polyprotein synthesis and cleavage by the NS2B-3 protease.[972,973] This assumption is based on the accumulation of viral proteins, but not dsRNA, in these membrane structures, but since CMs are largely devoid of ribosomes, this model is not easy to reconcile. Alternatively, CMs might serve as lipid stores or interfere with innate immunity. The latter might be mediated by disruption of MAMs, which play a critical role as signaling platforms to mount, for example, an interferon response or by sequestration of innate immune PRRs in CMs.[152] In any case, CMs appear to be dispensable for viral RNA replication as found for ZIKV, which induces CMs in human hepatoma cells, but not in human neuronal progenitor cells, yet replicates comparably well in both cell types.[184] A third membrane structure found in infected cells is the "paracrystalline array," which appears to be a highly ordered form of CMs.[490]

While the overall 3D architecture of the flavivirus replication organelle is well established, surprisingly little is known about the mechanism underlying its biogenesis and the components involved. At least two viral proteins, NS4A and NS4B, appear to play critical roles in the formation of VPs.[415,634,782] Owing to their distinct membrane topology, both proteins should be capable of inducing negative membrane curvature. This property might be augmented by homo-oligomerization of the two viral proteins.[870,1039,1040] Interestingly, expression of NS4A lacking the carboxy-terminal 2K fragment induces the formation of cytoplasmic membrane alterations resembling CMs, whereas full-length NS4A containing the 2K fragment remains bound to the ER membrane but does not induce membrane curvature.[634] Therefore, a regulated cleavage of the NS4A-2K-NS4B precursor appears to play a critical role in the formation of the replication organelle. However, the sole expression of NS4A or NS4B does not suffice to induce VP formation, arguing that additional viral components are required.

One likely component is NS1, which interacts with NS4A, NS4B, and the NS4A-2K-NS4B cleavage intermediate.[10,532,726,1010] In addition, NS1 binds to and remodels liposomes *in vitro* corroborating that this protein possesses membrane-altering properties.[10] Thus, NS1 is likely needed to induce VP

formation. Moreover, by using a replication-independent expression system, NS1 was found to be essential for the formation of VPs.[726]

An additional viral component possibly contributing to replication organelle formation is NS2A, a small polytopic membrane protein. This protein can affect membrane permeability and might interact with the viral replicase complex as deduced from its enrichment at dsRNA-containing sites.[147,987] Based on these observations, a model for the biogenesis of VPs can be proposed in which NS4A and NS4B oligomers, perhaps supported by NS2A, induce negative curvature. This might be enhanced by NS1 binding to NS4A and NS4B from the luminal side of the ER membrane and inducing a positive curvature. Although an appealing model, firm proof requires a more detailed analysis of *cis*- and *trans*-acting factors involved in VP formation, including viral RNA that has been reported for other positive-strand RNA viruses to play a crucial role in VP/spherule formation.[243]

Induction of membrane curvature is an energetically unfavorable process that is facilitated by the insertion of lipids inducing membrane asymmetry and altering fluidity. In addition, assembly and functionality of membrane-resident macromolecular complexes are often enhanced by specific lipids such as cholesterol and sphingolipids, forming raft-like membrane microdomains. It is therefore not surprising that lipids play a central role for the flavivirus replication organelle. In infected cells, the lipid composition is very much altered.[164,611,708] For instance, ceramides, a family of lipids that are composed of sphingosine and a fatty acid, are increased in WNV-infected human cells and in DENV-infected mosquito cells.[592,708] Moreover, in the case of WNV, ceramides are redistributed to sites of replication. Of note, depletion of ceramide by extensive treatment with myriocin had opposing effects on these two flaviviruses, being suppressive in the case of WNV, but enhancing replication and virus production with DENV.[12] The sphingolipid biosynthetic pathway is also a critical factor for efficient DENV replication in the transmitting *Aedes aegypti* mosquito vector, but whether these lipids directly contribute to replication organelle formation or replicase activity, for example, by forming lipid rafts, is not known.[164] In any case, flavivirus replication is highly sensitive to inhibition or depletion of acetyl-CoA carboxylase and fatty acid synthase (FAS), key enzymes in the fatty acid biosynthetic pathway.[616] DENV NS3 interacts with FAS, thus recruiting this cellular enzyme to sites of virus replication and possibly promoting lipid

biosynthesis for the sake of membrane expansion.[349,887] Along the same line, WNV increases the activity of 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR), the rate-limiting enzyme in cholesterol biosynthesis, and alters subcellular distribution of cholesterol from the plasma membrane to replication organelles.[579] Also in the case of DENV, infection increases HMGCR activity and cholesterol accumulation at the ER, correlating with increased viral replication.[862] In addition, lipophagy, a type of selective autophagy that targets LDs, plays an important role in the DENV replication cycle. At early stages of infection, DENV induces autophagy and enhances autophagic flux, whereas later on, autophagosome–lysosome fusion and endolysosomal trafficking are suppressed.[606,621] This early elevated autophagosome formation appears to increase β-oxidation of lipids and ATP levels as well as turnover of triglycerides to promote viral replication.[350]

Apart from viral and host factors described above, several comprehensive screens and proteome analyses of viral proteins and complexes have identified candidate host cell factors promoting or restricting flavivirus replication or interacting with viral proteins.[672] It is likely that some of these factors contribute to replication organelle formation and the definition of their precise function will be an important future task.

RNA Replication

After the flavivirus genome is translated, the NS proteins must recruit the genome out of translation and into a replication complex. The mechanisms of this switch are not fully understood but likely involve genome cyclization, which favors RNA replication over translation.[538,941] Replication begins with the synthesis of a genome-length minus-strand RNA, which has been detected as early as 3 hours after infection[528]; minus strands then serve as templates for synthesizing new plus-strand genomes. Viral RNA synthesis is asymmetric, with approximately 10-fold more positive strands accumulating compared to minus strands.[172,528] Based on metabolic labeling, three major species of flavivirus RNAs have been described: the plus-strand genome, a double-stranded replicative form (RF), and a heterogeneous population of RI that most likely represent duplex regions and recently synthesized RNAs displaced by nascent strands undergoing elongation.[166,172] Pulse-chase analyses indicate that RF and RI are precursors to genome RNA, indicating

semiconservative and asymmetric replication.[172]

In addition to genome-length products of RNA replication, 0.2 to 0.6 kb noncoding sfRNAs accumulate in infected cells.[523,930] sfRNAs are colinear with the 3′ end of the genome and are produced through stalled 5′ to 3′ degradation of the genome by the cellular 5′ exoribonuclease XRN1.[722] The XRN1resistance of this region is due to conserved, pseudoknot structures located within the 3′ NCR, such that the RNA forms a tight, triple-helical "slip knot," making it difficult for enzymes like XRN1 to proceed in a 5′ to 3′ direction, but allowing enzymes like NS5 to proceed in a 3′ to 5′ direction (inset, Fig. 7.4A).[11,150,151,282] Mutant flaviviruses that do not produce sfRNAs are less cytopathic in cell culture and less pathogenic in mice; however, cytopathic effects were restored by supplying sfRNA in *trans*.[282,540,722] The accumulation of sfRNA has several proviral effects on host cells, including reduced XRN1 activity and dysregulated host mRNA turnover,[649] inhibited RIG-I activation,[588] reduced ISG expression,[81] and insensitivity to type I interferons.[821] While it may seem counterintuitive for a virus to employ a genome-destroying strategy for its own gain, flavivirus genomes are produced in vast excess; it is not yet clear whether a subset of nascent viral genomes are left uncapped to facilitate sfRNA formation.

