Similar p7-like proteins are found in other hepaciviruses, although they can vary considerably in size. The largest and best characterized of these is the GBV-B p13 protein (~13 kDa), which has partial homology to HCV p7.[293] GBV-B p13 gene can be functionally replaced by HCV p7.[318] p13 is predicted to span the membrane four times and can be processed by signal peptidase into two tandem p7-like proteins.[293,884] The functional significance of the first half of p13 is unclear, since only the second half of p13, which has

greater similarity to the HCV p7 gene, is required for infectivity in tamarins.[884]

NS2 Protein

NS2 (~23 kDa) is a polytopic membrane protein with cysteine protease activity and a key regulator of virus particle assembly.[312,358,553,820] NS2 contains three N-terminal transmembrane segments followed by a C-terminal cysteine protease domain.[388,389] The only known substrate of the NS2 protease is the NS2/3 junction, and NS2 is often referred to as an autoprotease.[312,358,553] NS2 has intrinsic protease activity[98] that can be stimulated by the N-terminal zinc–binding domain of NS3 and a conserved hydrophobic surface patch in the protease domain of NS3.[312,358,377,820] Mutation of this surface prevents RNA replication and NS5A hyperphosphorylation, suggesting that NS2-3 cleavage precedes functional replicase assembly.[377]

A crystal structure of the HCV NS2 catalytic domain revealed a homodimeric cysteine protease with two composite active sites (Fig. 7.14E–G).[553] One monomer contributes catalytic histidine and glutamate residues to each active site, with the nucleophilic cysteine supplied by the other monomer. This structure is supported by mutagenesis studies wherein HCV NS2 protease mutants can be complemented in *trans*, a feature that is conserved among other hepaciviruses.[98,312,756] The C-terminus of NS2 occludes the substrate-binding groove, suggesting that this protease is inactive following cleavage.

NS2 has several noncatalytic functions in HCV assembly and egress. It is a central organizer of virion assembly, coordinating interactions with E1–E2, p7, NS3–NS4A, NS5A, and host factors involved in virus assembly.[97,389,423,571,715,731,865] For instance, the interaction of NS2 with NS3–4A is critical for trafficking of C from the surface of LDs into nucleocapsids.[178,185] NS2 also interacts with E2 and signal peptidase complex subunit 1,[879] perhaps to facilitate E2-p7 cleavage required for virus assembly. In addition to its role as a matchmaker, bringing together virion components, NS2 also mediates envelopment. Specifically, the MARCH8 E3 ligase K63-polyubiquitylates NS2, which then recruits HGS, a component of the ESCRT0 pathway, to facilitate fission.[50,455] Finally, NS2 helps to mediate

virus trafficking and release through interaction with the secretory vesicle coat adaptor complex proteins AP-1 and AP-4.[986] Consistent with this, some NS2 mutants display late, post-Golgi defects in virus particle egress.[197,587]

NS3 Protein

HCV NS3 is a large (~70 kDa) multifunctional protein, containing an N-terminal serine protease domain and a C-terminal RNA helicase/NTPase domain.[655] These enzyme activities play essential roles in virus gene expression, RNA replication, virus particle assembly, and subversion of host innate defenses. The serine protease, in particular, was the first HCV protein successfully targeted via DAA development.[471] While the first generation of HCV serine protease inhibitors were generally genotype specific and resistance arose with low fitness barriers, newer third-generation protease inhibitors are effective tools in combating HCV replication without these caveats.[670]

NS3 belongs to the chymotrypsin-like superfamily of serine proteases. Structurally, it is composed of two β-barrels flanked by α-helices, with the central peptide of NS4A contributing one strand to one of the β-barrels (reviewed in Ref.[655]). Thus, NS4A is an essential cofactor of the serine protease.[52,248,526] The protease domain also has a Zn^{2+} coordination motif,[555] which has a structural role in protein folding, as well as an N-terminal amphipathic helix,[108] which contributes to the membrane association of the NS3-4A complex. The serine protease active site is composed of residues His 57, Asp 81, and Ser 139, surrounding a shallow substrate-binding surface located between the two β-barrels.[655] Cleavage sites within the HCV polyprotein have the consensus sequence (Asp/Glu)XXXX(Cys/Thr)/(Ser/Ala),[55] which is conserved among other hepaciviruses. In order to form the serine protease, NS3 must first cleave the NS3/4A junction in *cis*, before it can cleave the NS4A/4B, NS4B/5A, and NS5A/5B junctions in *cis* or in *trans*. The preferred order of cleavage is NS5A/5B > NS4A/4B > NS4B/5A.[655,868] Interestingly, the structure of a single-chain, full-length NS3 shows the C-terminus coordinated by the serine protease, as would be expected from the NS3-4A *cis*-cleavage reaction (Fig. 7.7).[998]

In addition to the canonical cleavage sites within the polyprotein, HCV

NS3-4A also mediates internal cleavages within NS3, NS4B, and NS5A although the functional relevance of these cleavages are not yet known.[655] Many additional peptide sequences can also be cleaved by NS3-4A.[53,712,845] Given this low substrate specificity, it is unsurprising that NS3-4A has evolved to cleave cellular proteins of functional relevance, including MAVS, TRIF, PTPN2, TC-PTP, GPx8, DBB1, and Neuregulin 1.[402,654,655,822] MAVS is a mitochondrial membrane protein that transduces signals from cytoplasmic RNA sensors RIG-I and MDA5 to activate IRF3 and subsequent ISG expression. Several studies have demonstrated that NS3-4A cleavage removes MAVS from the mitochondria and attenuates ISG induction. In addition, HCV might also target TRIF, an adaptor molecule involved in the toll-like receptor 3 signaling, which senses endosomal dsRNA to initiate antiviral signaling. Thus, cleavage of MAVS and eventually TRIF serves to subvert innate antiviral defenses.[505,511,630]

Similar to other *Flaviviridae*, the C-terminal domain of hepacivirus NS3 proteins encode a superfamily 2 RNA helicase/NTPase. These enzymes are motor proteins, utilizing the energy derived from NTP hydrolysis to translocate along one strand of a nucleic acid substrate; if the substrate is double-stranded, this translocation leads to strand displacement and unwinding.[739]

Structurally, the HCV helicase domain contains two RecA-like subdomains, which bind and hydrolyze NTPs at their interface, as well as a third α-helix–rich subdomain. Nucleic acid substrates are bound in a cleft formed between the two RecA-like subdomains and subdomain 3.[425] NS3 can unwind RNA and DNA homo- and heteroduplexes by binding to an unpaired region of a template strand and translocating in a 3′ to 5′ direction, unwinding one base pair for each ATP hydrolyzed.[29,324,328] Helicase activity and substrate recognition are stimulated by the NS3 serine protease domain and NS4A, and the helicase in turn stimulates NS3-4A serine protease activity.[70], [71], [72] Thus, the essential enzymatic activities of NS3-4A are tightly coordinated. Helicase activity can also be up-regulated by NS5B, presumably through interactions with the serine protease domain.[1022] Likewise, the NS3 helicase activity enhances NS5B RdRP activity.[717] NS3-4A helicase activity is also down-regulated by the cellular arginine methyltransferase PRMT1, which methylates residues within the NTPase active site.[226,763]

Although the precise roles of the NS3 helicase are not fully understood, the NTPase and helicase activities are essential for HCV replication and viral infectivity,[442,470] and the helicase domain has been implicated in virus particle assembly.[391,574,715] Furthermore, the NS3 helicase activity is required in *cis* for RNA replication, suggesting that it functions on the RNA from which it was translated; that is, it may play a role in recruiting RNA from translation into RNA replication.[416]

The nonenzymatic regions of NS3 have also been implicated in HCV particle assembly. A mutation in the N-terminal amphipathic helix enhances transfer of C protein from LDs to the ER, thereby increasing the efficiency of virus assembly.[994] Furthermore, mutations in the peptide linker that connects the protease and helicase domains selectively inhibit assembly without impacting enzymatic function, suggesting potential protein–protein interactions.[439] A likely candidate is NS2 that, via interaction with the NS3 protease domain, could bring together the replicase and the NS2-associated envelope glycoprotein complex.

NS4A and NS4B Proteins

NS4A (~7 kDa) is a small 54-aa protein with multiple functions. Its N-terminal transmembrane domain anchors NS3-4A to the ER and promotes NS4A dimerization, which is important for RNA replication and virus particle assembly.[438] As mentioned above, the central region of NS4A facilitates proper folding of the NS3 serine protease domain, thereby acting as a cofactor for serine protease activity. The acidic C-terminal domain of NS4A stimulates NS3 NTPase/helicase activity,[70] NS5A phosphorylation,[401,434,531] RNA replication,[531,662] and virus particle assembly.[662,716,774] NS4A also physically interacts with NS2, NS4B, NS5A, and uncleaved NS4B-5A.[32,527]

NS4B (~27 kDa) is an integral membrane protein with cytosolic N- and C-terminal regions flanking four transmembrane domains.[310] The N-terminal cytosolic region encodes two amphipathic helices, the second of which can insert in the membrane, thereby inverting the topology of the first helix.[310,561] NS4B helix insertion into the ER leaflet is likely to generate positive membrane curvature, which may contribute to forming the HCV replication organelle.[309] The C-terminus of NS4B also encodes two α-helices, the second of which is membrane-associated.[308] A key feature of NS4B is that it

oligomerizes and plays a central role in organizing the membrane-bound replication complex.[311,700,1014] For instance, expression of NS4B is sufficient to induce membrane rearrangements resembling RNA replication compartments,[230,303] although other NS proteins (especially NS5A) are required for the formation of *bona fide* "membranous web" structures.[778] NS4B also binds to the cellular SAR1B GTP exchange factor, PREB, which is involved in COPII vesicle biogenesis and influences membranous web formation.[443] Cell culture–adaptive mutations have been mapped to NS4B (reviewed in Ref.[55]) and NS4B has been genetically linked to virion assembly.[309,393]

In addition to its role in rearranging cellular membranes, NS4B also inhibits innate immune signaling. Specifically, it binds to the innate immune adaptor STING, preventing its interaction with TBK1 and subsequent ISG induction.[209,678] NS4B also induces TRIF degradation in a caspase 8–dependent manner.[516]

NS5A Protein

NS5A (~56–58 kDa) is a homodimeric phosphoprotein that plays multiple roles in the viral life cycle. NS5A is a multidomain protein that contains an N-terminal Zn^{2+}–binding domain I (DI), a central conserved domain II (DII), and a C-terminal variable domain III (DIII); these domains are separated by two short linkers of low-complexity sequence (LCS), as illustrated in Figure 7.15A.[900] The N-terminus of DI contains an amphipathic α-helix that mediates peripheral membrane association and LD localization.[109,235,705] The remainder of DI has been crystallized into two major homodimeric conformations. In one conformation, DI dimers form a claw-like structure containing a positively charged groove, which is postulated to bind RNA (Fig. 7.15B, C).[901] In the other conformation, two DI monomers bind along their length, forming a barrel-shaped dimeric structure (Fig. 7.15D).[554] Both dimer conformations bury extensive surface area (~1,000 $Å^2$) and contain well-conserved residues at their interface, and mutations at these interfaces support the functional relevance of both dimer models in HCV replication.[829] NS5A DI has also been crystallized in two additional dimer conformations.[472] However, these latter models contain far less buried surface area and feature opposing membrane anchors, so their relevance

remains unclear. It should be noted that several highly effective and potent NS5A-specific DAAs emerged from extensive compound library screening, for example, daclatasvir. The main line of evidence that these compounds target NS5A is that mutations conferring resistance map to NS5A DI, more precisely in the membrane-proximal region of the molecule and often in the linker connecting the N-terminal amphipathic *α*-helix and DI; however, the mechanisms of action of these compounds are not yet understood. A key feature of these compounds is their symmetry, consistent with models predicting that they bind at the NS5A dimer interface.[286,498] One intriguing hypothesis is that these compounds inhibit virus replication by locking NS5A in one dimer conformation.

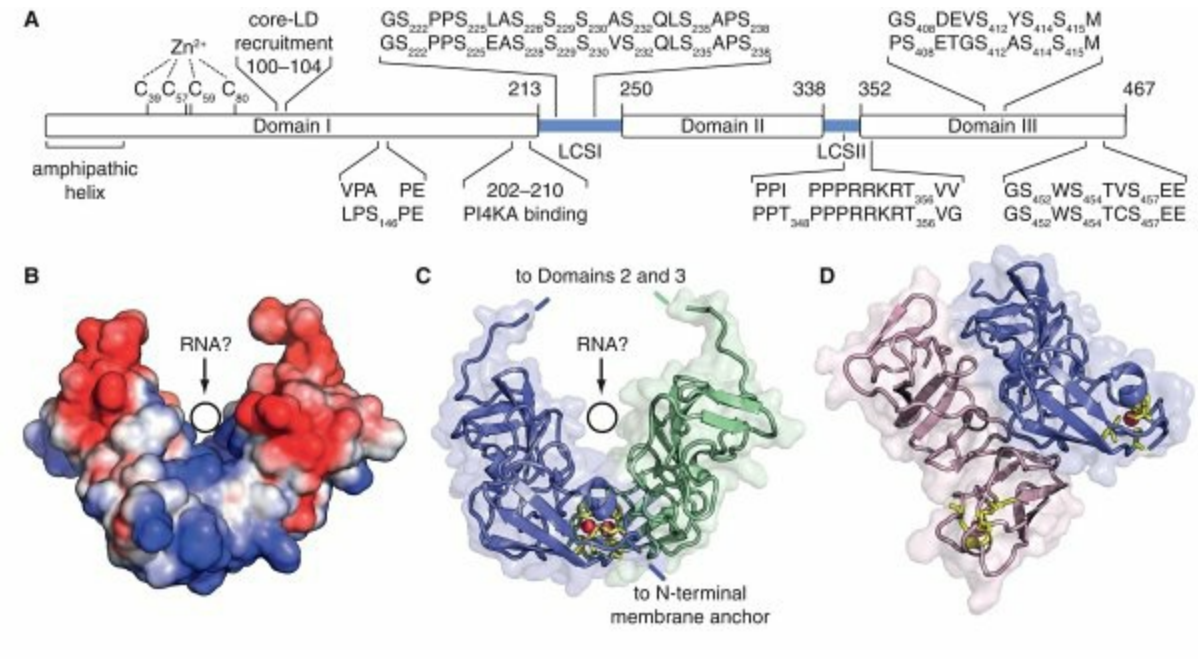

FIGURE 7.15 Structures of HCV NS5A protein. **A:** A map of NS5A is illustrated, highlighting structural features, including two low-complexity sequences (LCS), known interaction sites, and residue numbers of phosphorylated Ser and Thr residues. This figure is loosely based on prior analyses.[784,900] Sequences presented are genotype 1b (J4 isolate, upper sequence) and genotype 2a (JFH-1 isolate, lower sequence). **B:** Surface electrostatic potential of the dimeric NS5A zinc–binding domain,

as rendered from PDB 1ZH1.[901] Negative charges are in *red* and positive charges in *blue*. **C:** The NS5A zinc–binding domain (PDB 1ZH1), with individual monomeric subunits colored *purple* and *green*. Zn^{2+} ions are shown in *red*, and coordinating residues are shown in *yellow*. **D:** An alternative structure of the NS5A zinc–binding domain, as rendered from PDB 3FQM.[554] The *purple* subunit is structurally aligned the same as the *purple* subunit in **(C)**.

Downstream of DI lies DII and DIII, which have natively unfolded structures that contain some α-helical content.[39,519,937] In line with this flexibility, DIII is tolerant of large deletions and insertions.[27,368,535,603,653,899] This conformational flexibility is also observed in other hepaciviruses, such as in GHV, which has an exceptionally long NS5A with a 521-aa C-terminal region.[485]

NS5A is phosphorylated by multiple cellular Ser/Thr kinases and can be found in basally phosphorylated (56 kDa) and hyperphosphorylated (58 kDa) forms. These designations, however, greatly oversimplify NS5A phosphorylation status, which is quite complex and can differ between genotypes. Interestingly, many of the cell culture–adaptive mutations in genotype 1b replicons lead to increased basal NS5A phosphorylation and promote RNA replication.[92,547] Basal phosphorylation involves a central region of NS5A and a large C-terminal region of DIII.[889] Initial mutational analysis of genotype 1a HCV NS5A found that Ser residues within LCSI are required for hyperphosphorylation.[889] Subsequent analyses of genotype 2a HCV NS5A with phosphospecific antibodies or mass spectrometry definitively identified several phosphorylated residues, particularly in the LCS I region (Fig. 7.15A). Mutational analysis suggested that phosphorylation of Ser 225, Ser 229, Ser 232, and Ser 235 positively regulates RNA replication, whereas phosphorylation of Ser 222, Ser 242, and Ser 245 negatively regulates replication.[162,246,300,301,497,594,783,784]

Several NS5A kinases have been tentatively identified.[594,784] Basal phosphorylation likely involves phosphorylation at multiple sites by casein

kinase II subunit α, protein kinase A subunit Cβ, and/or serine/threonine–protein kinase PLK1. Hyperphosphorylation is likely due to sequential, clustered phosphorylation of Ser 232 → Ser 235 → Ser 238 and (Ser 247 and Thr 244) → Thr 242 by casein kinase Iα.[365,784,814] NS5A hyperphosphorylation requires prior phosphorylation at positions Ser 225 and Ser 229,[365] coexpression of NS3-5A in *cis*,[434,669] and interaction between NS4A and NS5A[32,401]; in contrast, hyperphosphorylation is inhibited by interaction with PI4K.[758] In addition to phosphorylation on multiple Ser/Thr residues, NS5A is also phosphorylated on Tyr 93 by c-Src.[432] Thus, NS5A phosphorylation is complicated and hierarchical and integrates multiple interactions as inputs. Depending on the viral genotype and strain, outputs of this mechanism may be expressed as altered protein–protein or protein–RNA interactions, differences in NS5A localization, and efficiencies of RNA replication or virus assembly.[300,301,594,784,785]

NS5A plays two key roles in HCV RNA replication: first, it alters ER membranes to build replication organelles; second, it is a nonenzymatic component of the replicase. To build the RNA replication organelle, NS5A binds and activates PI4KA[75,76,759,883] which generates phosphatidylinositol 4-phosphate, PI4P. PI4P then recruits membrane effectors like oxysterol-binding protein (OSBP), which shuttles cholesterol between membranes in coordination with VAMP-associated protein A (VAPA), as described below. Interestingly, VAPA is also an important NS5A interaction partner, preferentially binding to hypophosphorylated NS5A and stimulating RNA replication.[244,300] Thus, NS5A phosphorylation status regulates replication complex assembly, and it should be noted that one particularly potent cell culture–adaptive mutation (S232I) coordinately abrogates hyperphosphorylation and enhances RNA replication of most HCV strains in Huh-7 cells but dampens the activation of PI4KA, which is overproduced in Huh-7 cells.[92,337]

Once replication organelles are formed, NS5A localizes to sites of viral RNA synthesis.[303] NS5A binds to NS5B and can modulate its RdRP activity *in vitro*,[843] including increased RdRP processivity,[586] and mutations in NS5A that block NS5B interaction are detrimental for HCV replication in cell culture.[840] The interaction between NS5A and NS5B requires c-Src, which binds to these proteins via its SH2 and SH3 domains, respectively.[714] NS5A

also has RNA-binding activity, with the minimal RNA-binding domain in DI and LCSI,[371] although DII and DIII may also contribute to RNA binding.[272] The RNA-binding ability of NS5A can be regulated by cyclophilin A, a cellular proline *cis–trans* isomerase that is essential for HCV replication.[784] Furthermore, NS5A phosphorylation is postulated to competitively inhibit RNA binding.[472]

NS5A plays an important role in virion assembly, primarily through trafficking to LDs and interaction with the viral C protein.[28,595,638] Recruitment of NS5A to LDs is mediated by determinants located in DI[638,1005] and enhanced by the cellular enzymes DGAT1[133] and Rab18.[798] DGAT1, a diacylglycerol acyltransferase, is important for LD formation; Rab18, a small GTPase, regulates protein trafficking to LDs. Further downstream, DIII contains determinants of virus particle assembly; deletion of these determinants selectively inhibits virus assembly with minimal effects on RNA replication.[28,898,1005] More specifically, virion assembly requires NS5A phosphorylation on Ser 457 by casein kinase IIα.[898] These findings have led to a model wherein the major assembly function of NS5A is to traffic genomic RNA from replication compartments to LDs for nucleocapsid assembly. In support of this model, the NS5A inhibitor daclatasvir prevents transfer of HCV RNA to sites of assembly.[96] In addition, NS5A DIII recruits annexin A2, a cellular phospholipid-binding protein that enhances virus assembly.[38] NS5A also reportedly interacts with ApoE,[68,189] which is essential for HCV particle assembly; however, it remains unclear how cytosolic NS5A interacts with this secreted glycoprotein.

NS5B Protein

NS5B (~68 kDa) is the hepacivirus RdRP, the enzyme responsible for viral RNA synthesis, and a major target of DAAs. NS5B is a tail-anchored membrane protein, posttranslationally inserting its C-terminal 21 aa into the ER membrane.[383,817] The tail anchor of GBV-B NS5B can functionally substitute for the tail anchor of HCV NS5B.[110] Deletion of this domain in HCV alters NS5B localization and inhibits replication in cell culture,[651] although it does not affect RdRP activity *in vitro*.[993] This truncated, active form of NS5B can be efficiently purified in soluble form, enabling biophysical and biochemical characterization.

Like other RdRPs, the structure of NS5B resembles a right hand with distinct finger, palm, and thumb domains, with nucleotidyltransferase active site residues located in the palm domain and a template-binding groove located within the fingers (Fig. 7.8B).[5,115,116,499] HCV NS5B has been crystallized in both inactive "open" and active "closed" conformations, featuring an enclosed active site with extensive interactions between the finger and thumb domains. An unusual *β*-hairpin protrudes from the thumb into the active site, where it serves to stabilize the intermediates of *de novo* initiation.[30,362,681,750] In some structures, a C-terminal regulatory motif occludes the binding of RNA templates and inhibits RdRP activity.[30,501,750] A recent breakthrough in the field was structural determination of stalled NS5B initiation and elongation complexes, highlighting the molecular basis of RNA synthesis via an in-line geometry of nucleotide attack, as well as conformational changes needed to clear the active site.[30]

Recombinant HCV NS5B is capable of *in vitro* synthesis of full-length HCV RNA with nucleotide incorporation rates of approximately 150 to 200 nt/minutes.[548,684,751] The rate-limiting step of NS5B RNA synthesis is *de novo* initiation: essentially, the synthesis of a 2-nt primer with a 5′ purine, which can be mono-, di-, or triphosphorylated.[64,562,749, 750, 751, 752,839,1033] The efficiency of *de novo* initiation is enhanced by an allosteric GTP binding site[340,550] and correlates with the efficiency of replication in cell culture, with thumb residue 405, near the thumb–finger interface, greatly impacting the efficiency of initiation.[818,847]*In vitro* synthesis generally prefers to initiate with a GTP; however, most HCV isolates terminate with a 3′ uridylate, suggesting that negative-strand RNA synthesis initiates with ATP *in vivo*. Optimal RNA templates for *de novo* initiation contain limited secondary structure and an unpaired 3′ end.[404] However, the HCV 3′ NCR terminates with a stable 3′SL, suggesting that it is a suboptimal template for initiation. Indeed, when the HCV 3′ NCR is used as a template for *de novo* RNA synthesis, only internally initiated negative strands are produced.[404,424,685,877] However, addition of a 2-nt 3′ extension leads to the production of template-length minus-strand products.[685] Thus, authentic initiation of HCV minus-strand synthesis may depend on the local unwinding of the terminal stem-loop, perhaps by the NS3-4A helicase.

NS5B RdRP activity depends on intramolecular interactions and is

influenced by intermolecular interactions with other NS proteins. Important contacts between NS5B domains were revealed through structural studies with non-nucleoside RdRP inhibitors, which allosterically block polymerase activity.[88,158,173,208,323,556,917,918,949] Additionally, NS5B oligomerization can cooperatively stimulate polymerase activity.[742,946] NS3-4A, NS4B, and NS5A can all bind NS5B and influence its enzymatic activity *in vitro*.[717,843] Genetic studies indicate that NS5A primarily binds to NS5B via determinants located on the back of the thumb and inner surface of the fingers[742] and as mentioned above, c-Src mediates interaction between NS5A and NS5B.

In addition to RdRP activity, NS5B has terminal nucleotide transferase (TnTase) activity, adding a few untemplated nts to the 3′ end of an RNA substrate.[64,748,839] The TnTase activity of a highly purified NS5B preparation was shown to depend on RdRP active site residues; thus this activity is an inherent property of NS5B and not a contaminating enzyme.[748,753] Moreover, NS5B TnTase activity can convert an RNA lacking a correct 3′ end into a useful template for *de novo* initiation,[748] suggesting that this activity may act as a "telomerase" to maintain genome integrity.

As for many RNA viruses, only vanishingly small amounts of RdRP activity are needed to support hepacivirus replication. Indeed, protease protection experiments demonstrated that approximately 2.5% of NS5B protein resides inside membrane-bound replication compartments isolated from replicon-bearing cells yet fully accounts for all of the RdRP activity.[746] Thus, only a small fraction of NS5B may be actively involved in RNA synthesis at a given time; the other, larger fraction presumably may have other functions. Recently, mutations in p7 and NS5B were shown to cooperatively enhance the specific infectivity and lipid composition of a highly cell culture–adapted HCVcc,[16] suggesting that NS5B may also contribute to virus assembly.

Ultrastructure and Biogenesis of the HCV Replication Organelle

HCV RNA replication takes place in a membranous compartment. Consistently, viral RNA synthesis is resistant to protease and nuclease treatment unless membranes are permeabilized with

detergents.[9,15,237,338,468,639,746,997] Membrane fractions containing HCV RNA and viral proteins are not solubilized by treatment with cold Triton X-100, arguing for replicase assembly in lipid rafts. In agreement, extraction of cholesterol from these membrane fractions inhibits replicase activity.[699] Isolated membranous replicase complexes can use endogenous viral RNA but do not accept exogenous templates. Thus, the predominant reaction product from these complexes is elongation of RNA strands initiated *in vivo*. However, the observed inhibition of RNA synthesis by treatment with heparin[338] and the shift of single-stranded into dsRNA observed in pulse-chase experiments[468] suggest that a limited number of *de novo* initiation events do occur in these complexes.

Studies with liver biopsies and human hepatoma cells expressing viral proteins or containing a stably replicating subgenomic HCV replicon revealed small clusters of single-membrane vesicles embedded into an electron-dense matrix, designated as the membranous web (Fig. 7.16A, B).[230,303] In addition, enlarged ER and aberrant mitochondria were observed *in vivo*, which might be the result of a virus-induced stress response.[33,48] However, in hepatoma cell lines containing highly replication-competent HCV isolates, the predominant structures are double-membrane vesicles (DMVs) (Fig. 7.16C, D).[259,260,699,778] DMVs are heterogeneous in size (~150 nm diameter), enriched in the perinuclear region, and thought to be the site of HCV RNA replication because they contain active viral replicase and their abundance correlates with RNA replication.[699,778] In addition to DMVs, single-membrane vesicles are found in high-level HCV-replicating cells (Fig. 7.16D), and although they contain the majority of viral proteins as determined by immuno EM,[778] their role in RNA replication is unknown. It has been proposed that single-membrane vesicles might be precursors of DMVs,[259] similar to events occurring in poliovirus-infected cells where single-membrane structures originating from the *cis*-Golgi are later transformed into DMVs by membrane wrapping processes.[65] However, single- to double-membrane intermediates have not been observed in the case of HCV. Multimembrane vesicles (MMVs) are also found in HCV-infected cells (Fig. 7.16C), but since they become visible only after the formation of DMVs, MMVs are thought to be a by-product, for example, resulting from a cellular stress response, rather than contributing to RNA replication.[778]

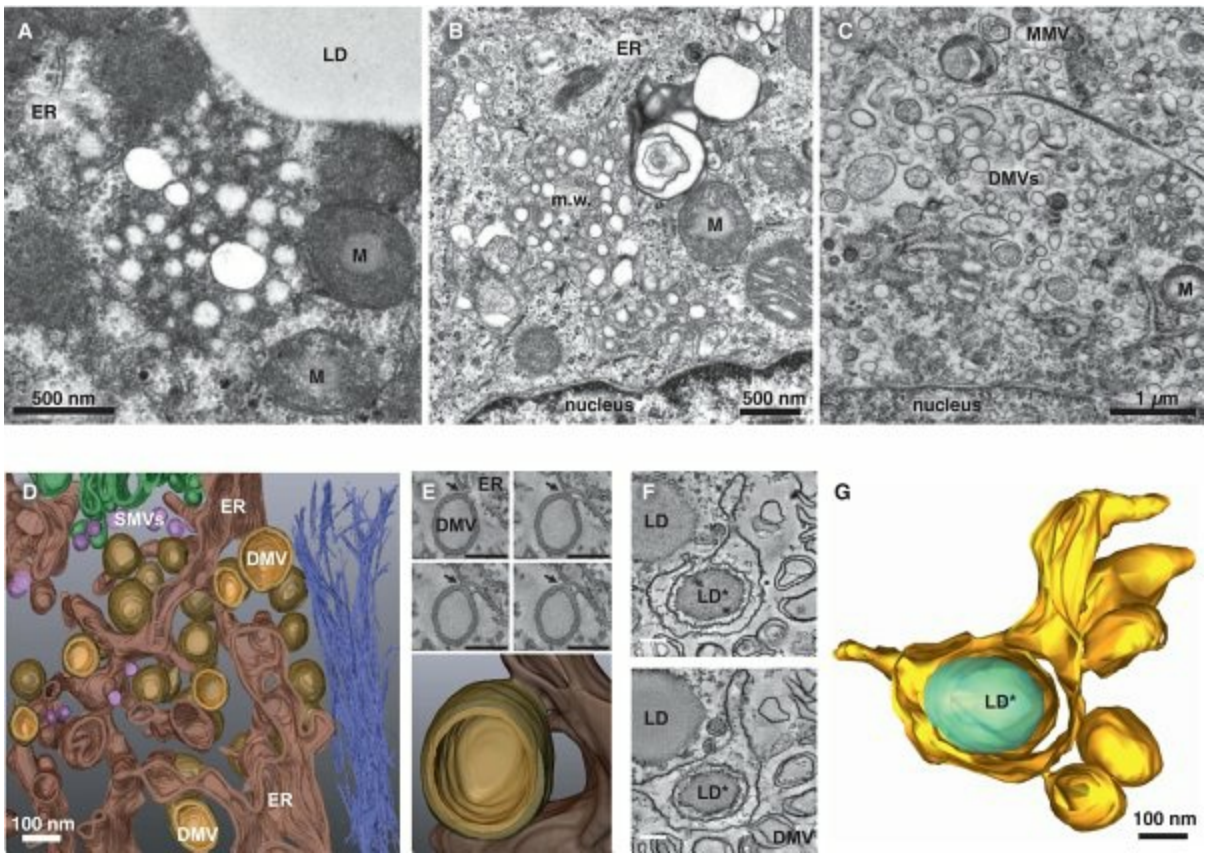

FIGURE 7.16 Hepacivirus replication organelles. **A:** Membrane rearrangements detected in the livers of a chronic HCV carrier. TEM image of a liver biopsy specimen showing a membranous web composed of small clusters of single-membrane vesicles. A representative cluster of 10 to 30 single-membrane vesicles residing close to the endoplasmic reticulum (ER), mitochondria, and a lipid droplet (LDs) are shown. **B:** Membranous web (m.w.) detected in a human hepatoma cell line containing a stably replicating subgenomic HCV replicon RNA. M, mitochondria. **C:** Membrane alterations induced in a human hepatoma cell line infected with a highly replication-competent HCV strain (JFH1) 36 hours after infection. DMVs, double-membrane vesicles; MMV, multimembrane vesicle; M, mitochondrium. **D:**3D surface reconstruction of a dual axis tomogram obtained with human hepatoma cells infected with a JFH1 variant and fixed 16 hours

after infection. ER, endoplasmic reticulum (*dark brown*); DMV, double-membraned vesicle (inner membrane in *yellowish brown*, outer membrane in semitransparent *light brown*); SMVs, single-membrane vesicles (*pink*). The Golgi apparatus is shown in green, intermediate filaments in *dark blue*. **E:** Single tomographic slices displaying a DMV and its link to the ER membrane are shown on the top. A 3D surface rendering of the DMV and its stalk-like connection to the ER is shown on the bottom. Color codes as in **(D)**. **F:** Single tomographic slice of an HCV-infected cell showing a lipid droplet staining positive or not for E2 as determined by light microscopy (LD* and LD, respectively). Note the tight wrapping of the E2-positive droplet (LD*) by an ER membrane, which is not the case with the E2-negative lipid droplet (LD). **G:**3D surface rendering of the E2-positive lipid droplet in **(F)**. Note the DMVs emanating from the wrapping ER membrane. Identification of the hepatitis C virus RNA replication complex in Huh-7 cells harboring subgenomic replicons. J Virol 2003;77(9):5487–5492. doi: 10.1128/JVI.77.9.5487-5492.2003. Reproduced with permission from American Society for Microbiology.[303] **Panel (C)** is from Romero-Brey, I. and Bartenschlager, R., unpublished. **Panels (D)** and **(E)** are reproduced under a Creative Commons license from Romero-Brey et al.[778] **Panels (F)** and **(G)** are from Lee, J.-Y. and Bartenschlager, R., unpublished.)

While the origins of SMVs are unclear, DMVs are derived from the ER with the outer membrane often observed in connection to the ER membrane via a small “stalk” (Fig. 7.16E).[778] Thus, topologically DMVs correspond to exvaginations, ballooning out of the ER toward the cytosol, which is the

opposite orientation found with flavivirus replication organelles (Fig. 7.16B–E). The exact site of HCV RNA replication within its membranous replication organelle is not firmly established and awaits a method to detect nascent viral RNA with high spatial resolution. However, the nuclease and protease resistance of HCV RNA and the reported exclusion of pattern recognition receptors from the membranous web suggest that HCV might shield its RNA in the lumen of DMVs.[673] In this case, only a small fraction of DMVs would be engaged in RNA replication because only approximately 8% of DMVs were found to have an opening toward the cytosol at a given time point.[778] Alternatively, HCV might generate a proteinaceous "pore" to allow passage of NTPs and RNA release from the vesicle lumen as originally proposed for *Coronaviridae*[433] or the viral replicase might reside on the DMV surface as proposed for the poliovirus.[83,229] Assuming that replication occurs within DMVs and a transport mechanism for viral RNA and membrane-impermeable metabolites would not exist, replication in these DMVs would cease upon vesicle closure, raising the question as to the turnover of these inactive DMVs. One possibility is the release of dsRNA-containing vesicles via the exocytic pathway.[125,218,322] Interestingly, in HCV-replicating cells, blocking the exocytic release of vesicles that occurs in an ESCRT-dependent manner induces TLR3-dependent interferon response suggesting that dsRNA release in the form of extracellular vesicles is a mechanism that dampens the activation of the interferon response in the HCV-infected cell.[322]

The striking structural similarity of DMVs to autophagosomes and their common origin from the ER suggest that HCV utilizes autophagy or components of this cellular machinery for membranous web formation. Indeed, activation of autophagy in HCV-infected cells has been reported by several groups, but the contribution of this cellular process to viral replication is controversial.[8,219,247,417,852,853,888] Several viral proteins, notably NS4B and NS5B, have been reported to activate autophagy.[325,876] In addition, formation of DMVs can be induced by the sole expression of NS5A.[777] However, efficiency of DMV formation by NS5A is low but strongly increased by coexpression of other NS proteins and profoundly blocked by clinically used NS5A inhibitors such as daclatasvir.[77] Thus, a concerted action of all HCV replicase factors, that is, NS3 to NS5B, is most likely required for efficient formation of the viral replication organelle.

Although DMVs are derived from the ER membrane, they have a different lipid composition. While ER membranes are low in cholesterol and sphingolipid, concentrations of these lipids are high in the case of DMVs.[699] A key mediator of this change in lipid composition is PI4KA, which is recruited, via binding to NS5A, to ER/DMV membranes.[75,503,759,883,921] There, the kinase synthesizes large amounts of PI4P, which are usually low in abundance at ER membranes but high in the Golgi and plasma membranes. In addition, NS5A, via association with VAPA/B, binds to and recruits nonvesicular transport proteins such as the cholesterol transfer protein OSBP.[950] By analogy to other cellular systems, we can assume that once recruited to the PI4P-enriched ER or DMV membrane, OSBP releases cholesterol into the ER/DMV membrane in exchange for PI4P.[619,620] Presumably by an analogous countercurrent mechanism, glycosphingolipids might be incorporated into membranes of the HCV replication organelle via the PI4P-dependent glucosylceramide transporter protein FAPP-2 that under normal conditions mediates the nonvesicular transport of glucosylceramide from the TGN to the plasma membrane.[418] Thus, by recruitment and activation of PI4KA, HCV sustains a PI4P gradient to enable the accumulation of distinct lipids in ER/DMV membranes. These lipids might provide building blocks for lipid rafts, promoting replicase assembly and/or activity. This conclusion is based on several observations. First, treatment with methyl-β-cyclodextrin, which extracts cholesterol from membranes, impairs replicase activity and causes DMVs to shrink in size.[699] Second, altering cholesterol metabolism pharmacologically leads to reduced geranylgeranylation, replicase disassembly, and inhibition of RNA replication.[406,1000] Third, the membranous web is poorly soluble in nonionic detergents, consistent with an enrichment of cholesterol and sphingolipids.[9,835] Fourth, genetic knockdown or pharmacological inhibition of PI4KA blocks HCV replication, concomitant with a clustering of DMVs that are reduced in size and rather homogenous.[759] Fifth, sphingolipids can stimulate HCV replicase activity.[361,967] Taken together, HCV might use components of the autophagy machinery to generate DMVs that are altered in lipid composition via a PI4KA-dependent lipid transfer pathway.

Although PI4KA is essential for HCV replication, the abundance of PI4P has to be kept within a certain range because high levels appear to be deleterious for replication. Some cell culture–adaptive mutations, which

promote HCV replication in Huh-7 cells, are loss-of-function mutations that reduce PI4KA activation, thus lowering PI4P production.[337] Since Huh-7 cells express much higher levels of PI4KA than primary human hepatocytes, reducing the interaction with the kinase via cell culture-adaptive mutations compensates for high-level expression of the kinase in hepatoma cells. Furthermore, PI4KA inhibitors can also enhance replication of unadapted HCV strains and allow efficient replication of primary isolates in cell culture.[337]

Apart from local enrichment of distinct lipids within the replication organelle, HCV-infected cells contain high overall lipid content as a result of reduced VLDL secretion and activation of lipid synthesis pathways.[637,709] These include the sterol regulatory element–binding protein (SREBP) pathway, which can be induced by NS4B- or HCV-triggered ER stress,[695,953] and activation of DDX3X, a cytosolic RNA helicase that senses HCV RNA and induces, via the cellular transcriptional coactivator CBP-p300, expression of SREBP.[509] In either case, the expression of lipogenic genes is activated, including FAS and HMGCR, the rate-limiting enzyme of the isoprenoid pathway, which feeds into both cholesterol biosynthesis and protein lipidation. In addition, replication organelle formation might exploit LDs, which are highly enriched in triacylglycerol and cholesterol esters. Consistent with this, DMVs are often found in close proximity to LDs, with ER membranes wrapping around nearby LDs (Fig. 7.16F, G). These membranes are often decorated by DMVs, arguing for a close spatial coupling of HCV RNA replication and assembly (Fig. 7.16F, G).

HCV RNA replication is stimulated by increased availability of saturated and monounsaturated fatty acids and inhibited by polyunsaturated fatty acids (PUFAs) or inhibitors of fatty acid synthesis,[406] suggesting that specific lipids and/or membrane fluidity are important for the function of the membranous web. Moreover, lipid peroxidation arising from ROS-induced conversion of PUFAs, which leads to covalent adducts of modified lipids with proteins, suppresses HCV RNA replication.[367,992] This block can be overcome by mutations in the transmembrane and membrane-proximal regions of NS4A and NS5B and by lipophilic antioxidants, such as vitamin E. Interestingly, Sec14L2, a lipid transporter protein expressed in the liver but not in Huh-7 cells, was identified as a host cell factor that renders human hepatoma cells permissive for non–cell culture–adapted HCV strains.[795]

Ectopic expression of Sec14L2 made Huh-7 cells permissive for primary HCV isolates in human serum and nonadapted viral strains. Although the precise mechanism is not known, SEC14L2 might enhance vitamin E–mediated protection of HCV against lipid peroxidation. Of note, the genotype 2a isolate JFH-1, which is the only isolate that replicates to high level in hepatoma cells without cell culture-adaptive mutations, is intrinsically resistant to lipid peroxidation.[992] To which extent this property contributes to its unique replication capacity remains to be determined.

RNA Replication

HCV genomes must be translated more frequently than they are replicated, since 1,000 viral proteins are produced per viral RNA at steady state.[746] Thus, only after an initial burst of translation is the hepacivirus genome recruited out of translation and into a replication complex. The mechanisms by which these processes are coordinated have not been elucidated but may involve crosstalk between the 5′ and 3′ ends.[677] For instance, the cellular PTB protein binds to the HCV 5′ NCR and C coding region, where it may modulate IRES activity[381,915] and to the 3′ NCR, where it may repress replication.[381,924] Another RNA-binding protein, HuR, competes with PTB for binding to the 3′ NCR and recruits La protein, which may promote genome cyclization.[457,846] Thus, it is plausible that hepacivirus genome cyclization may facilitate RNA replication. It has also been proposed that C protein contributes to the switch between translation and replication, enhancing IRES-mediated translation when C protein levels are low and inhibiting translation while C protein levels are high.[95,1027] However, this model does not explain the regulatory mechanisms of subgenomic replicons that do not express C protein. Finally, it has been noted that the RNA-binding and ATPase activities of the NS3 helicase domain are required in *cis* for HCV RNA replication.[416] One interpretation of these data is that the helicase binds to the RNA from which it was translated, perhaps to recruit the viral genome out of translation and into the replication compartment. This may parallel the role of the 1a RNA helicase protein of brome mosaic virus, another positive-strand RNA virus, in recruiting the viral genome into RNA replication.[947]

HCV RNA replication initiates with the synthesis of genome-length,

negative-strand RNAs, which may be found as partially double-stranded RI or fully double-stranded RFs.[15] Negative-strand RNA then serves as a template for multiple rounds of positive-strand synthesis, leading to the asymmetric accumulation of nearly 10 positive strands for every negative strand.[9,639,746]

Virus Assembly

HCV particles bud directly into the ER, transit the secretory pathway, and are released through exocytosis. A notable difference from flaviviruses is that HCV does not undergo proteolytic maturation and is infectious upon envelopment. Following SPP cleavage, mature C localizes to cytoplasmic LDs, the presumed site of nucleocapsid assembly.[605,638] NS5A also localizes to LDs and is thought to relocalize genomic RNAs from replication compartments to assembly sites.[28] Localization of C and NS5A to LDs requires the cellular DGAT1 and Rab18 proteins.[355,798] NS5A localization to LDs also requires CK1-dependent hyperphosphorylation. Core is thought to recruit the membrane-associated replication complex through its interaction with NS5A.[28,595,638] NS2 is a major scaffolding protein of virion assembly, interacting with NS3-4A possibly for nucleocapsid assembly and p7 to recruit nucleocapsids to sites of envelopment where they interact with E1/E2.[97,389,571,715,731,865] NS4B and 5B also are required for efficient virion assembly.

HCV particle formation is associated with VLDL assembly, which also takes place in the secretory pathway of hepatocytes. Virions have a lipid composition similar to LDL and VLDL.[618] HCV particles also incorporate ApoA1, ApoB, ApoC, and ApoE and require Apos for infectivity (reviewed in Ref.[488]). It is unclear whether VLDL components are incorporated as a hybrid viral/host envelope or if they are tethered. The amphipathic α-helices of the apolipoproteins are important for supporting assembly and infectivity.[281] Interestingly, the apolipoproteins seem to be playing a role similar to NS1 for flaviviruses or E^{rns} for pestiviruses, as they can partially substitute for each other in virion assembly.[280]

HCV egresses through the secretory pathway, where the ion channel activity of p7 may protect nascent virions from premature fusion induced by the low pH of the secretory compartment although released virions are pH-

resistant.[979] While intracellular HCV particles are infectious, their buoyant density becomes lower as they egress in a maturation process that parallels VLDL.[288] Virions are thought to undergo ER-to-Golgi transit in COPII vesicles, traffic through the *trans*-Golgi network and endosomal and recycling compartments in association with VAMP1-expressing vesicles, ultimately leading to secretion from the cell.[178,587,880] It is also clear that there is a distinct cell–cell spread pathway allowing the virus to spread between hepatocytes while avoiding antibody surveillance.[914] These pathways appear to be regulated in part by a NS2 interaction with AP-1 and four clathrin adaptors that sort cargo for post-Golgi trafficking.[986]

In addition to these major egress pathways, HCV RNA can spread from cell to cell via exosomes, albeit at low levels.[125,552] ESCRT components have also been implicated, although they probably have noncanonical functions, as opposed to a classical role in membrane scission.[50] In addition to the VLDL secretory pathway, a number of other host factors have been implicated in HCV assembly, including the NS5A-interacting annexin A2, autophagy proteins ATG7 and Beclin-1, HSC70,TIP47, PLA2G4A, FIG 4, ABHD5, and CIDEB.[488]

PEGIVIRUSES

Background and Classification

In 1967, serum from a surgeon “GB” who had contracted acute hepatitis was inoculated into four marmosets, causing hepatitis in all of them.[201] After 11 serial passages of the GB agent in tamarins, two viruses were eventually cloned in 1995 and named GBV-A and GBV-B.[851] Both viruses are similar to HCV yet genetically quite distinct.[658] Although GBV-A was initially thought to have originated from human serum, subsequent work showed that it is a cryptic monkey virus that was likely acquired during passage in tamarins.[123,492] GBV-B has not been reisolated, and its origin remains a mystery; nevertheless, GBV-B is now recognized as a member of the genus *Hepacivirus*, its closest relative being RHV-I.[910] A third related virus was identified in humans by two different groups and called GBV-C or hepatitis

G virus.[534,850] A virus distantly related to GBV-A and GBV-C was then discovered in Old World frugivorous bats in Bangladesh and designated GBV-D.[240] Based on sequence relatedness and overall genome structure, GBVs have been classified as members of the family *Flaviviridae*, with GBV-A, GBV-C, and GBV-D classified as a separate genus, *Pegivirus*, indicating that they are *pe*rsistent *G*B viruses.[857,866] GBV-A and GBV-C have been renamed simian pegivirus (SPgV) and human pegivirus (HPgV), respectively. Currently, six genotypes of HPgV are recognized.