Assembly and Release of Particles from Flavivirus-Infected Cells

Flavivirus particle assembly occurs in close association with intracellular membranes.[663] The assembly process is thought to commence by association of C protein dimers with genomic RNA, followed by budding into ER membranes containing the prM–E glycoprotein complex. As empty, preformed flavivirus capsids have never been observed, it is thought that nucleocapsid formation is tightly linked to envelopment. Immature virus particles pinch off into the ER lumen through noncanonical use of the ESCRT vesicle sorting and membrane scission machinery, with different component dependencies observed among flaviviruses.[881] Notably, the YFV NS3 protein interacts with Alix, which can recruit ESCRT III components.[135]

Electron tomography studies revealed that replication organelle pores are sometimes apposed to virus assembly sites, at least in the case of DENV and

ZIKV, with clusters of virus particles being frequently observed in enlarged ER cisternae.[184,966] This close apposition of VPs and assembly sites provides a simple, yet so far largely hypothetical, explanation for the coupling of flavivirus replication and assembly.[421] Early in the replication cycle, when the amount of viral proteins, including C protein, are low, viral RNA released out of the vesicle interior might associate preferentially with ribosomes, thus promoting RNA translation. Newly produced viral proteins will enhance RNA replication, which in turn leads to an increase of viral proteins. Later in infection, when viral proteins accumulate to high abundance in the infected cell, *de novo* synthesized RNA might associate preferentially with the structural proteins, notably C protein, thus "competing" with ribosomes. In this way, viral RNA gets rapidly recruited into assembling virions that form by budding into the ER lumen in close vicinity to the vesicle pore, the presumed RNA exit site (Fig. 7.9H).

Following assembly, nascent virions are transported through the secretory pathway and released at the cell surface.[580] During transit through the reduced pH of the Golgi, immature particles undergo acid-induced prM–E rearrangement and prM cleavage (Fig. 7.10). Additional virion maturation steps occur during egress, including glycan modification of prM and E (for some flaviviruses) by trimming and terminal addition.[141,596] This implies that virions move through an exocytosis pathway similar to that used for host cell-surface glycoproteins and may traffic through recycling endosomes prior to release.[537] In at least one case, ZIKV was observed to be released in monolayer aggregate "sheets."[537]

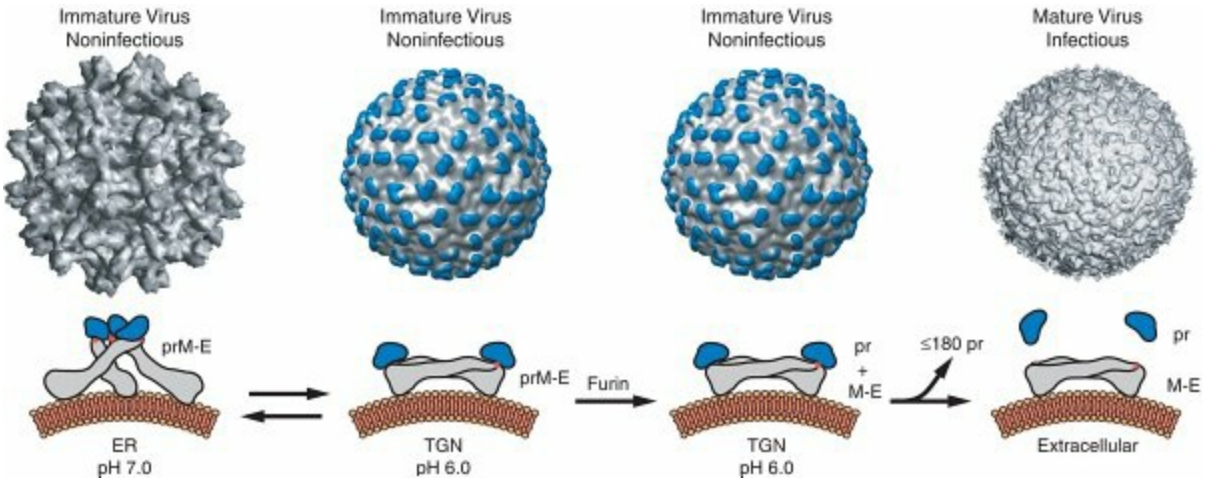

FIGURE 7.10 Flavivirus particle maturation. Nascent, noninfectious, immature particles undergo a pH-dependent conformational rearrangement of the viral glycoproteins E (*gray*) and prM (*blue*). Mature, infectious particles form upon furin cleavage of prM and release of the pr fragment. (Adapted from Perera and Kuhn[707] with permission from Elsevier Press.)

HEPACIVIRUSES

Background and Classification

The existence of a novel blood-borne hepatitis virus, then called non-A, non-B hepatitis (NANBH), was first realized in the mid-1970s.[256,734] Early attempts to culture this agent proved to be frustrating and difficult to reproduce. It took another 14 years before HCV was formally identified through expression cloning of an immunoreactive cDNA from a NANBH-infected chimpanzee.[163] This discovery rapidly led to the development of HCV diagnostics, which greatly reduced transmission through the blood supply.[462] Today, HCV is mainly transmitted via injection drug use, mother-to-infant care, and health care exposures and, infrequently, through sexual contact or unknown risk factors. Despite the recent development of highly effective HCV-specific direct-acting antivirals (DAAs), HCV currently infects 71 million people worldwide and remains a significant public health concern.[89] HCV causes chronic liver infections approximately 70% of the time, which can progress over decades to fibrosis, cirrhosis, and hepatocellular carcinoma (HCC). Despite slow disease progression, which can be accelerated by cofactors such as metabolic syndrome or alcohol consumption, mathematical models of HCV dynamics demonstrate robust replication in chronically infected individuals, with viral loads approximately 10^6 genomes per mL of serum, rapid viral clearance, and production of approximately 10^{12} virions per day.[706]

HCV is classified into seven genotypes, which differ from each other by greater than 30% at the nucleotide level.[664,859] These genotypes have distinct

geographic distributions, disease progression, and susceptibility to some treatments. Intergenotypic recombinant HCV genomes, which presumably arise through coinfection, have been described.[203,400] The high level of sequence diversity between the HCV genotypes presents a formidable challenge for vaccine development.

Despite the lack of a vaccine, major advances in treatment have been made. The prior standard of care, pegylated interferon alpha and ribavirin, has been replaced by DAAs that have much higher cure rates with fewer side effects and shorter treatment durations. Effective DAA formulations typically combine at least two drugs targeting distinct HCV proteins. HCV drug development has culminated in the first pangenotypic DAAs, which cure more than 90% of HCV infections with each genotype.[257,271]

All genotypes of HCV are taxonomically classified as a single virus species, *Hepacivirus C*. For many years, HCV was the sole member of the *Hepacivirus* genus. The first non–HCV member of this genus, GB virus B (GBV-B; species name *Hepacivirus B*), was discovered in a human-derived, primate-passaged sample during a search for additional hepatitis viruses that ultimately led to the discovery of a related genus, the *Pegiviruses*. Recent advances in metagenomics have led to the discovery of a whole passel of additional *Hepaciviruses* (Table 7.1, Fig. 7.1A). The first of these was isolated from a canine with respiratory disease and was originally called canine hepacivirus. However, follow-up studies indicated that it is actually an equine virus causing acute and chronic hepatitis in horses; this virus has been renamed nonprimate hepacivirus (NPHV; species *Hepacivirus A*).[126,409] Several additional hepacivirus species have also been found, including several rodent hepaciviruses (RHV-E, species *Hepacivirus E*; RHV-F, species *Hepacivirus F*; NRHV1, species *Hepacivirus G*; NRHV2, species *Hepacivirus H*; RHV-I, species *Hepacivirus I*; RHV-J, species *Hepacivirus J*), bats (BHV-K, species *Hepacivirus K*; BHV-L, species *Hepacivirus L*), cows (BoHV, species *Hepacivirus M*), and colobus monkeys (guereza hepacivirus [GHV], species *Hepacivirus N*). Surprisingly, the closest relative to GBV-B is RHV-I, so the source of GBV-B in human- or primate-derived samples remains mysterious. Although it awaits official taxonomic classification, a hepaci-like virus has even been identified in the graceful shark, known as the Wenling shark virus (WLSV).[341]

Experimental Systems

Although HCV research was limited by the lack of replication systems for the first decade after its discovery, these challenges are now largely overcome. Once the correct 3′ end of the HCV genome was determined,[441,886] full-length HCV cDNAs were assembled, and synthetic transcripts were shown to be infectious by direct hepatic inoculation of chimpanzees in 1997.[440,995] These infectious cDNA clones were used to show that the viral enzymes, the p7 gene, and 3′ NCR are essential for HCV replication[442,797,996] and to study HCV immune response and viral evolution *in vivo*.[477] Unfortunately, RNAs from these clones failed to replicate in cultured cells.