Virus discovery efforts have identified several additional pegiviruses in other animal species. Recently identified mammalian pegiviruses include rodent pegivirus (RPgV); porcine pegivirus (PPgV); two pegiviruses of horses, equine pegivirus (EPgV) and Theiler disease–associated virus (TDAV); as well as three distinct rat pegiviruses (BPgV-F, BPgV-G, and BPgV-I). An additional human-infecting pegivirus is known as hepegivirus (HHPgV) because it has some hepacivirus-like features yet classified as a pegivirus based on molecular phylogeny.[341,857] Pegiviruses generally produce subclinical, persistent infections. While TDAV was originally associated with acute hepatitis in equines, subsequent work identified a parvovirus as the etiologic agent of hepatitis.[210]

Clinical Perspective

Human infection with HPgV is surprisingly common: approximately 1% to 5% of blood donors in developed countries and approximately 20% in developing countries have detectable viremia. Nearly three-quarters of infections are cleared within 2 years,[74] with the remainder persisting for years without obvious symptoms.[21] Clearance usually correlates with the appearance of antibodies against E2.[729] HPgV appears to be primarily lymphotropic *in vivo*,[482,483] although evidence also exists for hepatotropism.[270] This virus can be transmitted parenterally or sexually, with vertical transmission also likely.[78,729] HPgV infection is associated with increased risk of non-Hodgkin lymphoma, although the underlying mechanisms of this linkage are unclear.[159] Surprisingly, HPgV may have beneficial effects to HPgV-HIV coinfected patients, with lower HIV titers, higher CD^{4+} T-cell counts, and slower HIV disease progression.[159] Based on these observations, as well as *in vitro* experiments, it has been proposed that

HPgV interferes with HIV replication by altering expression of cytokines, chemokines, and chemokine receptors,[729,985] decreasing T-cell activation,[582] directly inhibiting HIV-1 entry,[356,398,435,644] and/or eliciting cross-reactive antibodies that neutralize HIV particles.[645] A causal relationship is not clear, however, since HPgV is lymphotropic and higher HPgV titers could correlate with higher lymphocyte count.[931] It is also notable that this relationship does not extend to other pegiviruses and lentiviruses: SPgV does not protect against SIV coinfection.[41]

HHPgV is much less prevalent than HPgV, infecting approximately 0.4% of healthy blood donors. HHPgV may also be parenterally spread, as the infection rates increase to approximately 2% in HCV-, HIV- or HCV/HIV–coinfected individuals.[73,407,631] HHPgV infection has not been linked to any specific clinical symptoms or changes in HIV disease progression.

SPgV has been detected in several species of New World monkeys in the absence of experimental infection or overt disease.[123,491] Surprisingly, SPgV replicates to high titers without inducing an adaptive immune response[41] and exhibits remarkable genetic stability.[42]

Virion Structure and Entry

Similar to HCV, HPgV particles exhibit unusually low and heterogeneous buoyant density, with peaks near 1.08 and 1.17 g/mL.[612,804,984] A peculiarity of many pegiviruses is that they do not encode an obvious C gene, so it is unclear how nucleocapsids are formed. Treatment of virions with detergents to solubilize the viral envelope shifts the peak of viral RNA to a higher density form, suggesting that they may contain nucleocapsids.[612,804,984] Little is known about the pegivirus entry mechanisms, although it has been proposed that GBV-C utilizes the LDLR for entry.[4]

Genome Structure and Expression

Pegivirus genomes range from 9.4 to greater than 10.8 kb in length, containing long ORFs (2,973–3,469 codons) flanked by 5′ and 3′ NCRs (Fig. 7.17). Pegivirus 5′ NCRs can be considerably longer than their hepacivirus counterparts, up to 617 nt in length in the case of TDAV. Most pegiviruses, such as SPgV,[849] HHPgV,[849] and EPgV,[408] encode hepacivirus-like class IV

IRES elements, while others, such as TDAV, lack structural similarity to known IRES elements.[145] Pegivirus 3′ NCRs also differ considerably from other genera within the family, lacking a poly(U/UC) tract, but do sometimes contain short poly(G) tracts, as well as repeated structural elements reminiscent of the flaviviruses.[187,410]

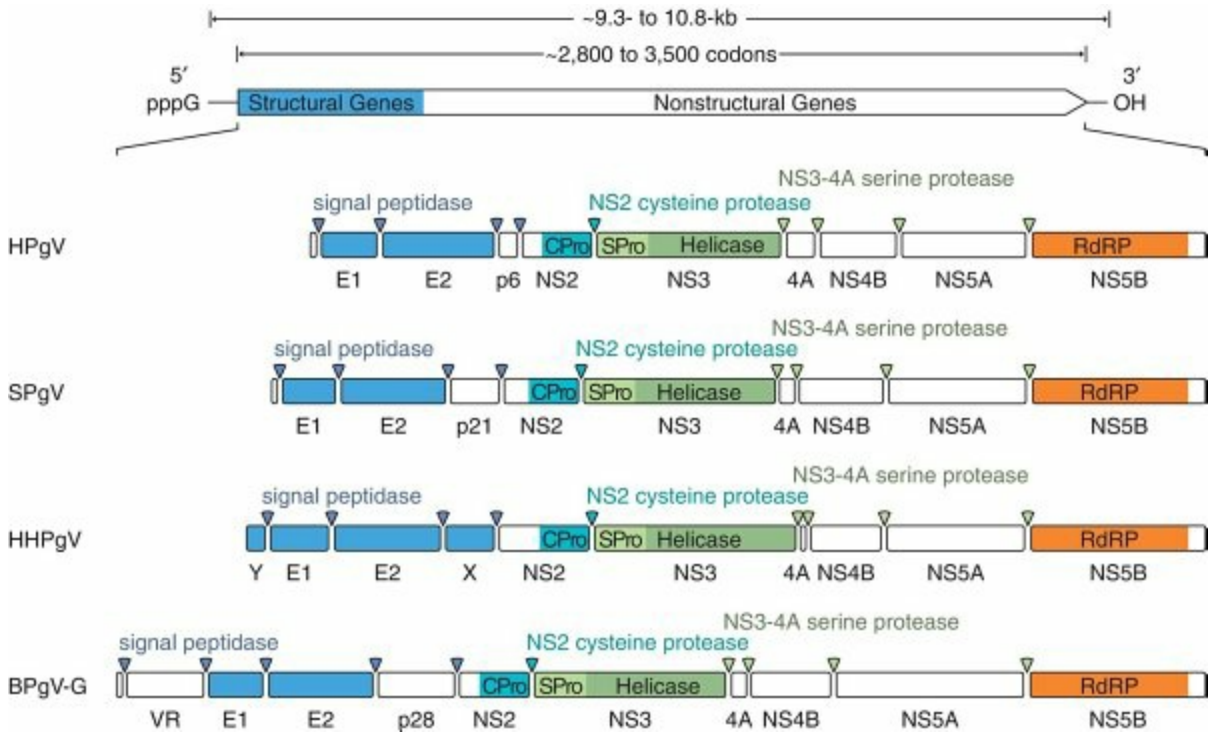

FIGURE 7.17 Pegivirus genome structure. The structural organization of several pegivirus genomes is illustrated. See text for details.

Structural Proteins

Several pegiviruses, like HPgV, SPgV, BPgV-I, EPgV, and TDAV, lack any obvious capsid- or core-like gene, initiating translation shortly upstream of a predicted signal peptide for E1.[534,658,857] Others, such as GBV-D and HHPgV, encode short (~57 and 60 aa, respectively), basic N-terminal peptides, which may function as capsid or core proteins (Fig. 7.17). In the case of HHPgV, this core-like protein has been called “Y protein” (Fig. 7.17).[407] Furthermore, some HPgV-infected individuals generate antibodies

against a small basic peptide that can be translated from an in-frame, upstream AUG, suggesting that such a protein is expressed *in vivo*.[984] Finally, bat-infecting pegiviruses encode "variable region" (VR) proteins in place of the C gene; VR proteins are predicted to contain N-terminal signal peptides, ectodomains of 20 to 150 aa, and two to four transmembrane domains (Fig. 7.17).[745] While these proteins are basic (pI ~8.16–9.12), it is not clear whether they are structural proteins, nor whether their membrane anchoring and topology are compatible with nucleocapsid formation. Alternative explanations for the lack of a capsid-like protein include the possibilities that pegiviruses may usurp a capsid-like protein or other polycationic molecule from the host cell or a coinfecting virus or that additional pegivirus proteins may be involved. In this regard, a region of the HPgV NS5A gene that exhibits a bias against synonymous mutation has been noted to potentially encode a small basic protein (~10 kDa, pI 11.5) in an alternate reading frame.[701]

Pegiviruses encode two viral glycoproteins of unknown structure, E1 and E2, which presumably mediate binding and entry. Consistent with this, the presence of E2-specific antibodies correlates with protection from HPgV reinfection in the context of liver transplantation.[345,913] HPgV E2 does not bind CD81,[414] indicating that it likely uses different entry factors than HCV. One curious feature of HPgV E1 and E2 is that these glycoproteins reportedly inhibit HIV-1 replication via a variety of mechanisms.[232,297,644,951] In addition to E1 and E2, HHPgV and EPgV encode a third glycoprotein, known as X, located between E2 and NS2 (Fig. 7.17). The function of X is unknown and its classification as a virion structural protein remains tentative.

Nonstructural Proteins

Many pegiviruses encode a small polytopic membrane protein, similar to the hepacivirus p7 protein, immediately following the structural proteins. These range in size from the approximately 6-kDa p6 protein of HPgV to the approximately 28-kDa p28 protein of BPgV-G.[408,745] It is unclear whether these proteins are true orthologs of the HCV p7 protein or are capable of forming ion channels. Surprisingly, EPgV and HHPV lack p7-like proteins but do encode X glycoproteins between E2 and NS2. Given that p7 is essential for hepacivirus virus assembly and secretion, perhaps the X

glycoprotein can functionally replace p7.

Of the remaining pegivirus NS genes, their overall architecture is remarkably similar to the hepaciviruses, although highly divergent at the amino acid level. Nevertheless, conserved active site and structural motifs are found in the corresponding locations for NS2 cysteine autoproteases, NS3 serine protease/NTPase–RNA helicases, NS4A membrane–bound serine protease cofactors, NS4B nucleotide–binding membrane proteins, NS5A Zn^{2+}–binding phosphoproteins, and NS5B RdRPs.[408,745] For HPgV, the membrane topology and autoprotease activity of NS2 have been confirmed,[66] the NS3-4A serine protease was shown to cleave MAVS and thereby inhibit type I interferon induction,[165] and the NS3 helicase domain possesses NTP-dependent RNA unwinding activity.[329,1032] One notable difference between pegiviruses and hepaciviruses is that their NS3-4A serine proteases have very different substrate recognition motifs. The HPgV NS3 serine protease is also reported to interfere with HIV-1 replication[290] and may bias infected T lymphocytes toward a Th1 phenotype.[794]

With no significant human or animal disease associations, the pegiviruses are woefully understudied, and virtually nothing is known about virus structure, virus entry, mechanisms of RNA replication, and virus assembly. From an evolutionary standpoint, it seems particularly interesting that some pegiviruses lack defined nucleocapsid-forming proteins, while others express VR and Y proteins; similarly, some pegiviruses lack p7-like proteins, while others encode p7-like proteins that are much larger than their hepacivirus counterparts. Clearly, these viruses are likely to exhibit interesting variations on virus assembly and release within the family.

PESTIVIRUSES

Background and Classification

Pestiviruses are animal pathogens of major economic importance, particularly for the livestock industry. They include the type member, bovine viral diarrhea virus 1 (BVDV1), classical swine fever virus (CSFV), border disease virus (BDV) of sheep, as well as several recently identified species that infect cows (BVDV2; HoBi-like pestivirus [HoBiPeV]), pigs and boars

(porcine pestivirus [PPeV], also known as Bungowannah virus; atypical porcine pestivirus [APPeV]), sheep (Aydin-like pestivirus [AydinPeV]), giraffes (giraffe pestivirus [GPeV]), pronghorns (pronghorn antelope pestivirus [PAPeV]), and rodents (rat pestivirus [RPeV]).[860] A partially sequenced pesti-like virus from bats awaits classification, but it is notable that rats and bats are the only known natural hosts of pestiviruses outside the order Artiodactyla, that is, cloven-hooved animals. It is also notable that CSFV has been adapted to grow in rabbits; this strain is attenuated in pigs and has been used as a live vaccine in China for over 60 years.[157]

Pestiviruses can be cultured in the laboratory and several highly permissive cell lines have been identified. It is notable that BVDV is found in most commercially available lots of pooled fetal calf serum, so permissive cells stocks must be validated as BVDV-free and maintained under serum-free conditions or with serum from other species. In cell culture, pestiviruses are generally noncytopathic (ncp), although stable cytopathic (cp) biotypes have been identified based on their ability to induce cell death in cell culture. Infectious cDNA clones and replicons have been assembled for several pestiviruses, allowing all aspects of their life cycle to be dissected at the molecular level.

Pestiviruses produce a range of diseases in their respective hosts; the two most economically impactful are CSFV and BVDV. CSFV is one of the most severe infectious diseases of pigs, with mortality rates up to 90%. CSFV infections may have an acute course, with malaise and gastrointestinal distress progressing to fatal hemorrhagic and neurological syndromes within 4 weeks, or follow a chronic course, typically in immunologically immature newborn piglets, producing a more extended (1–3 months) but no less lethal course of disease.[93] BVDV1 usually causes only subclinical or mild symptoms in adult animals, while some strains of BVDV2 have been associated with a severe, acute hemorrhagic disease.[704] However, vertical transmission of BVDV1, BVDV2, or BDV can lead to chronic infections of newborn calves or lambs that invariably lead to fatal mucosal disease (MD); interestingly, both ncp and cp viral biotypes can be recovered from animals with MD.[894] Effective vaccine strategies have been developed for CSFV; however, the development of BVDV vaccines has proven to be more challenging due to the inherent antigenic diversity of these viruses.[643] One promising approach has been the development of live, recombinant cpBVDV

strains containing in-frame deletions in the viral N^{pro} gene and inactivating mutations in the viral E^{rns} gene, which induce strain-specific immune responses but do not establish persistent infections or cause fetal death in immunized pregnant cows.[625]

Structure and Physical Properties of the Virion

Pestivirus particles are 40 to 60 nm in diameter, are lipid enveloped, and display viral envelope glycoproteins E^{rns}, E1, and E2 surrounding a nucleocapsid composed of the core (C) protein and viral RNA. Similar to HCV, pestiviruses are remarkably stable to low pH.[207,453] Virus particles are relatively featureless, although GPeV particles show an intriguing electron-lucent internal space to one side of the capsid (Fig. 7.18). Given the similarity of GPeV particle morphology to proposed HCV lipoviroparticle structures and that pestivirus particles have relatively light buoyant densities, approximately 1.090 to 1.134 g/mL,[486,599] it is tempting to speculate that this extracapsular space may be filled with lipids. Consistent with this, BVDV1 particles were found to have a high cholesterol, sphingomyelin, and hexosylceramide content for a virus that buds into the ER, although extracapsular spaces were not prominent.[132]

Binding and Entry

Pestiviruses exhibit broad cell tropism *in vivo*. Both CSFV and ncpBVDV1 infect epithelia, B and T lymphocytes, monocytes, and bone marrow cells, causing marked lymphopenia and thrombocytopenia as well as hemorrhage in lymph nodes and Peyer patches.[590,933] Pestiviruses can initially attach to cells via interaction of the E^{rns} glycoprotein with cell-surface GAGs.[372,373] However, only E1 and E2 are required for the entry of BVDV1 pseudoparticles, suggesting that E^{rns} serves to enhance avidity in native virions.[781] Recombinant CSFV E2 can bind to cells and block infection of both CSFV and BVDV, suggesting that both viruses share a common entry receptor.[370] In contrast, the BDV E2 exhibits virus-specific tropism.[518] An early report that LDLR serves as a receptor for BVDV1 has not held up to further scrutiny.[452] One validated entry receptor for BVDV1 and BVDV2 entry into bovine cells is CD46, which binds to these viruses via its first complement control protein repeat.[451,599] BVDV1 and CSFV are internalized via clathrin-mediated endocytosis and delivered to endosomes, where low pH-dependent fusion occurs.[320,453,493,837] Similar to HCV, pestiviruses are acid stable and must be primed to respond to low pH. Combined treatment of BVDV1 with a reducing agent and low pH allowed "fusion-from-without," suggesting that one or more protein disulfide isomerases on the cell surface

or endosomal compartments may contribute to priming.[453] The fusion process releases the nucleocapsid, which is presumably disassembled to release the viral genome. Interestingly, the growth of a unique CSFV mutant lacking core protein was highly restricted by ISG expression in target cells, suggesting that the nucleocapsid serves to protect the incoming genome from innate antiviral responses.[766]

Genome Structure

Pestivirus genomes are approximately 12.3 kb in length, lack a 5′ cap or 3′ poly(A) tail, and contain 5′ and 3′ NCRs of 372 to 385 and 185 to 273 nts, respectively, flanking one long ORF of approximately 3,900 codons (Fig. 7.19A).[118,180,650] Similar to hepaci- and pegiviruses, the 5′ NCRs of pestiviruses contain an IRES that directs cap-independent translation of the viral genome.[730] Upstream of the IRES are two 5′ SL structures (domains Ia and Ib in Fig. 7.19A) shown to be important for BVDV1 RNA replication.[279,1013] Surprisingly, all of domain Ia and part of Ib may be substituted or deleted; however, replication is strictly dependent on the 5′-terminal GUAU sequence.[62,279] Thus, pestiviruses and hepaciviruses differ in the organization of their 5′ signals needed for genome replication.[313]

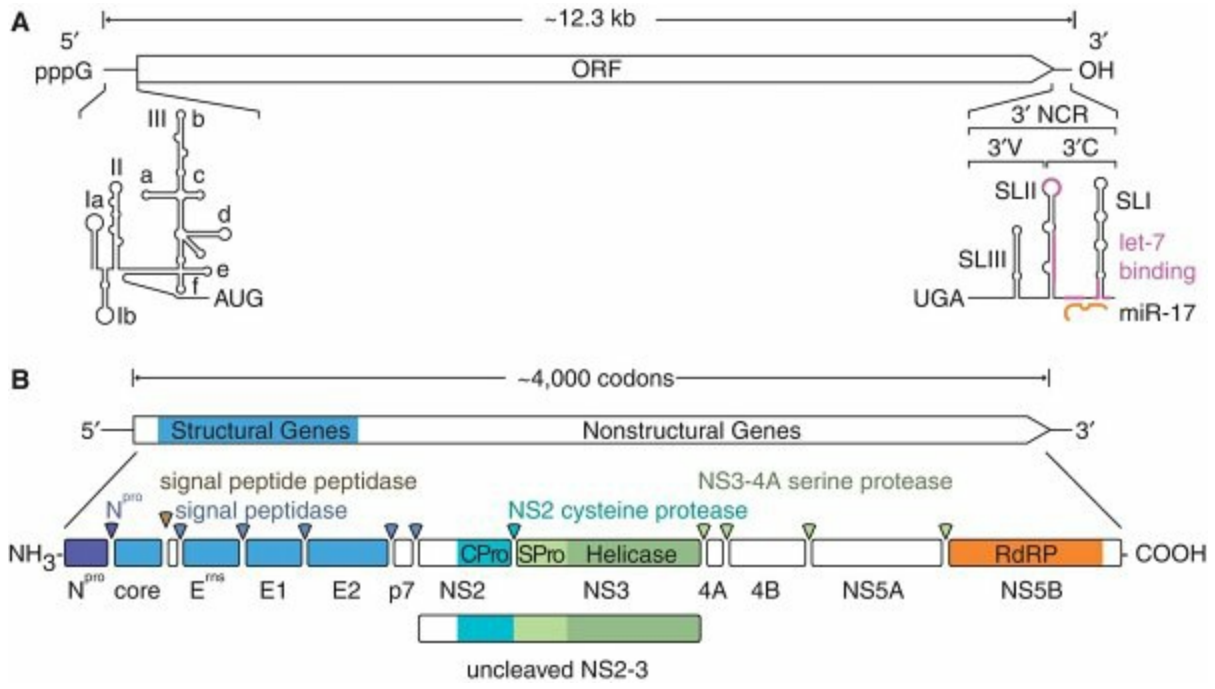

FIGURE 7.19 Pestivirus genome structure and protein expression. **A:** Genome structure and RNA elements. Important RNA elements are indicated as in Figure 7.4. **B:** Polyprotein processing and cleavage products. Symbols identifying proteolytic cleavages for the cpBVDV1 NADL strain are the same as those described in Figure 7.4 except for the autocatalytic cleavage releasing the N-terminal nonstructural protein N^{pro} from the pestivirus polyprotein, which is indicated by a closed bullet. See text for details.

Pestivirus 3′ NCRs contain a SL-containing variable region followed by a conserved region that contains two conserved SLs.[204,1011] Mutational analyses indicate that the 3′ variable region is important for translational termination and may coordinate translation and replication, while the 3′ conserved region is critical for RNA replication, likely to direct minus-strand initiation.[376,694,1011] A critical feature of the 3′ conserved region is to bind and sequester microRNAs miR-17 and let-7; these binding events are important for BVDV1 and CSFV RNA replication but also dysregulate expression of host genes dependent on miR-17 and let-7.[812] While miR-17 binds to one unstructured loop within the 3′ conserved region, let-7 can bind to several sequences located within secondary structures, presumably destabilizing them (Fig. 7.19A). Thus, these miRNAs may act as switches that stabilize or destabilize structures within the 3′ NCR, respectively.

Translation and Polyprotein Processing

The pestivirus IRES bears structural and functional similarity to that of hepaciviruses.[710,730,770] The minimal functional IRES includes 5′ NCR domains II and III, although its activity is influenced by RNA structures downstream of the initiation codon. Similar to hepaciviruses, the pestivirus IRES binds ribosomal 40S subunits without the need for translation initiation factors eIF4A, eIF4B, and eIF4F.[710,711,855] In fact, the CSFV IRES displaces eIF3 from its ribosomal position, so much so that eIF3 is held in the 43S subcomplex solely via its interaction with IRES domain III.[344]

The pestivirus polyprotein is proteolytically processed into individual

viral proteins: N^{pro}–C–E^{rns}–E1–E2–p7–NS2–NS3–NS4A–NS4B–NS5A–NS5B (Fig. 7.19B). Unlike for other members of the family, the first pestivirus protein, N^{pro}, is not a structural protein but a NS autoprotease responsible for cleavage at the N^{pro}/C site.[867,976] The pestivirus structural proteins are cleaved by signal peptidase at the C/E^{rns}, E1/E2, E2/p7, and p7/NS2 sites, with incomplete cleavage leading to accumulation of uncleaved E2–p7.[236,336,792] Similar to HCV, the pestivirus C protein is further processed by SPP, releasing mature C protein from the signal peptide.[351] The pestivirus E^{rns}–E1 polyprotein is processed slowly by an unknown protease, most likely signal peptidase.[86,792] In the NS region, the NS2 cysteine autoprotease cleaves the NS2/3 junction in a regulated manner,[465] while the NS3-4A serine protease cleaves the NS3/4A, NS4A/4B, NS4B/5A, and NS5A/5B junctions.[891,977,989] As will be discussed, the viral serine protease activity is reduced during late times of infection with ncp pestiviruses, leading to accumulation of uncleaved NS4A-B, NS4B-5A, and NS5A-B.[179,473] Genetic analysis suggest that NS4A-B is not essential for BVDV replication in cell culture.[284]

N^{pro} Autoprotease

N^{pro} is a bifunctional protein. The N-terminal region forms a cysteine protease with a unique fold and catalytic mechanism (dyad active site residues H49 and C69), classified as its own cysteine protease clade.[304,306,867,976,1036] This protease cleaves only once, at the N^{pro}/C junction, as the C-terminal peptide of N^{pro} remains tightly integrated in the protease structure once cleavage occurs (Fig. 7.20A).[306,1036] Upstream of the substrate peptide is a Zn^{2+}-binding TRASH domain, which binds to IRF3 and targets this immunoregulator for polyubiquitylation and proteasomal degradation, thereby inhibiting innate antiviral responses.[59,60,156,305,360,789,791] The mechanism by which N^{pro} targets IRF3 for polyubiquitylation, including the identity of the relevant E3 ligase, remains obscure. Other cellular N^{pro}-binding partners include IRF7 and IκBα, two immune transcription regulators; S100A9, a Ca^{2+}- and Zn^{2+}-binding immunomodulator; HAX1, a regulator of cortical actin and apoptosis; PCBP1, a single-stranded poly(rC)–binding protein; and uS10, a 40S

ribosomal protein involved in translational quality control.[194,212,262,390,506,570] N^{pro} is dispensable for replication in cell culture but is required for pestivirus pathogenesis *in vivo*; as such, N^{pro} deletion mutants have been tested as live vaccines.[600,919]

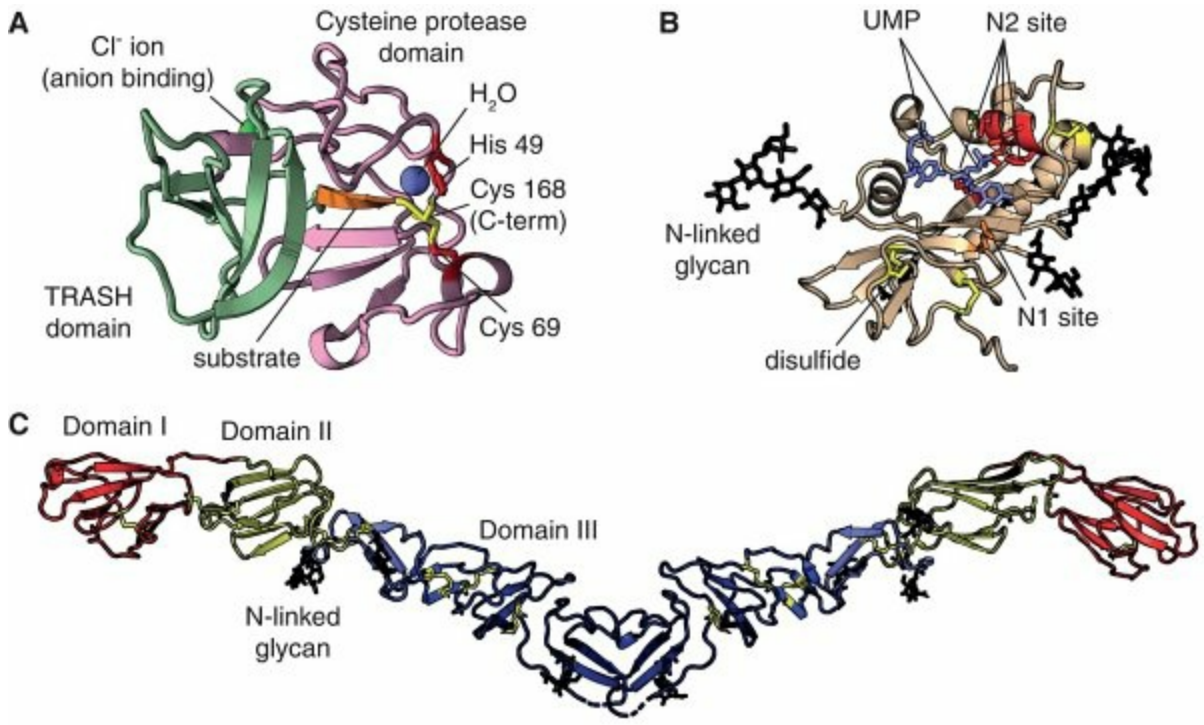

FIGURE 7.20 Pestivirus N^{pro} and structural proteins. **A:** Structure of HoBiPeV N^{pro} is shown, including the cysteine protease and TRASH domains. The molecule is in the postcleavage form, with the C-terminal residue, Cys 168 at the tip of the substrate peptide, and disulfide bonded to the catalytic Cys 69 residue. Catalytic moieties His 49 and H_2O are shown, as is an anion-binding pocket, postulated to bind an unknown ligand *in vivo*. Rendered from PDB 3ZFO.[1036] **B:** Structure of the BVDV1 E^{rns} ectodomain is shown, including two uridine monophosphates (UMPs) as RNA-like substrates within the N1- and N2-binding pockets. Disulfides and N-linked glycans are labeled in *yellow* and *black*, respectively.

Rendered from PDB 4DW4.[450] **C:** Structure of the BVDV1 E2 glycoprotein, which forms tail–tail disulfide-linked dimers. Domains I, II, and III are labeled; disulfides and N-linked glycans are labeled in *yellow* and *black*, respectively. Rendered from PDB 4ILD.[512]

Pestivirus Structural Proteins

The capsid (C) protein (~14 kDa) is a positively charged, natively unfolded protein that binds RNA with low affinity and specificity.[382,665] Remarkably, C protein can tolerate deletions, duplications, and insertions; for one of these mutants, profound defects in virus assembly were suppressed by a second-site mutation in the NS3 helicase domain.[767,768]

E^{rns} (44–48 kDa) is an unusual viral glycoprotein that forms disulfide-linked homodimers and is highly glycosylated on seven to nine Asn residues.[911] E^{rns} peripherally associates with membranes via a C-terminal amphipathic helix[1,261,906] and is also secreted in soluble form from infected cells.[792,960] The most surprising feature of E^{rns} is that it encodes ribonuclease activity with a RNase T2–like fold and specificity for uridine residues (Fig. 7.20B).[346,450,819] This RNase activity serves to inhibit host innate antiviral responses.[374,894] Viruses containing mutations in the E^{rns} catalytic active site are attenuated *in vivo*,[624,942] and antibodies that inhibit RNA cleavage tend to neutralize virus infectivity.[974] RNase activity does not require disulfide linkage of E^{rns} homodimers at C171, yet mutation of this residue gives rise to mutant viruses that are less virulent *in vivo*, suggesting that dimer formation contributes additional determinant(s) of pathogenesis.[907,974] E^{rns} binds to cell-surface–expressed GAGs and may translocate across cellular membrane via its C-terminal amphipathic helix[478] or be taken up by clathrin-mediated endocytosis.[1042] A key *in vivo* target of E^{rns} may be plasmacytoid dendritic cells, which abundantly produce type I interferons in response to CSFV-infected cells; this response is largely inhibited by E^{rns}.[740]

E1 (25–33 kDa) and E2 (53–55 kDa) are integral membrane glycoproteins that form disulfide-linked heterodimers and E2

homodimers.[911,961] Heterodimer formation is essential for viral entry and involves charge interactions within the E1 and E2 transmembrane domains.[781,948] E1 folds slowly and is poorly immunogenic, while E2 is immunodominant and has a well-defined structure. Surprisingly, E2 has a linear domain topology and forms tail-to-tail disulfide-linked homodimers that project out from the virus surface like opposing crane booms (Fig. 7.20C).[233,512] E2 lacks structural similarity to known fusion proteins and does not encode recognizable fusion peptides. Thus, E2 may only be involved in receptor binding, while E1 is the likely fusion protein. Indeed, E1 does contain two putative fusion peptides, although it is hard to reconcile the small size of this protein with known fusion protein mechanisms.[948]

Pestivirus Nonstructural Proteins

Pestiviruses encode a small p7 protein that is essentially a hairpin of two transmembrane domains flanking a central charged peptide. Similar to the HCV p7 protein, pestivirus p7 is dispensable for RNA replication[63] but required for the production of infectious virus particles[336,517] and appears to function as a viroporin with ion channel activity.[296,479, 480, 481,568]

The NS2 protein (~54 kDa) is a polytopic membrane protein with a C-terminal, cytosolic cysteine protease domain that is responsible for cleaving the NS2-3 precursor (~125 kDa).[464,466] This cleavage is temporally regulated in ncp pestiviruses, leading to accumulation of uncleaved NS2-3 late in infection. Uncleaved NS2-3 has reduced NS3-4A serine protease activity and is incapable of supporting RNA replication but is important for virus assembly.[3,63,465,656] Remarkably, NS2 cysteine protease activity requires stable interaction with a cellular HSP40-family chaperone, DNAJC14 (originally identified as Jiv for J-domain protein interacting with viral protein), which is required for the replication of all pestiviruses examined to date.[379,464]

As for other members of this virus family, the NS3 protein (~80 kDa) encodes an N-terminal chymotrypsin-like serine protease domain and a C-terminal NTPase/RNA helicase domain (Fig. 7.7).[954,977] The NS3 serine protease requires NS4A as a cofactor[989]; cleaves between leucine and small uncharged amino acids, L↓(S/A/N)[891,989]; and is essential for virus viability.[989] Surprisingly, the protease retains activity when threonine is

substituted for the serine nucleophile.[891] As for other members of the family, the pestivirus serine protease is also capable of internal autoproteolysis at one or two sites within NS3.[474] Interestingly, one of these cleavages releases a functional NS3-4A protease domain and a soluble helicase domain with unknown functions.

The pestivirus NS4A protein (~10 kDa) is functionally similar to the HCV NS4A protein, despite lack of sequence conservation. It has an N-terminal membrane anchor and an internal peptide that intercalates with the serine protease fold and is an essential cofactor for the NS3 serine protease activity.[223,892,989] NS4A also has an important but previously uncharacterized role in virus assembly.[223,517,656] Interestingly, structures of full-length CSFV NS3-4A reveal additional configurations between the serine protease and helicase domains previously not seen with other members of the family, as well as a molecular mechanism whereby interaction of the NS4A C-terminal peptide with the NS3 serine protease domain acts as a switch between RNA replication and virus assembly.[223]

NS4B (~38 kDa) is a polytopic membrane protein that associates with RNA replication complexes.[965] Like HCV, pestivirus NS4B proteins also encode an NTPase activity of unknown function.[295]

Similar to HCV NS5A, the pestivirus NS5A (~58 kDa) is a phosphoprotein that contains an N-terminal amphipathic helix mediating peripheral membrane association, a structured Zn^{2+}-binding domain, and two downstream domains separated by LCSs.[111,378,802,902] Also similar to HCV NS5A, pestivirus NS5A is tolerant of insertions and deletions in its second domain; insertion of a mCherry fluorescent protein demonstrated that pestivirus NS5A, like HCV NS5A, is trafficked to LDs.[378] Furthermore, NS5A is phosphorylated by serine–threonine kinase(s) similar to the enzymes that phosphorylate flavivirus NS5 and hepacivirus NS5A.[755] Genetic analysis revealed that defects in the NS5A gene can be efficiently complemented in *trans*, whereas mutations in other pestivirus NS genes were not.[755] NS5A may also serve to antagonize GBP1, an interferon-induced GTPase that inhibits CSFV and other viruses.[515]

NS5B (~75 kDa) is the key driver of pestivirus RNA replication, the RdRP. *In vitro*, recombinant NS5B has been shown to extend template-

primed RNA into double-stranded copy-back products[894,1031] or to catalyze *de novo* initiation from short, synthetic RNA or DNA templates, depending on the presence of sufficiently high GTP levels.[403,469] BVDV1 and CSFV NS5B are structurally similar to HCV NS5B, containing a canonical palm subdomain surrounded by finger and thumb subdomains but with some key differences (Fig. 7.8).[160,161,513] Notably, pestiviruses have a conserved, N-terminal approximately 90-aa extension not found in hepacivirus NS5B; structurally, this region has been captured in three different conformations interacting with the outer surface of the polymerase core. The function of the N-terminal domain is not clear; however, mutations or deletion of the N-terminal domain strongly impacts RNA synthesis, suggesting that it may regulate RdRp activity through allosteric mechanisms.[513]

RNA Replication

Pestivirus RNA replication requires NS3 through NS5B and is associated with cytosolic membranes, albeit without the profound membrane rearrangements described for flaviviruses or hepaciviruses.[63,816] Synthesis of new viral positive- and negative-strand RNAs is first detected between 4 and 6 hours of infection; at later times, viral RNAs are found in double-stranded RFs and partially duplex RIs, consistent with the asymmetric synthesis of excess positive-strand over negative-strand RNAs.[298,299,916,956]

The study of ncp and cpBVDV1 has provided key insights into the mechanisms of pestivirus RNA replication and virus assembly. A critical discovery was that ncp and cpBVDV1 isolates temporally differ in their expression of NS2-3, NS2, and NS3.[465] As mentioned above, uncleaved NS2-3 functions in virus assembly but not in RNA replication, and NS2-3 cleavage requires the cellular chaperone DNAJC14 to activate the latent cysteine protease within NS2. Thus, early in infection, when DNAJC14 is abundant, the NS2 protease is activated, leading to autocleavage of NS2-3, release of NS3, and enabling RNA replication. However, as DNAJC14 levels become rate limiting at later times, NS2-3 cleavage is greatly reduced, switching the life cycle of ncpBVDV1 from RNA replication to virus assembly.[379] cpBVDV viruses are able to promote continuous NS2-3 cleavage, despite limited DNAJC14 levels, through a variety of genetic rearrangements, as described below.

A second way that the study of cp versus ncp viruses has contributed to our understanding of pestivirus RNA replication is in RNA recombination. As will be discussed shortly, many cpBVDV have genetic insertions or rearrangements that must have arisen through RNA recombination, which led some groups to examine the molecular basis for these presumably rare but profoundly impactful events. One likely driver of RNA recombination is a copy-choice mechanism,[427] whereby an RdRP switches templates during minus-strand synthesis to produce chimeric transcripts that are consistent with the coding orientation of cellular inserts found in cpBVDV1 genomes. There is also evidence for the existence of one or more alternative mechanisms of RNA recombination that are independent of RNA synthesis. Namely, cotransfection of two BVDV1 transcripts, each lacking a different essential part of the genome, gave rise to viable viruses with signs of homologous and nonhomologous recombination.[284,285,429] Subsequent analysis of recombinants, and the factors influencing their biogenesis, suggested that this nonreplicative mechanism likely occurs via endoribonuclease activity and end-to-end ligation, presumably by cellular enzymes.[36]

Assembly and Release of Virus Particles

Pestivirus particles bud into the ER and transit through the secretory pathway.[82,314,816] Consistent with this, pestivirus envelope glycoproteins are retained within the secretory pathway,[315,962] and the secretion of virus particles, but not their assembly, is inhibited by brefeldin A, an inhibitor of ER–Golgi transport.[315,962] As the lipid content of purified virus particles greatly differ from the composition of the ER membrane, it appears that BVDV1 particles acquire additional lipids during their maturation.[132] Virus particles are sometimes observed in multivesicular bodies, suggesting that they may traffic through an endosomal compartment during their secretion.[816] Once released, it appears that BVDV1 is preferentially transmitted via cell-to-cell transmission, at least in cell culture.[617]

The assembly of pestivirus particles depends on several NS proteins, including uncleaved NS2-3, which accumulates during late times of infection. Indeed, chimeric BVDV1 genomes incapable of producing NS2-3 were found to be blocked in virus assembly[484]; further, genetic dissection of the

chimeras identified additional determinants in the NS2 cysteine protease domain and NS3 serine protease domain that allowed BVDV1 growth in the absence of uncleaved NS2-3.[431] Intriguingly, this region of the serine protease interacts with the C-terminus of NS4A in crystal structures of full-length NS3-4A, and mutations that disrupt or stabilize this interaction switch between RNA replication and virus assembly.[223]

Pathogenesis of Mucosal Disease and the Generation of cp Pestiviruses

BVDV- and BDV-associated MD, which is universally lethal, has a fascinating etiology. MD arises only after *in utero* infection with ncp viruses between 40 and 125 days of gestation, leading to birth of immunotolerant calves or lambs that remain persistently infected for life. By the time MD symptoms appear, usually between 6 and 24 months of age, both cp and ncp viral biotypes can be isolated; this can reflect superinfection of ncp-infected dams with a cp virus.[193,602,894] However, most cp strains arise *de novo*, generated via RNA recombination from the coinfecting parental ncp strain; only rarely do cp strains lack obvious genome rearrangements.[704,894] These rearrangements lead to increased NS3 expression independent of cellular DNAJ14 expression, enhanced RNA replication, and cytopathic effects in cell culture.

Some of the remarkable genetic rearrangements discovered in cpBVDV are illustrated in Figure 7.21. Most cpBVDV genome rearrangements lead to increased NS3 production and enhanced RNA replication. For instance, the cpBVDV1 strain NADL contains an in-frame fragment of the cellular DNAJC14 gene (aka Jiv) inserted within NS2 (Fig. 7.21B).[613,772] As described above, DNAJC14 is essential for proper folding and activation of the NS2 cysteine protease, and overexpression of a critical 90-aa DNAJC14 subdomain enhances NS2-3 cleavage, regardless whether the fragment is provided in *cis* or in *trans*.[465] Surprisingly, the cpBVDV1 strain CP7 contains an even smaller insertion in NS2, a 27-nt out-of-frame duplication from an upstream region of NS2, which also leads to increased NS2-3 processing and the ncp phenotype (Fig. 7.21C).[626,893] Several other virus- or cell-derived insertions at or close to the same site in NS2 have been described for other cpBVDV1 isolates.[45] Given these observations, it is tempting to speculate

that mutations in the NS2 gene of an ancient, NS2/3-cleaving cp pestivirus may have given rise to a ncp virus that became dependent on DNAJC14 but gained ecological fitness through reduced cytopathic effects and persistence. According to this model, insertions in NS2 may cause reversion of ncp viruses back to the cp biotype. Indeed, some cpBVDV isolates, such as BVDV1 strain Oregon, lack insertions or other genome arrangements yet retain NS2-3 autoprotease activity.[460] Thus, perhaps this strain cleaves NS2/3 like the putative ancestral cpBVDV isolate, without the need for insertions.

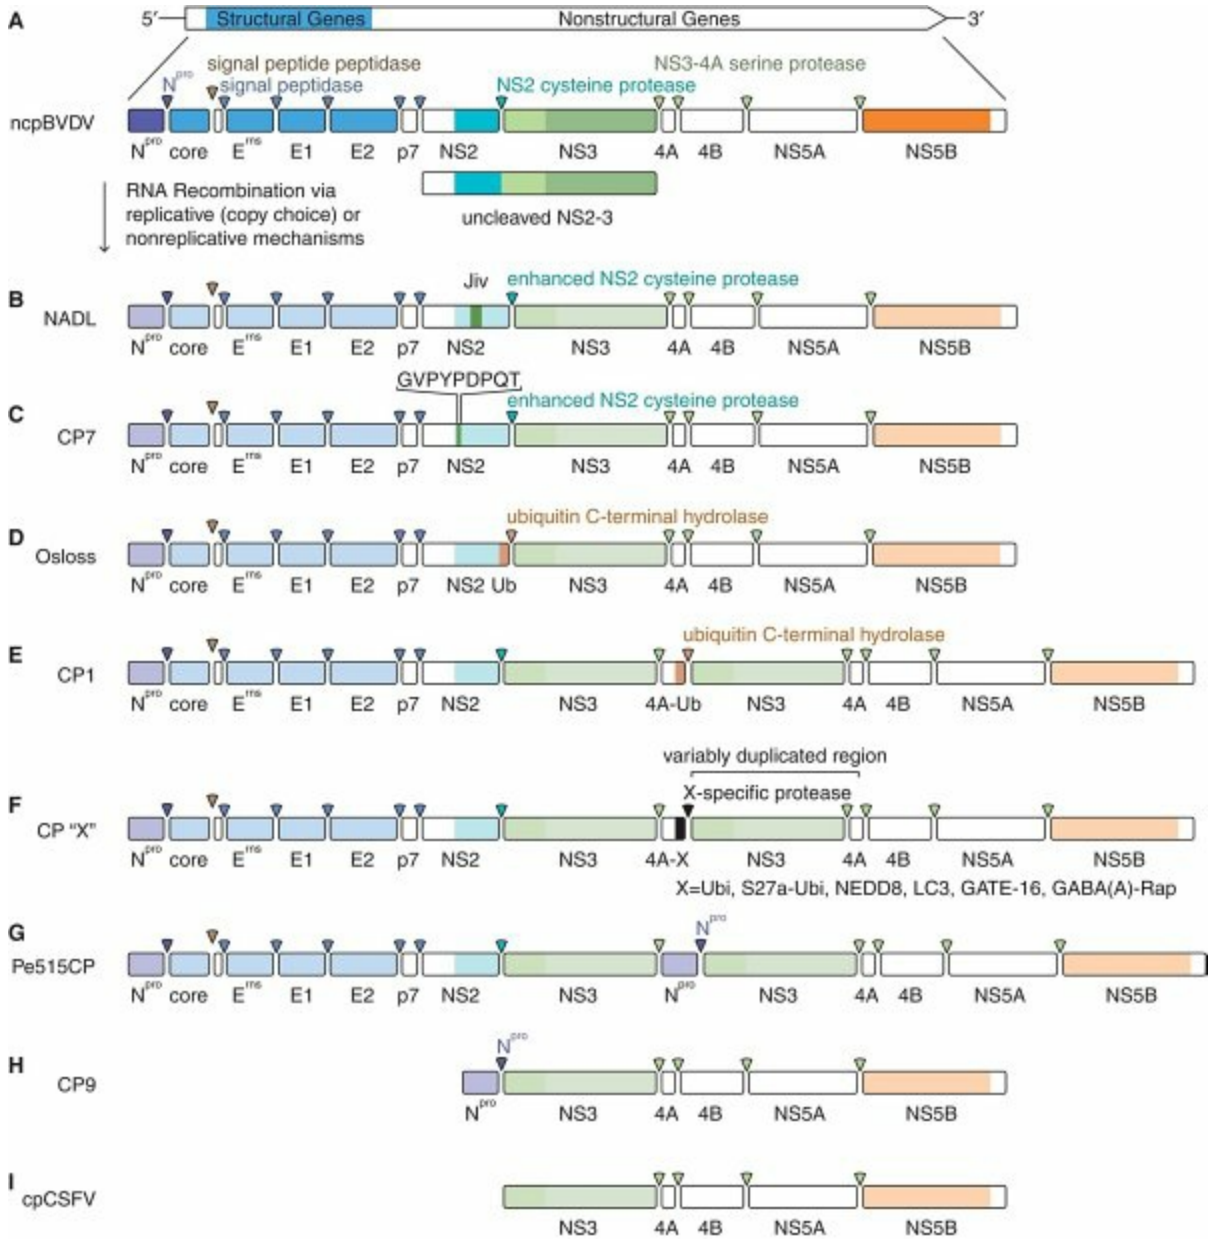

FIGURE 7.21 Pestivirus genome rearrangements associated with cp viruses. **A:** The polyprotein of a typical ncp pestivirus, for reference. **B:** The genome of cpBVDV1 strain NADL, showing the Jiv insertion within NS2. **C:** The genome of cpBVDV1 strain CP7, showing the nine-codon insertion within NS2. **D:** The genome of cpBVDV1 strain Osloss, showing insertion of the cellular ubiquitin (Ubi) gene at the 3′ end of NS2. **E:** The genome of cpBVDV1 strain CP1, showing the insertion of the cellular ubiquitin gene at the 3′ end of NS4A and duplication of the NS3-4A region. **F:** The genome organization of numerous cpBVDV isolates, similar to CP1, that have duplications in the NS3-4B region and insertion of ubiquitin or ubiquitin-like genes. **G:** The genome of cpBVDV1 strain Pe515CP, showing duplication of the NS3 gene, preceded by duplication of the N^{pro} gene. **H:** The genome of cpBVDV1 strain CP9, a naturally occurring DI genome that lacks the core–NS2 genes. **I:** The genome organization of numerous cpCSFV isolates, naturally occurring DI genomes that lack the N^{pro}–NS2 genes. As discussed in the text, these rearrangements increase NS3 expression relative to NS2-3 expression.