The first useful cell culture system to study HCV replication was the genotype 1b (Con1) subgenomic replicon, developed in 1999.[549] The original replicons were bicistronic, wherein the HCV 5′ IRES promoted translation of the neomycin resistance gene and the encephalomyocarditis virus (EMCV) IRES promoted translation of the HCV NS2-5B or NS3-5B genes (see Fig. 7.12C). Upon transfection into the Huh-7 human hepatoma cell line, the first replicon RNAs replicated to low levels and transduced G418-resistance to rare HCV-supporting cells.[549] However, within these replicon-containing cell clones, HCV replicated to high levels. Based on the HCV sequences within surviving cell clones, cell culture–adaptive mutations were identified that increase transduction efficiency by up to 10,000-fold.[92,547] These efficient replicons enabled genetic, biochemical, and cell biological studies of intracellular stages in HCV replication and turbo-charged drug discovery efforts, but because the structural genes were not included, infectious virus particles were not produced. Surprisingly, full-length genomes containing these cell culture–adaptive mutations failed to produce infectious virions in cell culture and were attenuated *in vivo*, likely because these mutations enhance RNA replication but inhibited infectious virus production.[721]

The HCV pseudoparticle (HCVpp) system was developed to study viral entry. HCVpps are retrovirus particles displaying the HCV envelope glycoproteins, typically expressing a reporter gene to monitor viral entry and gene expression.[58,221,366] HCVpps reproduce many of the events in *bona fide* entry, such as receptor-dependent and clathrin-mediated endocytosis; however, significant differences between HCV and HCVpp entry exist.[139]

In 2003, a genotype 2a subgenomic replicon was identified that had the unusual feature of efficient cell culture replication without adaptive mutations.[411] This strain was isolated from a Japanese patient with fulminant hepatitis and was therefore named JFH-1. Full-length JFH-1 genomes produced the first infectious HCV in cell culture (HCVcc), albeit at relatively low levels.[945] High infectivity titers could be attained by passage and adaptation of JFH-1 or by engineering chimeric genomes with a related genotype 2a strain, HC-J6, that serendipitously encodes more efficient structural genes than the original JFH-1 strain.[529,719,1030] We now know that the efficiency of JFH-1 replication is due to optimal NS3 helicase and NS5B RNA polymerase activities, optimal 3′ NCR sequences, as well as a relative insensitivity of this strain to lipid peroxidation.[85,661,795,992] In the past several years, the variety of HCV replication systems has increased dramatically, including replicons for each genotype, infectious chimeric JFH-1 genomes that express structural genes from other genotypes, as well as infectious cell culture–adapted full-length clones for other genotypes.[747,1004] Infectious clones and replicon systems have also been developed for a number of nonhuman hepaciviruses.[199,200] Additionally, hepatoma cells that overexpress the cellular protein Sec14L2 were shown to support pangenotype HCV replication, including patient-derived virus.[795] Sec14L2, a carrier protein for vitamin E, enhances HCV replication most likely by reducing lipid peroxidation and protecting viral proteins from oxidative damage, to which they are sensitive.[992]

The chimpanzee is the only animal model that supports HCV replication, reproduces many clinical aspects of HCV infection, and is useful for studying HCV-specific immune responses and assessing drug efficacy.[477] However, due to ethical concerns, there is a moratorium on the experimental use of chimpanzees, which has increased the urgency for developing small animal models for HCV infection. Mice do not naturally support HCV entry or replication. One approach has been to partially deplete immunodeficient mice of hepatocytes and then engraft human hepatocytes to generate mice with chimeric livers.[87,615,622] The human hepatocytes within these chimeric livers support HCV infection; however, the utility of this model is limited by the immunocompromised nature of these mice. Immunocompromised mice engrafted with human hepatocytes and hematopoietic stem cells reconstitute both the hepatic and immune compartments and produce HCV-specific T-cell

responses but do not support detectable viremia.[957]

Efforts to genetically humanize mice to make them permissive for HCV infection have provided incremental successes. Immunocompetent mice expressing the human HCV entry factors CD81 and occludin (OCLN) do support the early steps of HCV infection but greatly restrict viral replication.[216] HCV replication is improved by using mice genetically deficient in type I interferon signaling, suggesting that this pathway is critical in restricting viral replication.[215] An alternative approach has been to adapt HCV to use mouse host factors. HCV containing three mutations in the envelope glycoproteins can enter mouse hepatocytes *in vivo*; however, replication is not supported, suggesting additional incompatibilities.[943]

Given the challenges of studying HCV in immunocompetent mice, recent attention has turned to the related hepaciviruses that infect experimentally tractable animals. As the first non–HCV hepacivirus identified, GBV-B has been studied as a surrogate model system. It infects primary tamarin or marmoset hepatocytes[61,117,476] but replicates poorly in most immortalized cell lines.[122] Full-length GBV-B infectious clones have been assembled and produce hepatitis in tamarins, but not chimpanzees, suggesting that it does not infect apes, including humans.[124,591,807] More recently, *Hepacivirus G*, which naturally causes chronic infection in Norway rats, was found to cause acute infections in common laboratory mice and chronic infection in immunodeficient mice.[84,920] This model provides a powerful platform to evaluate strategies for hepacivirus vaccine development, recently confirming the role of vaccine-elicited $CD4^+$ and $CD8^+$ T cells in protecting rats from viral challenge.[342]

Structure and Physical Properties of the Virion

HCV particles derived from patients are heterogeneous in size, are 30 to 80 nm in diameter,[104,347,1018] and exhibit broad, unusually low buoyant densities of 1.03 to 1.10 g/mL.[105,359] Low-density virus particles have higher specific infectivity than high-density particles, suggesting that particle infectivity correlates with the degree of lipid association. HCVcc particles have relatively low specific infectivity (~1 infectious unit per 1,000 particles); most particles have a buoyant density of approximately 1.15 g/mL, while the peak infectivity is near 1.10 g/mL.[130,529,1030] The low specific infectivity of

HCVcc particles likely reflects their physical properties when grown in Huh-7 cells, as specific infectivity improves upon passage in animals or primary hepatocyte cultures, but goes back down upon reculture.[530,728]

HCV particles are lipid enveloped, display an unknown number of viral envelope glycoproteins E1 and E2 on their surface, and contain a nucleocapsid composed of the core (C) protein and the viral RNA genome. A key feature of HCV particles is their propensity to associate with host-derived serum lipoproteins, which likely contribute to their low buoyant density.[25,676,735,912] HCV particles have similar lipid content as low-density lipoprotein (LDL) and very-low-density lipoprotein (VLDL) particles and associate with apolipoproteins, which are expressed on the surface of lipoproteins and function in their secretion and trafficking.[618] Serum-derived HCV associates with apolipoprotein AI (ApoAI), ApoB, ApoC1, and ApoE,[446,623,676,912] while HCVcc particles associate with ApoE and ApoC1.[146,618,623] ApoB is less consistently associated with HCVcc particles, leading to controversy about its role in HCV particle infectivity.[56] In any case, serum lipoproteins are thought to impact virion stability, enhance virus particle entry, and block antibody neutralization.[980] Because of their association with lipoproteins, HCV particles are sometimes referred to as "lipoviroparticles."[26,533] Although the structural basis for these interactions remain elusive, they may be mediated, at least in part, by interaction of ApoE (and possibly other apolipoproteins) with the E1–E2 envelope glycoprotein complex.[494] Proteomic analysis of purified HCVcc particles also identified other components, including the viral NS3 protein and several cellular proteins.[569]

Ultrastructural analyses of HCVcc or serum-derived HCV particles reveal pleiomorphic particles, 40 to 100 nm in diameter, lacking regularly discernible surface features (Fig. 7.11).[140,287,618,725,945] Due to this pleiomorphism, a key challenge has been to confirm that particle types observed through the microscope correspond to virus particles. In this regard, immunogold labeling has been used to identify the viral glycoproteins, ApoE, ApoAI, and occasionally ApoB, on the surface of putative HCVcc particles approximately 60 nm in diameter.[140,287,618,725] In one study, partial purification of HCVcc particles yielded two major particle classes.[287] One class, presumably infectious virus particles, were approximately 55 nm in

diameter, contained a lipid bilayer and an electron-dense core and had a relatively smooth, featureless surface that reacted with E2- and ApoE-specific antibodies; the second class of particles, electron-dense structures approximately 45 nm in diameter, lack a lipid bilayer and are presumed to be naked nucleocapsids.[287] An independent study imaged tagged HCVcc particles directly capturing them on affinity matrices, revealing putative HCVcc particles of up to 85 nM in diameter.[140] A similar approach was taken to affinity capture serum-derived HCV particles, revealing pleiomorphic particles that range up to 150 nm in diameter, sparsely decorated on the surface with E2, ApoB, and ApoE.[725] Despite this progress, we still do not understand how HCV particles are organized, how the viral glycoproteins are arranged on the surface of virus particles, or the molecular basis of how HCV particles interact with serum lipoproteins.