Another common rearrangement is the insertion of cellular ubiquitin (Ubi) or Ubi-like genes immediately upstream of NS3 (Fig. 7.21D), leading to NS2/3 cleavage by ubiquitin C-terminal hydrolase or related enzymes (e.g., BVDV1 strain Osloss).[627,894] For some viruses, like BVDV1 strain CP1, Ubi insertion is also accompanied by duplication in the NS3–4A region (Fig. 7.21E) or other genome rearrangements (Fig. 7.21F).[628] These duplications give rise to viruses encoding an intact NS2-3 region for virion morphogenesis and an NS3–NS5B cassette for efficient RNA replication.

In yet another recurring configuration, cp pestivirus genomes contain the N^{pro} autoprotease immediately upstream of NS3. For instance, N^{pro} is duplicated together with the NS3 and NS4A genes in BVDV1 strain Pe515CP (Fig. 7.21G).[628] Other isolates, such as cpBVDV1 strain CP9,

contain a precise deletion of the C–NS2 coding region, resulting in the in-frame fusion of N^{pro} and NS3 (Fig. 7.21H).[895] These subgenomic DI RNAs are naturally occurring replicons, capable of autonomous RNA replication but requiring ncpBVDV helper viruses to provide packaging functions in *trans*.[63] Similarly, some cpCSFV subgenomic RNAs lack the entire coding sequence upstream of NS3 (Fig. 7.21I).[629]

The genome rearrangements in cp pestivirus genomes lead to increased NS3 expression, independence from cellular DNAJ14 expression, enhanced RNA replication, and cytopathic effects in cell culture. Efforts have been made to dissect these phenotypes and reveal the basis of viral cytopathic effects. For instance, a point mutation in NS2 confers a temperature-sensitive cp phenotype to the cpBVDV1 strain CP7; at higher temperatures, this mutant retains high NS3 expression but reduced RNA replication and cytopathic effects.[693] On the other hand, a point mutation in NS4B attenuates the cytopathic effect of cpBVDV1 strain NADL, which still produces NS3 and viral RNA at comparable levels to the cp parent.[743] Similarly, other ncpBVDV strains show changes in NS4B.[284] Given that NS4B is associated with membrane rearrangements,[965] and that cpBVDV causes ER stress,[396] one hypothesis is that the overcommitment of cellular membranes to viral replication may lead to cell death. In infected animals, viral cytopathic effects may enhance viral spread but induce widespread tissue injury and inflammation. Indeed, animals with MD have increased viral loads, greater distribution of viral antigens, and higher infected cell counts than animals persistently infected with ncp virus.[521] Another intriguing possibility is that viral tropism might be expanded by viral independence from DNAJ14 expression. Thus, enhanced cytopathology, increased tropism, and lack of immune control may all contribute to the severe pathogenesis observed in MD.

PERSPECTIVES

This is an incredible, exciting time to be studying the *Flaviviridae*. With widespread emerging and reemerging human DENV, YFV, JEV, WNV, and ZIKV infections, flaviviruses retain their high medical relevance, driving basic research and the development of novel vaccine and antiviral strategies.

HCV research has come full circle, from humble beginnings as a veritable backwater lacking a culturable virus into one of the most well-studied, positive-strand RNA viruses and an advanced armamentarium of highly effective DAAs. While these successes have largely ended HCV drug discovery efforts, significant challenges remain in understanding the structure and function of the virus particle, improving animal models of HCV pathogenesis, and developing vaccines that can prevent or cure HCV infection.[54] Moreover, the discovery of related hepaciviruses, pegiviruses, as well as segmented Jingmenviruses and large flavi-like viruses have raised far more questions than they have answered about the ecology, evolution, and molecular biology of this virus family. Some overarching questions include: How did the *Flaviviridae* evolve, particularly in relation to other positive-strand RNA virus families? How much diversity is still left to discover within this family? And, what threads link all members of this family together? Our field welcomes new talent and diverse, innovative approaches as we tackle these and other important questions.

Perspective

HISTORY

Posttransfusion hepatitis that could not be attributed to hepatitis A virus (HAV) or hepatitis B virus (HBV) infection was first reported in the mid-1970s.[202,365,610] This disease entity, designated non-A, non-B hepatitis (NANBH), was marked by elevated hepatic transaminases in recipients of blood products. Transaminase elevations often persisted and were associated in many cases with chronic inflammatory liver disease and cirrhosis.[202,365,610] Passage of blood components to a variety of Old and New World monkey species failed to replicate the transaminase elevation observed in humans. Only a great ape, the common chimpanzee (*Pan troglodytes*), developed NANBH after transfusion with blood that caused hepatitis in human recipients.[22,292,732] Serial passage of NANBH between chimpanzees provided critical insight into the nature of the infectious agent. Physicochemical studies revealed that NANBH was caused by a small (80 nm) filterable virus with an envelope that was sensitive to treatment with organic solvents.[73,203]

Well-established approaches used to identify other hepatitis viruses were not effective in the search for the NANBH agent[298] Virus particles were not visualized by electron microscopy in the liver or serum from patients with NANBH or in cultured primary and established hepatocyte cell lines after inoculation with these materials. Moreover, the cultured hepatocytes did not develop cytopathic effects or tubular ultrastructural alterations in hepatocyte endoplasmic reticulum that were diagnostic of NANBH.[298] Approximately 15 years after the first description of posttransfusion NANBH, a highly novel approach of blind immune screening was used to identify the infectious agent. This strategy, devised by Michael Houghton and his colleagues at Chiron Corporation, involved reverse transcription of nucleic acids from the liver and serum of infected humans and chimpanzees.[121] Recombinant λGT11 phage expression libraries constructed from the cDNA were then screened for recognition by radiolabeled IgG antibodies from NANBH patients. Tens of millions of λGT11 clones were screened over 2 years before a single positive clone designated 5-1-1 was identified.[121,298] This clone, derived from the serum of a chimpanzee with a high infectious titer of the NANBH agent, was extrachromosomal (i.e., not of host origin) and encoded a polypeptide recognized by antibodies from humans and chimpanzees with

NANBH but not HAV or HBV infections.[121] Molecular cloning revealed that the newly identified hepatitis C virus (HCV) had a positive-strand RNA genome of approximately 10,000 nucleotides that is transcribed as a single open reading frame.[121] Based on these features and organization of structural and nonstructural proteins, HCV was classified as member of the *Flaviviridae* family.[122] Serologic assays that incorporated antigen 5-1-1 derived from HCV nonstructural protein 4 (NS4), and other structural and nonstructural antigens identified in the λGT11 library, were rapidly developed.[20,388] Seroepidemiology revealed that almost all transfusion-related and community-acquired hepatitis was caused by HCV.[20]

Discovery of HCV laid the groundwork for development of new direct-acting antivirals (DAA) that recently replaced type I interferon-based therapies for chronic hepatitis C. Almost all chronic infections, including those that were previously difficult to treat because of HCV genotype resistance or comorbidities, can now be cured by 8 to 12 weeks of therapy with an all oral, once-a-day DAA regimen (see Treatment). Elimination of HCV by 2030, 40 years after the discovery of HCV, is now an objective of the World Health Organization (see www.who.int/hepatitis/strategies2016-2021/ghss-hep/en) that has gained support from many advisory and governmental agencies including the United States National Academy of Sciences[537] (see Public Health Measures).

INFECTIOUS AGENT

Classification

HCV is a genetically diverse virus that is classified into seven genotypes with a remarkable 35% nucleotide divergence between strains belonging to different genotypes. A total of 86 subtypes that differ in sequence by 25% are also distributed among the 7 genotypes (see http://talk.ictvonline.org/links/hcv/hcv-classification.html) (Fig. 8.1).[701]

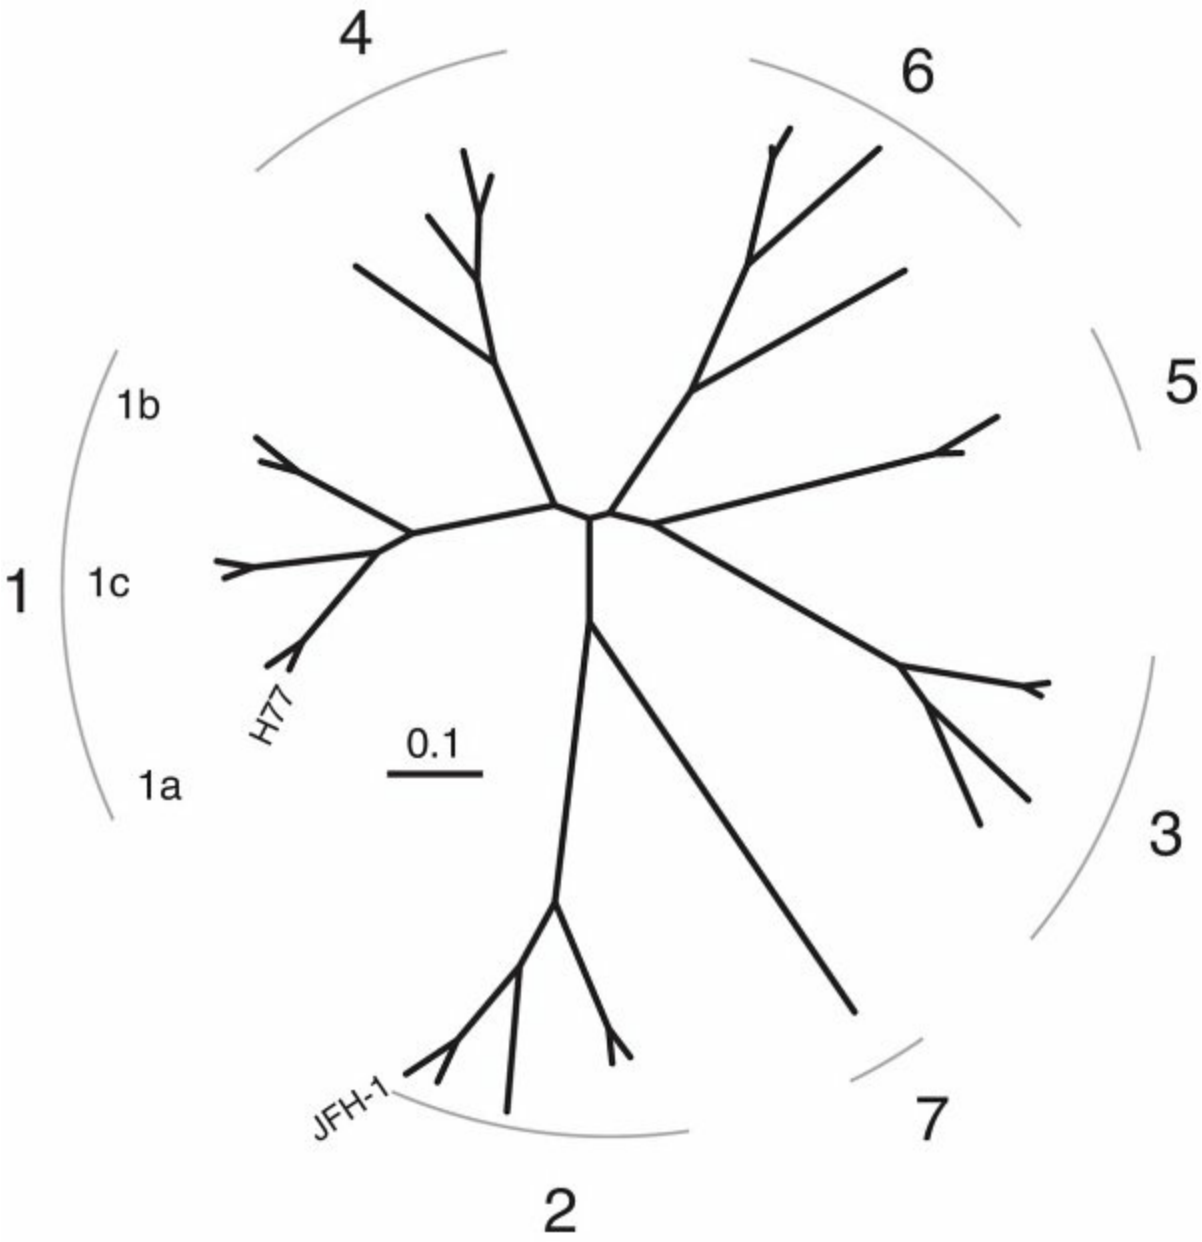

FIGURE 8.1 Phylogenetic tree of representative sequences from the seven proposed genotypes of hepatitis C virus (HCV). Full-genome nucleotide sequences were aligned and analyzed using a maximum likelihood model with estimation of invariant sites and modeling of variable rates using the gamma distribution, with bootstrap resampling to confirm support for each genotype cluster. Reference isolates H77 (AF009606) and JFH-1 (AB047639) are indicated. Subtypes of genotype 1 (1a, 1b, 1c) are indicated for

illustration.

HCV belongs to the *Hepacivirus* genus of the *Flaviviridae* family. The genus has expanded in recent years to include hepaciviruses isolated from a diverse array of animals including rats, bats, horses, and colobus monkeys.[165,700] Hepaciviruses are now classified into 14 discrete species (A–M) that vary largely by host range, with HCV genotypes grouped in *Hepacivirus* species C. The wide host range of the hepaciviruses is highlighted by the recent discovery of an unclassified, more divergent hepacivirus-like sequence assembled from liver tissue of a gracile shark.[681] Rodent and equine hepaciviruses that segregate into distinct species share only about 50% sequence homology with HCV and can also establish persistent infections in their hosts (Fig. 8.2). They have emerged as valuable animal models for the study of HCV infection and immunity (see Immune Responses).

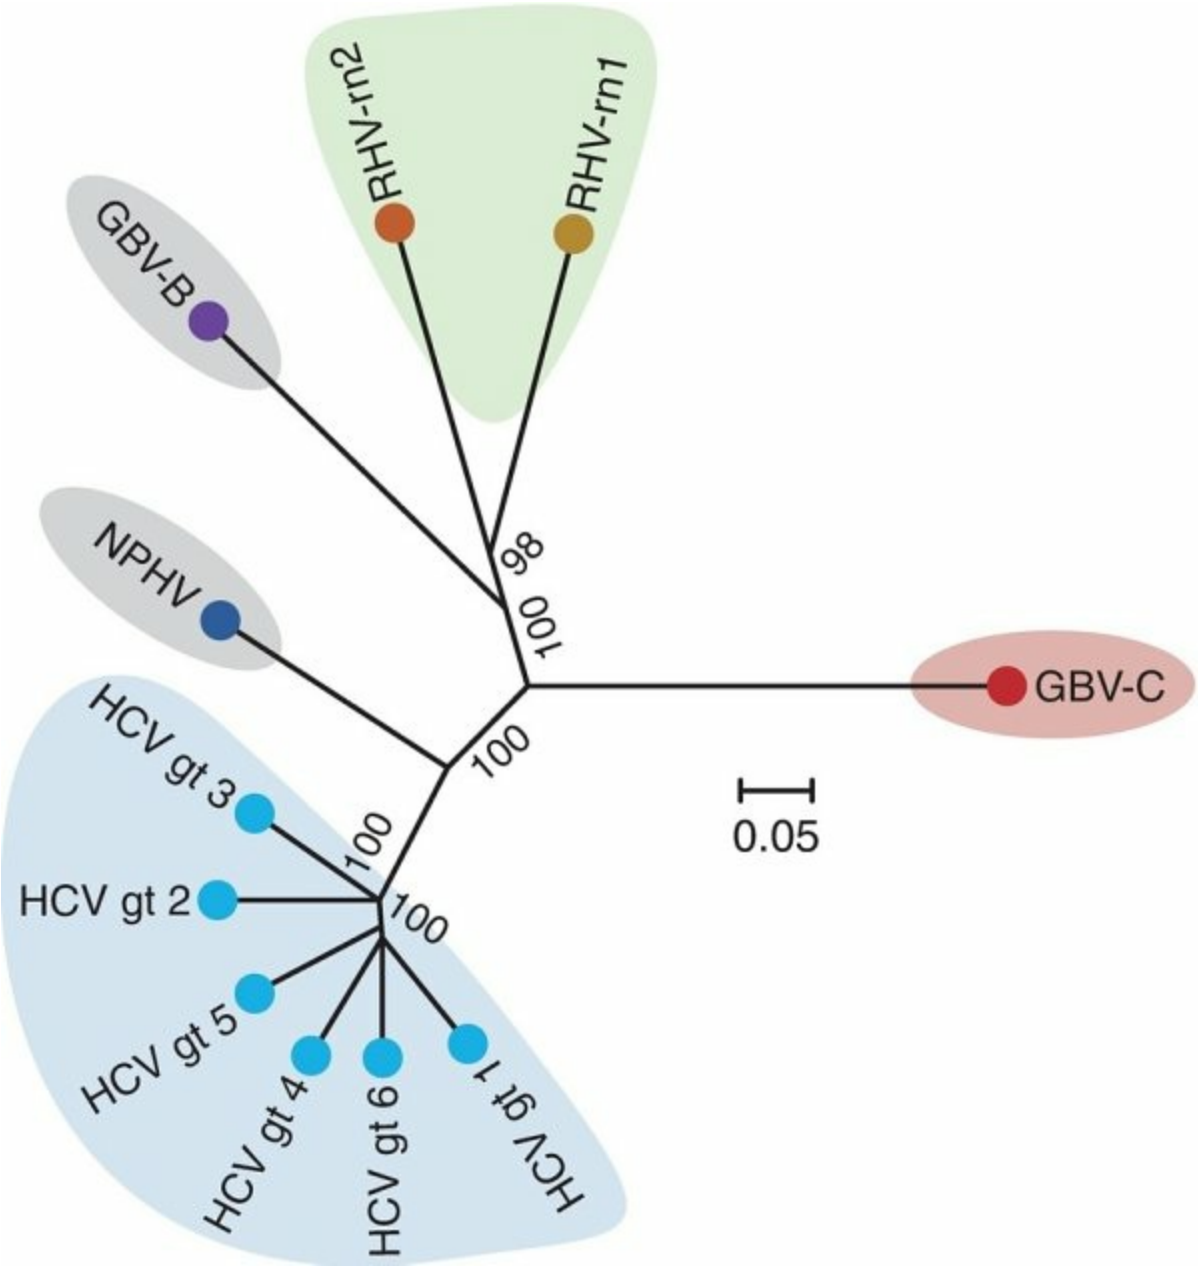

FIGURE 8.2 Evolutionary relationships and genetic distances between HCV, NPHV, GBV-B, rat hepacivirus (RHV), and GBV-C. A total of 629 amino acid positions of NS3 protein were aligned and used for comparative phylogenetic analysis using MEGA7 (1). The evolutionary history was inferred using the neighbor-joining method. The optimal tree with the sum of branch length = 2.07891938 is shown. The tree is drawn to scale, with branch lengths in the same units as those of the evolutionary

distances used to infer the phylogenetic tree. The evolutionary distances were computed using the p-distance method and are in the units of the number of amino acid differences per site. The rate variation among sites was modeled with a gamma distribution (shape parameter = 1). The analysis involved 12 amino acid sequences. All ambiguous positions were removed for each sequence pair. Kindly provided by Dr. Amit Kapoor.

HCV Particle Morphology

HCV exists in serum as lipoviral particles (LVPs) with a light buoyant density (≤1.055 g/mL) and diameter of 60 to 70 nm.[102,594] LVPs are formed around HCV core proteins that are in close association with the RNA genome of the virus. Ultrastructural studies of cell culture–derived LVP revealed that they are the most irregular members of the *Flaviviridae* family from a structural perspective, with spike-like projections and a heterogeneous size distribution.[102] They resemble very-low-density lipoproteins (VLDL) in structure and are associated with cholesterol esters, triglycerides, and host apolipoproteins, including apoE that is required for HCV infectivity.[107,149,303,326,492] They can associate with VLDL upon release from infected cells to form particle complexes.[39,819] Low-density particles recovered from patients were immunoreactive with antibodies against the HCV E1 and E2 envelope glycoproteins that are anchored in the particle membrane.[611] Moreover, LVPs recovered from the serum of persistently infected chimpanzees are highly infectious.[74]

The HCV Replication Cycle

Primary HCV isolates from humans replicate poorly, if at all, in cell culture models. Progress in unraveling the HCV replication cycle accelerated with development of viral pseudoparticles that display the HCV envelope glycoproteins,[47,300] subgenomic replicons,[63,441] and more recently viruses from all seven genotypes adapted for efficient replication in cell culture.[434,622,796,840] Chapter 7 provides a detailed description of HCV entry, replication, assembly, and egress from infected cells. Key features of this

process relevant to understanding HCV pathogenesis, immunity, and antiviral therapy are discussed below.

Entry of HCV into hepatocytes is mediated by the type I transmembrane E1 and E2 envelope glycoproteins proteins that are displayed on the surface of infectious virions as a cross-linked heterodimer (Fig. 8.3).[792] The initial step in entry is mediated by an interaction between apoE in the LVP and the heparan sulfate proteoglycans[149,325,400] and scavenger receptor class B type I (SR-BI) on hepatocytes.[141] Subsequent steps involve E2 binding to the CD81[591] and SR-BI[591,596] cellular receptors and clathrin-dependent internalization of particles into the endosome in a process mediated by two additional entry receptors, the tight junction proteins claudin-1[186] and occludin[596] (Fig. 8.3). Internalized HCV particles undergo membrane fusion in the acidified environment of the endosome in a process facilitated by the E1 envelope glycoprotein, resulting in release of HCV genomes into the hepatocyte cytoplasm (Fig. 8.3).[166,402,421,580,679,760]

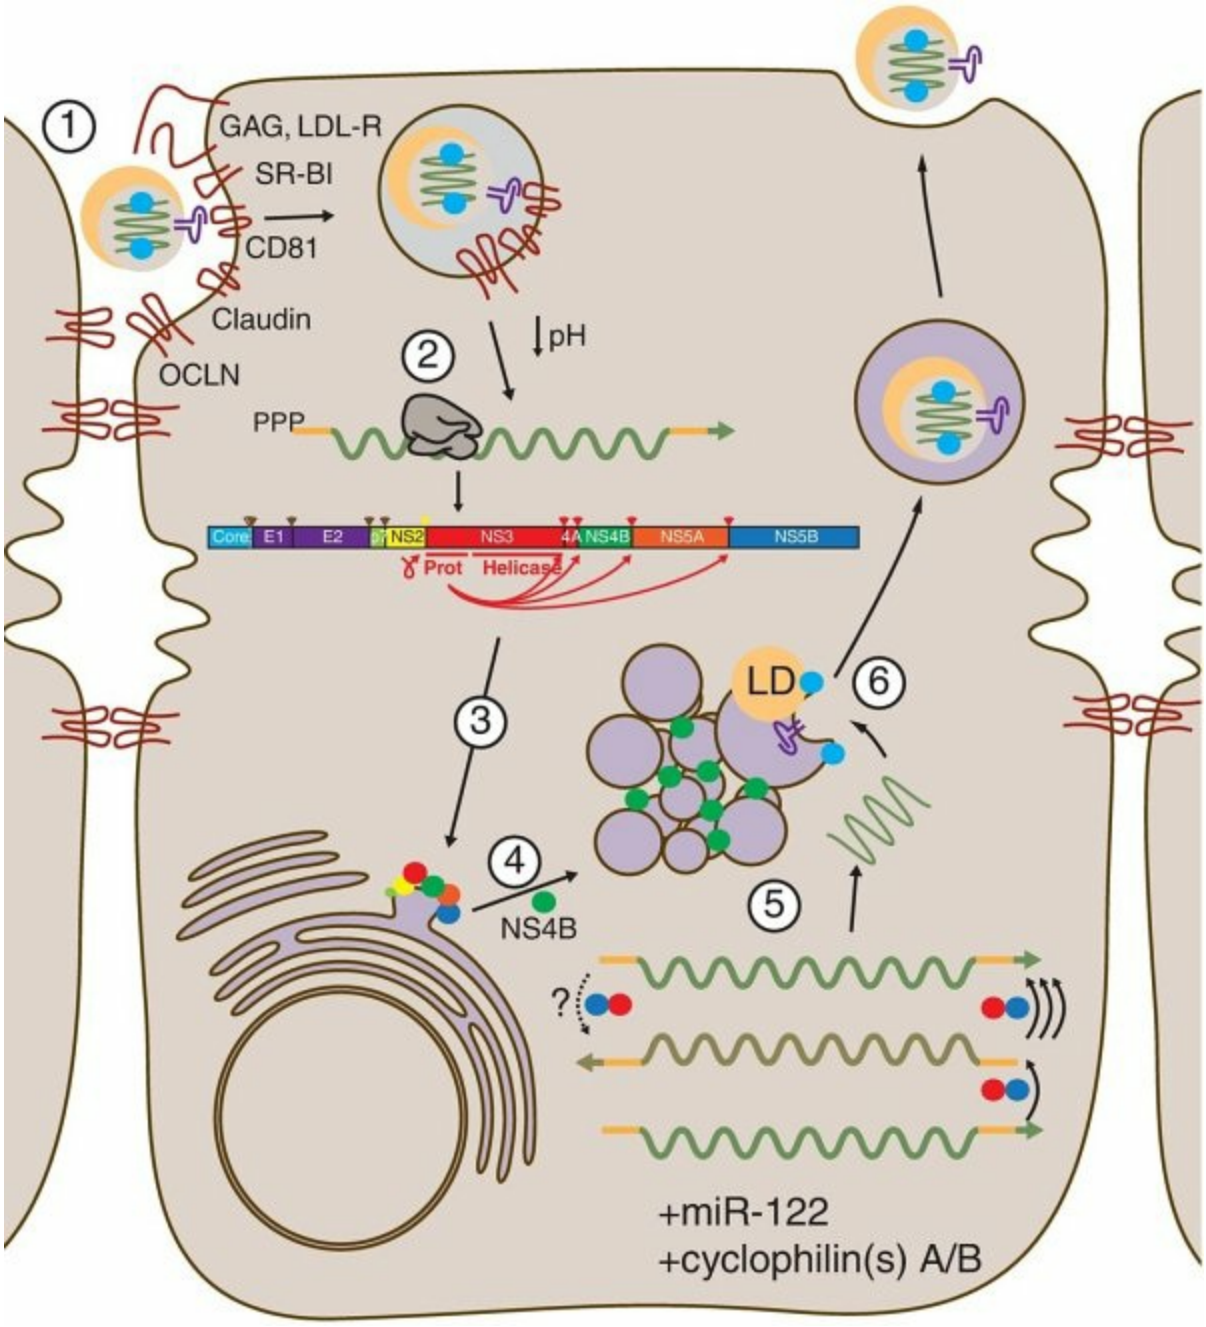

FIGURE 8.3 Life cycle of hepatitis C virus (HCV). Initial binding and internalization (*1*) probably involve glycosaminoglycans (GAGs) and low-density lipoprotein receptor (LDL-R), which may interact with viral envelope proteins or with virion-associated lipoproteins. Entry depends directly on binding of E2 with the tetraspanin CD81, as well as interactions with scavenger receptor BI (SR-BI) and tight junction proteins claudin-1 and occludin

(OCLN). The viral genome is released from late endosomes (*2*) in a pH-dependent manner, followed by internal ribosome entry site (IRES)-dependent polyprotein synthesis (*3*) with initial cleavages among the structural proteins mediated by signalase and signal peptide peptidase followed by cleavage of the NS2–NS3 junction by NS2–NS3 cysteine protease; the remaining junctions are cleaved by the NS3–NS4A serine protease. NS4B recruits and rearranges endoplasmic reticulum (ER) membranes (*4*) to form a *membranous web*, the principal site of viral replication. Minus-strand and subsequent plus-strand RNA syntheses are affected by the NS5B RNA-dependent RNA polymerase (RdRp) (*5*) and depend on miR-122 and cyclophilin B, as well as conserved structural elements at the 5′ and 3′ ends of the genome. Core protein associates with lipid droplets (LDs) in the lipoprotein assembly pathway (*6*), linked to NS5A and other members of the replication complex by interaction with NS2. Viroporin p7 is necessary for production of stable viral particles coated with E1 and E2, which fold in a cooperative manner and are glycosylated in a manner consistent with ER but not Golgi processing.

Cap-independent translation of the HCV genome occurs on the rough endoplasmic reticulum and is directed by a type III internal ribosome entry site (IRES) located in the 5′ nontranslated region (NTR) of the viral genome (Fig. 8.4).[550,766] Activity of the IRES is critically dependent on liver-specific microRNA 122 (miR-122) that recruits Argonaute 2 to stabilize and protect the HCV genome against the Xrn1 host cell exonuclease activity and to shift the balance between translation and transcription of genomes.[331,427,467,683,816] The product of translation is a single polyprotein of approximately 3,000 amino acids that is co- and posttranslationally processed by host and viral proteases. Junctional cleavage between the structural core, E1, and E2 proteins is mediated by host cell signal peptidase, while the seven nonstructural proteins are released from the polyprotein by viral proteases. HCV-encoded proteases include NS2 that mediates cleavage of the NS2–NS3

junction through C-terminal cysteine protease activity and NS3 with its membrane-anchoring NS4A cofactor that cut at the remaining junctional sites between NS proteins via serine protease activity (Fig. 8.4).[45,122]

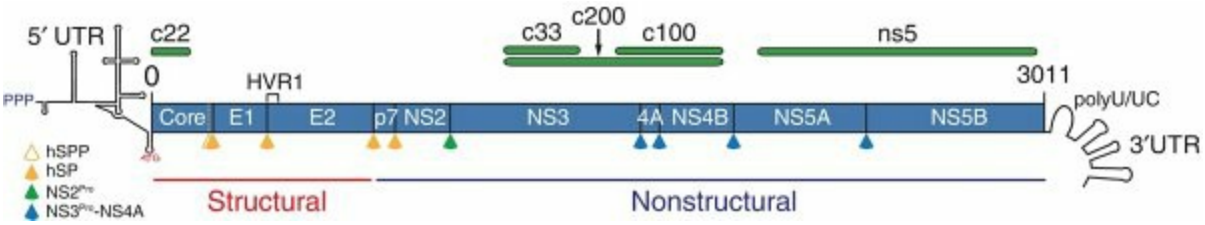

FIGURE 8.4 Map of the hepatitis C virus (HCV) genome. Structure of the HCV genome including the 5′ untranslated region (5′UTR), capsid core, envelope genes *E1* and *E2*, viroporin p7, membrane-anchored cysteine protease NS2, serine protease–helicase NS3, NS3 protease cofactor NS4A, membrane remodeling protein NS4B, phosphoprotein NS5A, RNA-dependent RNA polymerase NS5B, and the 3′UTR. Depicted as green bars are recombinant protein segments used as antigens in HCV enzyme immune assay (EIA) and recombinant immunoblot assay (RIBA). Cleavage of the polyprotein is due to the action of host signal peptidase (*solid orange*), signal peptide peptidase (*open orange*), NS2 cysteine autoprotease (*green*) and NS3-NS4A serine protease (*blue*).

Released NS proteins are organized into replicase complexes on a membranous web formed from 150-nm double-membrane vesicles (DMV) that are derived from the hepatocyte endoplasmic reticulum.[642] This structure concentrates cellular and viral factors required for replication and may also sequester HCV proteins and genomes from host innate sensors (see Innate Immunity). Web formation is directed by the membrane-associated NS4B and NS5A proteins.[641,642] NS4B is essential for HCV replication, but its functions are not well understood. It induces host cell membrane alterations[172] and may be involved in recruitment of autophagic factors into the membranous web.[190,269,690,737] NS5A, a phosphoprotein, serves several

functions including binding of HCV RNA genomes,[218,301] regulation of the NS5B polymerase,[644,688] and recruitment of multiple host proteins including cyclophilin A[112,450] and phosphatidylinositol 4-kinase IIIα (PI4P)[53] that are required for HCV replication. The NS5B RNA-dependent RNA polymerase (RdRp) directs synthesis of negative-stranded RNA templates and new positive-stranded RNA genomes within the replicase complex where required NS3-mediated RNA helicase and NTPase functions are localized.

Virion assembly occurs near replication complexes at sites that are in close proximity to lipid droplets (Fig. 8.3).[191,511] This complex process involving multiple NS proteins (p7, NS2, NS4B, NS5A) is still poorly understood, in part because it is tightly linked to liver lipid metabolism that may not be fully recapitulated in cell culture models. The p7 and NS2 proteins are thought to be enriched at cytosolic sites where they coordinate assembly of the core, E1 and E2 structural proteins.[72,150,328,449,600,711,830] NS5A has a key role in the transition from replication to assembly, in part by chaperoning newly synthesized RNA genomes to the assembly sites.[72,830] Components of the cellular VLDL lipoprotein assembly pathway, including microsomal transfer protein,[303] apoB,[303] and DGAT1,[287] are thought to be usurped for formation and possibly release of HCV particles. As noted above, apoE is an essential component of HCV particles and contributes to particle maturation, release, and infectivity.[411] LVP maturation occurs during transit through the secretory pathway that is regulated by the ESCRT system[30,191,207] and continues at a post-egress step.[207] HCV particles may also be released from cells in exosomes as part of the autophagy response to infection.[690,737] The function of HCV proteins and membranous structures in regulation or evasion of the innate immune response and development of antiviral inhibitors targeting the NS3/4A protease, NS5A replicase factor, and NS5B RdRp are described later in this chapter.

Genetic Diversity and Evolution

HCV replication within an infected host results in a mixture of highly diverse variants that are genetically distinct.[395,459] This swarm, called a quasispecies, is generated by low-fidelity transcription of the HCV genome by the NS5B RdRp that lacks a proofreading mechanism. The estimated error rate is approximately 2×10^{-5} substitutions per nucleotide and round of replication

of the 10-kB genome.[44,637] With daily production of about 10^{12} virions,[547] each progeny genome is likely unique, and every possible combination of two mutations is generated within an infected individual every day. The HCV replication strategy is therefore highly adapted for rapid evasion of selection pressure exerted by immune responses and antiviral drugs (see Immune Responses and Treatment). Analysis of quasispecies evolution during the acute phase of infection revealed two sequential population bottlenecks. The first occurred upon transmission of HCV from a donor to recipient.[85,798] Infection is initiated by a very small number of HCV genomes, with an estimated median of four founder genomes in a study of 17 acutely infected humans.[424] Single-genome sequencing revealed that HCV diversifies rapidly by a model of simple random evolution during the early phase of acute infection.[3,425] A second bottleneck several weeks later coincides with the onset of adaptive immune responses (see Immunity).[85] Envelope glycoproteins diversify more rapidly than do other regions of the genome,[258] reflecting selection pressure from neutralizing antibodies. Within nonstructural proteins, the rate of nonsynonymous mutation is higher within class I restricted epitopes targeted by CD8+ T cells when compared with flanking nontargeted sequences.[94] Diversification of the nonstructural proteins slows with the transition to chronic infection,[94,208,387] which is thought to reflect functional exhaustion of the T-cell response. Other forces shaping the HCV genome during infection include emergence of compensatory mutations to restore fitness[548,646] and reversion of nontargeted sequences to a subtype consensus sequence considered more fit for replication.[387,654] A transmission bottleneck has also been identified after vertical transmission of HCV from mother to child.[200] The second immune-related bottleneck does occur, but is delayed until about 1 year postinfection when maternal antibodies decline. This timing of diversification is consistent with delayed onset of adaptive immunity to HCV in very young children.[200] Additional detail on HCV mutational escape from immune responses and antiviral drugs is provided in Immune Responses and Treatment sections.

PATHOGENESIS AND PATHOLOGY

Spread

The mode of spread of HCV throughout the liver is poorly understood. Only 10% to 20% of hepatocytes harbor HCV genomes in the chronic phase of infection despite high replication and viremia.[430,714,808] The infection status of single hepatocytes within liver specimens from chronically infected patients has been assessed using laser capture microdissection.[335] Creation of a viral infection landscape by assessing the intracellular HCV RNA content of adjacent individual cells revealed that infected hepatocytes occur in small clusters of 4 to 50 cells.[335] Moreover, the HCV RNA content in a cluster formed a gradient, from the presumptive founder hepatocyte to cells at the periphery.[257] Mathematical modeling suggested that hepatocytes within the cluster were infected for about 5 days.[257] Clustering is consistent with a model of random hepatocyte seeding from blood followed by local spread that could occur by cell-free or direct cell-to-cell mechanisms. Cell-to-cell spread of HCV infection has been documented in cell culture models[759,811] and may involve cellular receptors that partially overlap with those required for cell-free spread.[192] Why infection is restricted to small hepatocyte clusters is not known. Localized cell-to-cell spread of HCV may be favored as it provides protection from neutralizing antibodies in cell culture models.[77,759] Infection also triggers a strong interferon-stimulated gene response that could render neighboring cells resistant to infection (see Innate Immunity), although there is as yet no direct evidence to support this possibility.

Entry into the Host

As discussed in the Transmission section later (under Epidemiology), the primary route of HCV entry is percutaneous, although permucosal infection has also been described. Experimentally, HCV infection can be achieved by intravenous injection of HCV virions or intrahepatic injection of HCV genomic RNA.[371,818]

Cell and Tissue Tropism

HCV replication occurs primarily or exclusively in hepatocytes, the major parenchymal cell of the liver. The basis for this tropism is likely to be multifactorial. Entry receptors may be a key restriction factor. SR-BI, as an

example, is preferentially expressed at high levels on hepatocytes.[591,596] Expression of other entry receptors such as CD81,[591] claudin-I,[186] occludin,[596] and cyclophilins[112,450] is not restricted to hepatocytes. Nonetheless, multiple receptors may be uniquely situated or patterned within subcellular spaces of the liver to support the dynamic, multistep entry process utilized by HCV. Dependence on liver-specific miR-122 for efficient replication of the HCV genome,[330,331] and utilization of the lipoprotein assembly pathway for virion production, may also contribute to hepatotropism of HCV.[303] Productive infection of cell types other than hepatocytes is controversial. HCV negative-strand replicative intermediates have been detected in cells of hematopoietic origin,[109,417,831] and compartmentalization of sequence variants has been described.[540,664] Apparent replication of HCV in cultured B and T cells has been described.[699,726] Viral dynamic modeling of data from the anhepatic phase of liver transplantation suggested that in a subset of patients with end-stage liver disease, an extrahepatic compartment exists that contributes no more than 3% to 4% of plasma viremia.[139,601]

Immune Response

Innate Immune Responses

Acute HCV infection induces potent innate immune defenses, including inflammasome activation,[110] expression of interferon-stimulated genes (ISG),[123,661] and expansion of natural killer (NK) cells. These responses are often persistent into the chronic phase of infection, indicating that HCV can deploy a multilayered defense that ensures ongoing viral replication in hepatocytes.

Inflammasome activation

Acute hepatitis C is characterized by elevated serum titers of IL-1β and IL-18, proinflammatory cytokines that are a product of inflammasome activation.[111,542,691] Cell culture models have demonstrated that the inflammasome response in macrophages and monocytes is triggered by direct binding of HCV to the toll-like receptor 7 (TLR7) innate sensor located in the

endosome of these mononuclear cells. Inflammasome activation in this model was independent of virus replication[110,542] and the IFN-driven ISG response.[110] Activation of proinflammatory mediators like CXCL10 via an interferon-independent mechanisms involving NF-κB has also been described.[79] This process may also contribute to progressive liver injury, as macrophages exposed to HCV also activate inflammasome and fibrosis markers in cocultured stellate cells through a mechanism involving the chemokine CCL5.[660]

Interferon-stimulated gene responses

ISG responses are initiated when cellular sensors bind HCV RNA in the form of double-stranded structures and replicative intermediates.[123,661] Activation of toll-like receptor 3 (TLR3) sensors located in the endosome, or the retinoic acid–inducible gene-1 (RIG-I) and melanoma differentiation antigen 5 (MDA-5) sensors located in the cytosol,[123,284,422] results in a signaling cascade to the nucleus and expression of type I (IFN-α and IFN-β) and type III (IFN-λ1, IFN-λ2, IFN-λ3, and IFN-λ4) interferons that drive ISG gene expression[284,422,661] (Fig. 8.5).

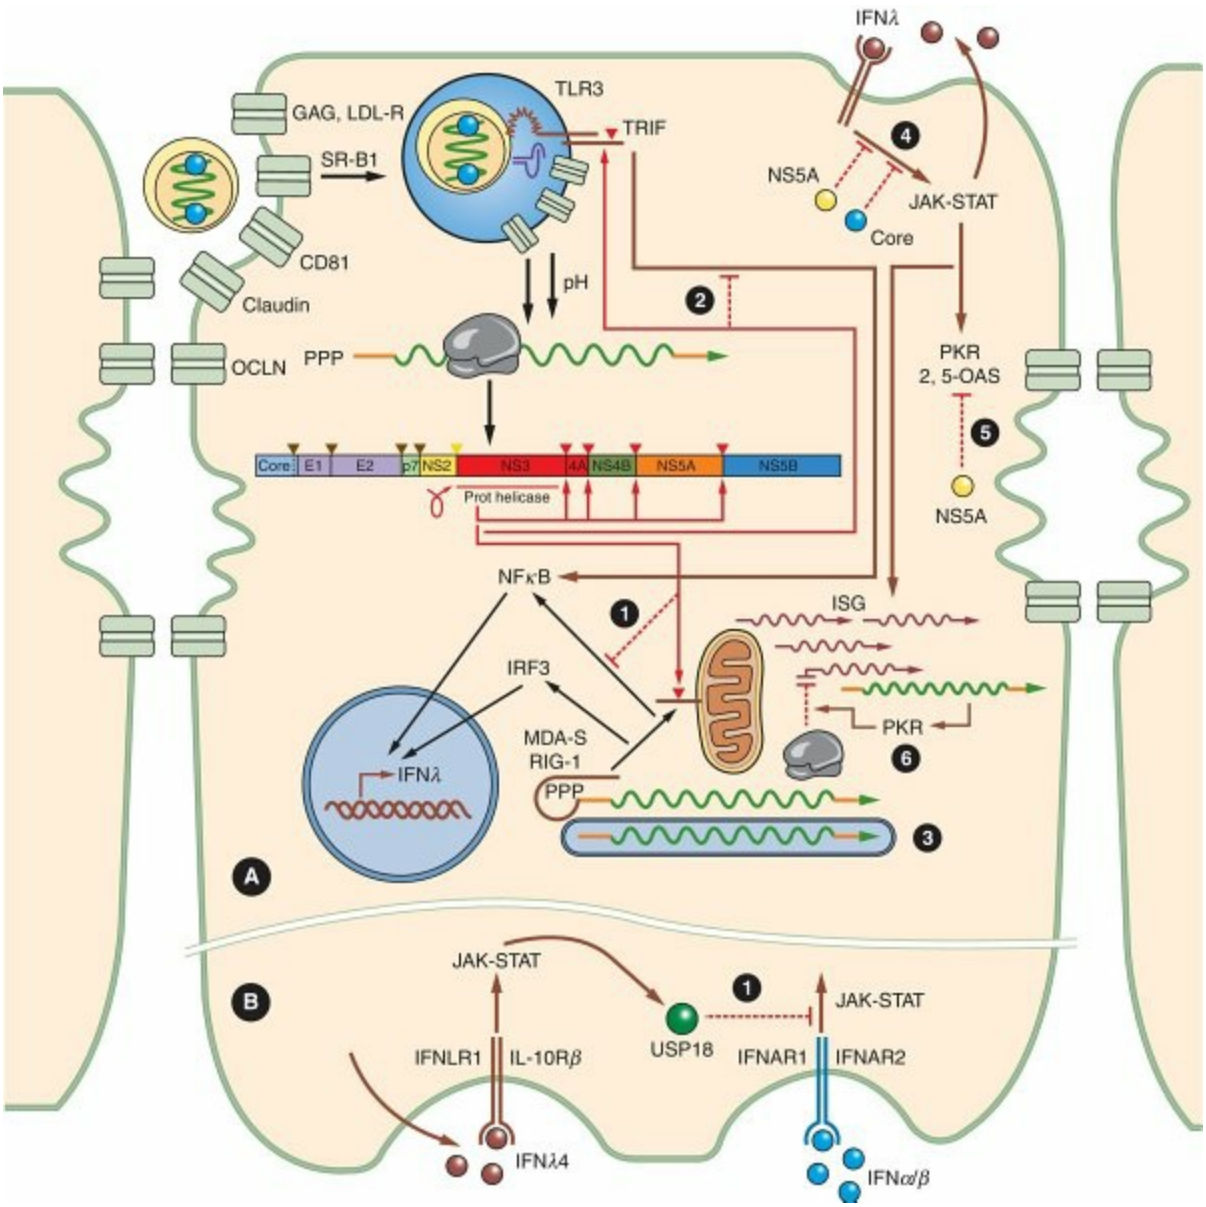

FIGURE 8.5 Interferon responses to hepatitis C virus (HCV) and their evasion by the virus. (*A*) Cytoplasmic HCV RNA genomes can be sensed by RIG-I and MDA-5 (*1*), resulting in signaling through mitochondrial antiviral signaling protein (MAVS) and subsequent nuclear translocation of nuclear factor (NF)-*κ*B and phosphorylated IRF3 that activate an antiviral program. Signaling through this pathway can induce expression of type I (IFN-*α* and IFN-*β*) and type III (IFN-*λ*1, IFN-*λ*2, IFN-*λ*3, and IFN-*λ*4) interferons (IFN), but only the latter are detected in

HCV-infected hepatocytes. HCV NS3-NS4A protease cleaves MAVS to block downstream signaling. (*2*) HCV RNA genomes are sequestered from RIG-I and MDA-5 detection in exosomes, vesicles generated by autophagy or the membranous web where HCV replicates. (*3*) HCV RNA may be sensed in endosomes by toll-like receptor 3 (TLR3), which signals via the adapter molecule TIR domain–containing adapter-inducing interferon-*β* (TRIF), resulting in nuclear translocation of NF-*κ*B and IFN gene expression; the NS3-NS4A protease cleaves TRIF, interfering with this response. Ectopic expression of HCV proteins in cultured cells can inhibit the (*4*) JAK-STAT pathway that transduces signals from IFN type I and III receptors to the nucleus for interferon-stimulated gene (ISG) expression and (*5*) antiviral activity of induced ISG including protein kinase R (PKR) and 2′,5′-oligoadenylate synthetase (2,5-OAS). HCV RNA in infected hepatocytes activates PKR, impairing cap-dependent translation of antiviral ISG but not IRES-mediated translation of the HCV genome (*6*). (*B*) IFN-*λ*4 induced in individuals with the *IFNL4* rs386234815-ΔG polymorphism stimulates a robust and sustained antiviral ISG response including ubiquitin-specific protease 18 (USP18) that impairs JAK-STAT signaling through the type I IFN heterodimeric (IFNAR1/IFNAR2) receptor but not the type III (IFNLR1/IL10R2) receptor. Further details and additional innate responses and evasive mechanisms are described in the text.