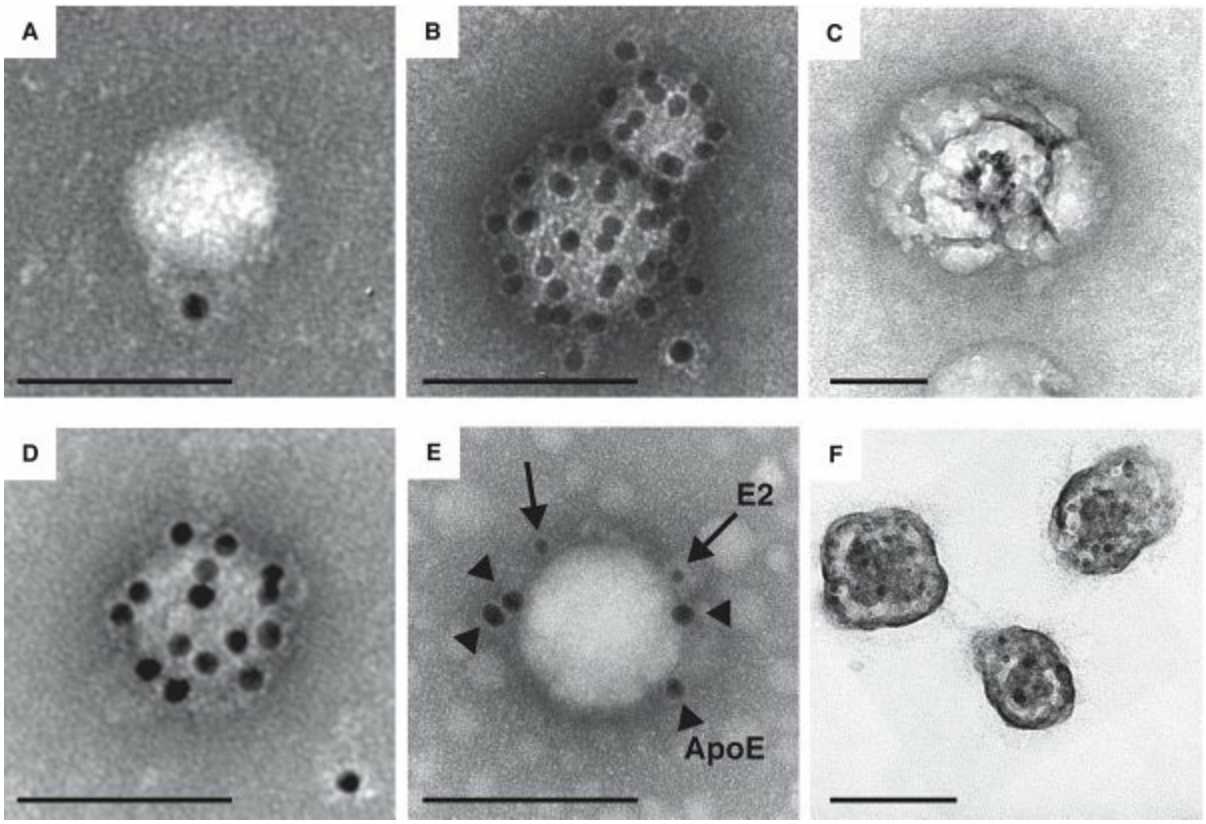

FIGURE 7.11 HCV particles. **A:** His-tagged HCVcc particles were affinity-captured on a Ni^{2+}-NTA–coated EM grid and immunogold labeled with antibodies specific for the HCV E2

glycoprotein. **B:** As in **panel (A)** but labeled with antibodies specific for ApoE. **C:** Human serum-derived HCV particles were affinity captured on the EM grid with the E2-antibody ARA3. **D:** As in **panel (B)** but labeled with antibodies specific for ApoA1. **E:** As in **panel (B)** but dual-labeled with antibodies specific for E2 and ApoE. **F:** Patient serum–derived HCV particles were affinity captured as in **(C)**. (**Panels (A**, **B**, **D)**, and **(E)** were adapted with permission from Catanese et al.[140]; **Panels (C)** and **(F)** were adapted with permission from Piver et al.[725] All scale bars, 100 nm.)

Binding and Entry

The mechanisms of hepacivirus entry are best characterized for HCV; very little is known about the entry of non–HCV hepaciviruses. HCV enters its target hepatocyte via an unusually complex, dynamic process with distinct spatiotemporal steps. Blood-borne virus particles initially bind to the basolateral surface of hepatocytes via low-affinity interaction with GAGs[57,291] and possibly the LDL receptor (LDLR).[4,646] Virion-associated ApoE binds syndecans 1 and 4, core components of heparan sulfate proteoglycans, to enhance entry.[387,834] Following initial attachment, HCV entry requires coordination between several “early” host factors, including scavenger receptor class B type I (SCARB1),[808] CD81,[723] and EGFR on the basolateral surface,[567] and the “late” factors CLDN1; OCLN, which localizes to tight junctions; and the Niemann-Pick C1–like 1 (NPC1L1) cholesterol absorption receptor, which localizes to the apical surface.[245,727,796]

SCARB1, which is greatly enriched on hepatocytes, is normally involved in the uptake of cholesterol and phospholipids from serum lipoproteins. Because other HCV entry factors are expressed by multiple cell types, the liver-specific expression of SCARB1 might help to define the hepatotropism of HCV entry. The HCV E2 glycoprotein directly binds SCARB1 via its N-terminal hypervariable region 1 (HVR1).[808] As HVR1 occludes the CD81 binding site on E2, the interaction with SCARB1 may facilitate subsequent

CD81 binding.[46] Consistent with this coordination, SCARB1- and CD81-specific antibodies inhibit HCV entry with similar postbinding kinetics.[405,1021] In addition to E2 binding, SCARB1's lipid transfer activity is involved in HCV entry, perhaps by serving to reduce virus-associated lipoproteins.[192,1019] Interestingly, there appears to be some functional redundancy between SCARB1 and LDLR, such that SCARB1 is not essential for HCV infection when LDLR is expressed.[991]

As a tetraspanin, CD81 coordinates the interaction of multiple other proteins into larger complexes. During HCV entry, CD81 is thought to be an initial, postattachment, high-affinity receptor that directly interacts with E2 via its large extracellular loop.[357,713] CD81-bound virus particles are trafficked to tight junctions, where internalization occurs.[43,112] This trafficking requires EGFR and RAS signaling, as well as Rho GTPase activation and remodeling of cortical actin.[533] In addition to binding, CD81 has two other key functions in HCV entry. First, CD81 binding can induce conformational changes in the HCV glycoproteins, priming the virion for low pH-induced fusion.[830] Second, CD81 recruits the cytosolic serum response factor binding protein 1, which aids HCV entry by an unknown mechanism.[292]

Once HCV-CD81 complexes migrate to tight junctions, they colocalize with CLDN1 and OCLN, which are essential for HCV internalization.[533] Proper CLDN1 and OCLN localization and HCV entry depend on expression of E-cadherin and tumor-associated calcium signal transducer 2 (TACSTD2).[510,825] In the absence of CLDN1, some HCV isolates can use CLDN6 or CLDN9 for entry[332]; however, other strains require adaptive mutations in E1 in order to use alternate CLDNs, suggesting that E1 may mediate interaction with CLDNs.[363] In support of this finding, soluble E1–E2 specifically binds to CLDN1-expressing cells.[217] There is no evidence for direct binding of OCLN to HCV virion components.

The HCV-CD81-CLDN complex is internalized via clathrin-mediated endocytosis.[90,177,255,609] Interestingly, HCV endocytosis requires active EGFR signaling.[43] Once internalized, virus particles are delivered to early endosomes, where the low pH likely induces fusion.[366,922] HCV entry requires endosomal acidification, yet virus particles are resistant to low pH, indicating that during the initial steps of virus entry, perhaps via binding to

one or more entry factors, a conformational change occurs that renders the virions pH sensitive. Available data suggest that this does not require proteolytic cleavage of the envelope glycoproteins but may involve isomerization of disulfides within the viral glycoproteins.[274] The mechanisms of HCV E1–E2 glycoprotein–mediated fusion are largely unknown.

Genome Structure

Hepacivirus genomes are approximately 8.9 to 10.4 kb in length, with the HCV genome weighing in at approximately 9.6 kb, and lack 5′ caps or 3′ poly(A) tails. As for other members of the family, hepaciviruses encode single long ORFs (2,748–3,335 codons, with HCV at ~3,011 codons), flanked by highly conserved 5′ and 3′ NCRs (Fig. 7.11A). The HCV 5′ NCR is relatively compact, is 341 nt long, and folds into four major structural domains that have overlapping functions in both RNA translation and replication. The 5′ 125 nt serves as a minimal replication element,[278] although nearly the entire 5′ NCR (or the complementary 3′ end of the negative strand) contributes to the efficiency of RNA replication.[307,313] Domain I forms a 5′ SL that is dispensable for translation but essential for RNA replication; domains II and III function as an IRES to mediate cap-independent translation of the viral genome and also contain cryptic replication signals.[313,354] The 5′ NCRs of other hepaciviruses have similar overall organization but can range up to 445 nt in length, in the case of GBV-B. Despite this size difference, regions of the HCV and GBV-B 5′ NCRs can be functionally exchanged.[397,769,771]

The HCV 5′ NCR can bind two copies of the abundant, liver-specific microRNA (miR)-122, which regulates numerous hepatic mRNAs and is required for efficient viral replication.[395,502] One or two miR-122 binding sites are also found in similar genome locations of other hepaciviruses.[341] Numerous functions have been proposed for the HCV-miR-122 interaction, including translation of the viral genome, modulating the switch from RNA translation to RNA replication, or regulating RNA–protein or RNA–RNA interactions during replication.[803] One major effect of miR-122 binding is that it stabilizes HCV RNA from degradation.[575] In the absence of miR-122, the viral genome is processed by cellular triphosphatases DUSP11 and DOM3Z,[22,426] rendering a 5′ monophosphorylated genome that is sensitive to

XRN 5′ to 3′ exonucleases.[508,824,841,909] Cells that lack DUSP11 support HCV infection in the absence of detectable miR-122, suggesting that miR-122 primarily acts to protect HCV RNA from degradation.[426] The HCV genome also acts as a miR-122 "sponge," causing derepression of cellular transcripts regulated by miR-122.[560] Small, miR-122–binding, locked nucleic acid "antagomirs" have shown antiviral efficacy in phase II clinical trials, leading to sustained virological responses in a subset of patients.[385]

The coding region of the HCV genome is extensively structured, containing several conserved RNA secondary structures, some of which have been shown to be critical for viral replication. For instance, nearly 90% of the core gene is base-paired into several discretely folding and interacting structures.[724] Mutations that disrupt these core-embedded structures, for example, SL588, can inhibit translation of viral RNA, RNA replication, or virus assembly.[607,724,936] However, since the HCV structural genes are dispensable for the replication of subgenomic replicons, these structural elements must function in concert with other structures. One structure in the NS4B-coding region, SL6038, can alternatively form a cloverleaf, which facilitates RNA replication, or a long SL, which inhibits RNA replication, suggesting that this region may act as a replication-mediating toggle.[724] Other RNA structures throughout the genome may serve to sequester UU/UA–rich sequences that are the preferred substrate of endoribonuclease RNaseL.[335,598]

The NS5B gene is particularly rich in functional RNA structures, including an essential *cis*-acting replication element (CRE), also termed 5BSL3.2.[1009] 5BSL3.2 can bind 40S ribosomal subunits[780] and also forms a critical long-distance base pairing with complementary sequences in the 3′ NCR (Fig. 7.12A).[277] This kissing-loop interaction, which influences translation, is competed by binding of the CRE to EWSR1, a cellular RNA-binding protein required for efficient HCV RNA replication.[682] Another loop within the CRE forms essential base pairing with a region approximately 200 nt upstream of the CRE.[211,925] The regions flanking the CRE also form competing long-distance base pairs with the CRE, as well as with the IRES region within the 5′ NCR.[780]