Type III IFN gene expression is dominant in the liver during acute[570,753] and chronic[24,155,551] HCV infection, and in HCV-infected cultured hepatocytes,[312,466,570,753] indicating that IFN-*λ* proteins are the major driver of hepatic ISG activity. Plasmacytoid and myeloid dendritic cells cocultured with HCV-infected hepatocytes produce type I[164,733] and III[715,827,837] IFN, but their contribution to ISG induction in the infected liver remains to be determined. Several hundred hepatic ISG are up-regulated, some more than

100-fold, within hours or days of HCV infection (Fig. 8.6).[284,422] ISG expression increases sharply in liver and peripheral blood mononuclear cells in parallel with viremia during acute infection.[58,719] The response normalizes after several weeks in spontaneously resolving infections,[643] with a transition to an IFN-γ gene signature that marks the onset of adaptive immune responses.[58,59,156,719,748] Hepatic ISG activity is sustained through the chronic phase of infection in humans[32,113,656] and chimpanzees[59,719] and provides no apparent control of persistent HCV replication (Fig. 8.6). Intensity of hepatic ISG activity is variable between chronically infected individuals.[32,58,113,656,719] High-level ISG expression predicts a poor response to treatment with pegIFN/riba as detailed below.[113,206,294,656]

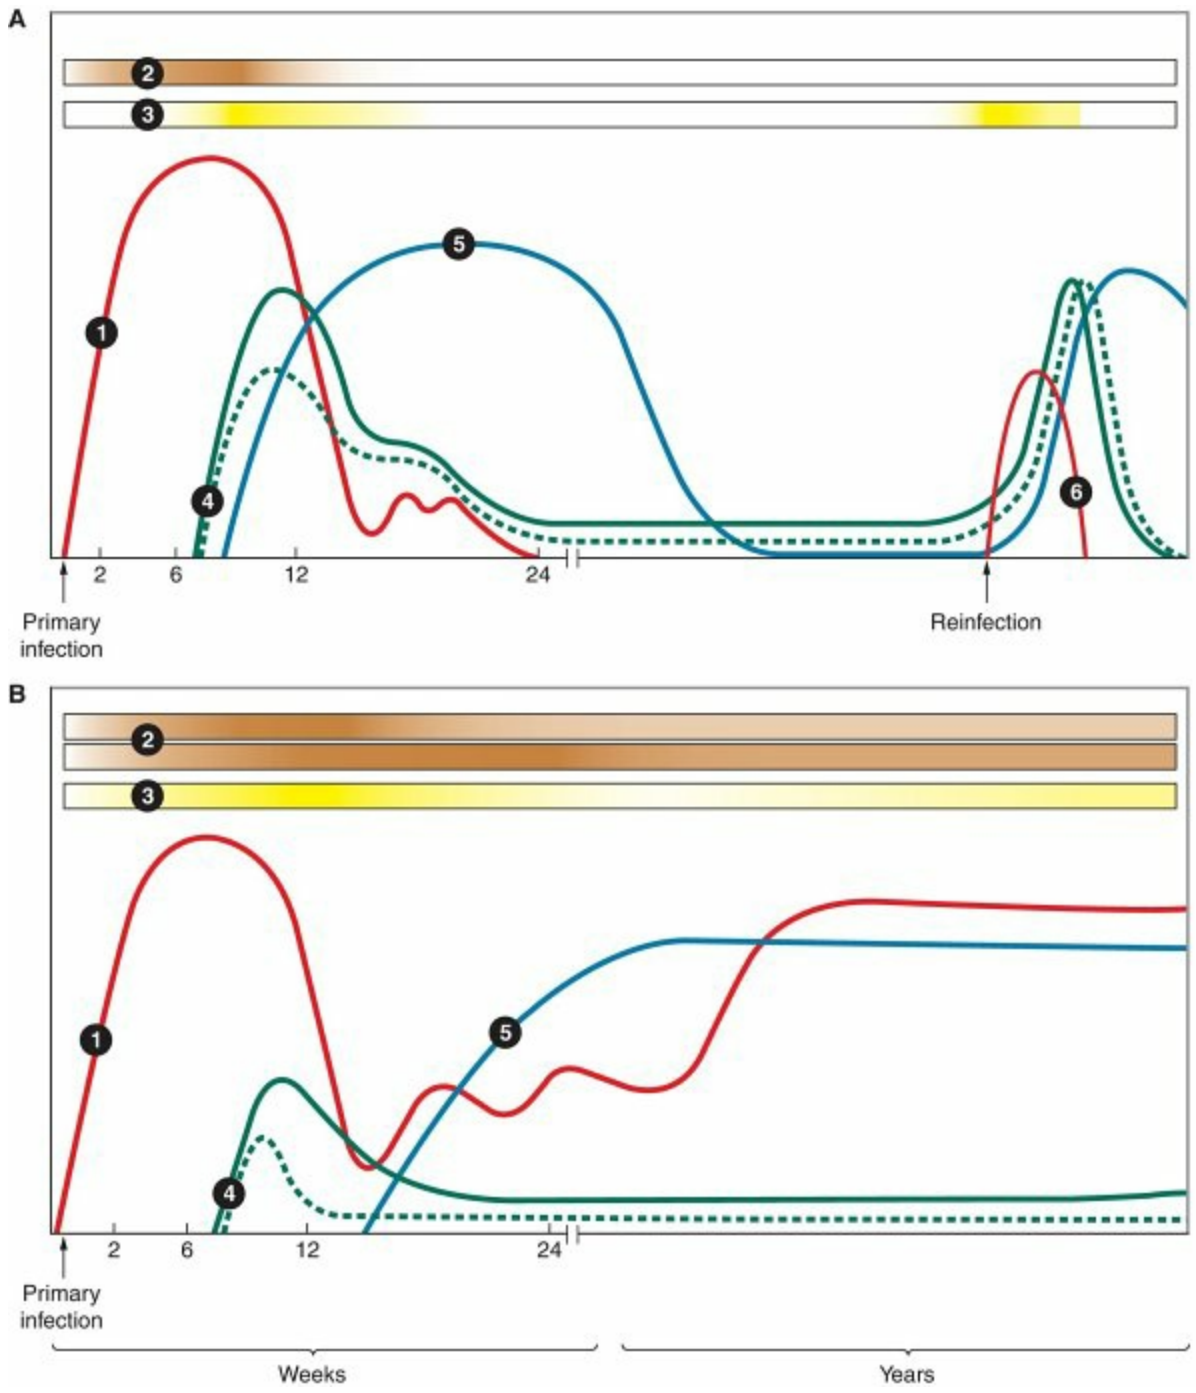

FIGURE 8.6 Profile of HCV replication, liver disease, and immune responses. A: Spontaneous resolution of infection. HCV viremia (*1*) and elevated hepatic interferon-stimulated gene (ISG) activity (*2*) are observed within days of infection. The ISG response closely tracks viremia and normalizes with termination of virus replication. A sharp decline in viremia is typically observed

after approximately 8 to 12 weeks of infection and is coincident with elevation of serum aminotransferases and signs and symptoms of hepatitis (*3*). CD4+ (*dashed*) and CD8+ (solid) T-cell (*4*) and neutralizing antibody responses (*5*) are also observed in this time frame. Time to resolution of infection is variable; low, oscillating level viremia can be detected for about 1 year in some cases. ISG expression normalizes after resolution of infection, and adaptive immune responses decline but are rapidly recalled upon reexposure to the virus (*6*). **B:** Persistent infection. Viremia (*1*) typically declines after 8 to 12 weeks of infection, but can remain high with no apparent control in some acute persisting infections (not depicted). Partial control of HCV replication for several months is not uncommon, but high (10^5 to 10^7 RNA genomes/mL serum) stable viremia is characteristic of chronic infection. Hepatic ISG activity remains persistently high in individuals carrying the unfavorable (ΔG) (2, bottom bar) versus favorable (TT) (2, top bar) *IFNL4* polymorphism rs368234815 (*2*). Signs and symptoms of chronic liver disease are typically evident after years to decades of infection (*3*). T-cell responses fail before resolution of infection (*4*); CD4+ T cells (*dashed line*) lose function and disappear from circulation, and CD8+ T cells gradually exhaust, losing effector functions. Neutralizing antibody responses are delayed when compared with resolving infections but persist at high titer through chronic infection (*5*).

Type III IFN polymorphisms

Polymorphisms in the *IFNL* gene locus determine the strength of the ISG response in the HCV-infected liver. *IFNL* haplotype and ISG activity are in turn associated with the outcome of acute HCV infection and treatment of chronic hepatitis C with pegIFN/riba.[554] More recent studies demonstrated that viral decay kinetics and risk of relapse in DAA-treated patients are also

associated with *IFNL* genotype[485,553] (see Treatment section). Two polymorphisms located in *IFNL4* are important from a functional perspective (Fig. 8.7). A compound dinucleotide polymorphism, rs368234815-ΔG or rs368234815-ΔG-TT, located in exon 1 of *IFNL4*, is determinative of gene expression.[612] Frameshifting of the *IFNL4* gene caused by the TT variant results in premature termination and non–sense-mediated RNA decay, while rs368234815-ΔG encodes a full-length 179–amino acid IFN-λ4 protein (Fig. 8.7).[612] Spontaneous clearance of acute HCV infection is much more likely in individuals who carry the loss of function rs368234815-TT allele when compared with those who carry a functional ΔG allele encoding IFN-λ4.[16,612] Hepatic ISG activity is higher in chronically infected patients who carry a rs368234815-ΔG allele, and the response to pegIFN/riba therapy is poor.[294,377,772] The favorable TT allele is much less common in individuals of African versus European or Asian ancestry, providing an explanation for racial disparities in the response to pegIFN/riba therapy.[612] The second polymorphism, rs117648444 located in exon 2 of the functional *IFNL4* (rs368234815-ΔG) gene, encodes serine (S) or proline (G) at amino acid 70 of IFN-λ4.[612] The IFN-λ4-S70 (rs117648444-A) variant elicits an inferior ISG response in cultured cells when compared with IFN-λ4-P70, perhaps because of reduced protein stability.[744]

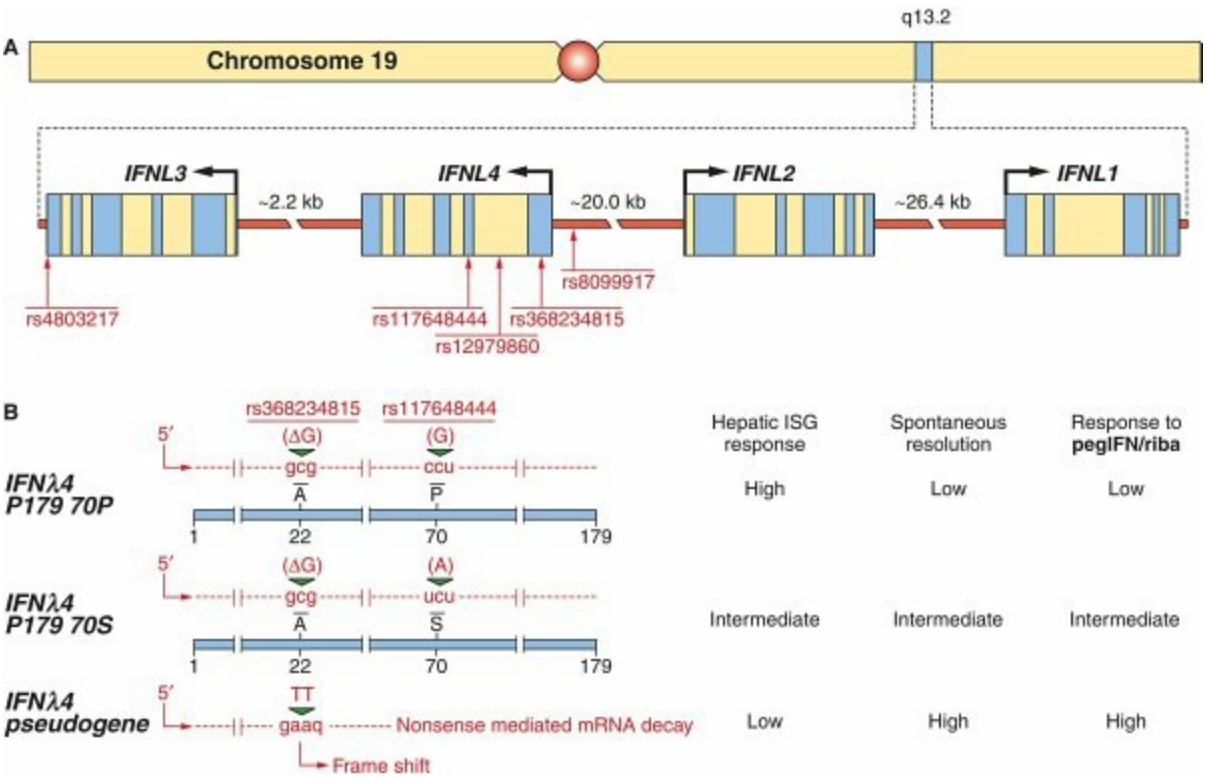

FIGURE 8.7 Influence of type III interferon on HCV infection outcome and treatment. A: Genomic organization and polymorphisms in the type III interferon locus located on human chromosome 19q13. Four genes (*IFNL1*, *IFNL2*, *IFNL3*, and *IFNL4*) express IFN-λ proteins in the indicated orientation. Polymorphisms associated with HCV infection outcome and treatment response are indicated. Polymorphisms rs8099917 (noncoding, upstream of *IFNL4*) and rs12979860 (noncoding, *IFNL4* intron 1) were associated with responsiveness to pegIFN/riba treatment[239,727,736] and infection outcome[623,754] by GWAS analysis. Polymorphisms rs368234815 (coding, *IFNL4* exon 1) and rs117648444 (coding, *IFNL4* exon 2) were identified with discovery of the *IFNL4* gene.[612] These polymorphisms are in strong linkage disequilibrium.[554] Polymorphism rs4803217 is located in a regulatory domain of the *IFNL3* gene. It is in linkage disequilibrium with rs12979860, and gene expression may be

modulated by HCV infection.[476] **B:***IFNL4* polymorphisms and consequences for gene expression and HCV infection and treatment. The *IFNL4* exon 1 polymorphism (rs368234815; ΔG/TT) results in expression of a 179–amino acid IFN-λ4 protein (ΔG) or a frameshifting loss of function variant (TT dinucleotide) that results in a premature stop codon and nonsense-mediated mRNA decay. The polymorphism in *IFNL4* exon 2 (rs117648444; G/A) determines expression of proline (G) or serine (S) at IFN-λ4 position 70. The *IFNL4* rs368234815:rs117648444 haplotype ΔG:G is associated with the highest levels of liver ISG expression and the lowest probability of a positive response to pegIFN/riba therapy and spontaneous clearance of infection. The ΔG:A haplotype is associated with intermediate ISG expression and treatment response or infection outcome. ISG activity is lowest in individuals carrying the rs368234815-TT loss of function variant and associated with higher rates of treatment response and spontaneous clearance of infection.

Homozygosity for rs117648444-A is associated with lower hepatic ISG levels and an intermediate response to pegIFN/riba therapy (Fig. 8.7).[744] Additional polymorphisms in the *IFNL* locus associated with a positive treatment response[239,727,736] and spontaneous clearance of HCV infection[623,754] were identified by genome-wide association studies (GWAS). These polymorphisms have less predictive power, and their association with HCV clearance is explained by strong linkage disequilibrium (LD) with rs368234815-ΔG/ rs368234815-TT.[554] As an example, one SNP (rs12979860-C or rs12979860-T) identified by GWAS is located in intron 1 of *IFNL4*, and the unfavorable variant (rs12979860-C) is almost always inherited with rs368234815-ΔG.[612] One additional polymorphism (rs4803217) is located in a 3′ untranslated region of *IFNL3* (Fig. 8.7).[476] The unfavorable allele is repressed by HCV-induced cellular microRNA species that destabilize or decay *IFNL3* mRNA.[476] The contribution of this mechanism to HCV infection outcome is not yet clear as the polymorphism is

in strong linkage disequilibrium with rs12979860.

How expression of IFN-λ4 in individuals carrying the unfavorable rs368234815-ΔG allele impairs spontaneous clearance of acute infection and type I IFN-based antiviral therapy is not understood. IFN-λ4 mRNA is detected in the HCV-infected liver,[24,155] although at low levels perhaps because of posttranscriptional or posttranslational control of gene expression.[296] IFN-λ4 binds to the same heterodimeric (IL-10Rβ/IFNLR1) cellular receptor as other IFN-λ proteins[278] and elicits a robust ISG response in primary human hepatocytes.[193,396,477,552] One notable feature of the ISG response is strong induction of negative regulatory factors including ubiquitin-specific protease 18 (USP18). USP18 blocks type I IFN signaling through the IFNAR1/IFNAR2 receptor,[193,552,724,725] but has no impact on type III IFN signaling through the IL-10Rβ/IFNLR1 receptor.[65] Silencing of USP18 expression in IFN-λ4–treated hepatocytes restores type I IFN signaling,[193,725] suggesting a role for negative regulatory mechanisms in the poor responsiveness to pegIFN/riba therapy. Consistent with this possibility, USP18 is selectively up-regulated in the liver of chronically infected patients with a preactivated ISG response associated with the rs386234815-ΔG haplotype.[113,156,552]

Constitutive ISG activity in the liver of persistently infected patients normalizes with initiation of DAA treatment.[17,86,99,620] These observations provide additional evidence that strong ISG activity in the chronically infected liver is driven directly by HCV replication. As noted above, unfavorable *IFNL* haplotypes are associated with a slower early decay in viremia during DAA treatment[485] and an increased risk of relapse.[553] Whether *IFNL* haplotype influences the timing or magnitude of ISG recovery, with effects on HCV decay and clearance during DAA treatment, remains to be determined. Intriguingly, two studies have demonstrated that an unfavorable *IFNL4* haplotype may exert pressure against HCV, selecting for amino acid substitutions in the HCV NS5A protein that could potentially facilitate virus replication in an environment of strong ISG activity or affect susceptibility to DAA inhibitors.[27,826]

Evasion of the type I/III IFN responses

ISG induced by HCV infection have the potential to interfere with every

stage of the viral replication cycle, including entry, replication, and release.[494,495,662,663,839] Viral evasion mechanisms that subvert the innate antiviral response were investigated by ectopic expression of individual HCV proteins in transformed cells lines and with replicons and HCV isolates adapted for replication in hepatocyte cell lines (Fig. 8.5).[169,422] More recently, mice repopulated with human hepatocytes have been infected with genetically modified HCV isolates to demonstrate the importance of viral proteins like NS5A in evasion of the interferon response.[289] Although these approaches have limitations, they suggest the possibility of a multilayered defense against antiviral effector mechanisms. Failure of cellular sensors to detect HCV RNA is a potential first line of defense. Consistent with this possibility, cytosolic receptors are excluded from the membranous web of rearranged cytoplasmic vesicles where HCV replicative intermediates are generated.[546] HCV RNA is also sequestered in DMV produced by autophagy[209] and in extracellular vesicles that are exported from cells via a pathway that bypasses the endosome and TLR3 detection (Fig. 8.5).[263] Blockade of signaling pathways downstream of the TLR and RLR receptors HCV proteins provides an additional defensive layer.[169,422] The NS3/4A protease targets the adaptor proteins MAVS[426,500] and TRIF[419] for cleavage in infected cells, effectively blocking ISG responses. TRIF may also be degraded by HCV NS4B through a caspase 8–dependent mechanism.[428] Reduced stability of transcripts encoding IFN-λ2 and IFN-λ3[476] or the type I IFN receptor[320] by microRNAs induced in hepatocytes by HCV has been described. Signaling from the type I and III IFN receptors through the JAK-STAT pathway may also be blocked by HCV proteins E2 and NS5A when expressed in cell lines.[169,422] HCV infection may also alter activation of the ISG PKR. On one hand, NS5A protein expressed in cultured cells and in transgenic mice bound to PKR and prevented activation of its antiviral ISG activity (Fig. 8.5).[229,381] However, it was also reported that HCV activates PKR to block cap-dependent translation of host effector ISG proteins,[31,234] an evasion mechanism that would not impair IRES-mediated translation of the HCV genome (Fig. 8.5). It is possible that blockade of PKR activation in the early stage of infection during initial translation of the RNA genome is advantageous for replication. A transition to PKR activation at a later stage in the replication cycle would impair translation of antiviral ISG effector proteins and perhaps provide an explanation for the paradoxical coexpression

of HCV RNA genomes and ISG mRNA in infected hepatocytes.[808] Finally, NS4A-mediated MAVS cleavage has been visualized *in situ* in infected hepatocytes, suggesting that this evasion mechanism is active in the liver.[419,500] Whether other evasion mechanisms defined in cell culture models contribute to evasion of innate immune responses or persistence of HCV remains to be established. Sustained HCV replication through the acute and chronic phases of infection, especially in subjects with high constitutive ISG activity associated with rs368234815-ΔG and related polymorphisms, cannot be fully explained by these models. Molecular mechanisms that contribute to evasion of the response may require a more detailed understanding of ISG activity in the membranous web where HCV genome replication and assembly occur (see Chapter 7). Differences in ISG kinetics, susceptibility to negative regulation, and the hepatic antiviral environment induced by one or more of the IFN-*λ* proteins are also likely to be important factors in understanding why innate IFN responses are ineffective at HCV control.[65,68,327,552,680]

NK cell responses and HCV evasion

NK cells with enhanced cytotoxic activity and production of antiviral cytokines are detected in blood during the acute hepatitis C.[23,370,575] NK cell activation is driven by direct binding of cytokines like type I IFN and IL-12 that are produced as part of the strong acute phase ISG response elicited by HCV. Monocytes also contribute to NK cell activation during acute hepatitis C through inflammasome-dependent secretion of IL-18.[677] NK cell–mediated suppression of HCV replication through killing of infected hepatocytes and production of IFN-*γ* and TNF-*α* that provide noncytolytic control of HCV replication was documented in cell culture models.[370,380,385,712] Their role in providing complete or partial control of HCV replication in patients with acute HCV infection is uncertain. This analysis has been hampered by limited access to the liver, where NK cells constitute one-third to one-half of all intrahepatic lymphocytes.[385] The timing and strength of the circulating NK- and HCV-specific T-cell responses appear to be linked in individuals with a robust pattern of acute phase HCV replication.[23,370,575] It is therefore difficult to separate the relative contribution of these innate and adaptive populations to virus control.[23,370,575] NK cell activation also occurs in individuals exposed to very low HCV inocula through intravenous drug use or

occupational needlestick injuries. Indeed, NK activation may be a very sensitive marker of exposure to HCV as it has been observed in cases where virus inoculum was low and there was no virologic evidence of infection. NK cells might contribute to an abortive or highly attenuated course of HCV infection in this setting. In support of this possibility, immunogenetic studies revealed that homozygosity for genes encoding the inhibitory KIR2DL3 receptor on NK cells and the HLA-C1 ligand on target cells increased the probability of spontaneous resolution of HCV infection.[356,751] The effect of this compound genotype on infection outcome was most apparent in injection drug users[246,356,720,751] and in cases of needlestick injury,[805] where a lower NK cell activation threshold may be advantageous in rapidly containing infections established with a low HCV inoculum. Other host factors may also regulate NK cell function in acute hepatitis C. For example, acute phase NK cell effector functions were enhanced in individuals with *IFNL* genotypes that favor virus control.[151] Because NK cells lack type III IFN receptors,[151,522] any effect of this cytokine family on activation or effector function must be indirect.

Chronic HCV infection has a pervasive effect on the NK cell compartment. Circulating NK cells are clearly activated in the chronic phase of infection as assessed by enhanced expression of HLA-DR, CD69, and multiple NK cytotoxicity receptors.[633] They are also skewed toward cytotoxic activity with decreased production of IFN-γ and TNF-α.[13,284,518,557,633,675] The repertoire of inhibitory and activating NK receptors is also altered in chronic infection.[718] NK cell activation and polarization toward cytotoxicity in the chronic phase of infection most likely reflect continuous stimulation by innate cytokines. Type I IFN is likely a key driver of this NK cell phenotype in chronic hepatitis C.[171,510] This mechanism is supported by the observation that the STAT1, an ISG that is essential for signaling and induced by type I IFN stimulation, is increased in NK cells from patients with chronic hepatitis C.[171,510] As with ISG responses,[17,86,99,620] NK cell function and responsiveness to type I IFN therapy are normalized by successful DAA therapy,[675,676] although alterations to the NK receptor repertoire imposed by chronic HCV infection are more durable and perhaps not reversible.[718]

Mechanisms to subvert NK cell effector function and recognition of

HCV-infected target cells have been identified using cell culture models. Expression of class I HLA-C and HLA-E molecules, which are ligands for inhibitory NK cell receptors, may be stabilized on the surface of infected hepatocytes by peptides derived from structural and nonstructural HCV proteins.[445,532,538] A direct inhibitory effect of HCV-infected cell lines, virions, and recombinant proteins on cultured NK cells has also been described.[136,633,765,820,824] HCV virions and component proteins could act by altering NK signaling or function, for instance, through cross-linking of cellular receptors,[136,765] but relevance of the mechanisms to evasion of the response in the liver remains to be established.

Cellular Immune Responses

Circulating HCV-specific CD4+ helper and CD8+ cytotoxic T cells are detected approximately 8 to 12 weeks after infection in humans and experimentally infected chimpanzees (Fig. 8.6).[129,410,506,689,748,749] The initial delay in generating a T-cell response, which is not yet explained, is a feature of most acute infections regardless of whether they resolve or persist. In overview, onset of the response is kinetically associated with a sharp decline in viremia and in some individuals with acute hepatitis (Fig. 8.6).[7,129,293,410,506,689,748,749] Resolution of acute infection requires a multifunctional CD4+[154,240,444,666,673] and CD8+[132,261,409] T-cell response that is sustained until after termination of HCV replication; premature loss of functional CD4+ T cell help is highly predictive of a persistent outcome.[7,293] Durable CD4+ and CD8+ T-cell memory is generated in humans and chimpanzees with infections that spontaneously resolve.[6,7,293,559,689,735] Reinfection elicits an accelerated memory T-cell response that is temporally associated with a sharply reduced duration and magnitude of viremia and a decreased risk of a persistent outcome when compared with primary HCV infection in humans[15,259,484,559] and chimpanzees (Fig. 8.6).[48,256,455,536,689] Antibody-mediated depletion of CD4+ helper[256] or CD8+ cytotoxic cells[689] from chimpanzees with naturally acquired immunity to HCV resulted in prolonged or persistent infection after rechallenge with the virus. Collectively, these observations provide a strong argument that sustained HCV-specific T-cell immunity is critical for spontaneous resolution of acute primary infections and secondary infections in immune individuals who are reexposed to the virus.

T-cell immunity in acute resolving and persisting infections

At least three functionally distinct HCV-specific CD4+ T-cell populations that provide help for CD8+ T-cell or B-cell responses are detected in blood during acute resolving infection. Help for the CD8+ T-cell response is provided by HCV-specific CD4+ T helper 1 (Th1)[221,673,770] and T helper 17 (Th17)[339] populations. A sustained response by CD4+ T cells that produce the signature Th1 cytokine IL-2 is associated with functional antiviral CD8+ T-cell immunity and resolution of HCV infection.[221,673,770] HCV-specific Th17 CD4+ T cells that produce IL-21, a cytokine that also supports development of effector CD8+ T-cell responses, are primed during acute infection.[339] Elevated serum IL-21 titers are associated with stronger circulating CD8+ T-cell responses and resolution of acute HCV infection.[339] Antiviral CD4+ T cells with a T follicular helper (Tfh) phenotype are also visualized in blood during acute HCV infection.[629] This response, which directs germinal center formation that is essential for humoral immunity, was associated with development of HCV-specific antibodies.[629] Premature loss of the CD4+ T-cell response is a defining feature of acute infections that persist.[215,221,506,705,774,813] Breadth of the response, defined by the number of HLA class II epitopes targeted by circulating CD4+ T cells, is not necessarily a determinant of infection outcome.[666] Approximately 10 class II epitopes (range 2–26) located predominately in NS proteins (particularly NS3 and NS4) were detected in the early phase of acute resolving infection, and this pattern was not significantly different in time-matched samples from infections that persisted.[666] HCV antigen–driven proliferation and cytokine production by early acute phase CD4+ T cells are, however, comparatively poor in infections that persist.[7,293,666] Failure of the response is marked by a progressive decline in CD4+ T-cell frequencies and a narrowing repertoire of targeted HCV epitopes.[132,143,409,666]

CD8+ T cells are multifunctional in infections that resolve. They degranulate, indicating the potential for cytotoxic killing of infected hepatocytes, and produce antiviral cytokines like IFN-γ and TNF-α.[132,262,338,506,749,774] The response is also considered broad, targeting on average 9 to 10 epitopes localized mostly to NS proteins but with no obvious

pattern of dominance.[397,399,706] CD8+ T cells in acute resolving infections follow a typical pattern of differentiation with transient expression of programmed cell death 1 (PD-1), a marker of T-cell activation during acute infection,[342,685] transcription factor T-bet (T-box expressed in T cells) that regulates effector functions,[389] and the antiapoptotic transcription factor BCL-2.[685] With resolution of infection, CD8+ T cells gain expression of CD127, a component of the IL-7 receptor that facilitates homeostatic proliferation required for maintenance of the memory response.[672,685,749,774] Progressive loss of CD8+ T-cell function, including HCV antigen–driven proliferation, cytotoxic activity, and production of antiviral cytokines, leads to transient and incomplete control of HCV replication.[132,262,338,506,749,774] Circulating CD8+ T cells can target multiple class I epitopes in the early phase of acute infection, but the repertoire typically narrows as persistence is established.[132,253,398,409] Intrahepatic CD8+ T cells do persist in the chronically infected liver, and the response is multispecific in some humans and chimpanzees.[254,379,499,544]

Evasion of T-cell immunity

CD4+ T-cell failure compromises CD8+ T-cell and B-cell responses, but the cause is unknown. CD4+ T-cell proliferation and cytokine production are impaired by HCV core protein binding to the cellular C1qR complement receptor[362] and HCV RNA genome binding to toll-like receptor 7 (TLR7).[486] All CD4+ T cells express C1qR and TLR7, however, and so these mechanisms are difficult to reconcile with a defect that is HCV specific. Host genetics may be a factor. Certain HLA class II alleles have been associated with spontaneous clearance (for instance, *HLA-DQB1*03:01*, *DRB1*01:01*, *DRB1*03:01*, and *HLA-DRB1*11:01*) or persistence (*DQB1*02:01*) of HCV infection.[167,238,280,503,750,790] There is as yet no clear evidence that the encoded class II molecules present dominant HCV epitopes that are more or less protective against persistence. Mutational escape in HCV class II epitopes driven by CD4+ T-cell selection pressure appears to be uncommon. Nonsynonymous polymorphisms in the HCV genome have been associated with shared class II HLA haplotypes in populations of chronically infected humans.[443] While these HLA-related polymorphisms in the viral genome are consistent with CD4+ T-cell selection pressure, emergence of escape

mutations in known dominant class II epitopes is difficult to discern in individual humans[213,577,666] and chimpanzees,[228] especially when compared with the very visible evidence of HCV evolution in epitopes targeted by CD8+ T cells and antibodies as described below. A mechanism by which CD4+ T cells exert direct selection pressure against HCV, for example, by cytolysis of virus-infected hepatocytes, has not yet been described. Many HCV-specific CD4+ T-cell populations detected in blood during the early acute phase of persisting infections drop below the threshold for detection. It is possible that they are deleted from the CD4+ T-cell repertoire, but localization of some populations to the chronically infected liver cannot be excluded.[577] HCV-specific CD4+ T cells that circulate in the chronic phase of infection express multiple inhibitory receptors, including PD-1, CTLA-4, CD305, and CD200R.[630] Th1 and Th17 helper function has been restored by antibody-mediated blockade of inhibitory receptor signaling in cell culture models.[339,630,776] Nonetheless, it is not yet clear if this mechanism fully explains functional silencing of CD4+ T cells. Other suppressive pathways may be operational, including T regulatory (Treg) activity that acts through production-suppressive cytokines like IL-10 and TGF-β.[630]

HCV-specific CD8+ T cells are maintained in the chronically infected liver for decades but provide no apparent control of persistent virus replication. Direct viral interference with antigen-processing machinery or class I MHC expression could protect infected hepatocytes from CD8+ T-cell recognition as demonstrated in cell culture models.[336,358] Enhanced regulatory T-cell activity during the acute and chronic phases of infection could also suppress CD8+ T-cell proliferation and effector functions,[67,89,339,721] but an association with infection outcome has not been observed. As detailed below, evasion of the CD8+ T-cell response in chronically infected humans and chimpanzees occurs by (a) mutational escape of HCV class I epitopes and (b) functional exhaustion.

Mutational escape of class I HCV epitopes occurs in humans[84,133,747,756,758] and chimpanzees[180] who develop chronic infections. Multiple cross-sectional studies have also demonstrated enrichment of amino acid changes in predicted or confirmed class I epitopes among chronically infected individuals with who share HLA alleles.[212,237,394,625,647,757] Approximately 25% to 50% of class I epitopes in the dominant NS proteins acquire escape mutations, although this frequency is variable between

individuals and studies.[132,387,489,647,758] Escape mutations are a consequence of CD8+ T-cell selection pressure as the rate of nonsynonymous mutation is significantly higher in class I restricted epitopes when compared with the remainder of the HCV genome.[84,94,180,387,589] The rate of mutation within class I epitopes slows as persistence is established.[67,94,133,208,387] This is consistent with stability of class I escape mutations over years of persistent HCV replication.[647,654,769] Mutation of intact epitopes during chronic infection has been described but is uncommon.[133,794] Failure to generate an effective CD8+ T-cell response against a class I escape variant may be due in some instances to a gap in the human T-cell repertoire.[812] In most cases, however, it almost certainly reflects impaired generation of new mutant-specific CD8+ T cells in an environment of inadequate HCV-specific CD4+ T-cell help and high antigen load. From a functional perspective, escape mutations within epitopes can impair class I MHC binding[133,756] or CD8+ T-cell receptor recognition.[758,812] Mutations in sequences adjacent to or within an epitope can also alter proteasome processing of the HCV polyprotein, resulting in epitope destruction.[360,671,797] Replicative fitness of HCV can be impaired by escape mutations.[144,654,769] An iterative process of amino acid replacement to efficiently balance replication and escape from CD8+ T-cell recognition can occur in the acute phase of infection while the epitope is still under selection pressure.[769] Impaired replication during the chronic phase of infection can also be offset by compensatory mutations that are sometimes distant from the epitope that contains an escape mutation.[212,548,558] Mutational escape of epitopes may spare cognate CD8+ T cells from a complete loss of function. They maintain the ability to proliferate in response to antigen stimulation, and expression of CD127 indicates a status that more closely resembles memory than exhaustion.[341,648] Effector function is sufficient to maintain selection pressure against some escaped epitopes in the chronic phase of infection.[295,756,832] As an example, reversion of HCV escape mutations was observed in chronically infected women during pregnancy, a setting where immune function is transiently attenuated.[295] Escape mutations were reacquired in the postpartum period with transient resurgence of a functional HCV-specific T-cell response.[295]

Class I epitopes that remain intact induce a more profound state of CD8+ T-cell exhaustion when compared with escaped epitopes.[51,341,648,773] A

transcriptional signature characteristic of exhaustion is evident in the early acute phase of infection (Fig. 8.8). Using integrative systems analysis, coordinated expression and rapid down-regulation of gene modules associated with metabolic function were observed in HCV-specific CD8+ T cells from patients with acute persisting but not resolving infections.[813] An early but transient transcriptional burst related to oxidative phosphorylation occurred within the first 12 to 18 weeks of infection and was linked to a pervasive effect on gene modules associated with nucleosomal regulation of transcription and T-cell differentiation and inflammatory pathways (Fig. 8.8). The unfavorable pattern of metabolic gene transcription in CD8+ T cells was also associated with loss of HCV-specific CD4+ T helper cells from circulation.[813] The exhausted phenotype in chronic infection is defined by low or no CD127 and sustained expression of PD-1 and other inhibitory receptors including cytotoxic T lymphocyte–associated antigen 4 (CTLA-4), T-cell immunoglobulin- and mucin-domain-containing molecule 3 (TIM-3), the NK receptor 2B4.[51,247,341,342,482,534,563,617,618,648,773,774]

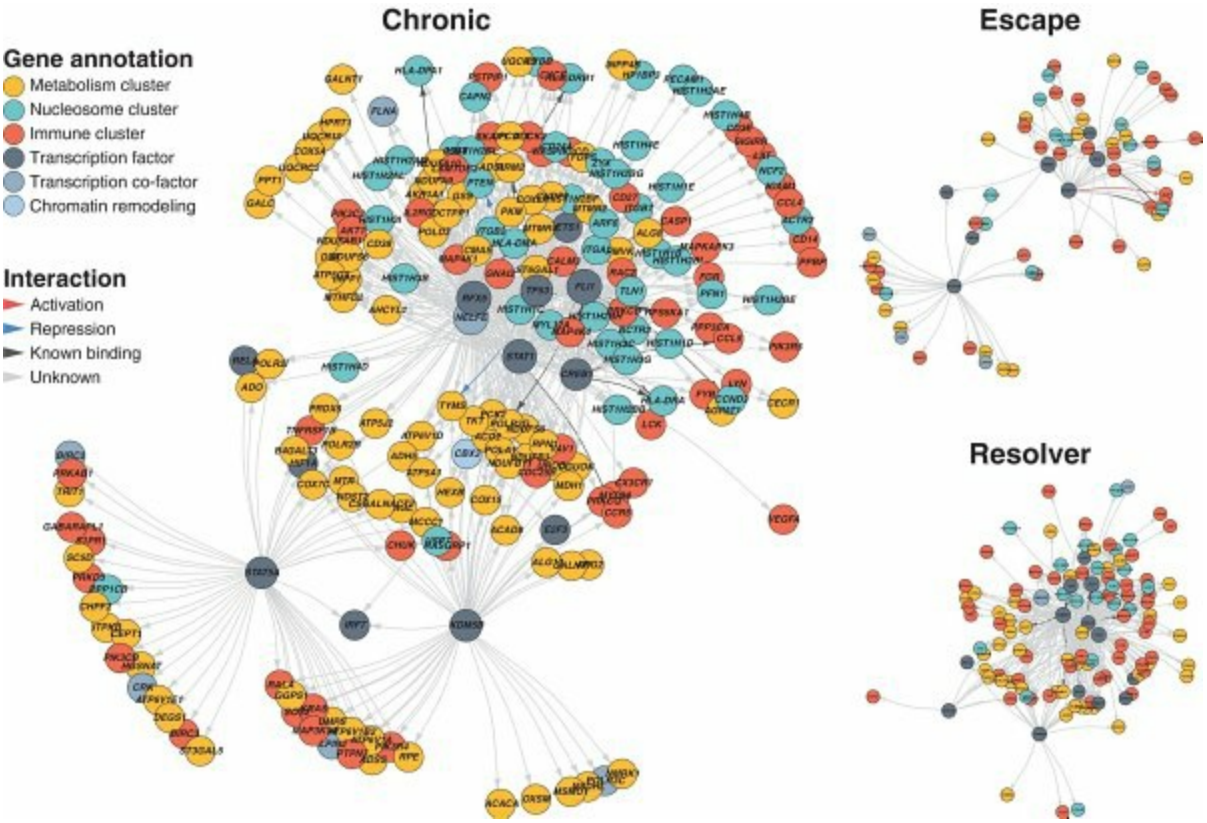

FIGURE 8.8 Transcriptional analysis of HCV-specific CD8+ T

cells in acute resolving and persisting HCV infection. Transcriptional activity was compared in HCV-specific CD8 T cells isolated at different time points from patients with resolving (resolver) and persisting HCV infections.[813] CD8+ T cells from chronically infected patients were further subclassified as (chronic) if they recognized intact class I HCV epitopes or escaped if they did not receive TCR signal due to viral escape mutations. A transcriptional network constructed from a weighted gene coexpression network analysis (WGCNA) is shown.[813] Dysregulated gene modules identified in the chronic but not resolver or escaped CD8+ T-cell populations were related to cell metabolism (most notably oxidative phosphorylation), nucleosomal regulation, and known immune response functions. Dysregulated gene modules were connected by coregulated transcription factors, demonstrating that the path to T-cell exhaustion is most likely an integrated process affecting different molecular pathways simultaneously and in a coordinated manner. (From Wolski, Foote, Chen, et. al. Early transcriptional divergence marks virus-specific primary human CD8(+) T cells in chronic versus acute infection. *Immunity* 2017; 47(4):648, with permission).

These CD8+ T cells also express eomesodermin (Eomes),[568] a transcription factor associated with exhaustion, and chromatin structure is more open at exhaustion regions than memory regions of the CD8+ T-cell genome.[674] Terminally differentiated CD8+ T cells are enriched in the chronically infected liver and programmed for death.[384,617–619] Of note, exhausted CD8+ T cells are continuously replenished from a pool of self-renewing HCV-specific $CD8^+$ T cells that are defined by expression of the CD127 memory marker and the transcription factor T-cell factor 1 (TCF1) that is important in formation and maintenance of immunological memory.[807]

Function can be restored to exhausted HCV-specific CD8+ T cells in culture models by antibody-mediated blockade of PD-1

signaling.[247,578,617,775] Anti–PD-1 antibodies have also been administered to persistently infected humans and chimpanzees. A greater than 4 log reduction in viremia was observed in 15% of subjects (3/20) who received the highest dose of a fully humanized IgG4 anti–PD-1 monoclonal antibody with no serious side effects.[236] By comparison, HCV viremia rarely varies by more than 0.5 log in the chronic phase of infection. An apparent cure of chronic HCV infection was achieved in one subject with an unfavorable *IFNL4* genotype who had previously failed type I IFN therapy.[236] Recovery of HCV-specific T-cell function was not assessed in these patients. Transient reduction of viremia and restoration of functional HCV-specific CD4+ and CD8+ T-cell immunity were also observed in one of three persistently infected chimpanzees treated with a humanized anti–PD-1 monoclonal antibody.[227] These studies provide direct evidence that signaling through coinhibitory receptor(s) contributes to CD8+ T-cell exhaustion in chronic hepatitis C. Failure of most treated individuals to respond to PD-1 blockade cannot yet be explained. Cell culture models have demonstrated that restoration of T-cell function may require blockade of additional inhibitory receptors like CTLA-4 or TIM-3.[482,533,563] Restoration of function to exhausted HCV-specific CD8+ T cells in cell culture may also be highly individualized as no clear hierarchy or dominance of inhibitory receptor usage has been observed.[563] Finally, anti–PD-1 antibodies probably act on the small pool of self-renewing CD8+ T cells[807] that are the source of exhausted, terminally differentiated CD8+ T cells. Success of inhibitory receptor blockade may depend on the size of the self-renewing pool, the repertoire of HCV epitopes they target, and the capacity of blocking antibodies to promote effector activity instead of exhaustion.

Recovery of T-cell immunity after antiviral therapy

T-cell immunity does not recover after successful treatment of chronic hepatitis C with pegIFN/riba.[5,7,293,507] DAA cure of infection leads to partial recovery of CD8+ T-cell effector function.[460,807] Termination of persistent HCV replication leads to loss of exhausted CD8+ T cells. CD8+ T cells that survive after DAA cure are derived from the $TCF1^{+}$ memory-like population. They proliferate after stimulation with escaped and intact epitopes, indicating that even the most profoundly exhausted populations can recover from this

self-renewing progenitor population.[460] Production of IFN-γ and TNF-α was weak, however, especially when compared with memory CD8+ T cells generated by resolution of acute infection.[807] To date, there have been few studies to assess the capacity of CD8+ T cells to control virus replication in a post-DAA setting. The question is of practical importance as reinfection after DAA cure has been documented.[461–463,501,592,665] In one study, 15/77 participants were reinfected at 18 months posttreatment, yielding a reinfection rate of 21.5/100 person-years, close to a recent estimated rate of HCV incidence among recent injectors (past 6 months) in the same community.[665]

Relapse of HCV replication in one subject 12 weeks after termination of DAA therapy resulted in expansion of memory-like TCF1+ CD8+ T cells that reacquired an exhausted phenotype as persistent infection was reestablished. In a second case study, CD8+ T cells targeting intact and escaped class I epitopes persisted in a chimpanzee for 2 years after DAA cure but failed to prevent a second chronic infection after experimental HCV rechallenge.[95] In summary, these early studies indicate that T-cell exhaustion is a pervasive and persistent mechanism of immune evasion that may be partially but not completely reversed after DAA cure.