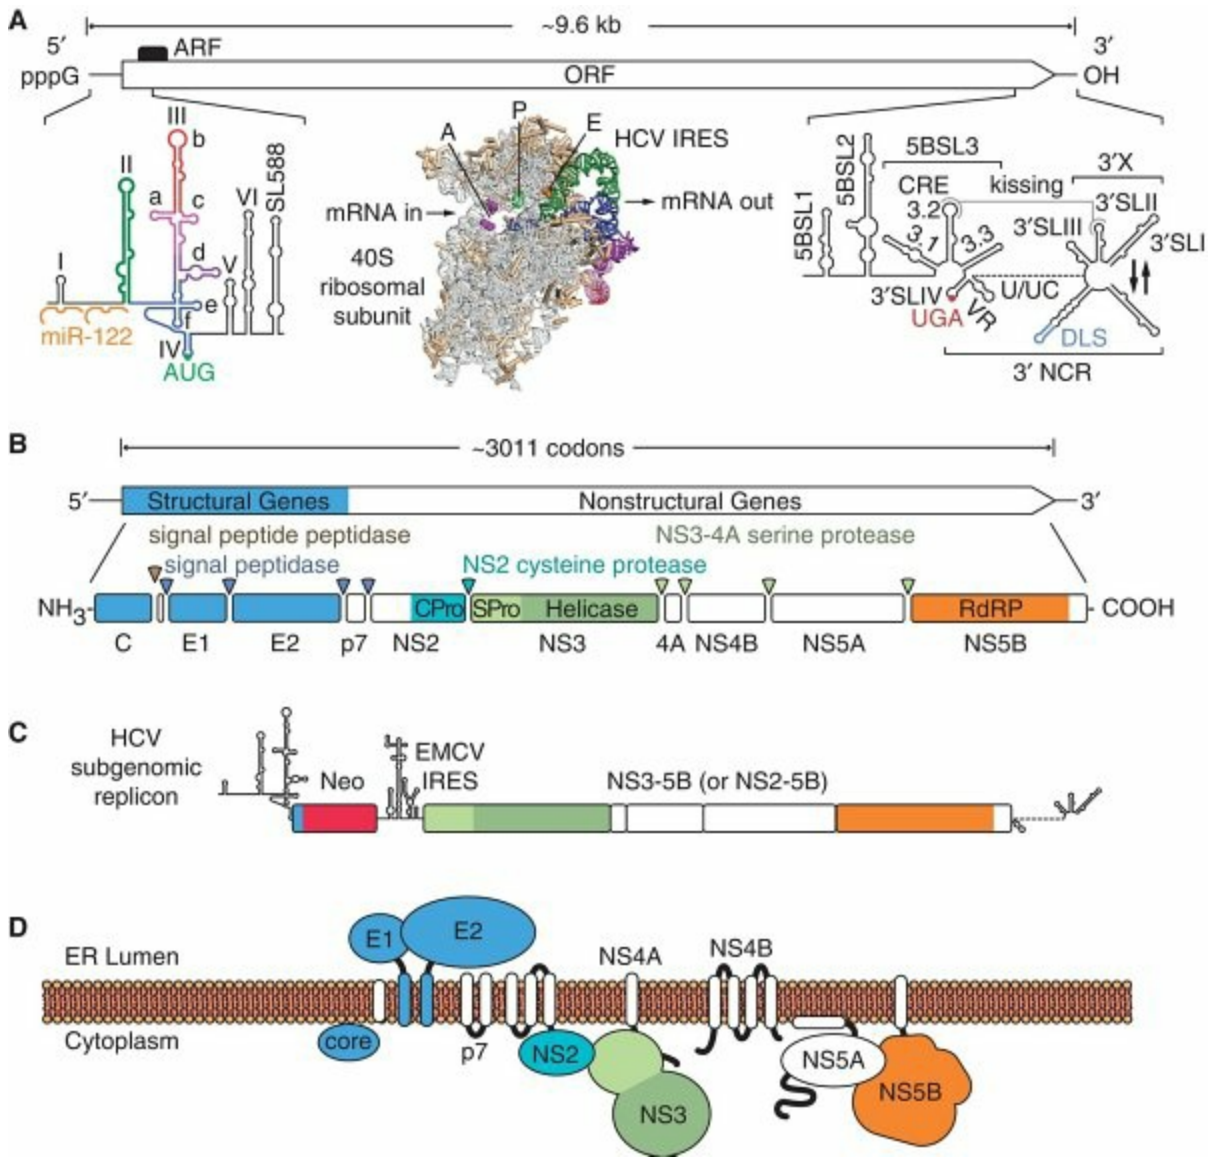

FIGURE 7.12 Hepacivirus genome structure and protein expression. **A:** HCV genome structure and RNA elements. Important RNA elements are indicated as in Figure 7.4. Two binding sites of miR-122 are indicated in *orange*; the ARF is indicated by a *black box*; the initiation (AUG) and termination (UGA) codons are indicated; and parts of the HCV IRES are color coded for interpretation of the inset, which shows the HCV IRES-40S human ribosomal subunit viewed from the perspective of an incoming 60S subunit and captured by cryo-EM at 3.9 Å resolution, as rendered from PDB 5A2Q.[744] For simplicity, the 18S

rRNA is colored *white*, ribosomal proteins are colored *wheat*. The 18S rRNA residues nearest the tRNA anticodon are labeled within the ribosomal acceptor (A), peptidyl (P), and exit (E) sites. **B:** Polyprotein processing and cleavage products. Cleavage sites are indicated as in Figure 7.4 except the NS2/NS3 cleavage, which is mediated by the NS2 cysteine autoprotease. **C:** The design of the original G418-selectable HCV subgenomic replicon is illustrated. **D:** Polyprotein membrane topology. See the legend of Figure 7.4 for symbol definitions and the text for further details.

The HCV 3′ NCR consists of a ~40-nt, structured variable domain, a poly(U/UC) tract of at least 26 nt, and a highly conserved 98-nt 3′X domain.[441,677,886] The HCV 3′ NCR enhances translation of the viral genome, in part through binding of the poly(U/UC) region to the 40S ribosomal subunit, suggesting crosstalk between the 5′ and 3′ NCRs.[40] The 3′X domain, which may adopt configurations containing either two or three SLs,[275] is essential for both RNA replication and virus assembly.[276,833,996,1001,1008] In the two SL configuration, a dimer linkage sequence (DLS) within the upstream SL (Fig. 7.12A) can mediate genome dimerization, at least *in vitro*; it is unclear whether genome dimerization is functionally relevant, but it is enhanced by the HCV core protein.[186,382] In the three SL configuration, the middle SL interacts with 5BSL3.2 in the essential kissing-loop interaction.[277,677,832] This kissing interaction has been alternately reported to both enhance and inhibit translation, differences that may reflect specific reporter designs.[677] Nevertheless, these results further indicate cross talk between the 5′ and 3′ ends of the viral genome.

A number of studies have suggested that, similar to flaviviruses, the HCV genome can cyclize via long-distance base pairing between its 5′ and 3′ ends.[275,441,779] However, these predicted interactions have been difficult to validate given the complexity and density of functionally important RNA structures within these regions. Several cellular factors and complexes can bind to both the 5′ and 3′ ends, likely impacting such cross talk. These include RNA-binding proteins PCBP2, IGF2BP1, PTB/hnRNPL, and NF90/45.[677] Other factors bind specifically to the HCV 3′ NCR, including

hnRNPC, GAPDH, and HuR.[514]

Among other hepaciviruses, the GBV-B 3′ NCR contains a short poly(U) tract followed by a unique 309-nt sequence.[124,806] Although this region lacks sequence homology to HCV, the terminal 82 nt is structurally similar to the HCV 3′X region. The NHPV 3′ NCR is also larger (~318 nt) than that of HCV and contains a short poly(A) tract, a variable region, a poly(U/UC) tract, a conserved structured region, a long poly(U) tract, and a conserved 3′X–like region.[811]

Translation and Proteolytic Processing

Hepaciviruses encode the prototype class IV IRES element,[593] which utilizes RNA structures to functionally replace a subset of translation initiation factors and drive cap-independent translation from a prepositioned AUG, that is, without scanning. Specifically, HCV IRES domains II, IIId to IIIf, and IV directly bind the 40S ribosome (Fig. 7.12A inset). The affinity of this interaction is largely driven by specific contacts between domains IIId to IIIf and the ES7 region of 18S rRNA.[744] Meanwhile, domain II forms an L-shaped structure that binds across the 40S subunit, reaching into the ribosomal intersubunit space to interact with the ribosomal E site, positioning the AUG within the P site, and inducing a conformational shift in the 40S subunit that helps to recruit the 60S subunit,[263,264,863] In addition, domain IIIb independently binds eIF3, thereby bypassing a requirement for the eIF4F 5′ cap-binding complex.[181,690,711,854,863] Recruitment of eIF2·GTP·Met-tRNA$_i$ then forms a 48S preinitiation complex.[384,386,690] Upon 60S ribosomal joining, eIF2 hydrolyzes GTP, resulting in the dissociation of the initiation complex and producing an active 80S ribosome in which the initiating AUG codon is positioned within the ribosomal P site.[386,690,711] SLV and SLIV in the core-coding region also play important but unknown roles in translation initiation.[936] In addition to this canonical pathway, the HCV IRES can utilize alternative mechanisms to initiate translation under stress conditions.[475,905] For instance, when eIF2 is phosphorylated by the innate immune sensor kinase PKR, eIF5B can recruit Met-tRNA$_i$, enabling translation initiation despite inactive eIF2. A number of cellular factors are reported to modulate HCV IRES activity, including miR-122 and RNA-binding proteins La, PSMA7, nucleolin, PCBP1, PCBP2, and PTB.[514]

Translation of the HCV genome produces a large (~3,011 aa) polyprotein that is cleaved by viral and host proteases to produce 10 viral proteins (Fig. 7.12B); these include the structural proteins core (C) and envelope glycoproteins E1 and E2, as well as the NS proteins p7, NS2, NS3, NS4A, NS4B, NS5A, and NS5B. The C/E1, E1/E2, E2/p7, and p7/NS2 junctions are cleaved by host signal peptidase, while the C-terminus of C is further processed by signal peptide peptidase (SPP) to remove the E1 signal peptide and generate mature C protein. NS2 contains a cysteine protease domain that cleaves the NS2/3 junction, while NS3-4A encodes a serine protease that cleaves all downstream NS junctions (Fig. 7.12B).

In addition to the large ORF, small alternative reading frame proteins (ARFPs) may be produced from a +1 reading frame located within the C gene. Different ARFP forms have been described, including ARFP/F (frameshift), ARFP/DF (double frameshift), or ARFP/S (short form). However, detection of these products varies greatly between HCV isolates and laboratories.[106] Evidence in support of ARFP expression include detection of protein products with ARFP-specific antibodies as well as the detection of ARFP-specific immune responses in HCV-infected patients. While it has been assumed that these products are produced via ribosomal frameshifting, alternate translational initiation sites may also be involved.[106] It is unclear what role ARFP expression plays in the virus life cycle. In addition, small amounts of an approximately 8-kDa “minicore” protein are reportedly expressed via initiation of translation at codon approximately 90 within the main ORF.[239] Given the mechanism of HCV IRES activity, it is unclear how the minicore start codon is recognized.