Humoral Immune Response

The HCV E1 and E2 envelope glycoproteins elicit an acute phase antibody response in all infected humans with normal immune function, regardless of whether the infection resolves or persists. Seroconversion measured by E1 and E2 antibody-binding assays occurs several weeks to months after infection,[115,545] a delay that may reflect the slow onset of CD4+ T-cell help during acute hepatitis C (Fig. 8.6) (discussed in Cellular Immune Response). Anti-E1 and anti-E2 antibodies persist for life in infections that become chronic.[545] Antibody titers decline after spontaneous resolution of infection in individuals without ongoing exposure to HCV (Fig. 8.6).[373,513,670,735] Seroreversion occurs over a period of years in a subset of these cases,[373,670,735] as illustrated by a single-source HCV transmission accident in the former East Germany, where HCV-specific T cells but not antibodies were detected in about 40% of subjects 18 to 20 years after spontaneous recovery from acute hepatitis C.[735] Reinfection can occur in humans[259,484]

and chimpanzees[48,195,609] after spontaneous resolution of acute hepatitis C (Fig. 8.6), indicating that antibody-mediated sterilizing protection is uncommon, if it occurs at all.

Neutralizing function of serum antibodies is assessed using hepatitis C virus pseudoparticles (HCVpp) bearing HCV E1 and E2 envelope glycoproteins[47,300] and hepatitis C virus cell culture (HCVcc) adapted viruses[796] that facilitate analysis of the kinetic, titer, and breadth of the response. HCV E1 and E2 sequence diversity, which ranges from approximately 30% between genotypes to 10% between subtypes,[701] is an important consideration in measuring neutralizing responses. Further complexity is observed within individuals, where HCV circulates as an evolving swarm of distinct strains that may differ in susceptibility to antibody neutralization.[194,459] Because E1 and E2 sequences vary and can evolve rapidly during acute infection, neutralizing antibody activity within HCV-infected individuals is measured against HCVpp bearing E1 and E2 glycoproteins from cocirculating (i.e., autologous) viruses. Neutralizing antibodies are not necessarily required for control of acute phase virus replication; spontaneous resolution can occur in cases of primary immune deficiency affecting B-cell development[10] and in chimpanzees where seroconversion is often not observed at the time of virus control.[49] These are exceptional circumstances, however, and accumulating evidence is consistent with a role for neutralizing antibodies in limiting HCV replication and spread in the liver. Antibodies that neutralize HCVpp infectivity appear at about the time of seroconversion,[163,401,585] and an early and broad response has been associated with spontaneous clearance of acute infection.[36,184,560,585] Single-source outbreaks of HCV infection have provided important insight into the acute phase neutralizing antibody response.[401,585] As an example, control of acute hepatitis was associated with rapid induction of neutralizing antibodies against the infecting virus in pregnant women treated with anti-D immunoglobulins contaminated with a single HCV strain.[585] Neutralizing antibody responses were absent or of low titer in subjects following a chronic course.[585] Antibody responses that broadly neutralize infectivity of HCVpp bearing multiple, diverse genotype 1 envelope glycoproteins are also associated with resolution of acute primary infection.[560] Rapid recall of broadly neutralizing antibodies may also contribute to the much shorter duration and magnitude of viremia, and decreased likelihood of HCV

persistence, in individuals who are reexposed to the virus after spontaneous clearance of infection (Fig. 8.6).[559]

Patterns of antibody neutralization against genetically diverse E1 and E2 species were defined using HCVpp and HCVcc panels representative of different genotypes and subtypes. These studies revealed that HCV genotypes and subtypes do not correspond to neutralization serotypes.[560,740] Sensitivity to neutralization instead varies widely for isolates within HCV genotypes and subtypes, as determined with HCVpp panels that encompass most of the known global diversity of HCV genotype 1 envelope sequences.[37,98,777] Mechanistic insight into antibody-mediated neutralization has advanced with resolution of the HCV E2 ectodomain structure by x-ray crystallography[357,375] and development of murine and recombinant human monoclonal antibodies against E1 and E2.[36,78,244,329,353, 498,561,562,581] Neutralizing epitopes map to the E1 and E2 glycoproteins and the E1/E2 complex that is cross-linked on the virion surface.[352,767,792] Neutralizing responses against E1 and the E1/E2 complex are the least well characterized. Two epitopes have been defined in E1,[332,349,498] including one that is recognized by monoclonal antibodies that neutralize several HCV genotypes.[498] Conservation of this epitope sequence across several genotypes indicates that E1 has an important but still undefined role in the HCV entry process. E2 is the dominant target of antibodies that neutralize HCV entry at a postattachment step.[652,791] This heavily glycosylated and compact globular structure is composed of β-strands and random coils flanked by two small α-helices.[357,375] It binds at least two entry receptors on hepatocytes, the CD81 tetraspanin and the high-density lipoprotein receptor scavenger receptor class B type I (SR-BI) (see Fig. 8.3).[101] The neutralizing antibody response is directed predominately against epitope clusters on the exposed surface of E2 (Fig. 8.9). The clusters localize to the conserved neutralizing face of E2 and hypervariable region 1 (HVR1; aa 384–410). HVR1 is functionally important for HCV entry as it guides or modulates E2 interaction with the SR-B1 cellular receptor,[606] but is under few structural constraints and readily tolerant of amino acid substitutions. Neutralizing antibodies directed against HVR1 are often isolate or strain specific and exert selection pressure leading to emergence of escape variants.[163,198,395] Broadly neutralizing antibodies recognize epitopes in the conserved, mostly hydrophobic neutralizing face of E2 that is essential for CD81 binding (Fig. 8.9).[36,329,561,562,581] The

neutralizing face is composed predominately of the E2 front layer (amino acids 421–459) and CD81 binding loop (amino acids 519–535), structures that are highly flexible[376] and not obstructed by glycans. Epitopes within the neutralizing face localize to three overlapping or adjacent clusters that are essential for CD81 binding, as determined by mapping with murine and recombinant human monoclonal antibodies that cross-neutralize viruses from different HCV genotypes (Fig. 8.9). One cluster, designated antigenic site 412 (AS412) or domain E, spans amino acids 412 to 423 immediately downstream of HVR1.[352,767] Immunogenicity of the AS412 E2 region is poor in natural infection, as broadly neutralizing antibodies are detected in only 2% to 15% of infected humans.[351,739,741] The other two epitope clusters within the neutralization face are composed of amino acids in the E2 front layer (aa 434–446, designated AS434 or domain D) and discontinuous amino acids from the front layer (aa 426–443) and CD81 binding loop (aa 529–531) (designated antigen region 3, AR3) brought together by the overall fold of the E2 protein (Fig. 8.9).[352,767] Passive transfer of broadly neutralizing monoclonal antibodies targeting epitopes in AS412,[152] AS434,[350] and AR3[244,404] protected humanized mice from challenge with HCV, including a complex quasispecies in one study.[404] Termination of an established infection in a humanized mouse was also observed after infusion of monoclonal antibodies against AR3 epitopes.[146] Broadly neutralizing monoclonal antibodies targeting conserved AS412 epitopes in the neutralizing face also prevented or modified the course of HCV infection in chimpanzees and humans.[124,517,702]

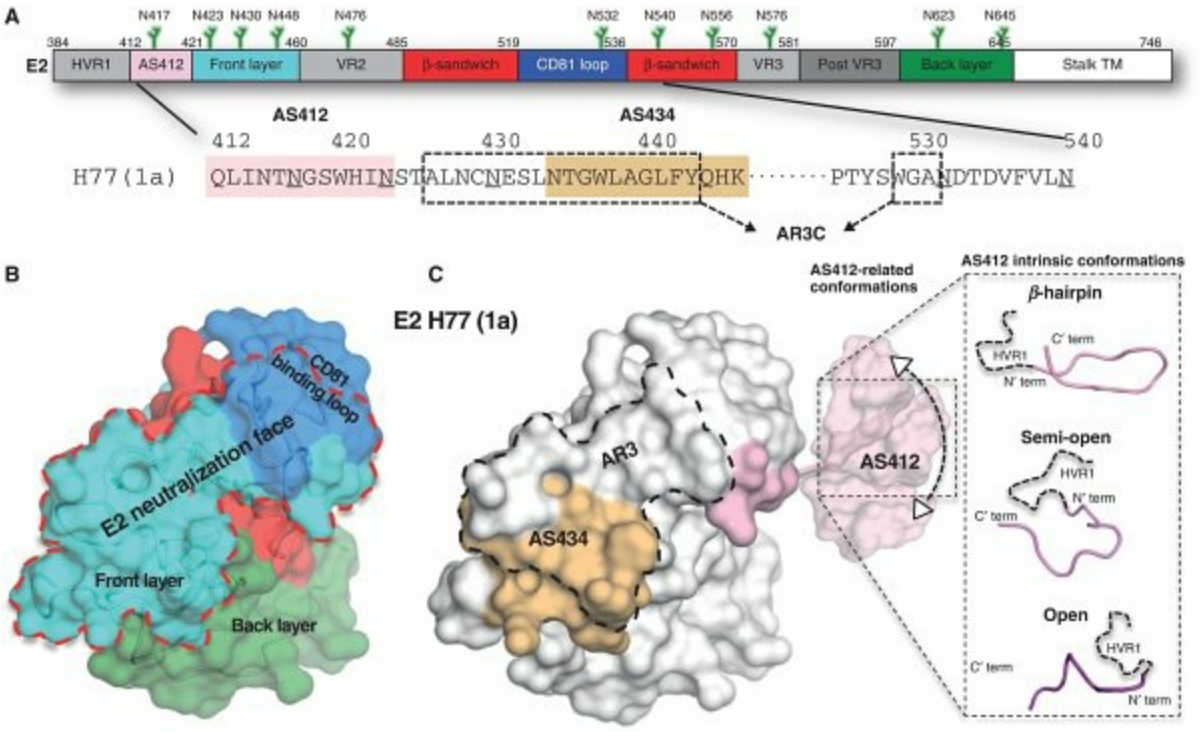

FIGURE 8.9 The HCV E2 neutralizing face and localization of epitopes. The x-ray crystallographic structure of an HCV genotype 1a (H77) E2 envelope glycoprotein complexed with an antibody against the AR3 region. **A:** E2 ectodomain schematic (aa 384–746, based on the prototypic isolate H77 numbering). Structural components including variable regions (*gray*), AS412 (domain E) (*pink*), front layer (*cyan*), *β*-sandwich (*red*), CD81 binding loop (*blue*), back layer (*green*), and the stalk and transmembrane regions (*white*) are shown. The AS412, antigenic region 3 (AR3), and AS434 neutralization epitopes are marked in *pink*, *dashed rectangle*, and wheat. The N-linked glycosylation sites surrounding the neutralizing face (N417, N423, N430, N532, and N540) are underlined. **B:** Surface representation of the E2 structure[375] with the structural components colored as in **(A)**. The neutralizing face is marked by a *red dashed line*. **C:** Neutralizing epitopes on the E2 structure. The conformational flexibility of AS412[376] related to E2 is schematically shown. The three known AS412 conformations (*β*-

hairpin, semiopen, and open) for neutralization are shown on the right. (From Tzarum N, Wilson IA, Law M. The neutralizing face of hepatitis C virus E2 envelope glycoprotein. *Front Immunol* 2018;9:1315, with permission.)

Common features of broadly neutralizing human monoclonal antibodies that recognize epitopes in the E2 neutralizing face have emerged. Those targeting the AS434 and AR3 epitopes utilize immunoglobulin heavy chains with a V_H*1-69* encoded variable segment.[36,490] A detailed analysis of monoclonal antibodies from two subjects who spontaneously cleared HCV infection suggests that antibody genes contain few somatic mutations, but those that do appear are important for efficient neutralization of the cocirculating HCV quasispecies swarm late in acute infection.[36,361] Of note, broadly neutralizing antibodies with these features also appear in individuals with chronic hepatitis C.[352,767] It is likely that they appear too late in the course of acute infection to limit virus replication, but differences in their physical interaction with conserved epitopes in highly flexible E2 structures can't be excluded.

HVR1 is susceptible to selection pressure by neutralizing antibodies because of its highly flexible structure and tolerance of amino acid substitutions (Fig. 8.10).[344,738,802] Timing of the first appearance of antibody-driven mutations first appears in HVR1, and the consequence for infection outcome may depend on the kinetics and breadth of the acute phase neutralizing response.[163,198,395] An early, rapid pace of nonsynonymous mutation in HVR1 is associated with spontaneous resolution of infection[437] and marks the coincident onset of a broadly neutralizing antibody response targeting HVR1 and epitopes in the conserved neutralizing face of E2 that are constrained from mutation.[163,361,560,585]

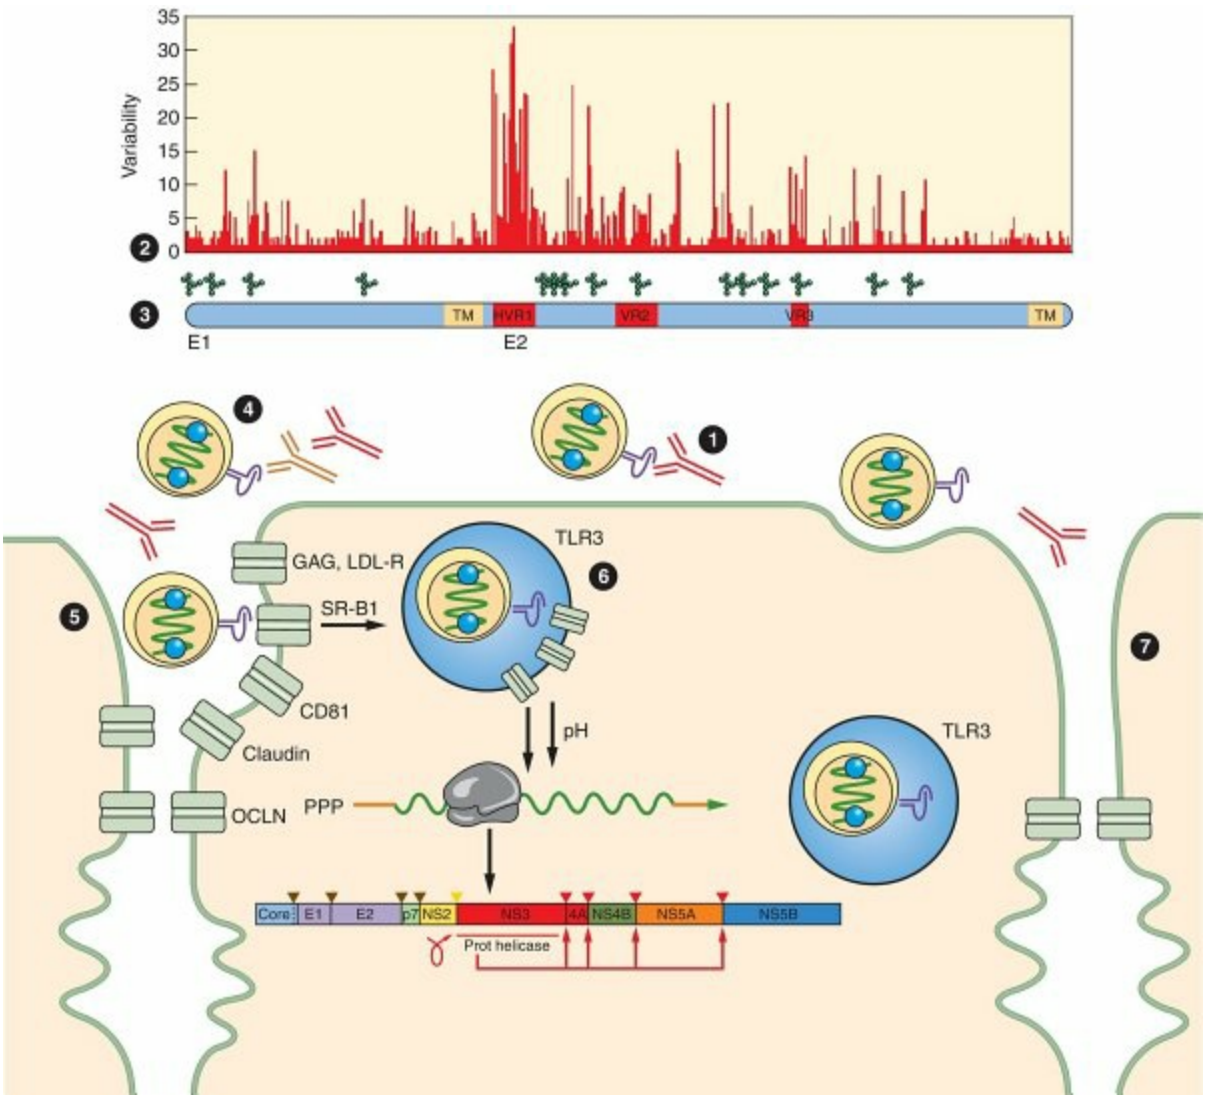

FIGURE 8.10 Evasion of anti–hepatitis C virus (HCV) antibody-mediated responses. Neutralization of HCV by antibodies can block infection of the cell (*1*). Binding of neutralizing antibodies (*red*) can be evaded by variability in the envelope proteins (*2*) illustrated here in a plot of Wu-Kabat amino acid variability[815] and by dense glycosylation at approximately 15 positions (*3*). Nonneutralizing antibodies (*4*, *green*) and lipoproteins (*5*) may hinder neutralizing antibody binding to HCV envelope glycoproteins, and delayed exposure of conserved domains until late in the entry process may prevent their recognition on free virions (*6*). Cell-to-cell transfer of virions is

resistant to neutralizing antibodies *in vitro*, suggesting an additional mode of escape for local spread of infection (*7*). Along the envelope gene map are indicated transmembrane regions (TMs), hypervariable region 1 (HVR1), and variable regions 2 (VR2) and 3 (VR3, the intergenotypic variable regions IgVR).

Onset of the neutralizing antibody response and HVR1 diversification is typically delayed in acute infections that persist.[300,440,496,585,713] The pace of HVR1 diversification accelerates with the transition to chronic infection.[436] Nonsynonymous mutation continues through the chronic phase of infection and provides escape from neutralization[46,440,496,794] as illustrated by longitudinal study of a patient through 25 years of acute and chronic infection.[794] Narrowly focused acute phase neutralizing activity broadened significantly in chronic infection to neutralize distant genotypes and autologous viruses present at earlier acute and chronic time points. Serum antibodies did not, however, neutralize contemporaneous viruses, and resistance was associated with ongoing nonsynonymous mutation within HVR1.[794] Escape mutations do occur in conserved epitopes of the neutralization face, but appear to be uncommon[559,639] and can impair HCV fitness because of their proximity to CD81 binding residues.[348,361] As an example, accumulation of polymorphisms in the E2 front region and VR2 caused a partial resistance to early, broadly neutralizing antibodies targeting the conserved AR3 region.[361] Resolution of acute HCV infection was associated with reduced E2 binding affinity for CD81 and SR-B1 and progressive loss of HCV replicative fitness.[361]

Extraepitopic mutations can also impair recognition of E2 by broadly neutralizing antibodies,[37,175,347] in some instances by modulating the use of SR-BI and CD81 in virus entry (Fig. 8.10).[175] Nonneutralizing antibodies that bind HRV1 and other E2 domains may also sterically interfere with recognition of the neutralizing face by broadly neutralizing antibodies.[346,838] The E2 neutralization face is also physically shielded by HVR1,[608] extensive glycosylation,[285] and lipoproteins that associate with the virion (Fig. 8.10).[40,102,201,607] Direct cell-to-cell transmission of HCV may also sequester the virus from broadly neutralizing antibody responses, as demonstrated in

cell culture models.[77,759,811]

Immunity and Animal Models of Infection

The common chimpanzee was the only model of HCV that recapitulated most features of human infection. The model was essential for the initial discovery of HCV and provided key insights into pathogenesis and immunity but is no longer used in research.[392] A number of rodent models were engineered for susceptibility to HCV infection.[306,491,596,801] Examples include mice with a severe combined immunodeficiency phenotype reconstituted with human liver by ectopic implantation under the kidney capsule,[306] immunodeficient mice transgenic for the urokinase plasminogen activator (uPA) gene that facilitates reconstitution with human hepatocytes,[491] and genetically humanized mice that express murine CD81 and SR-BI and human claudin-I and occludin required for HCV entry.[596] These animals permit the study of HCV entry and antibody-mediated neutralization of HCV infectivity (see Humoral Immunity) but are limited by other species restrictions on HCV replication or a functioning adaptive immune response.

Newly discovered equine and rodent hepaciviruses have great potential to provide new insight into mechanisms of immune control and failure leading to persistence. A nonprimate equine *Hepacivirus* is hepatotropic in horses[586] and like HCV has an NS3/4A protease that cleaves MAVS.[25,569] Experimental challenge of horses results in spontaneously resolving and persisting infections. Importantly, horses that resolved acute infection had very transient viremia upon reinfection, indicating immune protection similar to that observed in reinfected humans and chimpanzees.[588] Hepaciviruses isolated from rats are hepatotropic, have the potential to persist in their host species, and have a dependence on miR-122 for replication.[764] Transmission of the rat *Hepacivirus* to mice resulted in transient infection that persisted with antibody-mediated depletion of CD4+ T cells.[60] Natural persistence of the virus in rats was associated with a defect in acute phase T-cell immunity. Importantly, vaccination with a recombinant adenovirus expressing the nonstructural proteins protected most rats from persistence, and antibody-mediated depletion of CD4+ and CD8+ T cell abrogated protection or delayed resolution.[282] These models are emerging as an important new approach for understanding defects in immunity that lead to persistence and

how they can be circumvented by vaccination.

EPIDEMIOLOGY

Morbidity and Mortality

Morbidity and mortality caused by HCV infection are related primarily to liver failure and/or liver cancer as a result of chronic infection. In the Unites States, the Centers for Disease Control and Prevention estimates that chronic HCV infection contributes to 15,000 deaths per year, is the leading cause of liver failure leading to transplantation, and in 2007 superseded HIV as a cause of death.[187,448,810] By 2012 to 2013, the annual number of HCV-related deaths exceeded 60 other nationally notifiable infectious diseases combined (Fig. 8.11).[446] HCV-related liver morbidity and mortality increase with older age and greater duration of HCV infection and are expected to rise in the coming decades. HCV-related liver failure and cancer are predicted to increase until 2020–2023 without widespread treatment.[142] This trend may be exacerbated by failure to identify and treat patients with advanced liver diseases including fibrosis and cirrhosis.[250,364,515] Liver-related mortality is predicted to rise from 146,667 cases in 2000–2009 to 283,378 in 2020–2029 in the United States. Global estimates of HCV-related disease burden at the level of individual countries are emerging.[105] They suggest a trend similar to the one predicted for the United States, where mortality associated with HCV infection continues to increase through 2030 with the exception of a small number of countries with higher DAA treatment rates.[105]

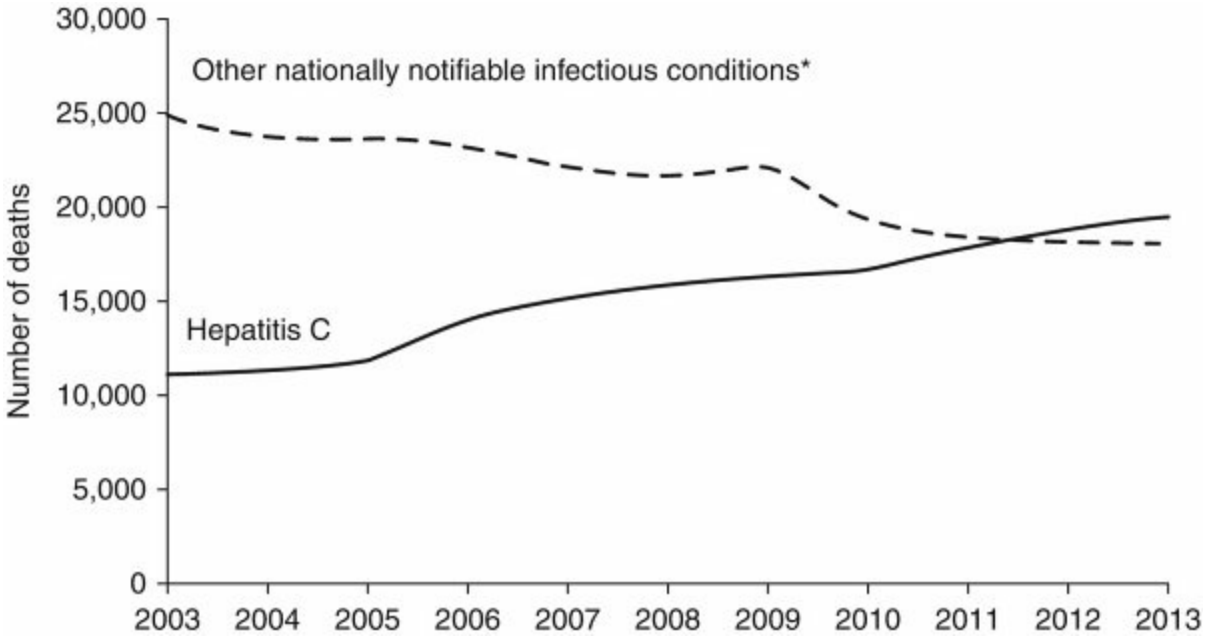

FIGURE 8.11 Annual number of deaths associated with hepatitis C virus and all other nationally notifiable infectious conditions* listed as multiple causes of death in the United States between 2003 and 2013. *Identified in the absence of hepatitis C. The list of 60 other nationally notifiable infectious conditions was obtained from the Centers for Disease Control and Prevention National Notifiable Diseases Surveillance System Web site. (From Ly KN, Hughes EM, Jiles RB, et al. Rising mortality associated with hepatitis C virus in the United States, 2003–2013. *Clin Infect Dis* 2016;62(10):1287–1288, with permission.)

HCV-infected persons are at increased risk of mortality from causes other than liver failure. In one study, 10,259 HCV antibody–positive blood donors were compared to donors matched by year of donation, age, gender, and zip code and followed for a mean of 7.7 years.[271] Compared to the HCV-uninfected donors, the risk of death was 3.13-fold higher in HCV-infected donors, who were more likely to die of not just liver-related but also drug/alcohol-related events, trauma/suicide, and cardiovascular causes. Persons with HCV infection are also at much higher risk of some medical conditions such as mixed cryoglobulinemic vasculitis and porphyria cutanea

tarda (PCT) (see Clinical Features).[147] The degree to which HCV infection contributes to less specific medical syndromes such as chronic fatigue/arthritis or mental illness is more difficult to establish.

Prevalence and Seroepidemiology

Transmission

Percutaneous exposure to contaminated blood is by far the most common mode of HCV transmission globally. Surveys of epidemiological literature have established that inadequate infection control measures including reuse of needles for medical and nonmedical practices are a significant risk for HCV transmission in many developing regions of the world.[131,355,692] Injection drug use is a dominant mode of HCV transmission globally, especially in countries with well-established screening programs for blood products and a low incidence of infection.[131,355,692] The size of the transmitted inoculum is a significant factor that determines whether infection is established. HCV RNA titers range from 5 to 7 $\log_{10}$ copies/mL of serum or plasma, and so almost all transfusion events with large volumes of contaminated blood products result in infection.[183,795] The risk of infection with a very small inoculum is apparent from chimpanzee studies, where low amounts of HCV RNA (~10–100 copies) similar to what might be found in a contaminated needle is sufficient to initiate productive infection.[87,343,455,787] The risk of HCV seroconversion after percutaneous accident involving health care workers in the United States has been estimated at 1.8%,[768] although a more recent analysis of 1,361 mucocutaneous and percutaneous exposures among health care workers at a large academic medical center over 13 years provided a lower seroconversion rate of 0.1% related to blood transmission. In addition to the quantity and titer of infectious material transferred, seroconversion is also determined by the type of injury (superficial or deep) and use of hollow-bore needles and syringes with low or high dead space volume.[363,821] In one study of percutaneous accidents involving health care workers, the risk of HCV infection was 11-fold higher in those exposed to an inoculum of greater than 10^6 RNA versus less than 10^4 genomes/mL of serum.[821] More recently, mathematical modeling has demonstrated how the minimum estimated HCV inoculum size required for infection via IDU

needle sharing varies with frequency of exposure and changing virus load through the acute and chronic phases of infection.[454] Other simulations have demonstrated that HCV titers decline in syringes over time, but virus infectivity can be maintained for weeks.[61,158,566,567] HCV RNA is stable for weeks in body fluids other than blood[587] and is detected in tears, seminal fluid, and CSF by sensitive molecular techniques.[210,488,799] There is no evidence that HCV RNA is present in these fluids at a titer sufficient for transmission of infection.[587] Nonmedical percutaneous exposures such as body piercing, tattooing, and other cultural practices emerge as plausible risks for HCV transmission in some regions of the world.[692]

The frequency by which HCV is transmitted sexually is controversial. Transmission is relatively rare among long-term monogamous partners of individuals with HCV infection. HCV prevalence among partners was 4% in one cross-sectional study of 500 anti–HCV-positive, human immunodeficiency virus-negative index subjects and their long-term heterosexual partners.[745] Of the 20 infections detected, nine couples had concordant genotypes. Viral isolates in three couples (0.6%) were highly related, consistent with transmission of virus within the couple. The maximum incidence rate of HCV transmission by sex was 0.07% per year, or approximately 1 per 190,000 sexual contacts.[745] HCV infection does occur in persons acknowledging high-risk sexual practices with no other risk factor such as injection drug use.[782] Transmission between HIV-infected and HIV-uninfected men who have high-risk sexual exposures with other men is well established and is thought to result from traumatic sexual practices.[439,621,779–781,804]

The rate of vertical HCV transmission is estimated at 2% to 10%.[470,636,829] How and when infection occurs in this setting is not known, but risk is increased by maternal HIV infection and/or high HCV RNA levels, prolonged rupture of membranes, and internal fetal monitoring.[235,473,763]

Global Burden, Incidence, and Prevalence

An estimated 71 million people, or 1% of the human population, are infected with HCV globally as defined by viremia.[597] HCV prevalence varies widely between regions and countries (Fig. 8.12).[80,597] In an analysis of 16 countries by literature search and expert consensus, viremic prevalence estimates

ranged from 0.3% in Austria, England, and Germany to 8.5% in Egypt.[80] The largest viremic populations were in Egypt, with 6,358,000 cases in 2008, and Brazil with 2,106,000 cases in 2007.[80]

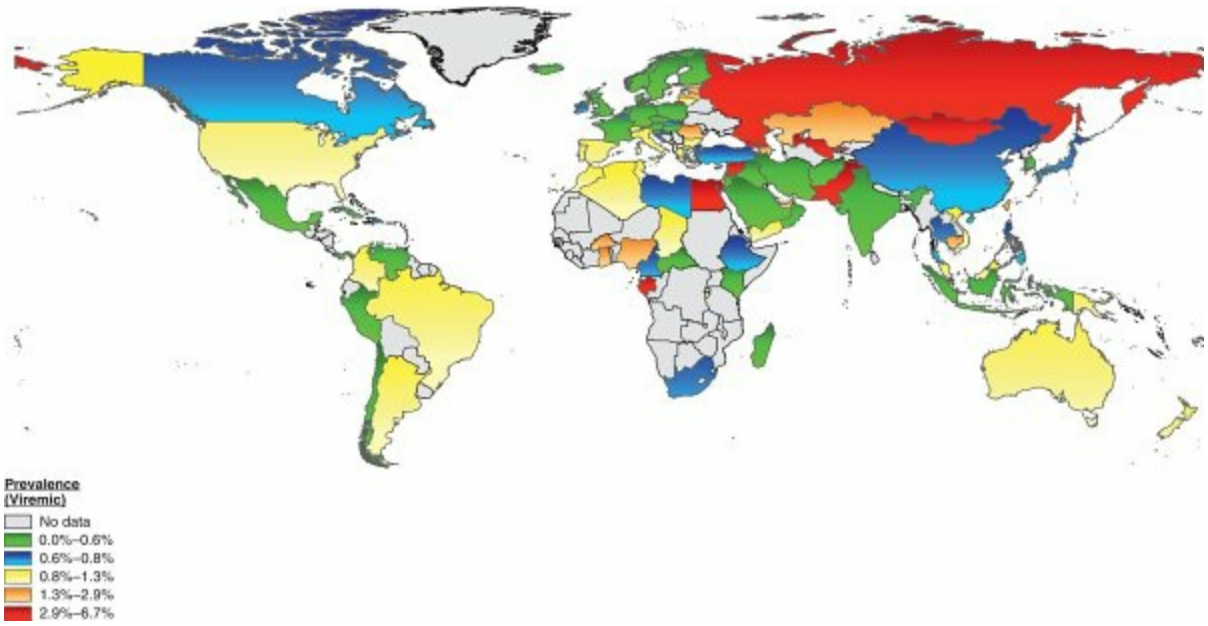

FIGURE 8.12 Map depicting geographic variation in the relative prevalence of hepatitis C virus (HCV) infection. Shading of country indicates prevalence. (Reprinted from Global prevalence and genotype distribution of hepatitis C virus infection in 2015: a modelling study. Lancet Gastroenterol Hepatol 2017;2(3):161–176. Copyright © 2017 Elsevier. With permission.)

The high prevalence in Egypt has historical roots in a campaign to eradicate schistosomiasis infection by intravenously administering tartar emetic to millions of citizens.[717] The effort, commended at the time as a public health model, occurred before there was widespread appreciation for blood-borne transmission of infectious agents. HCV was transmitted extensively because of the widespread reuse of insufficiently cleaned injection equipment.[222] Consequently, the prevalence of HCV infection can exceed 50% in persons alive during that campaign while being 1% to 2% in those born after. In addition, more than 90% of HCV infections in Egypt are genotype 4, which

make up less than 10% of genotypes in most other regions of the world.[624] Of note, Egypt is now at the forefront of national programs to eliminate HCV through a combination of public health measures as well as identification and treatment of infections (see Prevention and Control).[682] Diagnostic testing programs for HCV infection are highly refined and on track to identify and treat millions of people who are unaware of chronic HCV infection.[174]

United States Prevalence and Incidence

An estimated 1% of the US population, or 2.1 million people, were HCV RNA–positive in a survey that spanned 2013–2016.[291] Approximately 4.1 million were seropositive for antibodies against HCV.[291] Of note, this estimate was generated by combining data from the National Health and Nutrition Examination Survey (NHANES) that estimates infection rates among noninstitutionalized civilian populations and a literature review to define prevalence in incarcerated and unsheltered homeless populations, active duty military, and nursing home residents. Inclusion of the populations who were not surveyed by NHANES increased the number of viremic (actively infected) individuals by 0.25 million.[291] Disparities associated with sex and race have been noted. Estimated HCV RNA prevalence is 1.5 to 2.5 times higher in males when compared with females.[276] When stratified by race, HCV RNA prevalence is highest among the non-Hispanic Black population (2.43), followed by non-Hispanic White (1.05) and Hispanic/other (0.74) populations.[276] Genotype distribution also differs by race and geography,[251] a consideration in DAA treatment with some non–pan-genotypic regimens.

Prevalence among the civilian noninstitutionalized population estimated from the most recent NHANES spanning 2013 to 2016 (0.9%)[291] is lower than the estimate from the 2003 to 2010 survey (1%).[148] This difference may reflect continued mortality (HCV-related and all-cause) and an impact of DAA therapy. Reductions associated with mortality and treatment may be offset by a changing epidemic of HCV transmission in the United States.[374,728,843] The annual incidence of acute HCV infection rose from 0.3 to 0.7 cases per 100,000 from 2004 to 2014, an increase in the overall rate of 133% (Fig. 8.13).[843] The greatest increase, and cause for concern, occurred among non-Hispanic Whites and Hispanics in the 18 to 29 (400%) and 30 to

39 (325%) age groups.[843] This increase was directly related to an epidemic of opioid and heroin drug use (Fig. 8.13).[843] A survey of data from the National Notifiable Diseases Surveillance System also documented a doubling of the number of reproductive-aged women with acute or past or present HCV infection between 2006 and 2014.[447] Estimated HCV prevalence was 3.2 times higher for children aged 2 to 3 years when compared with the 12- to 13-year age group.[447] Reasons for this disparity are not known, but may reflect in part a decrease in testing frequency among older children once HCV status is established, or spontaneous clearance of infection that occurs at an older age in children.[447]

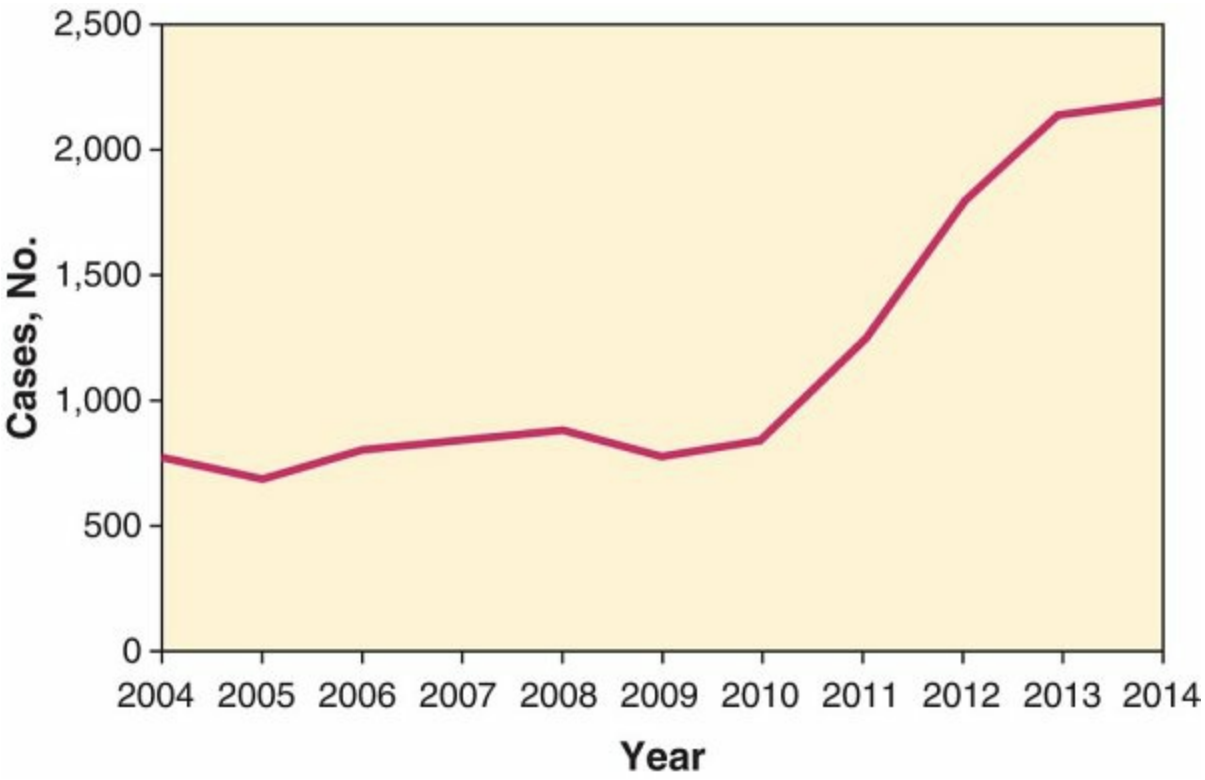

FIGURE 8.13 Cases of HCV infection by year reported to the National Notifiable Disease Surveillance System, United States. The annual incidence rate of acute HCV infection increased by 133% from 2004 to 2014 due to an epidemic of opioid use. (From Zibbell JE, Asher AK, Patel RC, et al. Increases in acute hepatitis C virus infection related to a growing opioid epidemic and

associated injection drug use, United States, 2004 to 2014. *Am J Public Health* 2018;108(2):175–181, with permission.)

Global Molecular Epidemiology and Origin

The seven HCV genotypes are not uniformly distributed globally or regionally (Fig. 8.14).[493,597] Genotype 1 is prevalent worldwide. HCV prevalence is highest, and genetically most diverse, in Africa.[493] Genotype 3 is dominant in the Asia South region. Genotype 4 is found almost exclusively in the North Africa/Middle East and sub-Saharan Africa Central and Eastern regions.[493] The global distribution of HCV genotypes and subtypes has been shaped by human migration, catastrophic events including war, and early widespread adoption of medical practices like transfusion before infectious diseases risks were appreciated. Of the 86 recognized HCV subtypes, only a few that represent a small fraction of HCV diversity account for the overwhelming majority of infections worldwide.[493,695] Epidemic subtypes 1a, 1b, 2a, and 3a spread rapidly in most regions of the world over the past 50 to 100 years with the development of practices that promoted parenteral exposure.[314,614,695] Bayesian evolutionary analysis has provided insight into the spatiotemporal spread and probable causes of epidemic transmission of these subtypes. Most studies are consistent with spread of genotype 1 viruses, the most widely dispersed globally, from approximately 1940 until a plateau was reached about 4 to 5 decades later. Phylodynamic analyses are consistent with global expansion of subtype 1b in the early decades by iatrogenic transmission through transfusion, reuse of needles, and other procedures that caused exposure to contaminated blood. Spread of genotype 1a in later decades was likely facilitated by injection drug use until harm reduction practices for PWID became commonplace.[125,451,614] The impact of widespread use of nonsterile needles on HCV spread in the middle of the 20th century is exemplified by campaigns to treat schistosomiasis in Japan and later Egypt.[512] For example, the extremely high prevalence of HCV genotype 4a in Egypt that persists until today can be traced to mass distribution of antischistosomal medication with unsterilized injection equipment between 1930 and 1950.[512,615]

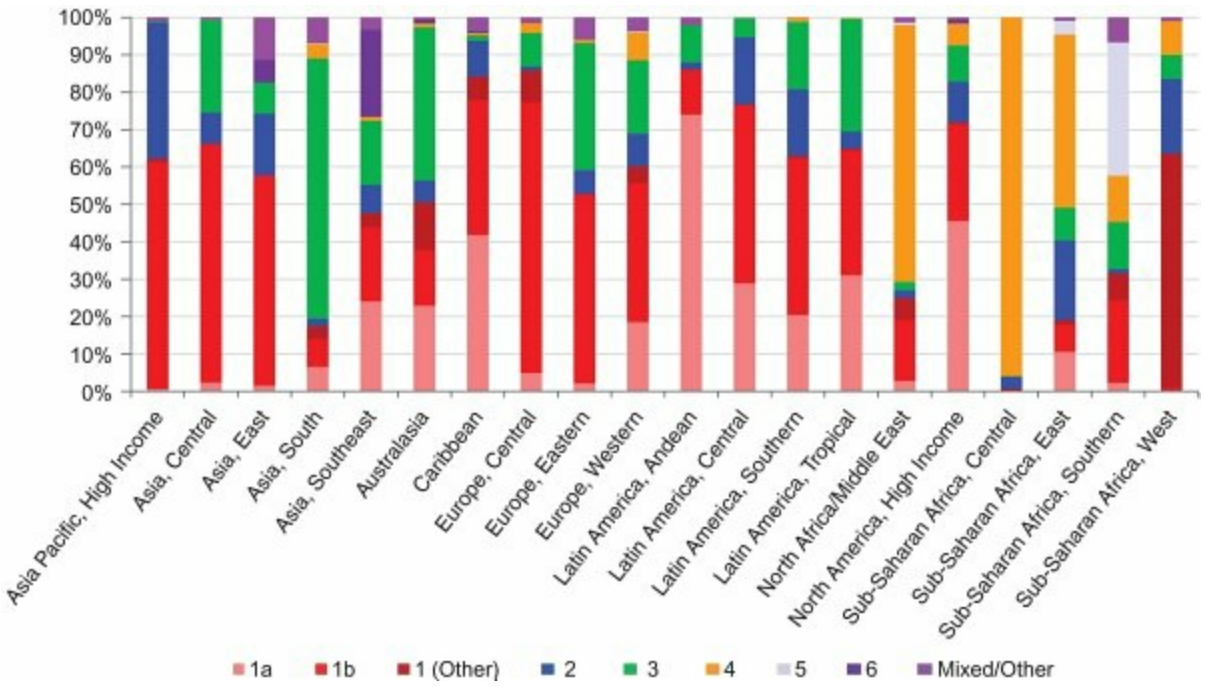

FIGURE 8.14 Global distribution of medically relevant HCV genotypes. HCV prevalence is highest, and genetically most diverse, in Africa. Genotype 1 is prevalent worldwide. Genotype 3 is dominant in the Asia, South region. Genotype 4 is found almost exclusively found in the North Africa/Middle East and sub-Saharan Africa Central and Eastern regions. (Reprinted from Global prevalence and genotype distribution of hepatitis C virus infection in 2015: a modelling study. Lancet Gastroenterol Hepatol 2017;2(3):161–176. Copyright © 2017 Elsevier. With permission.)

Endemic spread of HCV genotypes is also apparent from phylogenetic studies that demonstrated highly divergent subtypes of the same genotype in geographically contiguous areas. By this measure, HCV genotype 2 is considered endemic in West Africa, genotypes 1 and 4 in Central Africa and the Middle East, and genotype 6 in Asia.[97,321,487,541,613] This pattern is consistent with circulation of a given genotype in a defined geographic location for hundreds or thousands of years long-standing association of the virus with human populations.[694] This concept is supported by recent estimates of the time to most recent common ancestor (tMRCA) for these

endemic genotypes. The tMRCA for genotype 3 in South Asia and the ancestor of genotypes 1 and 4 in Central Africa were estimated to be in the 800 BCE to 700 CE range, while genotype 6 endemic in Southeast Asia had an estimated origin of at least 2,000 years ago.[216]

Estimates of tMRCA for the seven HCV genotypes range from approximately 1,000 to 3,000 years ago.[216,423,442,614,695,704] These estimates for HCV genotypes are in the same time frame (or perhaps slightly earlier) than the tMRCA of CE 1100–1800 estimate for equine hepaciviruses.[216,616] These estimates do support the concept that HCV entered human populations relatively recently, although it must be acknowledged that extrapolation of short-term substitution rates to longer evolutionary periods has limitations. It is conceivable that human HCV originated from a cross-species transmission event, a possibility that seems plausible with the recent isolation of hepaciviruses from a variety of disparate species. From an evolutionary perspective, however, the animal hepaciviruses discovered to date are probably too distant from the diverse constellation of HCV genotypes and subtypes found in humans to have an ancestral relationship.

CLINICAL FEATURES

Acute HCV

Acute HCV infection is usually asymptomatic,[134,524] though a minority of persons will present with more typical symptoms of acute viral hepatitis (malaise, fatigue, anorexia, nausea, abdominal pain, jaundice, dark urine, and sometimes pale stool). While HCV can cause fulminant hepatitis, this presentation is rare.[196,249,334,814,817,825] In general, the latent period (from exposure to symptoms or laboratory abnormalities) is approximately 7 weeks (range 1–16 weeks) (Fig. 8.6).[524] In many cases, the only sign of acute infection may be elevation of hepatic transaminases.[1,134,793]

Most exposures that result in HCV infection are percutaneous (see Transmission), after which hematogenous infection of the liver is presumed to occur. Viremia is detectable within days[524] and reaches levels of 10^5 to 10^7 IU/mL within weeks (Fig. 8.6). A decrease in viremia 1 to 2 weeks later is associated with expansion of HCV-specific T cells and in some individuals a

sharp rise in hepatic transaminase levels in blood (see Immune Responses) (Fig. 8.6). This sharp ALT increase is thought to result from immune-mediated cytolysis by adaptive responses as the virus is not considered to be directly cytopathic.[9,134,197,524,684] HCV-specific cytotoxic CD8+ T cells are detected individuals who clear infection regardless of whether a sharp transaminase increase is observed.[748] This suggests that control of infection may be mediated in some individuals by noncytotoxic mechanisms involving production of antiviral cytokines.[748] The mechanism of acute phase liver injury, when it is observed, is likely to be complex. One recent study established an association between host *IFNL4* genotype and symptoms of acute hepatitis C that could explain the higher spontaneous clearance observed in some patients with symptomatic disease.[565]

A low oscillating pattern of viremia can persist for up to a year until resolution (Fig. 8.6).[275,479] Protective sterilizing immunity is uncommon after spontaneous resolution of infection, if it occurs at all. Reinfection is associated with a reduced duration and magnitude of viremia, and the risk of persistent infection is decreased (Fig. 8.6).[138,260,484,559,653] A similar drop in viremia is observed in many acute persisting infections (Fig. 8.6). After several months, it reaches a higher set point that is stable or increases gradually over a lifetime of persistent HCV replication (Fig. 8.6).[274] Transient partial control of HCV replication is not observed in some individuals following a chronic course, suggesting an absence of apparent immune control during the acute phase of infection (see Immune Responses). Late spontaneous resolution has been observed[619] but is rare when treatment is not initiated and spontaneous clearance does not occur within 12 months.

Predictors of Spontaneous Clearance

Spontaneous clearance of HCV RNA usually occurs within 6 months of infection and is associated with having overt symptoms of hepatitis, non-African descent, and lack of HIV infection.[241,793] GWAS have identified significant associations between spontaneous clearance of HCV infection and the *IFNL* locus.[554,623,754] The compound dinucleotide polymorphism rs368234815-ΔG or rs368234815-TT located in exon 1 of *IFNL4* is most notable from a functional perspective, as a ΔG/ΔG haplotype results in production of IFN-λ4 and a higher risk of persistent infection (see Innate

Immunity).[612] The protective IFNL genotypes are also more frequently found in Asians and least frequently among persons with African ancestry, in keeping with the clinically observed effect of race.[554,623,754] HLA class I and II associations with the outcome of acute infection have also been observed.[167,211,238,280,481,503,750,790,844] Specific class II alleles that associate with spontaneous clearance (*HLA-DQB1*03:01*, *DRB1*01:01*, *DRB1*03:01*, and *HLA-DRB1*11:01*) or persistence (*DQB1*02:01*) have been identified in multiple studies.[167,238,280,503,750,790] The *IFNL* and MHC association has been confirmed by meta-analysis, including one study that provided a dense multiracial GWAS analysis that included individuals of African ancestry.[790] This study provided an additional association with G-protein–coupled receptor 158 gene (GPR158). These three loci (IFNL, MHC, and GPR18) had independent, additive effects on HCV clearance. Persons of African or European ancestry carrying all six clearance-associated variants were 24-fold and 11-fold, respectively, more likely to clear HCV infection when compared with individuals carrying one or none of them.[464]

Chronic HCV

The level of HCV RNA in the blood tends to be stable over long periods of time in chronic hepatitis C, within 1 $\log_{10}$ of 10^6 IU/mL in 90% of individuals. Conditions associated with modest increases include HIV infection, male gender, and increasing age and body mass index, whereas lower levels may be found in those with ongoing HBV infection and more advanced stage of liver disease.[21,127,308,752,755,761] Chronic HCV infection is a heterogeneous condition, with highly individual manifestations and rates of progression (Fig. 8.15).[248] Associated morbidity and mortality occur almost exclusively when the disease progresses to cirrhosis and end-stage liver disease that may manifest as hepatocellular carcinoma (HCC). Chronic HCV infection is characterized by high-level viremia and fluctuating hepatic inflammation and transaminase levels,[363,582,809] yet chronically infected people typically have few symptoms that are directly attributable to HCV infection. It is difficult to establish a causal relation between HCV and nonspecific symptoms, though they do tend to improve after successful therapy.[56,220]

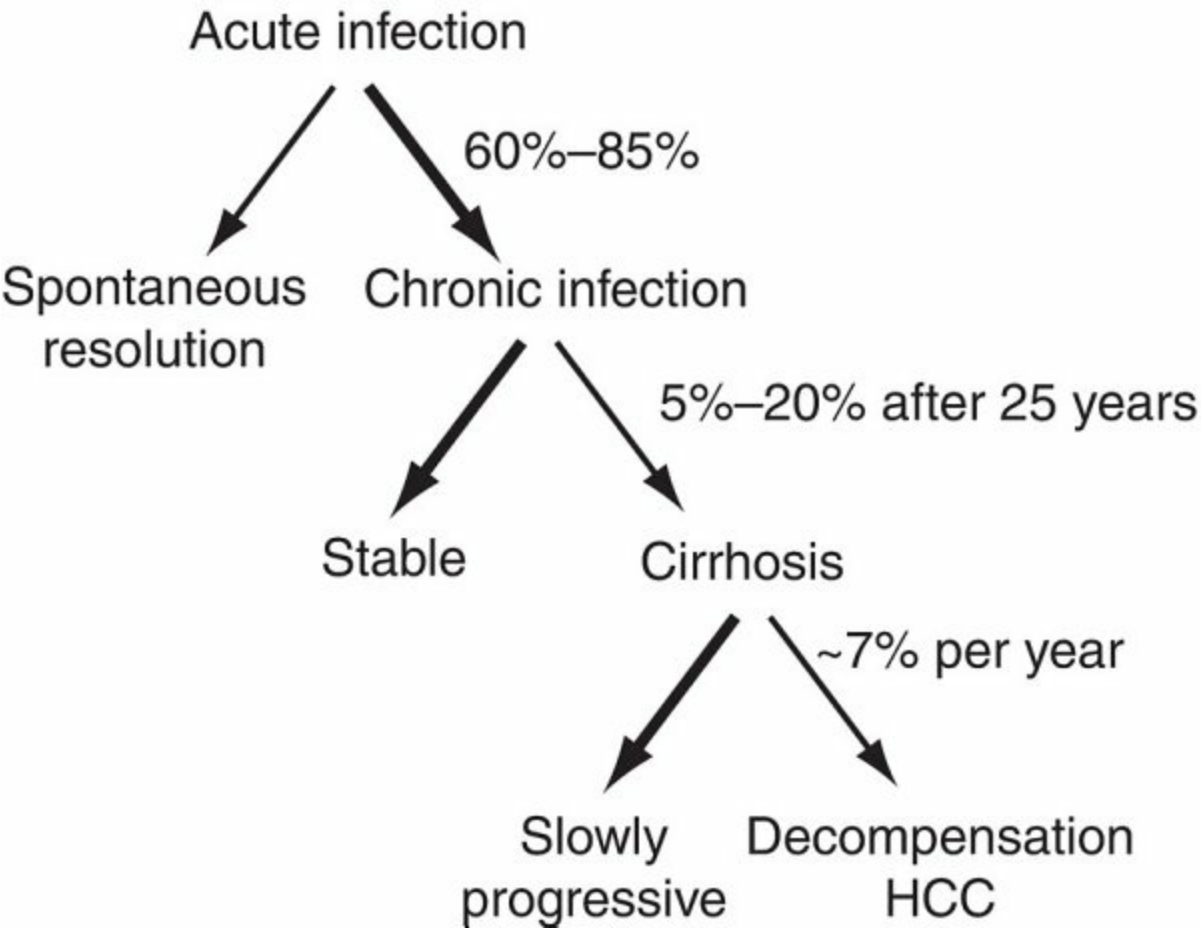

FIGURE 8.15 Progression of hepatitis C virus (HCV) infection. Most HCV infections are persistent and stable, but a minority will progress to cirrhosis within 20 to 30 years. Of those with cirrhosis, most are slowly progressive, but 7% per year will develop either hepatocellular carcinoma (HCC) or decompensated liver disease.

Chronic HCV infection is associated with varying degrees of chronic inflammation and steatosis. Lymphocytic infiltrates are typically found in periportal regions of the liver (Fig. 8.16), though these do not correlate strongly with liver disease progression.[678] For reasons that are not clear, many individuals will not develop significant fibrosis despite decades of high-level viral infection, while others have more production than resorption of collagen, also initially in the periportal region. This process may be stable or progress to formation of septa that expand to form bridges between lobules, and further expansion may result in the severe scarring and

regeneration that characterize cirrhosis. Increasing portal venous pressure may lead to portal hypertension, and neoplastic transformation may lead to HCC, hallmarks of end-stage liver disease.

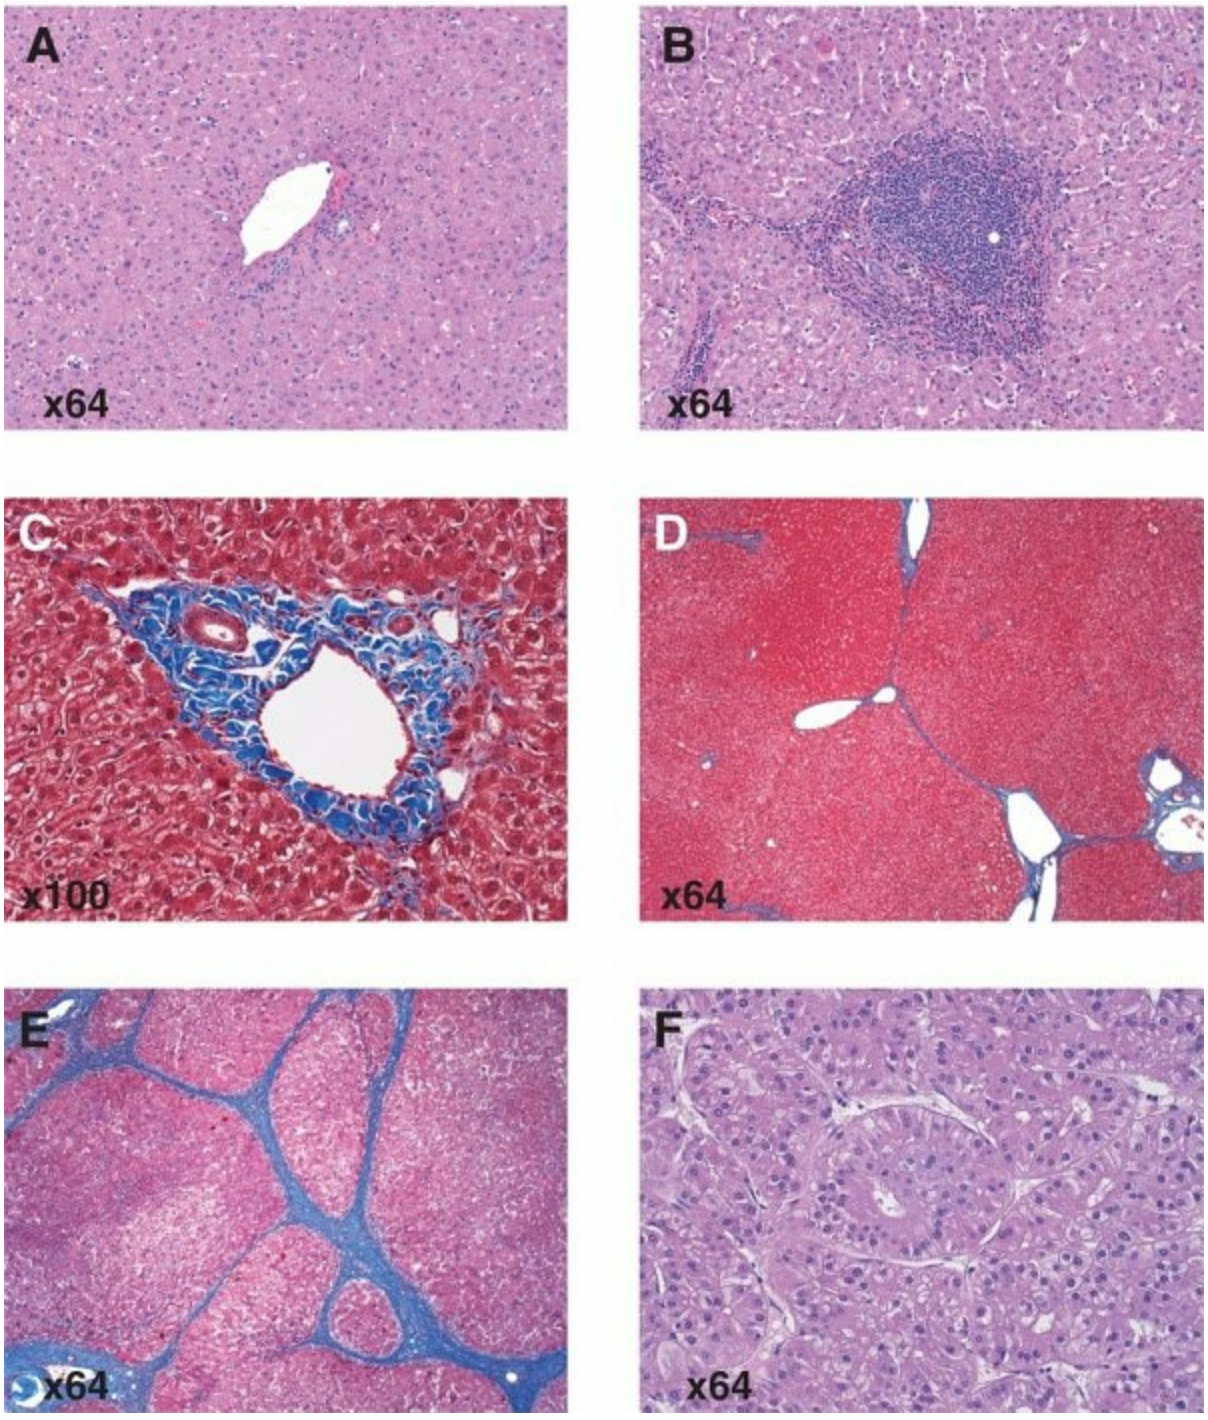

FIGURE 8.16 Histology illustrating progression of hepatitis C

virus (HCV)-related liver disease. A: Normal portal tract (hematoxylin and eosin [H&E] stain). **B:** Portal inflammation (H&E stain). **C:** No fibrosis (trichrome stain). **D:** Bridging fibrosis (trichrome stain). **E:** Cirrhosis (trichrome stain). **F:** Hepatocellular carcinoma (HCC) (H&E stain). (Courtesy of Michael Torbenson, MD.)

The risk of fibrosis is associated with *IFNL4* genotype through viral and/or nonviral mechanisms that have not yet been identified,[14,66,181,182] but extend the pervasive effect of polymorphisms linked to IFN-λ4 production on HCV pathogenesis. Studies demonstrating that the *IFNL4* CC genotype (associated with clearance of infection) is linked to more severe fibrosis in those who are chronically infected[66,182] are consistent with higher rates of chronic infection with milder inflammation and slower progression of fibrosis among people of African descent.[135,746]

Of note, liver disease progresses slowly in children with vertically transmitted HCV. Liver inflammation with no or very mild fibrosis is often evident in children who were infected as infants. Only 1% to 2% develop cirrhosis,[270,324] but it is likely that they will develop serious liver disease over a lifetime of persistent HCV replication if untreated.[286,514,529]

Alcohol consumption is frequent in persons with chronic HCV and is strongly associated with liver disease progression.[18,584] Along with its well-known hepatotoxicity, alcohol use is associated with reduced access to and early discontinuation of HCV treatment.[584] Elimination of alcohol consumption should be attempted to reduce complications in all persons with chronic HCV.[242,243,508,710,822]

Chronic HCV infection is also associated with metabolic dysfunction including insulin resistance, type 2 diabetes, lipid derangement, and steatosis that may be more common in (but not exclusive to) persons infected with HCV genotype 3.[130,304,469,483,543] This association is stronger for HCV than for HBV, suggesting that the mechanism may be specific to HCV.[687,806] Potential contributing mechanisms to metabolic dysfunction in HCV include down-regulation of hepatocyte insulin receptor substrate 1[71] and glucose

transporter 2[340] and up-regulation of PP2A.[55,168] Flares of hepatitis (with elevated serum transaminases and/or bilirubin), common in HBV infection,[583] are rare in chronic HCV and should prompt a search for other causes. For example, acute HAV infection during chronic HCV infection may be associated with severe acute hepatitis, including liver failure[789]; for this reason, persons with chronic HCV infection should be vaccinated for HAV and HBV if susceptible.

Hepatocellular Carcinoma

HCC is a growing problem in countries like the United States with relatively recent HCV epidemics and is a major established problem in countries like Japan and Egypt where the epidemic of HCV infection occurred 10 to 20 years earlier. This is consistent with studies demonstrating a lag of approximately 40 years between onset of transfusion-associated chronic hepatitis C and HCC diagnosis.[333] Chronic HCV infection is strongly associated with development of HCC.[176,429,696] The risk of HCC is increased approximately 17-fold in individuals with chronic hepatitis C when compared with uninfected controls.[160] Moreover, serologic or virologic evidence of HCV infection is found in serum and liver tissue in approximately 40% of patients with HCC.[8]

Successful eradication of HCV with IFN-based therapy dramatically reduced but did not eliminate risk of HCC.[38,177,516,531,555] There is now sufficient experience to conclude that IFN- and ribavirin-free DAA treatment also does not increase,[593,697] but instead substantially decreases, the probability of developing liver cancer by more than 70%.[100,310,337] Importantly, after SVR, the absolute risk of developing HCC remains high at approximately 1% per year in patients with established cirrhosis, so continued monitoring is recommended. This may reflect persistence of epigenetic alterations associated with liver cancer after a sustained virologic response (SVR).[277] Two small uncontrolled trials suggested a higher rate of HCC recurrence in DAA-treated patients,[128,634] but larger studies have so far not confirmed this effect.[26,117,302,530] From these studies, it can be concluded that DAA treatment should be undertaken before development of cirrhosis.

Mechanisms of hepatocarcinogenesis in chronic hepatitis C are not known. Repeated cycles of hepatocyte destruction and regenerative cell

proliferation caused by the chronic inflammatory process could promote tumorigenesis. This mechanism is consistent with significantly higher rates of HCC (~1%–4% per year) in patients after several years of inflammatory liver disease leading to cirrhosis.[81,82,199,277,429,655,696] The possibility that HCV contributes directly to development of HCC can't be excluded, but it should be emphasized that HCV has no potential for integration of viral RNA sequences into the host genome. Induction of protooncogenes and suppression of apoptosis have been observed by overexpression of the core protein under control of a strong promoter in rodent models.[108,114,116,471,626–628,726,842] HCC developed in the absence of inflammation, suggesting a direct oncogenic effect of the transgenic HCV core.[416,519] As noted above, HCC in the absence of cirrhosis is a rare occurrence, and it is perhaps more likely that the virus acts by altering the intracellular environment through activation of protooncogenes like *β*-catenin or disruption of tumor suppressor pathways involving retinoblastoma protein Rb and the RNA helicase DDX3.[106,504,527] Function of the tumor suppressor proteins like p53 may also be modulated through direct interaction with HCV proteins[527] or as a function of PKR activation in the infected cell.[509] Model systems suggest that HCV may also act by induction of reactive oxygen species and oxidative stress.[520]

Insights from human studies are limited. Activation of the telomerase reverse transcriptase promoter may be a frequent early neoplastic event in HCC, including cases associated with chronic HCV infection.[539] Hepatic epigenetic changes associated with liver cancer risk have been reported to persist after DAA treatment of chronic hepatitis C.[277] Genetic variants associated with HCC risk in patients with chronic hepatitis C have been assessed by GWAS. For instance, polymorphism rs17047200 in the tolloid like gene 1 (*TLL1*) was associated with development of HCC after SVR.[472] Other polymorphisms in or near HCP5, PNPLA3, DEPDC5, and MHC loci have been associated with progression to or protection from cirrhosis or HCC.[386,393,412,502,771,778] The mechanistic significance of these polymorphisms is not yet understood.

Extrahepatic Manifestations

Chronic HCV infection is associated with a wide variety of extrahepatic

manifestations that are mostly inflammatory in nature.[90] A common feature of these conditions is chronic inflammation. Essential mixed cryoglobulinemia, a condition in which cold-precipitating immune complexes are deposited in multiple organ systems, is strongly associated with HCV infection, though other inflammatory conditions may be implicated. Manifestations often include purpuric rash, weakness, and joint pain but may also include Raynaud syndrome and vasculitis complicated by membranoproliferative glomerulonephritis and neuropathy.[91,458,505] The chronic stimulation of B cells implicated in HCV-related cryoglobulinemia[651] may also explain the elevated risk of non-Hodgkin lymphoma.[140] PCT, characterized primarily by disorders of the skin (blistering, hyperpigmentation) and nails (onycholysis) worsened by sun exposure and complicated by scarring, is associated with liver disease and is caused by reduced activity of uroporphyrinogen decarboxylase. It is a multifactorial disease, potentiated by mutations in the *HFE* gene (associated with hereditary hemochromatosis and found in 15% of persons with PCT), as well as HCV infection, alcohol, and estrogen use—all of which should be evaluated in persons presenting with PCT.[69] Thyroiditis and antithyroid antibodies have been associated with chronic hepatitis C by meta-analysis, though the mechanism remains unclear.[28]

SVR following DAA therapy can provide relief from mixed cyroglobulinemia.[92,126,179,255,650] Clinical and immunological improvements may not be immediate, however.[179] Approximately 60% of patients had complete or partial resolution of mixed cryoglobulinemia 12 weeks after completion of therapy in one study.[179] Consistent with gradual improvement after SVR, clinical outcomes improve with longer follow-up.[126,179] Recovery of affected organ systems may not be uniform, with less success in resolving renal and neurologic complications.[126,179] Regression and prevention of relapse of non-Hodgkin lymphoma associated with DAA therapy has been reported (reviewed in Ref.[309)]

DIAGNOSIS

HCV infection is suspected in persons with otherwise unexplained liver disease. In asymptomatic persons, this infection should be suspected in any

person reporting risk factors for infection (see Epidemiology) or having elevated hepatic transaminases even in the absence of known risk factors, because the infection is highly prevalent. Because of shared risk factors and increased severity of disease, the U.S. Public Health Service recommends HCV testing for all HIV-infected persons upon entry into health care.[703] Because more than two-thirds of persons with HCV infection in the United States were born between 1945 and 1965, the U.S. Public Health Service has recommended that everyone in that "birth cohort" be tested once for HCV infection.[703] The cost-effectiveness of birth cohort testing has already been demonstrated.[635] Retrospective analysis demonstrated that 68% of persons with HCV infection would have been identified with a birth cohort testing strategy whereas only 27% would have been screened with the risk-based approach.[452] A recent survey of screening practices in 51 high-income countries in the top quartile of the United Nations Human Development Index (HDI) countries revealed consistent risk and age-based recommendations similar to those in place in the United States.[311] Screening recommendations may be reconsidered in the near future for additional populations. Simulations indicate that expanded screening for those greater than 18 years of age is cost-effective.[43] Screening pregnant women is also under debate given the sharp increase in new HCV infections associated with opioid use and risk of vertical transmission.[104,323]

Differential Diagnosis

Other viral causes of acute hepatitis (described in Clinical Features) include the named hepatitis viruses (HAV, HBV with or without the delta hepatitis agent, or hepatitis E virus), yellow fever virus, and a wide range of viruses with broader tropism including Epstein-Barr virus and cytomegalovirus. In immunocompromised hosts, adenovirus and other agents with broad tropism can also cause hepatitis. Nonviral causes of acute hepatitis include leptospirosis, tuberculosis, rickettsia and rickettsia-like organisms, numerous toxins (alcohol, acetaminophen, isoniazid, and *Amanita phalloides* toxin being prominent), anoxia/hypoperfusion, and autoimmune disease. Chronic hepatitis may be caused by HBV and occasionally HEV (in immunocompromised hosts), as well as nonviral etiologies (e.g., toxoplasmosis, autoimmune hepatitis, and nonalcoholic steatohepatitis).

Laboratory

Algorithms for laboratory diagnosis of HCV infection are available for guidance on use and interpretation of assays to detect serologic responses and viral genomes.[103] Most persons recommended for HCV screening are tested initially for serum antibodies against HCV.[103,185] A laboratory-based enzyme immunoassay (EIA) incorporating HCV proteins is most commonly used.[2,185] Rapid diagnostic assays that detect antibodies in whole blood by finger-stick capillary or oral (cervicular) fluid are also available, avoiding venipuncture and costly blood processing procedures. One point-of-care assay that delivers a result in 20 minutes with sensitivity and specificity similar to the EIA is available in the United States.[413]

A positive test result for HCV antibody indicates either current infection that is acute or chronic, past infection that has resolved, or a false-positive result.[572] An HCV nucleic acid test (NAT) to detect viremia is necessary to confirm active HCV infection and guide clinical management, including initiation of HCV treatment. HCV RNA testing is recommended for persons with a negative HCV antibody test who either are immunocompromised (e.g., persons receiving chronic hemodialysis) or might have been exposed to HCV within the last 6 months because these persons may be HCV antibody negative. An HCV RNA test is also required to detect reinfection in HCV antibody–positive persons after previous spontaneous or treatment-related viral clearance or in vertically exposed infants prior to loss of transplacentally acquired maternal antibodies. Quantitative or qualitative NAT with a detection limit of 15 to 25 IU/mL or lower is used to detect HCV RNA.

HCV genotype is an important variable in DAA treatment decisions, particularly in patients with prior treatment experience or cirrhosis who will not be treated with a pan-genotypic regimen.[2,185] Genotyping is performed with an assay (typically line probe) that targets the 5′ NTR to accurately discriminate subtype 1a from 1b.[118] A second target, from either core or NS5B coding region, is also incorporated into the test.[118]

Prevention and Control

Treatment

Antiviral therapy for chronic HCV infection has undergone revolutionary change since 2013. Type I interferon alpha (IFN-α), the cornerstone of HCV therapy for almost 30 years, has been replaced by combinations of two or more DAA that inhibit function of the HCV NS3/4A protease, NS5A replicase factor, and/or NS5B RNA-dependent polymerase required for virus replication. A brief recounting of major milestones in the type I IFN treatment era provides a baseline for understanding the transition to a rapid cycle of DAA development, licensure, and replacement over the past 6 to 7 years (Fig. 8.17). The first study of IFN-α monotherapy for NANBH was initiated in 1984, well before discovery of HCV in 1989.[297] Sustained normalization of liver function and resolution of hepatitis were observed only in a subset of patients after discontinuation of therapy.[297] With development of assays for detection and quantification of HCV genomes, it was apparent that infection was cured in less than 20% of treated patients with chronic genotype 1 HCV infections.[686] Cure rates increased gradually over the next 2 decades with addition of the broad-spectrum antiviral agent ribavirin to the treatment regimen,[480,602] pegylation of IFN-α to extend its half-life,[435,833] and monitoring of the early virologic response to guide decisions on the duration or early discontinuation of therapy (Fig. 8.17).[170] Approximately 80% of previously untreated genotype 2 and 3 infections could be cured with these modifications to therapy, but the success rate for most genotype 1 infections was a very unsatisfactory 40% even with 48 weeks of treatment.[272]

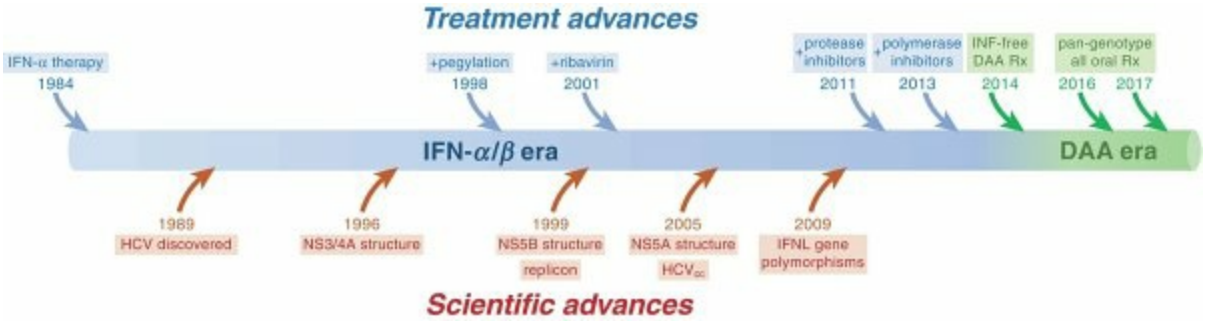

FIGURE 8.17 Timeline of scientific and treatment advances leading to highly effective pan-genotypic direct-acting antiviral therapy. The first exploratory trial of type IFN for cure of non-A, non-B hepatitis was initiated in 1984, 5 years before the discovery of HCV as the causative agent. Treatment response rates improved

gradually over 30 years, with pegylation to improve IFN half-life (1998), addition of ribavirin as a second antiviral (2001) and direct-acting antivirals targeting the NS3/4A protease (2011) and NS5B polymerase (2013). The first IFN-free DAA formulation was approved for use in 2014. All oral, pan-genotypic DAA combinations taken as single tablet once a day were approved for use in 2016 and 2017. Scientific advances after discovery of HCV in 1989 that drove DAA development include crystallization of nonstructural proteins NS3, NS5A, and NS5B, the targets of current therapeutic agents. Development of the HCV replicon system (2000) and HCVcc replication system (2005) were also essential for DAA characterization. Association of IFN lambda (*IFNL*) gene polymorphisms with type IFN treatment outcome in 2009 provided predictive power and remains relevant given an unexpected influence on DAA therapy.

Tolerability of IFN-*α*–based therapy was limited by fatigue, headache, nausea, pyrexia, and a number of other adverse effects. Other variables that reduced the cure rate and complicated pegIFN-*α*–based therapies included the stage of liver disease (cirrhosis less responsive than early stage) and obesity and host factors such as sex (males less responsive than females), age (>40 years less responsive), and race (most notably African ancestry). As detailed in Innate Immunity, the influence of race on pegIFN-*α* treatment outcome was associated with polymorphisms in *IFNL* genes just as the transition to the DAA era began (Fig. 8.13).[239,727,736]

The end of this treatment era was presaged by new therapies that combined pegIFN-*α*, ribavirin, and a DAA. Combination therapy with pegIFN-*α*, ribavirin, and a first-generation NS3/4A protease inhibitor (telaprevir or boceprevir) received FDA approval in 2011 for treatment of chronic HCV genotype 1 infections (Fig. 8.18).[170,242] Triple therapy that included one of these protease inhibitors increased the cure rate to approximately 70% compared with 40% for pegIFN-*α* and ribavirin alone. Other DAA subsequently approved for use with pegIFN-*α* and ribavirin in

the United States or Europe in 2013 included a third protease inhibitor (simeprevir)[315,456] and the first inhibitors of the HCV NS5A (daclatasvir)[162,288] and NS5B (sofosbuvir)[406,407] proteins. As an example, triple combination therapy with pegIFN-α, ribavirin and sofosbuvir yielded an overall cure rate of 92% in patients without cirrhosis after only 12 weeks of therapy.[406,407] Treatment failures were not due to selection of NS5B resistance variants.

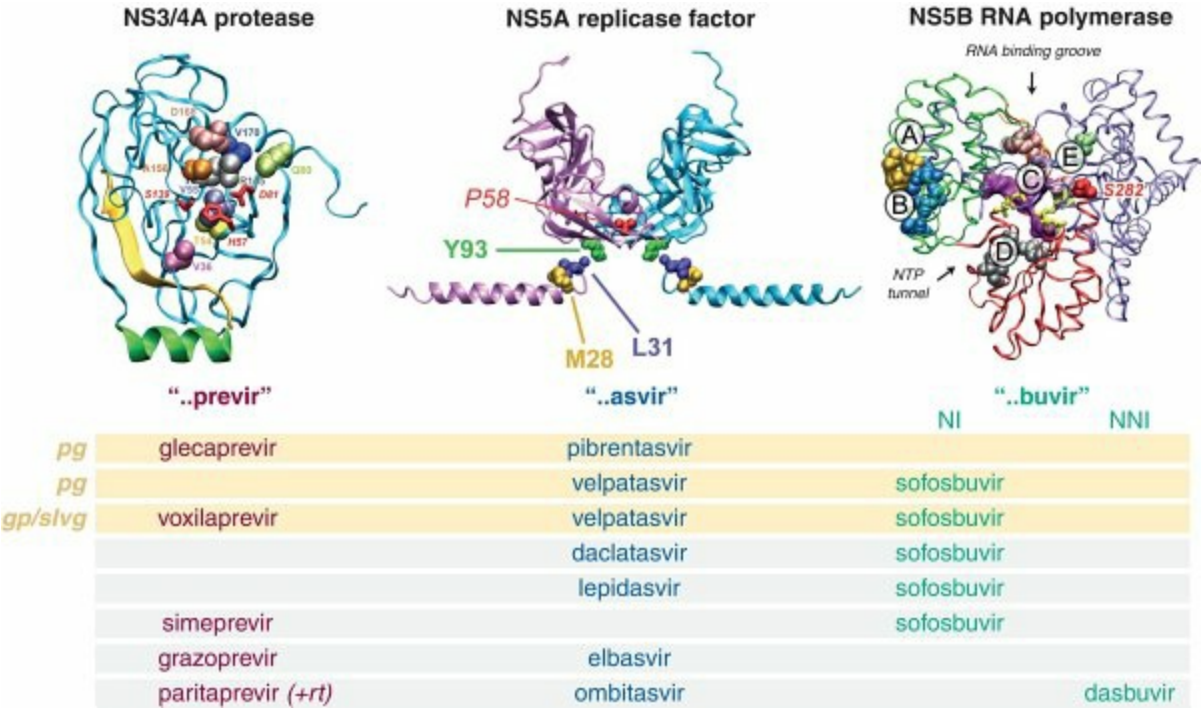

FIGURE 8.18 Direct-acting antiviral (DAA) combinations approved for use in Europe and the United States. Three DAA classes are used in therapy of chronic HCV infection targeting the NS3/4A serine protease (suffix *previr*), NS5A replicase factor (suffix *asvir*), and NS5A RNA-dependent RNA polymerase (suffix *buvir*). Ribbon diagrams illustrating the structure of the targeted HCV proteins and location of resistance-associated substitutions (RAS) are shown (see Chapter 7 for structural detail). The NS3 protease domain (left) is shown with the central NS4A activation domain (yellow) and the catalytic triad (His57, Asp81, Ser139)

diagrammed as red sticks. Mutations that confer resistance to protease inhibitors are shown with side chains as colored van der Waals spheres. Side view of the NS5A D1 dimer structure with RAS sites (center). Pro58 mutations are associated with secondary resistance to daclatasvir but do not confer resistance on their own.[226] Structure of the NS5B RNA polymerase is shown with the RNA binding groove, NTP tunnel (right). Five distinct sites (A–E) targeted by nonnucleotide inhibitors are shown with side chains of some amino acid residues that confer resistance to NNI. The position of the major resistance mutation for nucleotide/nucleoside inhibitors (Ser252) is indicated. Three DAA combinations that are effective against all HCV genotypes and subtypes are highlighted (pan-genotypic, *pg*). One pan-genotypic combination (SOF:VEL:VOX) is approved for salvage (*slvg*) therapy in cases of prior treatment failure with DAA. Effectiveness of the protease inhibitor paritaprevir is boosted with ritonavir (+*rt*) as indicated. Updates to approved combinations and guidelines for use are provided by the European Association for the Study of the Liver (EASL)[185] and the American Association for the Study of Liver Diseases (AASLD).[2] A Web-based resource is also provided by AASLD (HCVguidelines.org). (Adapted from Bartenschlager R, Lohmann V, Penin F. The molecular and structural basis of advanced antiviral therapy for hepatitis C virus infection. *Nat Rev Microbiol* 2013;11(7):482–496, with permission. Ribbon diagrams of targeted HCV proteins with RAS were kindly provided by Dr. Ralf Bartenschlager, the University of Heidelberg.)

Based on this very promising profile, the first trials of IFN-*α*–free therapy were undertaken with sofosbuvir in combination with ribavirin, simeprevir, or daclatasvir. These early studies provided proof that pegIFN-*α* could be eliminated from treatment regimens, but also revealed that outcome was

influenced by HCV genotype, patient treatment history, and/or severity of liver disease. Development and licensing of new DAA combinations that overcome these limitations has continued at a stunning pace since 2013 (Fig. 8.17). As detailed below, therapy is now converging on newly licensed DAA combinations that cure almost all treatment-naïve patients with chronic HCV infection, regardless of genotype, with a single pill taken daily for 8 or 12 weeks. Options for difficult-to-treat patients with decompensated cirrhosis, prior treatment failure, or renal impairment have also expanded. This almost certainly represents one of the most impressive triumphs of antiviral drug development in recent history.

Treatment endpoints and goals

The endpoint of antiviral therapy is to permanently clear HCV RNA from circulation. Undetectable HCV RNA genomes in serum or plasma at 12 weeks (SVR12) or 24 weeks (SVR24) after completion of DAA therapy are considered a cure as the risk of relapse is less than 1%.[457] Quantitative or qualitative NAT assays with a lower detection limit of 15 international units (IU) (or less) of HCV RNA per ml of serum or plasma are the standard for determining SVR.[465] SVR24 can also be established using an EIA for circulating HCV core antigen if it is measurable in patients before initiation of treatment.[11,119,120,224]

The goal of antiviral therapy is to reverse or arrest chronic progressive liver disease related to HCV infection. Benefits to health and quality of life afforded by cure of chronic HCV infection were established in the era of type I IFN-based therapy. Termination of chronic infection by antiviral therapy decreases liver necroinflammation and fibrosis in patients without cirrhosis.[603] Patients with advanced fibrosis remain at increased risk for serious liver diseases,[784] but progression of fibrosis and clinical manifestations including portal hypertension and splenomegaly improve.[603] Resolution of cirrhosis is observed in approximately half of cured infections, and a sharp reduction (>70%) in the risk of liver cancer is a consistent finding across studies.[35,366,516,603] Extrahepatic diseases associated with chronic HCV infection such as cyroglobulinemia[189,390,453,698] and lymphoproliferative disorders[245,474,734] also improve with antiviral cure (see Extrahepatic Manifestations). The benefit of curative antiviral therapy is

underscored by dramatic reductions in the risk of liver-related and all-cause mortality[81,531,785] and markedly improved quality of life.[70,828] It is now apparent that DAA therapy expands the health benefits of antiviral cure to chronically infected patients with severe liver disease who were often poor responders to pegIFN/riba therapy.[100,366,378,571,783] In one large study of patients with advanced liver disease and comorbidities followed for almost 3 years after DAA cure, a significant reduction in liver-related and all-cause mortality and HCC was observed.[100] As noted above, approved DAA regimens are remarkably safe, and so far no direct long-term impact on health has been observed except for an increased risk of HBV reactivation in some coinfected patients that is as yet not fully unexplained.[62,525]

Current treatment landscape

DAA therapies are approved for all adults and children 12 years of age or older with chronic hepatitis C. Several studies have demonstrated safety and effectiveness of IFN- and ribavirin-free DAA regimens in children as young as 3 years old.[4,19,178,528,564,667] Approval of these therapies for children under 12 years of age is expected in the near future.[556] Treatment is highly cost-effective when compared with deferral until chronic infection is established.[57]

Treatment of chronic HCV infection is based upon a complex matrix of factors that must be considered when selecting effective DAA combinations.[2,185] Patient-related factors of importance include HCV genotype or subtype, treatment history with early-generation DAA that may have selected for resistant variants, pregnancy, and comorbidities such as compensated or decompensated cirrhosis, impaired kidney function, and HCV/HBV coinfection.[2,185] These factors must be considered when selecting the optimal DAA combination and duration of therapy to maximize the probability of achieving SVR while minimizing health risks in those with comorbidities. This complexity, along with the rapid cycle of DAA approval and withdrawal and refinements to therapy duration, precludes a detailed description of treatment options for chronic hepatitis C. Treatment of acute hepatitis C, defined as the first 6 months of infection, is recommended to prevent progression to chronic hepatitis C, onward transmission of the virus, or loss to follow-up. The reader is directed to evidence-based guidelines

provided by the European Association for the Study of the Liver (EASL),[185] the American Association for the Study of Liver Diseases (AASLD), and the Infectious Diseases Society of America (IDSA) who jointly publish updates[2] and provide detailed web-based guidance for pre- and on-treatment assessment, DAA regimen selection, and posttreament follow-up where required (www.HCVGuidelines.org). The World Health Organization also publishes guidance for treatment of chronic hepatitis C (www.who.int/hepatitis/publications/hepatitis-c-guidelines-2018).

Eleven single or coformulated DAA were available for use in the United States at the close of 2018 (Fig. 8.18). DAA carry a suffix that identify inhibitors targeting the NS3/4A protease (*previr*), the NS5A replicase factor (*asvir*), or the NS5B RNA polymerase (*buvir*) (Fig. 8.18). Some DAA combinations have restricted use because they are not active against certain HCV genotypes, are toxic in the setting of advanced liver or kidney disease, interact with other drugs, or are ineffective in the setting of retreatment. As an example, genotype 3 infections are more difficult to cure for reasons that are not understood and fewer DAA regimens are available for treatment.

Two DAA combinations approved for use in 2016 (sofosbuvir and velpatasvir, SOF:VEL) and 2017 (glecaprevir and pibrentasvir, GLE:PIB) provided a significant advance in treatment of HCV infection. Both have pan-genotypic antiviral activity and cure almost all chronic HCV infections when taken orally as a single pill once per day. In open-label trials (POLARIS-2 and POLARIS-3) of SOF:VEL for 12 weeks, 96% to 98% of patients representing all HCV genotypes with and without compensated cirrhosis achieved an SVR.[317] Shortening therapy to 8 weeks failed to show noninferior efficacy,[188] and so this pan-genotypic combination is currently approved for 12-week regimens. Efficacy of the GLE:PIB combination was established in a series of 8- to 16-week treatment trials involving patients with and without comorbidities (cirrhosis and kidney disease) and inclusive of six HCV genotypes. SVR rates approaching 100% were observed against most genotypes (ENDURANCE 1, 2 and 4; SURVEYOR-1),[33,834] including those with compensated cirrhosis (EXPEDITION-1)[217] and severe kidney disease (EXPEDITION-4)[230] reflecting the limited metabolic activity of GLE and PIB in the liver and kidney. Very high SVR rates were also documented in liver and kidney transplant recipients with chronic hepatitis C (Magellan-2).[631] GLE:PIB is currently approved for 8 weeks of therapy in noncirrhotic

patients infected with any HCV genotype. A longer (12-week) course of therapy is recommended under several circumstances including compensated cirrhosis, kidney disease, and liver and kidney transplant. Prior treatment experience with NS5A and NS3/4A DAA also adds complexity for GLE:PIB and SOF:VEL (see www.HCVGuidelines.org for details). A third pan-genotypic regimen approved in 2017 (SOF:VEL plus voxilaprevir, VOX) provides salvage therapy for those who failed prior DAA treatment due to emergence of stable resistant variants (Fig. 8.18). Importantly, large-scale postlicensure studies have demonstrated that the very high DAA cure rates observed in clinical trials are mostly replicated in a real-world setting, with low rates of discontinuation or adverse events.[34,83,93] Improved real-world SVR rates also extend to patients with advanced liver disease[632] and genotype 2 or 3 infections[205,803] who were difficult to cure with early-generation DAA combinations.

Mechanism of DAA action and resistance

The structure of HCV NS3 protease and NS5B polymerase proteins, how they function within the virus replication cycle, and DAA inhibition of enzymatic function are now well defined.[45,264] NS5A lacks enzymatic activity, and the functions that are impaired by DAA to achieve viral suppression remain somewhat less certain. The requirement for combination therapy with at least two classes of current-generation DAA underscores the tremendous potential of HCV for adaptive mutation and susceptibility of all three targeted NS proteins to resistance mutations. The rapid response of the HCV quasispecies to DAA selection pressure is explained by a high inherent replication rate, the error-prone replicase function of NS5B, and capacity for compensating mutations elsewhere in the viral genome (see Infectious Agent for details). Substitutions in the HCV genome that confer resistance to antiviral agents are termed resistance-associated substitutions (RAS).[573] HCV quasispecies populations that carry RAS are defined as resistant variants (RAV).[573] Emergence of RAV while on treatment is termed a virological breakthrough, while resurgence of virus replication after cessation of therapy is called a relapse. There is a consensus that baseline (i.e., pretreatment) RAS do not have an impact on DAA treatment outcome if present at a frequency of less than 15%, which is approximately equivalent to the lower limit of sensitivity (10%–25%) for the widely used Sanger sequencing method.[573] As

noted above, the importance of RAS testing before treatment has diminished for current frontline pan-genotypic therapies.[2,185] The structure and function of the NS3/4A protease, NS5A replicase factor, and NS5B polymerase in the HCV replication cycle are detailed in Chapter 7 but are reviewed briefly below to provide a foundation for understanding the current concepts of inhibitor function and antiviral resistance. RAS active against each inhibitor class have been catalogued.[709] Use of DAA to suppress HCV replication in cell culture models has provided important insight into the emergence and fitness of RAS,[279,590] as well as antiviral potency[369] and the virus replication cycle.[52,478]

Virologic response to DAA treatment. A detailed profile of HCV RNA decline in serum after treatment with pegIFN/riba was obtained by frequent sampling of patients after initiation of therapy.[547] A delay of about 8 hours observed before the initial decline in viremia was attributed to the time required for IFN to initiate an ISG response. A rapid decline in HCV RNA from serum over the 1st day occurs with a calculated half-life of approximately 2.7 hours.[547] From the decay kinetic, virus production was calculated as 10^{11} to 10^{12} virions per day to maintain the typical viral titers of 10^{6} RNA genomes/mL of serum observed during untreated chronic infection.[547] A much slower decline after day 2 is attributed to gradual loss of infected cells that are not replaced.[547]

A decline in viremia is observed within 2 hours of initiating DAA therapy, and the first and second phases of viral decline are substantially shorter than for pegIFN/riba therapy.[233] The analysis of viral decay kinetics on DAA therapy has provided insight into the mechanism of action of different DAA classes and to predict duration of treatment. As an example, the first phase of viral decline is much faster during treatment with NS5A inhibitors when compared with NS5B inhibitors or pegIFN/riba.[233,266,267] A 1,000-fold decline in serum HCV RNA titer 12 hours observed after a single dose of the NS5A inhibitor daclatasvir[233] would predict a half-life of 45 minutes[265] versus the estimated 2 to 3 hours based on the response to IFN-based therapy.[547] As noted below, studies of NS5A antiviral mechanisms[52,54,72,478] and mathematical modeling[265] demonstrated that accelerated decay is due to a dual mode of action that includes rapid inhibition of viral export from infected cells in addition to suppression of

HCV RNA replication.