Features of the Structural Proteins

Core (C) Protein

C is a conserved, *α*-helix–rich RNA-binding protein that encapsidates the HCV genome within virus particles. While C lacks a well-defined structure, it does contain three functionally distinct domains. Domain I is approximately 120 aa in length, enriched in basic residues, binds structured RNAs, and is capable of forming nucleocapsid-like complexes *in vitro*.[461] Domain II is smaller, is approximately 55 aa, and forms two amphipathic helices that,

together with palmitoylation at residue Cys 172, mediate peripheral membrane interaction.[100,583] Domain III is a transmembrane region that acts as a signal peptide for translocation of E1 into the ER; this region is only found on the 191-aa immature form of capsid because, following signal peptidase cleavage of the C/E1 junction, it is removed from mature core via SPP cleavage between residues 177 and 178.[569,686]

C forms native homodimers[102,558] that can be stabilized by disulfide bonding[463] and/or *trans*-glutamination.[558] C dimers also form higher-order, capsid-like structures *in vitro*.[428,461] These homotypic interactions may also mediate interaction with the E1 glycoprotein in cells,[543,667] although C does not appear to form preformed capsids prior to virus assembly. Domain II also contains a highly conserved YXXø motif that interacts with AP2M1 and is required for virion assembly.[674]

The peripheral membrane association of C allows it to traffic to ER-associated LDs,[47,100,605,652] where virus particles' assembly is thought to occur.[638,831] Trafficking of C to LDs requires the cytosolic phospholipase A2 and is enhanced by DGAT-1, an ER-resident enzyme that catalyzes triglyceride synthesis.[355,614] C also alters the size, distribution, and protein composition of LDs, in part by inhibiting adipose triglyceride lipase and causing lipid accumulation.[99,134,206] In humans, this accumulation likely contributes to hepatic steatosis that occurs during chronic HCV infection, particularly with genotype 3 viruses.[776] Mutations in C that disrupt LD trafficking greatly inhibit virus assembly,[101] although it is unclear why HCV prefers that C traffic to LDs. One possibility is that it serves to sequester C away from sites of viral translation and genome replication, yet easily accessible for virus assembly. Indeed, C protein has been reported to both enhance and inhibit HCV IRES–mediated translation.[95,842]

In addition to the posttranslational modifications mentioned above, C can be phosphorylated by protein kinases A and C, which can alter C localization and down-regulates the ability of C to inhibit the replication of hepatitis B virus.[557,838] Furthermore, C has been reported to manipulate numerous cellular pathways, including signal transduction pathways, transcriptional control, apoptosis, and cellular transformation.[604,903]

Envelope Glycoproteins

Hepacivirus glycoproteins show limited but significant interspecies conservation,[745] with the HCV glycoproteins being the best characterized. HCV E1 (~30 kDa) and E2 (~70 kDa) are highly glycosylated type I transmembrane proteins that mediate virus attachment and membrane fusion. Each has a large lumenal domain and a single C-terminal transmembrane domain.[224,227,787] To generate this topology, both transmembrane regions contain charged residues, driving the formation of intramembrane hairpin structures during glycoprotein translocation.[688] Following signal peptidase cleavage, the lumenal C-termini reorient to face the cytoplasm, yielding tandem proteins each with a single-membrane anchor.[176] The transmembrane domains of E1 and E2 interact, contributing to heterodimerization, and also act as an ER retention signal of the E1–E2 complex.[168,169,252,688]

During folding in the ER, HCV E1–E2 heterodimer formation is slow and interdependent,[113,632,696] requiring the ER chaperone calnexin.[225] In addition to the transmembrane domains, heterodimerization involves interactions between the E1 and E2 ectodomains,[1002] as well as the membrane-proximal region of E2.[222] Although ER-localized E1 and E2 interact noncovalently, they form large covalent complexes stabilized by disulfide bonds in purified virions.[939] These linkages may contribute to the acid resistance of virus particles[922] and suggest that virus maturation may require disulfide bond isomerization. Analysis of virion-associated glycoproteins also indicates that E1 drives trimerization of E1–E2 heterodimers.[252]

The structures of E1 and E2 are not fully known, but it is clear that they have unique folds and do not resemble other known fusion proteins, including the corresponding flavivirus and pestivirus envelope glycoproteins. HCV E1 consists of four functional regions, including an ~80-aa N-terminal domain, a putative fusion peptide, an ~30-aa conserved region, and a C-terminal transmembrane domain (Fig. 7.13A). Crystallization of the N-terminal domain revealed a network of covalently linked homodimers with an intermolecular disulfide bridge (Fig. 7.13B).[234] Consistent with this, E1 can form stable trimers on HCVcc particles.[252] Mutations in the N-terminal domain influence the fidelity of virion assembly and CLDN specificity during entry,[330] consistent with the observation that mutations in E1 can

influence CLDN utilization.[363] Intriguingly, the N-terminal domain has distant structural similarity to phosphatidylcholine transfer protein, which transfers phosphatidylcholine between membranes.[234] Given the complicated relationship(s) between HCV particles and lipids, it will be interesting to determine whether this observation is functionally relevant to the mechanisms of viral assembly and/or entry. Mutations in the putative fusion peptide inhibit E1–E2 heterodimerization and HCVcc assembly[657] and lead to production of noninfectious HCVpp.[220] The function of the membrane-proximal conserved region is poorly understood. Mutations in this region primarily affect entry and the sensitivity of entry to CLDN1- and SCARB1-specific antibodies, suggesting possible interaction with these receptors.[657]

FIGURE 7.13 HCV glycoprotein structures. **A:** A map of the HCV E1–E2 glycoproteins is illustrated, showing the locations of the E1 N-terminal domain (NTD), putative fusion peptide (FP?), and conserved region (CR); the E2 hypervariable regions (HVRs) 1, 2, and 3 are shown. The cleavage sites for signal peptidase are shown, as in Figure 7.12. The regions for which structures are available are indicated; the C-terminal transmembrane domains are indicated with *dark purple*. **B:** Structure of the E1 N-terminal domain is shown, forming a disulfide-linked multimer. Four full N-terminal chains are shown in *purple*, *blue*, *green*, and *orange*; two partial chains within the asymmetric unit are shown in *pale yellow* and *red*; intramolecular and intermolecular disulfide bonds are shown in *yellow* and *green*, respectively. The view is looking down on the surface of the molecule, with N-linked glycans (*black*) pointing up from the page, as rendered from PDB 4UOI.[234] **C:** Structure of the partial E2 ectodomain is shown, highlighting spatial arrangement of the HVRs and CD81 loop around a compact globular core. Intramolecular disulfide bonds are indicated in *yellow*. The location of residues that, when mutated, disrupt CD81 interaction are shown in *orange*. The view is looking down on the surface of the molecule, with N-linked glycans (*black*) pointing up from the page, as rendered from PDB 6MEI.[269]

E2 is the HCV attachment protein, directly binding to CD81 and SCARB1 on target cells, and the major neutralizing antigen displayed on the surface of virus particles.[723,808] Structures of a minimal E2 "core" domain[419,444] or near–full-length E2 ectodomains[269] reveal a central β-sheet–rich, C2-set (e.g., CD2) immunoglobulin–like fold containing a hydrophobic core stabilized by intramolecular disulfide bridges and surrounded by extensive flexible loops, including three HVRs (Fig. 7.13C). This multifaceted structure presents distinct interaction surfaces, including the Ig-like β-sandwich, a conserved

CD81-binding loop that projects from the *β*-sandwich, a glycan-rich "front" that is conformationally flexible, and a back surface. While the CD81-binding loop is the primary determinant of interaction with this receptor, CD81 actually interacts with a much larger conformationally defined surface on E2, including parts of the front layer and a major epitope, termed antigenic site 412.[269,419,444] Thus, the CD81-binding surface of E2 is a major target for broadly neutralizing antibodies.[339,489,926,935] As mentioned, HVR1 partially protects the CD81-binding region from neutralizing antibodies.[46,808] Thus, HVR1-specific antibodies can also neutralize virus infectivity[412,963] and protect chimpanzees from homologous challenge[254]; early induction of HVR1-specific antibodies also correlates with viral clearance in humans.[17,1035] Based on this immunologic selection pressure, HVR1 exhibits a high level of sequence variability even within individual patients.[253,601,647,964]

While the structure of the E1–E2 complex has not yet been experimentally determined, a computational model of this complex has been proposed, partially based on the existing E1 and E2 structures, mutational analysis, and immunoreactivity profiling.[137] This model predicts that E1–E2 forms a compact structure held together by an intermolecular disulfide bond. Clearly, solving the structure of the E1–E2 complex is a high priority for understanding the mechanisms of HCV entry and antibody-mediated neutralization.