The shortened second phase of viral decline under DAA treatment may not be explained by cell death alone. Cure of infected hepatocytes by highly effective drugs is an alternate explanation that is consistent with elimination of replicating HCV genomes from cultured cells by prolonged treatment with protease or polymerase inhibitors.[64,638] Decay kinetics can also be employed to estimate the duration of DAA therapy required to cure infection. From a theoretical perspective, cure is defined as less than 1 virus particle in extracellular body fluid or less than one infected cell, a concept known as the cure boundary.[268,707] The decay kinetic of viremia in patients treated with combined protease and polymerase inhibitors yielded an estimate of approximately 8 to 12 weeks to cure in the absence of viral breakthrough.[231] This estimate is consistent with the recommended minimum duration of treatment for the two pan-genotypic DAA combinations that have a high barrier to resistance (8 weeks for GLE:PIB and 12 weeks for SOF:VEL in treatment-naïve patients). Low SVR rates in patients treated with 4- or 6-week ultrashort DAA regimens further support this estimate.[345,367,368]

Inhibitors of the NS3/NS4a protease. The HCV NS3 protein has protease and helicase activities, but only the former has been targeted for antiviral development because of structural similarities between NS3 and cellular helicases.[45] NS3 protease function requires a physical association with the NS4A cofactor for tethering to the membranous web where HCV replicates and for stabilization of the NS3 protease domain and substrate recognition site.[45,75,359] The active site of the NS3 serine protease is a cleft formed by two β-barrel subdomains with a chymotrypsin-like structural fold (Fig. 8.18).[45,75,359] Specificity of the protease is defined by a substrate motif consisting of an acidic residue at position P6 (6 amino acids N-terminal of the cleavage site), a cysteine residue at position P1, and small amino acid side chain at the P1' site (immediately after the cleavage site).[372] Low substrate specificity imparted by this motif and weak interactions along an extended surface of the protease active site may facilitate cleavage of adapter proteins MAVS and TRIF to impair interferon signaling pathways (see Innate Immunity section). It also posed challenges for antiviral design. Early inhibitor design capitalized on the observation that an N-terminal hexapeptide product (DDIVPC-OH) derived from cleavage of the NS3-4A junction inhibited protease function.[307,438] Mutagenesis and single amino acid

substitutions led to development of the first peptide inhibitors of HCV protease function.[307,438] Protease inhibitors act by blocking the NS3 catalytic site and fall into two major classes based on physicochemical and structural properties. Boceprevir and telaprevir, the two first-generation FDA-licensed protease inhibitors that are now discontinued, were linear ketoamide peptides that acted by reversible covalent binding to the NS3 protease site.[433,788] All subsequent protease inhibitors are macrocyclic (P1-P3 or P2-P4) or linear acyclic peptides that bind noncovalently to NS3.[475] The potential for emergence of NS3 RAV is illustrated by studies of monotherapy with protease inhibitors.[432,658] In one early study, telaprevir caused a rapid initial decline in viremia, but virologicial breakthrough was evident before cessation of drug dosing at day 14.[658] RAV were replaced by wild-type virus within 3 to 7 months after withdrawal of therapy,[658] a finding common to all generations of protease inhibitors under conditions of functional monotherapy.[88,415,723] Resistance in patients is caused by a complex pattern of distinct but overlapping NS3 RAS that can vary by HCV genotype, replication rate, and fitness as well as drug potency,[659] an observation that has been recapitulated in cell culture models with a large panel of protease inhibitors assessed against multiple HCV genotypes.[322] Three mutations at NS3 positions 155Arg(Lys/Thr/Gln), 156Ala(ValThr), and 168Asp(Ala/Val/Thr/His) are in general the most fit across genotypes[322] and were identified as major drivers of resistance to early-generation NS3 inhibitors (Fig. 8.18). Improvement in protease inhibitor function has been directed toward reducing toxicity and RAS susceptibility while enhancing potency and pan-genotypic activity. For example, the protease inhibitor grazoprevir is not inhibited by RAS Arg155 because of structural modifications that alter its interaction with the NS3 active site.[640] Importantly, baseline NS3 RAS have no impact on effectiveness of protease inhibitors glecaprevir and voxilaprevir incorporated into the recently approved pan-genotypic regimens,[382,657] and they are effective against common RAS engineered into HCV replicons representing six genotypes.[279,590]

Inhibitors of the NS5A replicase factor. HCV NS5A is a multifunctional phosphoprotein important for replication of viral genome, assembly and egress of virions, as well as interaction with many cellular proteins essential for virus replication including cyclophilin A and the phosphatidylinositol 4-

kinase IIIα (see Infectious Agent).[29,50,219,431,644] It is composed of three domains (D1–D3) separated by low-complexity sequences anchored to intracellular membrane layers by an N-terminal amphipathic α-helix (Fig. 8.18).[576,644,743] The three domains are involved in RNA binding and replication as well as assembly and transport of infectious particles through interaction with lipid droplets.[468,644,742,823] NS5A proteins exist as multiple phosphovariants and form dimers or perhaps oligomers to tether HCV RNA genomes to the membranous web.[45,644,823] NS5A was not an obvious target for antiviral drug development given its lack of enzymatic activity and complex interaction with HCV proteins and genomes as well as cellular proteins. HCV replicon models facilitated a chemical genetics strategy to identify NS5A inhibitors.[233] A screen of large compound libraries revealed a small molecule, daclatasvir, that suppressed HCV replication and selected for mutations in NS5A.[233] Several NS5A inhibitors are now used in combination with a NS3/4A protease and/or NS5B polymerase inhibitors for treatment of chronic infection (Fig. 8.18). How these inhibitors suppress HCV replication is poorly understood, but they may have a pervasive effect on patterns of NS5A phosphorylation[226] and subcellular localization.[414] Although they were initially identified as inhibitors of HCV replication, it is now apparent that they also act through additional mechanisms including a rapid independent block of viral assembly[54,478] and transfer of genomic RNA to assembly sites.[72] A mode of action targeting virion assembly or export in addition to inhibition of RNA replication is also consistent with accelerated decay of viremia in patients treated with NS5A inhibitors[233] and provided the best fit for mathematical models seeking to explain the viral dynamics.[265] Further analysis of NS5A antiviral activity in cell culture models demonstrated that replicase complex stability is variable between viruses and is determined by sequence differences in NS5A proteins.[52] As a class, these inhibitors have pan-genotypic antiviral activity that may be facilitated by binding to a conserved site on NS5A monomers or dimers that stabilizes their structure, preventing further conformational changes important for virus replication.[54,233] NS5A RAS are detected in the HCV quasispecies before treatment and amplify under selection pressure from inhibitors. The most potent RAS that provide resistance across four or more genotypes are located within NS5A D1 domain (93Tyr) or the linker sequence between D1 and the N-terminal α-helix (31Leu) (Fig. 8.18).[45] Genotype and even subtype

differences in RAS diversity and barrier to resistance have been described[836] and may be related to differences in evolutionary pathways to inhibitor resistance observed in genotype 1a versus 1b infections during a short course of monotherapy with an NS5a inhibitor (elbasvir).[841] NS5A RAV that emerged under selection pressure due to treatment failure with earlier-generation DAA combinations are very stable for years.[383,826] As noted above, persistence of NS5A RAV is an important consideration in selection of DAA for retreatment. The high SVR rate with current pan-genotypic DAA combinations may reflect in part a higher barrier to resistance for pibrentasvir and velpatasvir. When compared with earlier-generation NS5A inhibitors, pibrentasvir and velpatasvir had high uniform antiviral activity against all seven HCV genotypes in a cell culture model of virus replication.[252] Three days of monotherapy with these inhibitors selected for RAS in some patients but the barrier to resistance was generally higher. Unlike other NS5A inhibitors, resistance usually required replacement of amino acids at more than one position, and fitness for replication was impaired.[405,549]

Inhibitors of the NS5B RNA-dependent RNA polymerase. Synthesis of HCV RNA genomes by the membrane-anchored NS5B RdRp is mediated by a catalytic core with right-handed "finger, palm, thumb" subdomains (Fig. 8.18).[12,45,76,418] Structural studies and comparison with other viral RdRps indicate that the catalytic core is closely tethered to the membrane in a closed conformation for initiation of synthesis with a single-stranded RNA template.[281,693] Conversion to an open conformation with a large cavity accommodates double-stranded RNA for the elongation process (Fig. 8.18).[45,523] Polymerase inhibitors fall into two major classes based on mode of action. The nucleotide and nucleoside inhibitors (NI) are mimics of ribonucleosides or ribonucleotides that competitively inhibit binding of the natural substrate to the HCV RdRp active site. Once incorporated into the catalytic site during transcription, NI 2′-C-methyl or 5′-fluoro groups sterically hinder further incorporation of nucleotides resulting in chain termination.[145] As a class, NI are nonphosphorylated prodrugs that must be converted into the active nucleoside 5′ triphosphate by cellular enzymes, an inefficient and rate-limiting process. Sofosbuvir (SOF), the only NI approved for treatment of chronic hepatitis C, is a ProTide that overcomes this limitation by adding one phosphate during synthesis.[708] All NI including SOF have pan-genotypic antiviral activity and a high barrier to resistance because

they bind the functionally conserved catalytic pocket of the polymerase.[316,407] One RAS, Ser282Thr, provides escape from SOF in a cell culture model, but it substantially impairs virus replication (Fig. 8.18).[408] Selection of RAS including Ser282Thr by SOF is rarely observed in clinical studies.[159,406,729] Nonnucleoside inhibitors (NNI) bind allosteric sites in the NS5B thumb and palm domains outside of the catalytic pocket. They act noncompetitively by preventing RdRp conformational changes after binding to one of five allosteric sites outside of the catalytic grove (Fig. 8.18).[45] The only NNI licensed for treatment of chronic hepatitis C is dasbuvir that binds a site at the junction of the palm and thumb subdomains to block a step before RNA chain elongation.[599] Unlike NI, NNI readily select for RAS that do not impose a high fitness for HCV replication. Failure to achieve SVR with early DAA combinations containing dasbuvir was associated with emergence of NS5B RAS Met414Thr and Ser556Gly in genotype 1a viruses (Fig. 8.18).[204,598,835] Several NS5B NNI RAS occur naturally at high frequency.[153] For instance, the RAS Ser556Gly was found in approximately 8% of HCV-1b sequences and a remarkable 97% (genotype 4) to 100% (genotypes 2, 3, 5) of other clinically significant genotypes.[153]

Host-targeting agents

HCV has a pervasive impact on the infected hepatocyte, subverting and repurposing multiple cellular pathways to support entry, translation and replication, assembly, and export of virions. Development of host-targeting agents (HTA) to inhibit HCV replication has occurred in parallel with DAA development, with the objective of finding alternative or complementary pan-genotypic antivirals with a high barrier to resistance. HTA designed to block almost every stage of the virus replication cycle have been developed, and a small number were assessed in clinical studies. They include small molecules designed to block HCV binding to the SR-BI entry receptor,[645,722] the cyclophilin A:NS5A interaction required for replication and membranous web formation,[535,574] and core protein trafficking to lipid droplets.[232] None were sufficiently potent against HCV when compared with DAA combinations. One potential exception is an inhibitor of miRNA-122 designated miravirsen (SPC3549). Miravirsen is an antisense locked nucleic acid–modified phosphorothiate oligonucleotide that demonstrated strong pan-genotypic suppression of HCV replication in cell culture models.[330,331,420]

Weekly dosing of patients with chronic hepatitis C demonstrated that the compound is safe, an important consideration given the role of miR-122 in host lipid metabolism. It was highly effective in dose-dependent suppression of HCV replication. Virological relapse within 14 weeks of completing treatment and wide variation in patient responsiveness indicated that miravirsen will only be effective in combination with other agents.[318,786]

Public Health Measures and Treatment to Reduce Transmission

A global strategy to eliminate HCV and HBV by 2030 was adopted by the World Health Organization (WHO) in 2016 (see www.who.int/hepatitis/strategies2016-2021/ghss-hep/en). This goal is aligned with a 2017 recommendation from the National Academy of Sciences to undertake elimination of these viruses in the United States.[537] Elimination of infection is distinct from eradication and is defined as the reduction of infection and/or disease in a given geographic area through deliberate control efforts that must be continued indefinitely to prevent reemergence. The 2030 elimination target for viral hepatitis is a 90% reduction in new chronic infections caused by HCV and HBV and a 65% reduction in deaths when compared with a 2015 baseline. HCV elimination programs have been initiated in a number of countries but are most advanced in Egypt, Georgia, Iceland, and Australia.[161,173,669]

Safety of the blood supply has improved dramatically with implementation of effective screening measures for HCV antibodies and nucleic acid testing to identify contaminated units. In countries with effective screening measures, the estimated risk of HCV infection from blood transfusion is now 1:1,900,000 donated units, a dramatic reduction from the era before the discovery of HCV when the risk was approximately 1:10.[157,319,605] Further progress in reducing transfusion-associated infections in low-income countries will require more uniform adoption of effective blood screening measures.[137] Unsafe injection practices caused by reuse of needles and an absence of sterile equipment in medical settings also continue to be a source of HCV infections in many parts of the world despite improvement.[305,579,604] As noted above (Epidemiology), new HCV infections are increasing globally and in the United States because of needle sharing

associated with injection of opioids and heroin. Needle exchange and opioid substitution therapy sharply reduce the risk of HCV transmission,[521,595] but these programs have not been instituted in much of the world. Regional disparities in availability exist in many developed countries including those in Europe and the United States.[223,649,800] Availability of DAA to treat HCV safely and with fewer side effects can reduce prevalence.[291,313] It also has the potential to interrupt transmission,[283,526] but will require a commitment to diagnosis and treatment in many regions of the world where new HCV infections still outpace cure of chronic hepatitis C.[290] Expanded treatments, along with other harm reduction strategies discussed above, are cornerstones of national elimination programs in Egypt, Australia, Iceland, and Georgia that may provide models for the future.[161,173,283,669]

Vaccines

Vaccines to prevent and treat chronic HCV infection have been a major research focus since discovery of the virus. Therapeutic vaccines directed at restoring HCV-specific T-cell immunity were assessed in chronically infected humans, but they provided no significant control of persistent virus replication.[41,762] Two studies demonstrated the challenge in restoring T-cell immunity under conditions of persistent HCV infection. Chronically infected chimpanzees that received a genetic vaccine expressing HCV nonstructural proteins NS3-NS5B while viremia was transiently suppressed with DAA failed to clear the virus.[96] The HCV genes, delivered by priming and boosting with recombinant adenoviruses, elicited a CD8+ T-cell response against epitopes that were unique to the vaccine or had acquired escape mutations earlier in infection.[96] The same highly immunogenic vaccine also failed to elicit CD8+ T cells targeting the circulating virus in humans treated with pegIFN/riba.[354,731] Therapeutic vaccines are no longer a priority with the advent of DAA therapy.

A preventive vaccine is considered a high priority for prevention of primary infection and reinfection after DAA cure, especially in those who remain at risk for reexposure to the virus.[461,462,501,592] Modeling studies indicate that even a partially effective vaccine would reduce HCV transmission[273,454,668,716] and contribute directly to the goal of global HCV elimination that for now relies entirely on public health measures and

expanded access to DAA therapies.

The objective of vaccination is to prevent persistent infection. As detailed above (see Clinical Features), acute hepatitis C is often subclinical, and so there is no apparent requirement to induce sterilizing immunity by vaccination. Two observations support the concept that a vaccine to prevent persistence, but not necessarily infection, is feasible. Most importantly, spontaneous resolution of infection elicits long-lasting adaptive immunity that responds rapidly upon reexposure to the virus. Duration and magnitude of viremia are reduced, and the risk of persistent infection is sharply lower in individuals with naturally acquired immunity. Protection against an array of HCV genotypes has been observed in chimpanzees after clearance of primary infeciton.[391] In addition, there is clear evidence that control of acute primary and secondary infection is associated with onset of sustained HCV-specific neutralizing antibody and T-cell responses (discussed in detail in Immune Responses).

Two parallel approaches to vaccine development have been pursued. The first is immunization with envelope glycoproteins to induce protective humoral immunity. This approach is exemplified by immunization with recombinant HCV genotype 1a envelope glycoproteins E1 and E2 produced in CHO cells and formulated in an oil/water emulsion adjuvant (designated MF59) for induction of neutralizing antibodies.[299] This strategy, developed at Chiron Corporation, elicited antibodies that provided apparent sterilizing immunity to HCV challenge in some chimpanzees.[299] Breakthrough infections were observed, but virus replication was attenuated and spontaneous resolution was more likely when compared with mock vaccination controls.[299] The vaccine induced strong CD4+ T-cell immunity and antibodies that had broad neutralizing activity against most HCV genotypes in cell culture studies.[497] Safety and immunogenicity of this vaccine was assessed in human volunteers with no risk factors for HCV infection. Pan-genotypic neutralizing antibodies and robust CD4+ T-cell memory were also elicited in the human volunteers.[225,403] Expanded immunogenicity and efficacy trials have not yet been undertaken.

The second approach to preventive vaccination involves induction of T-cell immunity with a nonstructural NS-NS5B gene cassette delivered using a prime boost strategy with virus vectors. This vaccine is unlike others developed for protection against virus infections, as it was designed to prime

CD4+ and CD8+ T cells that are resistant to exhaustion during acute infection. Preclinical studies demonstrated that this vaccine elicited strong memory T-cell immunity in chimpanzees that was rapidly recalled upon HCV challenge.[214] A typical pattern of robust acute phase HCV replication observed in mock-vaccinated animals was suppressed by several orders of magnitude in the group that received the vaccine.[214] Safety and immunogenicity of this vaccine was assessed in human volunteers. Vaccinees who received two immunizations with serologically distinct adenovirus vectors developed robust T-cell immunity targeting class I and II epitopes encoded by the NS3-NS5B gene cassette.[42] The second adenovirus vector was replaced with a modified vaccinia Ankara (MVA) vector in a immunogenicity second trial. The MVA vector provided substantially stronger boosting of HCV-specific T-cell immunity.[730] The combination of adenovirus and MVA vectors containing the HCV NS3-NS5B gene cassette has been assessed in a staged phase I/II clinical trial in Baltimore, San Francisco, and Santa Fe, New Mexico (see Clinical Trials.gov NCT01436357). The objective of the trial was to assess protection from HCV persistence in participants who are HCV-naïve but at risk for infection. An initial report of results was provided on the ClinicalTrials.gov Web site (NCT01436357) in 2019. The frequency of incident persistent infections (5.1%) was identical in the vaccine and placebo arms. Analysis of a subset of subjects in both arms revealed that HCV-specific immune responses were present in 97% of vaccinees versus 4% of subjects who received the placebo. Why this vaccine failed to protect against HCV persistence is not known. A detailed analysis of immunogenicity in vaccinated subjects at risk of HCV exposure, as well as the nature of the recall response in those who were infected, sequencing matching between the vaccine and circulating virus, and evolution of HCV genomes in acute and chronic phases of infection should provide critical insight into this question.

PERSPECTIVE

The landscape of HCV research and treatment has changed dramatically over the past 6 to 7 years. From a research perspective, the discovery of new rodent and equine hepaciviruses provides new opportunities to study key elements of the host–virus relationship that are difficult to approach in

humans. Important unanswered questions about *Hepacivirus* subversion of hepatic innate and adaptive immune responses can be addressed in these tractable animal models. Whether immune responses recover or afford protection after DAA cure is also unknown and will be assessed in humans and possibly the new animal models. Understanding failure and recovery of virus-specific T cells is likely to provide general knowledge relevant to other persistent human infections and diseases where immune exhaustion is a barrier to cure.

The rapid evolution of DAA to pan-genotypic regimens of 8- to 12-week duration with a single daily pill has revolutionized treatment for chronic HCV infection. It has also made the concept of HCV elimination a possibility, although it is clear that the task will be difficult with enhanced public health measures and antiviral treatment alone. Mathematical modeling indicates that a vaccine with 30% efficacy would have a measurable impact on transmission.[273,454,668,716] A detailed understanding of why the first efficacy trial of a preventive HCV vaccine failed is an imperative. New animal models may also provide guidance on the critical unanswered question of what constitutes protective immunity. Success will ultimately also require a sustained commitment to assess vaccines in humans, and to learn from setbacks, in an era of highly effective DAA therapy.

Acknowledgments

Flaviviruses acquired their name from the jaundice associated with the liver dysfunction caused by yellow fever virus (YFV) infections. YFV played an important historical role in defining the nature of viruses. Seminal studies by Walter Reed and colleagues demonstrated that the etiology of yellow fever was a filterable agent that could be transmitted through the bite of a mosquito, confirming the postulates of Carlos Finlay.[1064] YFV was the first flavivirus isolated (in 1927), the first flavivirus to be propagated *in vitro*,[1073,1113] and the first flavivirus for which a vaccine was developed and deployed.[770] Experiments with louping-ill virus (LIV) in 1931 established that ticks also could transmit viruses associated with human disease.[152] The discovery that flavivirus-immune sera could be cross-reactive with other flaviviruses that caused similar diseases (e.g., encephalitis) provided a method to investigate relatedness among these viruses.[167–169,1188] These evolutionary concepts were refined further with new serologic assays that

allowed them to be distinguished from alphaviruses.[168] Advances in the molecular genetics of flaviviruses confirmed and advanced an understanding of the evolution, biology, pathogenesis, and immunity to these viruses. Fifty-four species within the *Flavivirus* genus have since been defined by the International Committee on Taxonomy of Viruses.

FLAVIVIRUS EVOLUTION, DIVERSITY, AND DISTRIBUTION

Molecular Phylogeny and Evolution

Phylogenetic relationships among viruses within the *Flavivirus* genus reflect key features of the biology and ecology of these viruses (Fig. 9.1). Four groups of flaviviruses cluster according to their natural host and mode of transmission, including tick-borne flaviviruses (TBFVs), mosquito-borne flaviviruses (MBFVs), those with no known vector (NKV), and insect-specific flaviviruses (ISFs).[577,701,948] Flaviviruses have an African origin. Efforts to determine the date of the appearance of the first flavivirus using molecular clock approaches vary considerably depending on analysis parameters, including the event used for calibration in time.[379,795] For example, a recent study hypothesized the introduction of the TBFV Powassan virus (POWV) into North America occurred 11 to 15 thousand years (kyr) ago and was linked to use of the Beringian land bridge that once connected Alaska and Asia. Analysis of the timing of the origin of flaviviruses with respect to this reference led to the conclusion that flaviviruses are older than previously appreciated and emerged approximately 80 kyr.[872] Flaviviruses diverged from an ancestor that was not vectored by arthropods into groups containing the TBFV and MBFV; two groups of NKV viruses cluster among both branches of the phylogenic tree, as detailed below.[380]

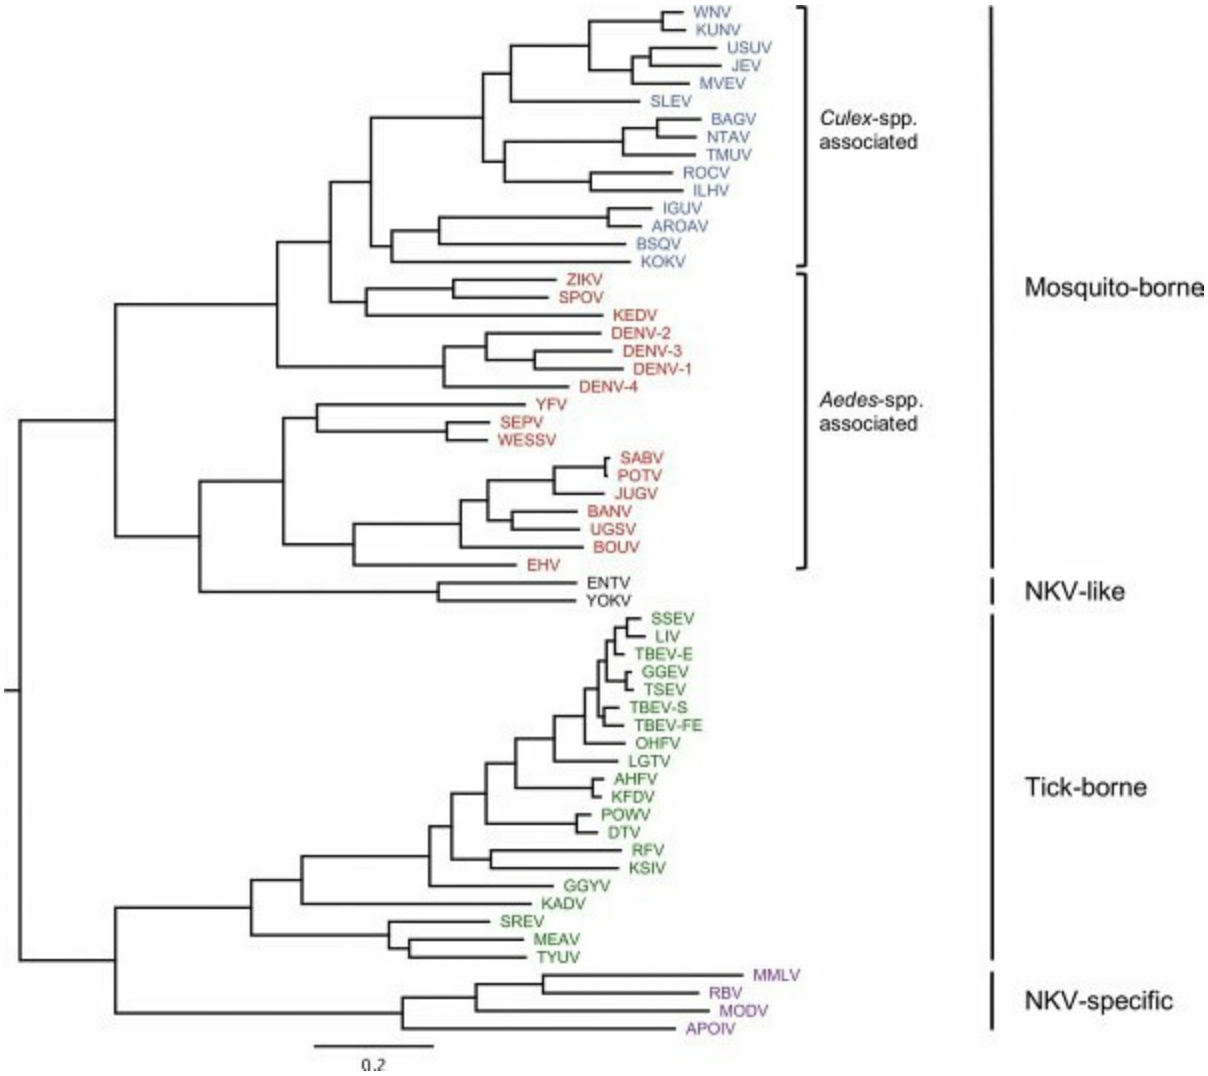

FIGURE 9.1 Phylogenetic tree of viruses in the *Flavivirus* genus. A maximum-likelihood (ML) tree was generated using the complete polyprotein amino acid sequence of the indicated flaviviruses. The polyprotein amino acid sequence alignment was generated using Clustal W2 provided in Geneious v11.1.2, and the ML tree was constructed using PhyML v3.2.2. The tree is midpoint rooted, and vertical length is arbitrary. The scale bar represents substitutions per site. The viral taxa are abbreviated and colored according to their mode of transmission. Apoi virus; MODV, Modoc virus; RBV, Rio Bravo virus; MMLV, Montana myotis leukoencephalitis virus; TYUV, Tyuleniy virus; MEAV, Meaban

virus; SREV, Saumarez Reef virus; KADV, Kadam virus; GGYV, Gadgets Gully virus; KSIV, Karshi virus; RFV, Royal Farm virus; DTV, deer tick virus; POWV, Powassan virus; KFDV, Kyasanur Forest disease virus; AHFV, Alkhurma hemorrhagic fever virus; LGTV, Langat virus; OHFV, Omsk hemorrhagic fever virus; TBEV-FE, tick-borne encephalitis virus Far Eastern subtype; TBEV-S, tick-borne encephalitis virus-Siberian subtype; TSEV, Turkish sheep encephalitis virus; GGEV, Greek goat encephalomyelitis virus; TBEV-E, tick-borne encephalitis virus-European subtype; LIV, louping ill virus; SSEV, Spanish sheep encephalomyelitis virus; YOKV, Yokose virus; ENTV, Entebbe bat virus; EHV, Edge Hill virus; BOUV, Bouboui virus; UGSV, Uganda S virus; BANV, Banzi virus; JUGV, Jugra virus; POTV, Potiskum virus; SABV, Saboya virus; WESSV, Wesselsbron virus; SEPV, Sepik virus; YFV, yellow fever virus; DENV-4, dengue virus serotype 4; DENV-1, dengue virus serotype 1; DENV-3, dengue virus serotype 3; DENV-2, dengue virus serotype 2; KEDV, Kedougou virus; SPOV, Spondweni virus; ZIKV, Zika virus; KOKV, Kokobera virus; BSQV, Bussuquara virus; AROAV, Aroa virus; IGUV, Iguape virus; ILHV, Ilheus virus; ROCV, Rocio virus; TMUV, Tembusu virus; NTAV, Ntaya virus; BAGV, Bagaza virus; SLEV, St. Louis encephalitis virus; MVEV, Murray Valley encephalitis virus; JEV, Japanese encephalitis virus; USUV, Usutu virus; KUNV, Kunjin virus; WNV, West Nile virus; NKV, species with no known vector. The tree was created by Ms. Katherine Burgomaster (NIAID, NIH).

Mosquito-Borne Flaviviruses

MBFVs diverged early into two lineages that principally use *Aedes* or *Culex* genus mosquitoes as vectors[389,536] (Fig. 9.1). Viruses in these two MBFV clades generally cause hemorrhagic disease or encephalitis, respectively, in

humans and livestock. While many of the viruses in the *Culex* clade infect avian hosts, *Aedes* viruses do not. Conversely, *Culex* viruses are not maintained in infection cycles involving primates. Viruses of the *Aedes* clade are a paraphyletic group thought to predate and give rise to the *Culex* viruses.[380,389] One branch of the MBFV phylogenic tree includes viruses of the YFV group, the recently proposed Edge Hill virus (EHV) group, and three NKV viruses discussed in detail below. The YFV group includes Wesselsbron virus (WESSV), Sepik virus (SEPV), and YFV. WESSV is a veterinary pathogen transmitted by *Aedes* mosquitoes that causes a nonfatal febrile illness in humans. Very little is known about the clinical significance and vector biology of SEPV infection. Both SEPV and WESSV are found in Africa and Asia.[389] YFV biology and pathogenesis are detailed below. The seven viruses of the EHV group are transmitted predominantly by *Aedes* mosquitoes, found primarily in Africa (except for EHV, which is present in Australia), and share the unique property of encoding five (instead of six) disulfide bridges in the envelope (E) glycoprotein. Among this group, human cases have been associated only with Banzi virus (BANV) infection.[389] The second branch of the MBFV phylogenic tree contains dengue viruses (DENV), which are transmitted by *Aedes* mosquitoes, a large group of viruses vectored by *Culex* mosquitoes (e.g., Japanese encephalitis virus [JEV], West Nile virus [WNV]), and a group of *Aedes*-vectored viruses closely related to the *Culex* flaviviruses including Spondweni virus (SPOV) and Zika virus (ZIKV).[536] The biology, pathogenesis, and diversity of viruses in the JEV serocomplex, ZIKV, and DENV are described in detail below.

Tick-Borne Flavivirus

The TBFVs include three groups that differ with respect to their vertebrate host and tick vectors.[390,536] The largest group of TBFVs infect mammalian hosts (typically rodents), are vectored by *Ixodes* ticks, and can cause encephalitis (e.g., tick-borne encephalitis viruses [TBEVs]) or hemorrhagic fever (e.g., Kyasanur Forest disease virus [KFDV]) in humans. Mammalian TBFVs that are not linked to human disease include Royal Farm virus (RFV), Karshi virus (KSIV), and Gadgets Gully virus (GGYV). Analysis of the evolution of viruses of the TBEV serocomplex has demonstrated that the rate of nonsynonymous nucleotide changes in the E protein correlates with geographic distance from the point of origin of these viruses.[1237] This is

reflected by the asymmetrical, stepwise branching pattern of the phylogenetic tree of the mammalian viruses[1238] (Fig. 9.1). This pattern of evolution has been confirmed using larger datasets.[453] These studies conclude that TBFVs evolved from a common ancestor in Africa approximately 28 kyr ago. The subsequent distribution and spread of early TBEVs, such as GGYV and POWV, may have been constrained by climate conditions of Asia until the glacial retreat at the outset of the Holocene epoch. POWV diverged further in North America into two lineages, which now includes deer tick virus (DTV).[458] These two viruses remain the only autochthonous TBFVs in the New World. Viruses of the TBEV serocomplex emerged into central Russia approximately 5 to 7 kyr ago, at which time they spread and diversified in eastward and westward directions.[453]

The second group of TBFVs replicates within seabirds and ornithophilic ticks but does not cause disease in humans. Viruses in this group include Meaban virus (MEAV), Saumarez Reef virus (SREV), and Tyuleniy virus (TYUV).[153] These viruses have a broad geographic range that presumably reflects the migratory patterns of their avian hosts.[380,390] A serological surveillance study for MEAV-reactive antibodies in residents of southern France, where the virus was first discovered, proved negative,[180] whereas SREV and TYUV may be capable of causing mild disease in humans.[701]

The TBFV Kadam virus (KADV) is the sole representative of a third lineage that arose early in the evolution of these viruses. An understanding of the relationship between KADV and other members of the TBFVs has emerged. While KADV was assigned to both the mammalian and seabird groups of flaviviruses, a more recent analysis of the complete coding sequence of TBFVs places KADV in its own group, which is supported by unique features of its E protein and the fact that it encodes a polyprotein that is smaller than the rest of the TBFV.[390,453] KADV is found in Africa, vectored by hard ticks that feed on mammals, and typically infects livestock.[380] KADV has not been associated with human infections.

No Known Vector Flavivirus

In comparison to the vector-borne flaviviruses, relatively little is known about viruses of the NKV group. These flaviviruses are reviewed comprehensively by Blitvich and Firth.[103] The 14 known NKV-like viruses

are found in rodents or bats, in which they do not appear to cause disease or a high viremia. NKV viruses of rodents are found only in the New World, whereas those infecting bats are found globally.[379] Several NKV viruses can cause human disease following occupational exposure, and while natural infection resulting in clinical illness has been reported, it appears uncommon. Two groups of NKV flaviviruses have been defined. The first cluster forms a clade that is more closely associated with TBFV than those vectored by mosquitoes and may contain the common ancestor from which both groups arose. This group of NKV flaviviruses can be divided further into two lineages that define those infecting rodents and bats.

The Entebbe bat virus group (Yokose virus [YOKV], Sokoluk virus [SOKV], and Entebbe bat virus [ENTV]) forms a lineage within the *Aedes*-vectored MBFV from which the YFV and EHV groups may have evolved. That some of these viruses can replicate in mosquito cell cultures raises the possibility that they, or their ancestors, were once transmitted by mosquitoes and then lost this trait[379,576,1097] (Fig. 9.1). This concept is supported by sequence features in the untranslated regions (UTR) of the viral genome that are similar to those present in MBFVs. However, one study reported the isolation of SOKV from a field-caught tick, suggesting that a capacity to replicate in arthropods has not been lost completely. A recent analysis of dinucleotide frequency among viruses of this group suggests greater adaptation to arthropods than mammals.[103] The natural history and vector competence of this group require further study to reconcile these observations.

Insect-Specific Flavivirus

The last 15 years has brought progress in the identification of ISF and insights into their biology.[212] The first ISF cell-fusing agent virus (CFAV) was discovered in 1975 as the causative agent of cytopathology in insect cell cultures occurring when exposed to materials derived from other mosquito cells.[1075] The isolation of Kamiti River virus (KRV) from *Aedes* mosquitoes in Kenya in 2003[967] was the first discovery of ISFs from mosquito populations. A detailed discussion of the molecular phylogeny is provided by Moureau and colleagues.[795]

Global Distribution

Flaviviruses are found on six continents where they are responsible for endemic and epidemic disease each year (Fig. 9.2). The geographic distribution of flaviviruses has proven dynamic, enabling emergence in new areas and with increased disease incidence.[685] Many examples of flavivirus emergence with impacts on global health have occurred. The recent materialization of ZIKV from a virus of minimal clinical significance in Africa to a pathogen of global health concern following its introduction into the Americas in 2015 is a clear demonstration of the threat posed by the shifting distributions of flaviviruses. Likewise, it took only 4 years for WNV to spread across the United States, where it is now an endemic pathogen, following its introduction into New York City in 1999.[943] The contribution of human activity toward the spread of flaviviruses is significant.[380] Prior to the development of rapid intercontinental transportation, the movement of flaviviruses between the Old World and New World was uncommon. YFV (and potentially the *Aedes aegypti* mosquito) was introduced into the Americas during the slave trade 300 to 400 years ago.[137] The distribution of DENV was enhanced as a consequence of the large-scale troop movements during World War II.[399] The continued spread of flaviviruses globally due to enhanced travel, urbanization, and climate change presents a persistent threat and highlights a need for the countermeasures against this genus of viruses.

FLAVIVIRUS COMPOSITION

Flavivirus Structural Proteins

Flaviviruses encapsulate a positive-stranded RNA genome encoding a single open reading frame flanked by two structured UTRs. The single viral polyprotein is processed by host and viral proteases into three structural (capsid [C], premembrane [prM], and E) and seven nonstructural proteins (NS1, NS2A, NS2B, NS3, NS4A, NS4B, and NS5), the latter of which mediate genome replication, viral polyprotein processing, and modulation of the host response. Flavivirus virions are spherical particles composed of three viral structural proteins, an approximately 11-kb genomic RNA, and a lipid envelope. The E protein is an approximately 53-kDa structural protein that functions in multiple steps of the virus replication cycle including virion assembly and budding, attachment of the virus to target cells, and viral membrane fusion (reviewed by Ref.[444]) It is also the major target of neutralizing antibodies (reviewed by Ref.[1044]) The E protein ectodomain structure has been solved for several flaviviruses, revealing an elongated finger-like protein composed of three domains connected by flexible hinges (Fig. 9.3). This structural organization is similar to other class II viral fusion proteins, such as alphavirus E1 proteins.[924] The E protein domain I (E-DI; shown in red) is an eight-stranded β-barrel located in the center of the E protein molecule. This central domain contains two of the six disulfide bonds present in the E protein, as well as a site for the addition of an asparagine-linked (N-linked) carbohydrate. E protein domain II (E-DII; shown in yellow) is an elongated structure that mediates dimerization of E proteins on the mature virion. A glycine-rich loop composed of 13 amino acids is located at the tip of E-DII, called the E-DII fusion loop (E-DII-FL; shown in green). In the context of the E protein dimers present on mature virions, the E-DII-FL sits in a hydrophobic pocket formed at the interface of E-DI and E protein domain III (E-DIII; shown in blue). The highly conserved fusion loop plays a

key role in viral membrane fusion by inserting into the membranes of target cells.[19,123,758] The introduction of mutations into the fusion loop blocks fusion between virions and the membranes of synthetic liposomes.[215] For some flaviviruses, E-DII contains a second N-linked glycosylation site, which facilitates attachment to host lectins during virus entry. E-DIII adopts an immunoglobulin-like fold and is stabilized by a single disulfide bridge. The E protein ectodomain is tethered to the viral membrane by a helical stem (the stem anchor) and two antiparallel transmembrane domains.[20,1244]

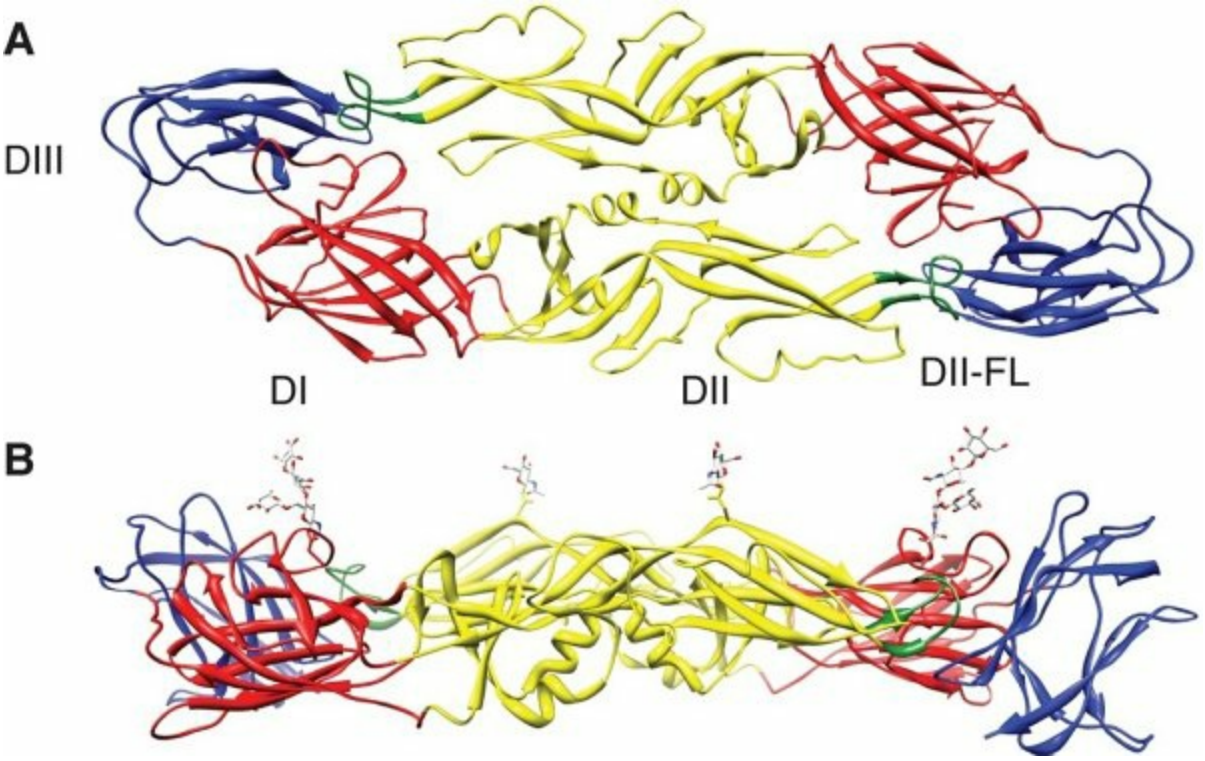

FIGURE 9.3 Structure of the flavivirus E protein. The envelope (E) proteins of flaviviruses are elongated class II viral fusion proteins composed of three structurally distinct domains.

A: Ribbon diagram of the DENV E protein dimer as seen from the top; individual domains of each E protein monomer are indicated (domain I, E-DI, *red*; domain II, E-DII, *yellow*; and domain III, E-DIII, *blue*). The fusion loop at the tip of E-DII is shown in *green*.

B: DENV E protein as viewed from the side. The stem anchor connecting the E protein to the viral membrane is not shown. The two N-linked

carbohydrate modifications at positions Asn67 and Asn154 are shown. We thank Mr. Phong Lee (NIAID, NIH) for preparation of the figure.

The precursor to membrane protein (prM) is an approximately 20-kDa protein that facilitates E protein folding and trafficking.[668] Interactions with the E protein also prevent the adventitious fusion of the virus during egress.[452] Virion maturation is regulated by the proteolytic cleavage of prM, which results in the formation of a “pr” protein and is ultimately released from the virion, and an approximately 8-kDa membrane associated M peptide. The structure of the “pr” peptide has been solved at the atomic level and is composed of seven β-strands held together by three disulfide bonds.[623] prM interacts with the E protein near the tip of E-DII adjacent to the E-DII-FL.[1245,1248] prM is anchored into the viral membrane via two antiparallel transmembrane domains.[797,1244]

The flavivirus capsid (C) protein is an approximately 12-kDa protein that orchestrates the encapsidation of the viral genome into the virus particle during morphogenesis.[146] The C protein contains four helical domains that interact as homodimers.[273,498,683,1017] In this arrangement, one surface is highly basic and capable of interacting with membranes.[702] The opposite face of the protein is concave, is positively charged, and binds nucleic acids.[524] The amino terminus of the protein exists in an ensemble of different states.[108] Flavivirus capsid proteins also have other roles in the replication cycle including interactions with host lipid droplets,[962] modulations of host signaling,[11] and antagonism of innate immune responses.[1160]

Flavivirus Assembly and Structure

Flaviviruses assemble on a network of highly organized virus-induced membranes derived from the endoplasmic reticulum (Fig. 9.4). Virions bud into the lumen of these membrane structures as immature virus particles on which E and prM proteins interact as trimers of prM-E dimers that project as spikes away from the viral membrane. The structure of the immature noninfectious form of the virion has been solved at high resolution for WNV, YFV, DENV, and ZIKV.[554,892,1234,1245,1248] These studies reveal that each virus particle contains 60 trimers arranged with icosahedral symmetry (Fig.