Features of the Nonstructural Proteins

p7/p13 Proteins

The HCV p7 protein is a small (~7 kDa), 63-aa polytopic membrane protein with ion channel activity, often called a "viroporin."[316,559,648,702,732] While p7 is dispensable for RNA replication,[549] it plays important roles in virus particle assembly, virus particle release, and antagonism of type I interferons. Signal peptidase cleavage of E2–p7 and p7–NS2 are somewhat inefficient, leading to the accumulation of proteolytic processing intermediates, especially E2–p7, which may impose an inverted topology on p7.[375,525,640,720,826] The N-terminal α-helix of p7 is a major determinant of E2–p7 cleavage efficiency,[823] which in turn influences virus particle

assembly.[205]

Structurally, p7 is predicted to contain two transmembrane domains, forming a membrane-bound hairpin with N- and C-termini that face the ER lumen, separated by a short, basic, cytoplasmic loop (Fig. 7.14A).[136] However, it is unlikely that p7 remains as a monomer and more likely that it functions through homo- and heterotypic interactions. Most notably, p7 ion channel activity requires homo-oligomerization.[581] EM and single particle reconstruction of p7 hexamers in detergent micelles revealed a flower-shaped oligomer with six petals protruding from a conical base (Fig. 7.14B).[559] However, the 16 Å resolution achieved was too low to definitively fit p7 monomers within this structure. Currently, two competing structural models of hexameric p7 have been proposed based on additional EM and NMR measurements of different HCV p7 proteins in various membrane-mimetic environments.[559,581,691] In one model, p7 hairpins interact with neighboring p7 hairpins around a common axis, much like a pinwheel (Fig. 7.14C).[559] In the other model, each p7 extends through the plane of the membrane to intercalate with all five other subunits to form a conical pore (Fig. 7.14D).[691] While this latter model can nicely account for the flower-like electron density observed via EM, it requires a more rigid structure that seems inconsistent with other considerations. For instance, molecular dynamics simulations predict that p7 can form structurally plastic, minimalist ion channels through multiple oligomeric configurations, and indeed p7 oligomers containing 4, 5, and 7 subunits have also been described.[144,170]

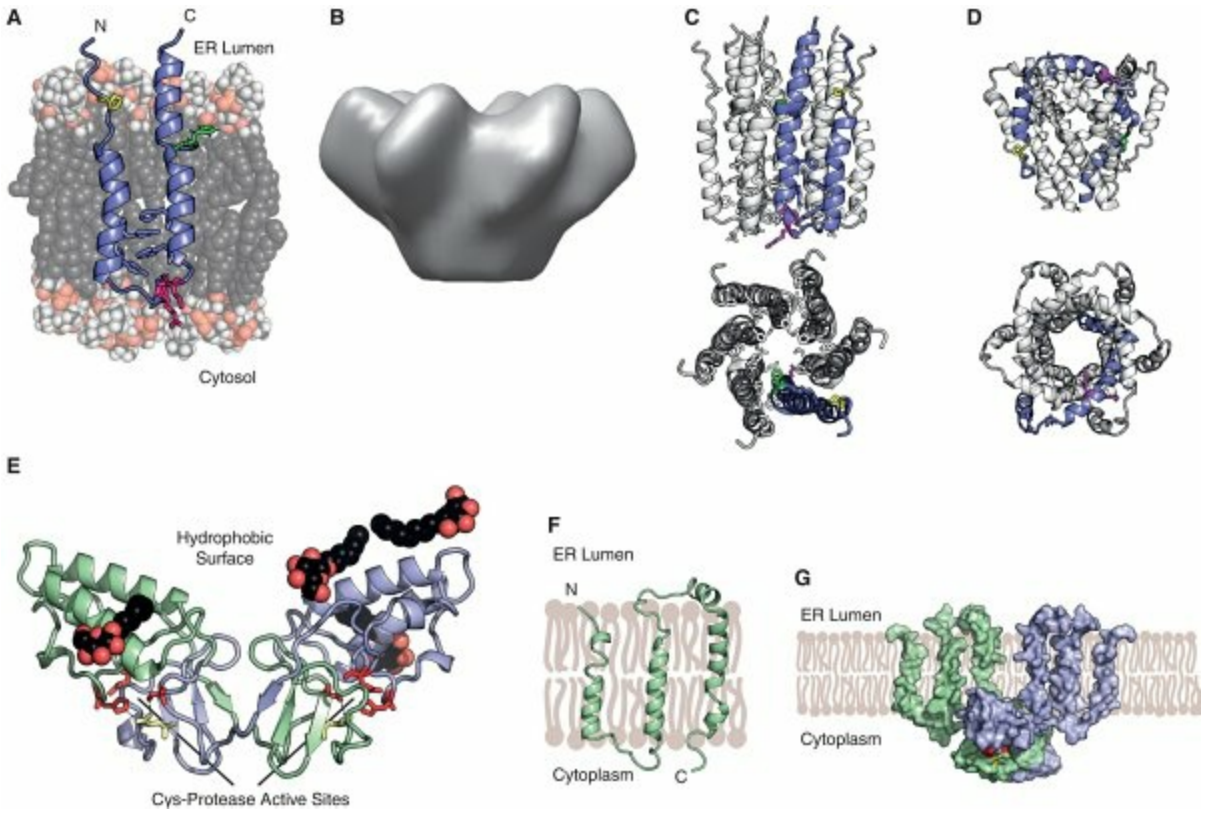

FIGURE 7.14 Structure of the HCV p7 and NS2 proteins. **A:** Model of the p7 monomer in a lipid bilayer.[648] Functionally important, conserved residues His 17 (*green*); Lys 33 and Arg 35 (*magenta*); Pro 58 (*yellow*); and Phe 26, Trp 30, Tyr 42, and Tyr 45 (*slate*) are shown. NMR coordinates and membrane modeling kindly provided by R. Montserret and F. Penin. **B:** EM reconstruction of a hexameric p7 conical flower, as rendered from EMD-1661.[559] **C:** The pinwheel model of a p7 hexamer as viewed from the side or from the ER lumen. Rendered from PDB 2M6X.[691] **E:** The dimeric NS2 cysteine protease domain. Monomeric subunits are colored *green* and *blue*; active site residues, *red*; C-terminal residues, *yellow*; cocrystallized detergent molecules are shown as *spheres*. Rendered from PDB 2HD0.[553] **F:** Model of NS2 TM domains, based on

NMR data.[389] **G:** A model of the full-length NS2, based on the models presented in **(E)** and **(F)**.

HCV p7 is essential for virus assembly in cell culture and for infectivity *in vivo*.[392,797,869] During virus particle assembly, p7 mediates critical interactions with NS2 and the viral glycoproteins.[97,389,571,938] There is also evidence that delayed E2-p7 cleavage allows for the N-terminus of p7 to be (at least transiently) cytosolic, where it may mediate interactions between NS2 and NS5A.[205] Indeed, genetic interactions link p7 and NS5A during virus assembly,[813] and additional genetic interactions link p7 and NS5B in influencing the lipid composition and infectivity of virus particles.[16]

During HCV particle secretion, p7 has a critical role as a cation-selective, class IIa viroporin, modulating proton conductance to neutralize pH gradients in the secretory pathway, which may prevent premature acid-induced fusion of the viral glycoproteins.[979] In keeping with this model, the influenza A virus M2 viroporin can partially complement HCV mutants lacking p7 ion channel activity.[69,979] Two highly conserved basic residues located in the central cytosolic loop are required for p7 ion channel activity in vitro and for HCV infectivity *in vivo*.[317,797] Furthermore, inhibitors of p7 ion channel activity reduce virus particle release.[581]

In addition to its essential roles in virus assembly and release, p7 also has anti-inflammatory activities. Specifically, HCV p7 binds to the interferon γ-inducible DNA-binding protein IFI-16 and can prevent IFI-16 activation by modulating mitochondria membrane potentials, thereby subverting activation of the type I interferon system.[741] HCV p7 can also enhance cellular SOCS3 expression in a JAK/STAT- and MAPK-dependent manner, thereby reducing cellular response to TNF-α.[183]