9.5). Analysis of the immature virion structure using methods that do not assume symmetry demonstrates that the capsid core of the virion is not located in the center of the virus particle, but positioned close to one side, with a disruption of the structural protein shell on the opposing pole. Although further studies are required to explore the functional significance of these “imperfections” in symmetry, these features may have implications for mechanisms of virus assembly and fusion.[1117] Transit of the immature virion through the acidic compartments of the trans-Golgi network (TGN) triggers an extensive rearrangement of E proteins on the immature virion. Under these conditions, E proteins lie flat against the viral membrane as antiparallel dimers, analogous to the arrangement of E proteins on the mature virions discussed below.[1234] In this configuration, prM remains associated with the fusion loop and protrudes as a bump from the surface of an otherwise smooth virus particle. This pH-dependent conformational change exposes a cleavage site on prM recognized by host serine furin-like proteases.[1061] Cleavage of prM by furin-like proteases is the hallmark of the virion maturation process and a required step in the virus replication cycle.[302] The release of the virion into the neutral conditions of the extracellular milieu results in the dissociation of the pr peptide.[623,1234]

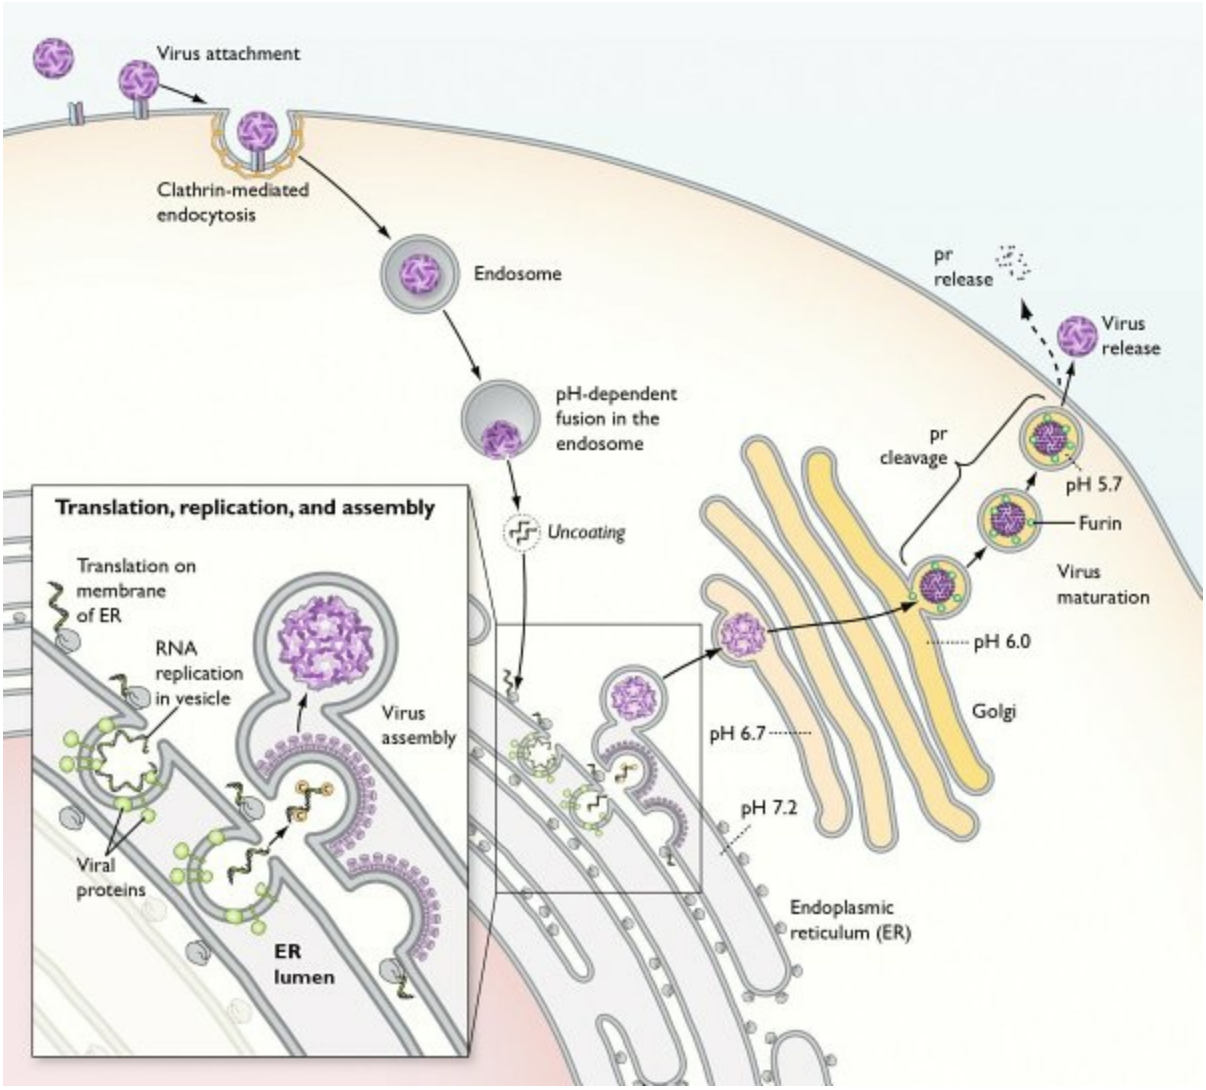

FIGURE 9.4 The replication cycle of flaviviruses. Flaviviruses bind cells via interactions with one or more cell-surface molecules. Viruses are internalized via clathrin-mediated endocytosis and fuse with membranes of the late endosome in a pH-dependent manner. Viral RNA replication begins shortly thereafter in association with cellular membranes. Infected cells reveal striking host membrane rearrangements thought to coordinate the processes of genomic RNA replication and virus assembly. Virus particles assemble at and bud into the endoplasmic reticulum and are secreted from the cell. During egress, virion maturation occurs in the acidic compartments of the Golgi and is characterized by cleavage of the

prM protein by a furin-like protease. The cleaved “pr” peptide is released from the virus particle once released into the neutral pH of the extracellular space.

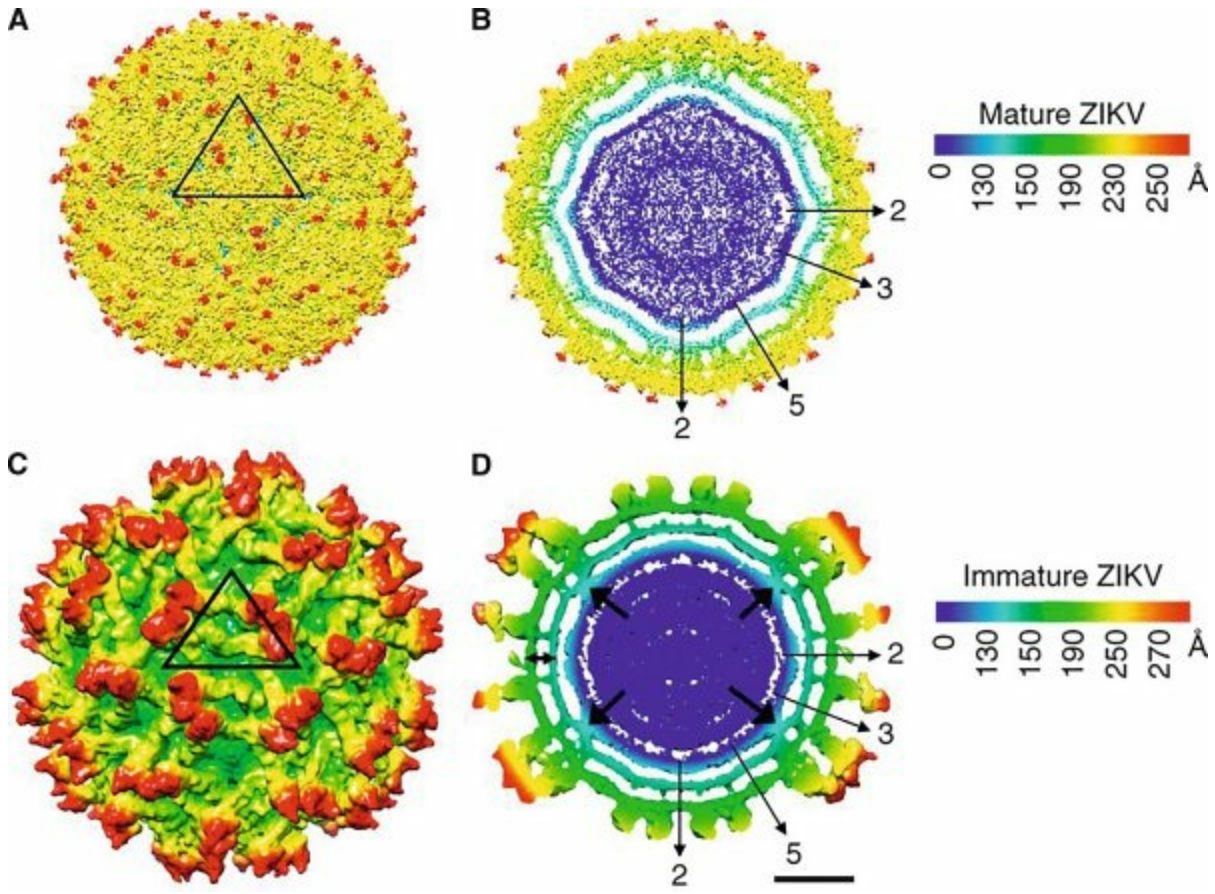

FIGURE 9.5 The structure of flaviviruses. Flaviviruses assemble as immature virus particles decorated by trimers of prM-E dimers. During virion egress, prM is cleaved by a host furin-like serine protease in a pH-dependent process. Release of the virus particle into the neutral environment of the extracellular space results in the disassociation of the cleaved “pr” fragment and formation of the mature virion. Surface and cross-sectional view of the structure of the mature ZIKV **(A and B)**. The thin black arrows depict the three symmetry axes of the herringbone arrangement of E proteins on the relatively smooth surface of the virion. The virion is colored

radially. Surface and cross-sectional view of the structure of the immature ZIKV virion **(C and D)**. The thick black arrows highlight the interactions between the core of the virion and the inner leaflet of the virion, whereas double-ended arrows mark the inner and outer layers of the viral membrane.
(This image was published by Prasad VM, Miller AS, Klose T, et al. Structure of the immature Zika virus at 9 A resolution. *Nat Struct Mol Biol* 2017;24:184–186, and included with permission.)

Pioneering cryoelectron microscopic studies of DENV by the Kuhn and Rossmann laboratories revealed that mature virions are relatively smooth in appearance and incorporate 180 copies of the E protein arranged in a herringbone pattern (Fig. 9.5).[563] Subsequent studies of WNV, JEV, and ZIKV confirmed this organization, and advances in cryoelectron microscopy now allow the interactions among structural proteins of the virion to be viewed with atomic resolution.[552,553,1013,1041,1172,1247] One striking structural feature of the virion is that virtually the entire surface of the membrane is covered by viral proteins. This dense arrangement likely is linked to the structural mechanisms that orchestrate viral fusion but presents unresolved steric challenges for host factors that bind directly to the viral lipid envelope during virion attachment, such as TIM-1 or Gas6 as detailed below. A second key feature of the mature virion structure is that E proteins are not arranged with true icosahedral symmetry. The significance of this is that E proteins of the virion exist in three chemically distinct dimer environments defined by their proximity to the two-, three-, or fivefold symmetry axes. An important biological implication of this arrangement is that antibodies[833] and host factors may be capable of engaging only a subset of E proteins that constitute the virion.

Subviral Particles

Expression of the flavivirus structural proteins prM and E is sufficient for the production of subviral particles (SVPs) that share many functional and antigenic features with infectious virions.[981] SVP expression systems have been used to examine the cell biology of structural protein folding and trafficking, virus particle morphogenesis, mechanisms of viral membrane fusion, and antibody epitope mapping.[221,668,669,981] The atomic structure of

SVPs remains uncertain. Early cryoelectron microscopic reconstruction studies of TBEV SVPs revealed an icosahedral structure of roughly 30 nm in diameter composed of 30 antiparallel E protein dimers.[319] A similar structure was recently reported for a variant of DENV SVPs that encoded an optimized furin cleavage site.[1020] However, other studies demonstrate SVPs are heterogeneous in structure and size.[21] Because SVPs are used as vaccine candidates for multiple flaviviruses,[331,549,550,561,710,880] a more detailed understanding of the structures of these virus-like particles is needed.

Virion Heterogeneity and Dynamics

Implications of Inefficient prM Cleavage

While atomic resolution structures of the mature virion exist, it is now clear these images do not capture all biologically active forms of the infectious virus.[876] Cleavage of prM is a required step in the flavivirus replication cycle; mutation of the RRXR/S motif in prM recognized by furin-like proteases renders TBEV noninfectious.[302] However, biochemical studies of preparations of flaviviruses produced *in vitro* indicate that a substantial amount of prM remains uncleaved; greater than 90% of DENV virions could be precipitated with anti-prM antibodies.[500] Electron microscopy studies identified virus particles with structural features of both mature and immature virions (hereafter referred to as “partially mature virions”).[887] Several lines of evidence indicate that partially mature virions are infectious: (a) virions that retain significant uncleaved prM are less sensitive to inactivation by acid pH conditions sufficient to trigger the E-protein rearrangements that drive viral membrane fusion, presumably because pH-mediated changes in the arrangement of E protein are reversible when in complex with prM[401]; (b) uncleaved prM can modify the efficiency and mechanism of virion attachment to cells[241,253,796]; (c) antibodies that target prM can enhance virus infection *in vitro* and *in vivo*[52,251,1240]; and (d) the efficiency of prM cleavage may influence the sensitivity of virions to neutralization by antibodies targeting the E protein.[281,818] Although these studies demonstrate that virions containing prM may be infectious, the stoichiometric requirements of prM cleavage have not yet been determined. Thus, virion infectivity, antibody recognition, and host–factor interactions have the potential to be influenced

by levels of uncleaved prM. The efficiency of prM cleavage *in vivo* remains an important question and should be considered for both vector and mammalian hosts. Of interest, recent analysis of DENV serotype one (DENV-1) isolates from human plasma demonstrated that viruses in this compartment are largely mature.[914]

Implications of Dynamic Virions

Flaviviruses present a dynamic antigenic surface that is not fully captured by static models of virion structure. It has long been appreciated that proteins are in constant motion and sample an ensemble of conformations at equilibrium.[106] Proteins incorporated into virus particles also are structurally dynamic.[493,1207] Conformational dynamics, or virus "breathing," has been demonstrated for several unrelated classes of viruses[112,614,801] and may affect antibody recognition.[441,627,1226] The first example of the impact of conformational dynamics on the structure of flaviviruses arose from studies of the recognition of a DENV serotype 2 (DENV-2) virus by a neutralizing E-DIII–reactive monoclonal antibody (mAb) 1A1D-2.[664] Analysis of the binding interface of 1A1D-2 suggested occupancy of this site would be prevented by steric clashes arising from the dense arrangement of E proteins on the virion. Binding of 1A1D-2 Fab fragments was possible only at physiological temperatures. Cryoelectron microscopic reconstruction of mature DENV-2 bound by the 1A1D-2 Fab fragment revealed changes in the arrangement and orientation of E proteins on the surface of the virus particle, suggesting antibodies can trap the virion in states distinct from the herringbone arrangement found on mature virions. Subsequent structural studies of this strain at physiological temperatures in the absence of mAb revealed a heterogeneous population of virions that included an expanded "bumpy" conformation more permissive for 1A1D-2 recognition,[324,1249] although not all DENV strains adopt this configuration. Neutralization studies with multiple flaviviruses suggest that the conformational dynamics of virions frequently contributes to the efficiency of antibody recognition, although the degree to which this is observed correlates with the accessibility of the antibody epitope on the mature virus particle.[279,281] Virions that retain prM also sample multiple states at equilibrium.[281,950] That temperature, viral strain, and even single amino acid substitutions influence the structural ensemble of flaviviruses highlights the importance of understanding how

interactions among viral structural proteins determine the average state of the virion, its stability, antigenicity, and capacity for fusion.[278,373] The recent application of hydrogen/deuterium exchange mass spectrometry (HDX-MS) to explore these issues is a promising technical advance.[636,637]

CLINICAL AND PATHOLOGIC SYNDROMES OF THE FLAVIVIRUSES

Dengue Virus

History, Global Distribution, and Epidemic Cycle

The natural cycle of epidemic DENV infection is between the mosquito vector (*Aedes aegypti* or *Aedes albopictus*) and humans (Fig. 9.6). After mosquito inoculation, DENV infection causes a spectrum of clinical disease ranging from self-limited dengue fever (DF) to a life-threatening hemorrhagic and capillary leak syndrome (dengue hemorrhagic fever [DHF]/dengue shock syndrome [DSS], now termed “severe dengue”). Globally, there is significant diversity among DENV strains, including four serotypes (DENV-1, DENV-2, DENV-3, and DENV-4) that differ at the amino acid level in the viral envelope proteins by 25% to 40%. DENV causes an estimated 390 million infections and 500,000 cases of DHF/DSS per year worldwide, with 2.5 billion people at risk.[90,419,765]

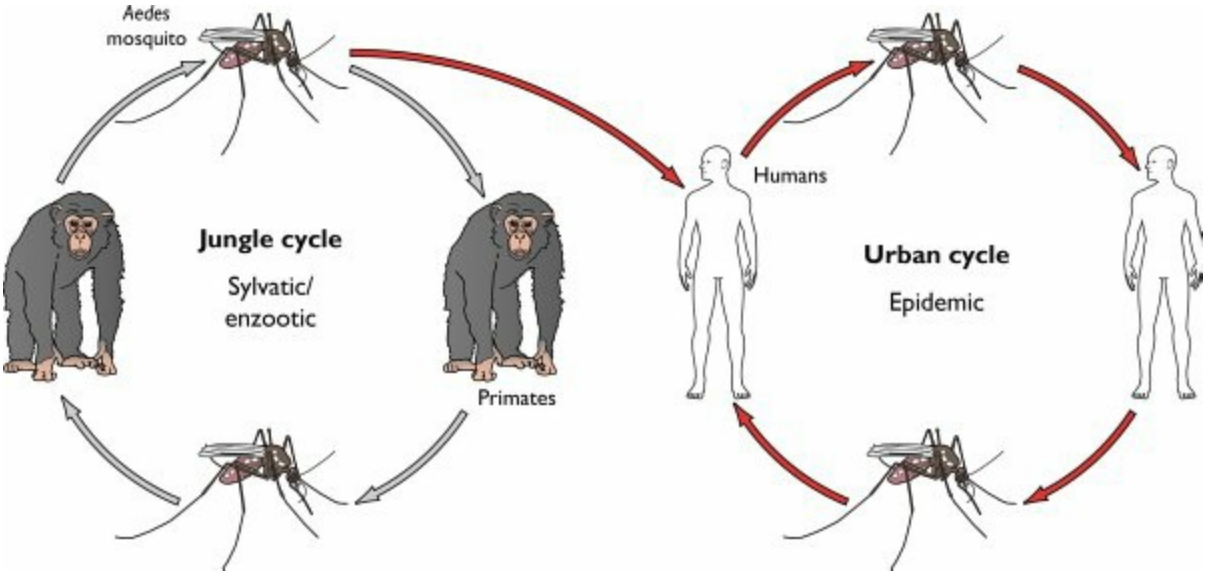

FIGURE 9.6 Life cycle of dengue virus. DENV circulates in nature in two relatively distinct transmission cycles vectored by *Aedes* spp. mosquitoes. DENV infection of humans results in a sufficiently high viremia to support infection of feeding mosquitoes; DENV transmission cycles do not require an enzootic amplifying host. DENV may also replicate in a sylvatic cycle. While incompletely understood, the contribution of sylvatic strains of DENV to human infections appears minimal.

Although a dengue-like syndrome may have occurred in China several times during the first millennium AD, the initial description of a DENV epidemic is attributed to Benjamin Rush, a physician in Philadelphia, in his article reporting a febrile outbreak in 1780.[951] Primary DENV infection and epidemics were common in North America, the Caribbean, Asia, and Australia during the 18th and 19th centuries, presumably due to the widespread distribution of the mosquito vectors. During World War II, DENV spread to and through Southeast Asia. Troop movement and the destruction of the environment and human settlements are believed to have promoted the spread of DENV and their mosquito vectors.[575] Since 1950, the number of people infected has risen steadily, such that today dengue is the most prevalent arthropod-borne viral disease in the world. With the spread and cocirculation of multiple DENV serotypes, secondary infection with

heterologous serotypes and epidemic DHF/DSS emerged 50 years ago in Southeast Asia[435] and more recently in the Americas in 1981[556] and South Asia in 1989.[740] Since the 1950s, epidemics involving thousands of people with multiple DENV serotypes and strains occur annually in multiple parts of the world including the Americas, Asia, Africa, and Australia, in essence wherever the primary mosquito vector *Aedes aegypti* is present. Indeed, after an outbreak of DENV in Key West, Florida, in 2009, a serosurvey conducted by the CDC reported that 5.4% of households had evidence of recent DENV infection.[28] As a reflection of this, the global incidence of DHF/DSS has increased over 500-fold, with more than 100 countries affected by outbreaks of dengue.[585]

DENV Diversity

Globally, there is significant diversity among DENV strains. The four serotypes of DENV (DENV-1, DENV-2, DENV-3, and DENV-4) are genetically distinct but cause similar diseases and share epidemiological features. All DENV strains are members of the dengue antigenic complex; inclusion of a strain as DENV is based on antigen cross-reactivity, sequence homology, and genomeorganization.[153] The four serotypes of DENV were historically distinguished by limited cross-neutralization or hemagglutination inhibition using serum from infected individuals. Subsequent sequencing analysis revealed that individual serotypes of DENV can differ from one another at the amino acid level significantly with 30% to 40% variation in the viral envelope proteins. Thus, individual DENV serotypes (e.g., DENV-1 vs. DENV-4) vary far more than distinct viruses in the Japanese encephalitis serocomplex (e.g., WNV and JEV vary by 10%–15% at the amino acid level), which has led some to consider DENV as a group of four different viruses that are linked by serology, epidemiology, and disease pathogenesis. Notwithstanding these sequence differences, recent analysis suggests that some DENV strains have greater antigenic resemblance to viruses of a different serotype than to some viruses of the same serotype, which has implications for clinical disease and DENV evolution.[511] Differences in severity associated with individual serotypes or particular sequences of serotypes in sequential infection have been observed, and it still is unclear whether some serotypes are inherently more pathogenic than others. DENV-2 viruses are most commonly associated with DHF/DSS,[49,142,1115] as are

DENV-1 and DENV-3.[384,442,740] In comparison, DENV-4 appears more commonly to be clinically mild, although it can cause severe disease.[829]

Genetic variation of DENV, however, is not limited to serotype. Geographic variants within a serotype were initially identified by RNAse fingerprint assays.[923,1154] Subsequently, nucleic acid sequencing confirmed differences within each serotype, allowing for classification of genotypes that vary further by up to approximately 6% and 3% at the nucleotide and amino acid levels, respectively.[470,931] DENV genotype classification originally was defined by sequence variation within a given genomic region (e.g., E and NS1 sequences). More recent analysis has used full-genome sequencing to assign a phylogenetic classification. Although there remains some dissonance among investigators because of a lack of defined, formal definitions,[226] most classification schemes include five DENV-1 genotypes, four or five DENV-2 genotypes, four DENV-3 genotypes, and two or three DENV-4 genotypes.[932,1186] Beyond serotype and genotype, two further types of DENV complexity should be mentioned: strain variation and quasispecies. DENV strain variation refers to the limited amino acid change that occurs among isolates of a given genotype. Strain variation may be functionally important as it can affect antibody neutralization, presumably due to changes at key sites within or that affect the display of antigenic epitopes.[124,1078,1162,1258]

In addition to serotype, genotype, and strain variation, DENV has the capacity to accumulate variation rapidly within an individual host. Viral quasispecies is composed of a cloud of variants that are linked by a spectrum of mutations. It is observed during infection by many RNA viruses (e.g., HCV, HIV, and influenza) and creates the diversity that allows a viral population to adapt rapidly to dynamic environments and evolve resistance to immune responses, vaccines, and antiviral drugs.[598,1155] DENV (and other flaviviruses) exist as a collection of highly similar variants forming a quasispecies[1173] by virtue of its error-prone NS5 polymerase, which has an estimated mutation rate of 10^3 to 10^5 substitutions per nucleotide copied per round of replication.[179,1137] DENV intrahost diversity in humans appears to be driven by immune pressures as well as replicative success in cells.[859] Hot spots for intrahost variation were identified in the viral E and prM/M proteins and appeared to be immune escape variants. In other studies, DENV quasispecies generation was associated with the development of rapid drug

resistance against nucleoside inhibitors of the RNA-dependent RNA polymerase.[712] Apart from these reports, the study of genetic and intrahost diversity for DENV is still in its relative infancy, and thus more analysis is warranted to define how mutation and variation impact fitness, tropism, and drug or immune system resistance.

Clinical Features of Acute Dengue Fever: Primary DENV infection

DENV infection of humans after mosquito inoculation causes a spectrum of clinical disease ranging from inapparent disease (~50% of infections[50,142,304]) and self-limited DF to severe dengue. A classical presentation of DF is an abrupt onset of a debilitating febrile illness characterized by headache, retro-orbital pain, myalgias, arthralgias, and a maculopapular rash that occurs 2 to 7 days after mosquito inoculation.[956] Some individuals experience severe bone and joint pain ("breakbone fever") and develop petechial hemorrhages that are associated with mild to severe thrombocytopenia. There is no specific constellation of signs or symptoms to differentiate DF from other acute flu-like viral syndromes, so a health care provider must have a high index of suspicion for diagnosis in the setting of the appropriate epidemiology. DF also may present in a less classical form as an undifferentiated febrile illness with rash along with mild upper respiratory symptoms (cough, pharyngitis, rhinitis), particularly in children. DF is usually self-limited, lasting 1 to 2 weeks, although some (up to 25% of hospitalized patients) experience a prolonged postinfectious fatigue and depression syndrome that can persist for weeks, akin to that seen after Epstein-Barr virus infection and mononucleosis.[1006] Because of the debilitating fever and musculoskeletal symptoms, the morbidity toll is high in clinically apparent DF, although the mortality rate is exceedingly low.

Clinical Features of Severe Dengue: Secondary and Infant DENV Infection

The incidence of severe dengue (which includes DHF/DSS) varies considerably between primary and secondary infections. A secondary DENV infection results when a person previously infected with one serotype is exposed to a different serotype and is the single most important risk factor for

severe dengue disease.[142,304,412,428] Epidemiologic data in Thailand have shown greater than 10-fold higher rates of DHF/DSS during secondary compared to the primary infection of children.[1148] It should be pointed out that even during secondary infection, severe dengue is quite rare, with only 0.5% of secondary infections progressing to this disease. Severe dengue is characterized by rapid onset of capillary leakage accompanied by thrombocytopenia and mild to moderate liver damage reflected by increases in serum levels of hepatic enzyme (e.g., aspartate aminotransferase and alanine aminotransferase).[422] Severe dengue usually occurs as a second phase of the illness, after a short period of defervescence from the initial fever. Hemorrhagic manifestations are observed in a subset of cases and include petechiae, epistaxis, gastrointestinal bleeding (hematemesis or melena), menorrhagia, and a positive tourniquet test. Use of the term hemorrhagic fever instead of dengue capillary leak syndrome has led many to anticipate that bleeding is the greatest threat. Rather, fluid loss into tissue spaces with hemoconcentration and hypotension can result in shock, which carries the highest risk of mortality.[822] From a diagnostic standpoint, an elevated hematocrit and upper abdominal ultrasonogram showing a thickened gallbladder wall, hepatomegaly, ascites, or pleural effusions are evidence of fluid shifts associated with a capillary leak syndrome.

Whereas severe dengue occurs largely after secondary infection by a different DENV serotype in children and adults,[384] in infants less than age 1 born to dengue-immune mothers, a primary infection can cause significant morbidity and mortality.[428,486,1038] In clinical studies, maternal anti–dengue neutralization antibody titers and age of the infant correlated with disease. The actual age at which severe dengue occurs in infants (peak at 7 months) corresponds to the age at which serum antibodies most efficiently enhance the infection of primary monocytes observed *in vitro* via a mechanism called antibody-dependent enhancement (ADE) of infection, described below.[538] Clinical manifestations of severe dengue are more prevalent in infants,[436] and there is an approximately fourfold higher mortality rate compared to other age groups.[506] Infants represent approximately 5% of children hospitalized with severe dengue in many parts of Southeast Asia.[183,384,425] The more prevalent or severe clinical manifestations associated with infant dengue include seizures, hepatic dysfunction, thrombocytopenia, high-grade fever, diffuse rash, peripheral edema, ascites, and frank shock.[486]

More recent clinical studies have suggested that severe DENV infection also can have neurological manifestations including transverse myelitis, Guillain-Barré syndrome (GBS), encephalitis, and encephalopathy,[1051,1145] occurring in as many as 1% to 6% of severe dengue cases.[157,455,624] In contrast to other encephalitic flaviviruses (e.g., JEV, WNV, or TBEV), DENV historically has not been considered as neuroinvasive. However, the discovery of DENV and anti-dengue IgM in the cerebrospinal fluid of patients with encephalopathy suggests that it may be capable of causing central nervous system infection as part of a severe syndrome, at least in a subset of individuals.[677,1051] In support of this, focal imaging abnormalities have been detected in brain MRI scans of DENV-infected patients.[157,1184] Although it is increasingly appreciated that neurological involvements of DENV in the CNS peripheral nervous system can occur,[624] a more complete understanding of the molecular determinants of neurotropism remains to be defined.

Pathological Features of Severe Dengue

Although DENV is the most prevalent mosquito-transmitted viral infection in the world, there are few detailed autopsy series of patients who succumbed to severe dengue, and fewer performed with newer molecular techniques and markers. Detailed histopathological studies that might inform a basic understanding of DENV pathogenesis are rare because much of the lethal disease occurs in regions lacking sophisticated laboratory infrastructure, highly trained personnel, and repositories for long-term tissue storage. Forensic studies also are complicated by the lack of standardization of histological procedures and variation in the quality of specimen preparation and storage.

A summary of the autopsy literature from a total of 160 fatal DHF/DSS cases occurring primarily in children and adolescents has been published.[705] Pathological findings in the liver include centrilobular necrosis, changes in fatty tissue, inflammatory leukocyte infiltration, and Kupffer cell hyperplasia.[89,141] Gross macroscopic examination revealed multiple hemorrhagic foci. Microscopic analysis has shown increased inflammatory infiltrates around the portal vessels, sinusoidal congestion, small hemorrhages, midzonal hepatocyte necrosis, and microvesicular

steatosis.[309,411] In other tissues (spleen or lung), hemorrhage, tissue edema, and plasma leakage have been observed.[66]

A key to understanding the pathogenesis of severe DENV infection is defining the cellular tropism of infection, which could influence the host inflammatory response that results in the capillary leak syndrome. Autopsy series have shown the presence of DENV antigen or nucleic acid in cells of the skin, liver, spleen, lymph nodes, kidney, lung, thymus, or brain.[51,66,216,411,508,525,744,945] However, several of these studies used *in situ* hybridization or RT-PCR–based assays and thus have not definitively shown that infectious virus is produced in a given cell of a target tissue. Infectious virus can be isolated reliably from blood, lymphoid tissues, and the liver, although the cellular source of the virus remains controversial. Studies in humans, nonhuman primates, and small animal models support a role for infection of myeloid cells (blood monocytes, tissue macrophages, Kupffer cells) and possibly other cells including hepatocytes[417] and endothelial cells.[66,1240]

Zika Virus

History, Global Distribution, and Epidemic Cycle

ZIKV was first isolated in 1947 in the Zika Forest of Uganda.[266,267,1004] Over the next 60 years, ZIKV was isolated from mosquitoes in East Africa, West Africa, and Southeast Asia, and serological surveys suggested that ZIKV circulated sporadically in humans in these regions (reviewed in Ref.[1203]). Despite evidence of ZIKV circulation, reports of human cases were rare, with the first known significant ZIKV outbreak occurring in 2007, in Micronesia.[287,592] The introduction of ZIKV into a small island population without prior immunity may have provided an opportunity to observe ZIKV disease that went unnoticed in endemic transmission settings. This outbreak marked the emergence of ZIKV as a globally significant human pathogen, as over the next decade the virus spread throughout Oceania, causing a large outbreak in French Polynesia,[160] and then in Latin America. The first autochthonous ZIKV cases in the Americas were reported in Northeast Brazil in 2015, though the virus most likely was introduced at least 1 year prior.[158,317,741,1236] Within a year of the first reports, the virus had spread

throughout Latin America and the Caribbean, in explosive fashion with infection rates of 50% to 90% in many areas. With more than 200,000 confirmed cases and more than 500,000 suspected cases from 2015 to 2017, and only approximately 25% to 50% of ZIKV infections being symptomatic,[36,287,671,754] it is likely that millions of people were infected. The rapid and intense spread of ZIKV in the Western Hemisphere likely was enabled by an abundance of *Aedes aegypti* mosquito vectors and immunologically naïve populations in urban areas. While ZIKV transmission has waned in the Americas (possibly due to herd immunity), infections continue to occur in Africa and Asia[334,459,1039,1220]; the attention resulting from the emergence of ZIKV in the Americas is likely to bring greater recognition of ZIKV-associated disease in areas where it previously went unnoticed.

ZIKV initially was isolated from a sentinel rhesus macaque, an Asian monkey not necessarily representative of primate hosts native to the Zika Forest. ZIKV subsequently was isolated from *Aedes africanus* mosquitoes, and multiple monkey species in the Zika Forest were found seropositive for ZIKV, implying that ZIKV circulates in a sylvatic cycle between mosquitoes and monkeys.[415,722] Small mammals in the Zika Forest did not show serological evidence of ZIKV infection.[415] Other historical studies have reported ZIKV seropositivity in a variety of vertebrate species, but analyses that detect antibody binding (e.g., hemagglutination inhibition, complement fixation, or ELISA) should be interpreted with caution, as antigenic cross-reactivity between flaviviruses can make it difficult to ascertain specificity, particularly in areas where multiple flaviviruses co-circulate. Recent work using more specific serological assays found ZIKV-seropositive grivets and ZIKV-seropositive baboons in Tanzania and the Gambia.[139] Altogether, these studies are consistent with a model in which primates (both humans and monkeys) are the primary vertebrate hosts for ZIKV.

Both Old World and New World primates can be infected with ZIKV experimentally (see “Animal Models”). However, it remains an open question whether ZIKV will establish a nonhuman primate reservoir in Latin America, as did YFV. Alternatively, ZIKV may behave more like DENV, which has a sylvatic cycle in Old World monkeys but in Latin America is maintained exclusively through transmission between humans and mosquitoes.

ZIKV Diversity

ZIKV is classified in the Spondweni serogroup, and to date, these two viruses are the only members of this clade. ZIKV strains form a single serotype[277] but are genetically divided into African and Asian lineages. The African lineage includes the prototype strain isolated in 1947, as well as strains isolated from mosquitoes in Senegal and the Central African Republic in the 1970s and 1980s. This lineage continues to circulate, as African lineage strains were detected in contemporary samples from West Africa.[459] Asian lineage strains include ZIKV strains isolated from Southeast Asia and all outbreak strains from Oceania and Latin America.[317,741] Following the emergence of ZIKV in the Americas, Asian lineage strains were detected in individuals in Africa, suggesting that both Asian and African lineage strains now may circulate in Africa.[973] Furthermore, while American ZIKV strains have been reintroduced to Asia by travelers, Asian lineage strains distinct from those in the Americas continue to circulate in Southeast Asia and were responsible for a 2016 outbreak in Singapore and a 2018 outbreak in India.[1039,1099,1220] ZIKV strains associated with disease in the Americas, particularly congenital Zika syndrome (CZS), have genetic differences compared to earlier African and Asian strains not associated with significant disease. The causal role for these variants in ZIKV pathogenesis remains unclear, but they may have the potential to enhance neurovirulence or the efficiency of mosquito transmission.[184,659,1235]

ZIKV Transmission

ZIKV endemic and epidemic transmission can be sustained by direct transmission between humans and *Aedes aegypti* mosquitoes in an urban/peridomestic cycle without a requirement for other vertebrate animals as amplifying hosts (Fig. 9.7). ZIKV has been isolated from many species of *Aedes* mosquito, but only a subset are competent vectors for transmission (reviewed in Ref.[305]). *Aedes aegypti* is a key vector for ZIKV transmission because of its high competence, abundance throughout the tropics and subtropics, and anthropophilic nature. During the emergence of ZIKV in the Americas, autochthonous transmission in the United States occurred in southern Florida and Texas, where *Aedes aegypti* mosquitoes are found.[397,634] Subsequent spread to regions where *Aedes albopictus*

mosquitoes dominate did not occur, but it is difficult to ascertain whether this was because *Aedes albopictus* is not an efficient ZIKV vector or because interventions that limit mosquito exposure prevented extensive spread.

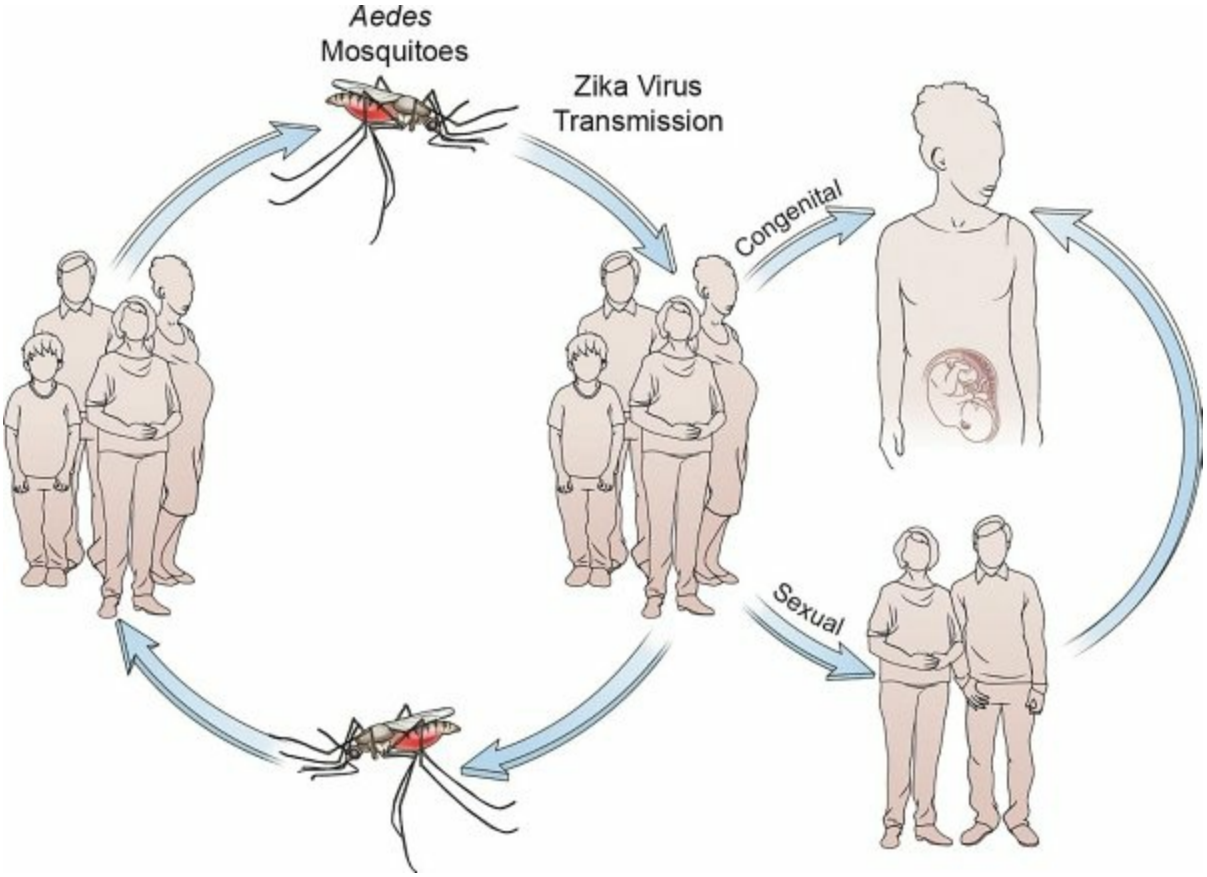

FIGURE 9.7 Transmission cycle of Zika virus. ZIKV infection in humans produces sufficiently high viremia to allow direct transmission between humans and *Aedes* spp. mosquitoes; this transmission mechanism is similar to other *Aedes*-borne flaviviruses and is responsible for most ZIKV infections. Unlike other flaviviruses, ZIKV also can be transmitted directly between humans through congenital and sexual routes. These vector-independent transmission mechanisms are notable because they involve distinct tissue tropism compared to mosquito-borne transmission and can produce distinct disease outcomes, most notably neurodevelopmental defects in infants infected *in utero*

(congenital Zika syndrome).

ZIKV outbreaks are driven by mosquito transmission. However, ZIKV is unusual compared to other flaviviruses in also being transmitted directly between humans through sexual contact. While ZIKV sexual transmission became evident through travel-associated cases in the Americas,[274,780] the first reported case predates this epidemic and resulted from ZIKV infection in Africa.[334] Even with decades of comparable travel-associated DENV cases,[171,490,933,1204] there is no evidence of DENV sexual transmission. As it is difficult to evaluate ZIKV sexual transmission in regions that also support mosquito transmission, the epidemiologic significance of ZIKV sexual transmission remains uncertain. However, vector-independent transmission may broaden the geographic area over which ZIKV outbreaks can be sustained. The mechanisms that enable ZIKV sexual transmission are unknown, but likely include tropism for tissues in the male and female reproductive tracts. ZIKV infects human testicular cells in culture[716,1035] and targets the testes in mouse models.[382,684,1140] However, sexual transmission from vasectomized men and mice implies that tissues other than the testis contribute to the presence of ZIKV in semen.[33,288,338] ZIKV RNA can be detected in semen for months following the resolution of acute infection,[726,825,863,1135] suggesting that ZIKV infection may persist in the testes or other tissues of the male reproductive tract. ZIKV also has been detected in vaginal secretions of infected women[805,863,867] and replicates in the vaginal epithelium of experimentally inoculated mice and macaques.[149,165,1103,1229]

ZIKV can traverse the placental barrier and cause fetal infections, producing congenital ZIKV syndrome (CZS) in a subset of exposed pregnancies. While other arboviruses are known to be teratogenic in livestock,[272] and other flaviviruses have been associated with adverse pregnancy outcomes,[853] ZIKV is the first example of a flavivirus with clear evidence of teratogenicity in humans. Congenital infection is a transmission dead end for arboviruses, so fetal/placental infection likely is an incidental outcome rather than an adaptive trait. However, congenital infection is associated with prolonged maternal viremia,[283,727,842,1005] potentially extending the period during which infected individuals can transmit the virus

to mosquitoes.

Clinical Features of ZIKV Infection

Most ZIKV infections are asymptomatic, with approximately 25% to 50% progressing to febrile illness. Maculopapular rash is the most common manifestation of ZIKV infection, along with fever, headache, myalgia, and conjunctivitis.[754,807] Symptoms typically manifest within 3 to 7 days of a mosquito bite and usually are self-limited. Prior to its emergence in the Western Hemisphere, ZIKV was considered a benign infection, but large-scale outbreaks after 2013 revealed more serious disease manifestations. ZIKV infection has been associated with GBS, a postinfectious autoimmune peripheral neuropathy.[118,159,835] There also are isolated reports of more severe manifestations of ZIKV including meningitis, encephalitis, and thrombocytopenia, usually in individuals who are immunocompromised or have other comorbidities.[166,509] ZIKV also can target tissues in the eye, leading to uveitis and other ophthalmological diseases.[341,545,739] ZIKV also targets tissues in the male reproductive tract, allowing for sexual transmission and causing urogenital disease including hematospermia.[334,808] Although ZIKV generally is considered to be an acute illness, infection of immune-privileged tissues such as the eye and male reproductive tract allows for viral persistence.[10,466,726,825,863,1135]

Although ZIKV infection in adults rarely causes significant or durable morbidity, infection during pregnancy can result in intrauterine growth restriction and a spectrum of neurodevelopmental defects.[218] The teratogenic effects of ZIKV were first noted in 2015 in Northeast Brazil as an increase in cases of microcephaly following the ZIKV outbreak in that region.[855] Subsequently, microcephaly and other neurodevelopmental defects were associated with the ZIKV outbreak throughout Latin America,[156,197,245,247,248,335,471,605,755,851,971] and retrospective studies found an increase in similar outcomes associated with the 2013 to 2014 ZIKV outbreak in French Polynesia.[85,170] Studies in nonhuman primates corroborate the teratogenic effects of ZIKV during pregnancy.[4,5,209,286,408,465,687,708,761,823,1007] Though the mechanisms that cause congenital anomalies are still being determined, ZIKV appears to target neural progenitor cells in the developing brain,[440,625,1101] eliciting a range of

neurological effects including microcephaly, seizures, impaired motor function, vision and hearing loss, arthrogryposis, and cognitive impairment. Neural progenitor cells could be damaged directly by viral infection or indirectly by inflammatory responses, which can inhibit cell proliferation, trafficking, and differentiation.[678] ZIKV infection also can damage the placenta, resulting in intrauterine growth restriction and impaired fetal development.[465,830,908,916,1096] The long-term effects of ZIKV exposure *in utero* remain to be determined, but the 2-year follow-up of the earliest cohorts of CZS cases has found severe motor impairment, seizure disorders, hearing and vision abnormalities, and sleep difficulties; these children are developmentally delayed and likely will require long-term support.[794,974] Congenital ZIKV infection also may result in subtle cognitive or functional deficits that could become apparent as affected children develop. The rate at which ZIKV infection during pregnancy results in CZS is still under investigation, as are the factors modulating this risk, with one study identifying rates as high as 42% of ZIKV-infected pregnant women[117] and other studies finding rates of approximately 5%.[1018] ZIKV infection at any gestational stage can result in CZS, although exposure earlier in pregnancy seems to produce more severe manifestations. Fetal outcome does not depend on maternal disease severity, and even asymptomatic maternal infection can result in CZS. Although ZIKV can circumvent the placental barrier and access the fetal compartment, the mechanism by which it does so remains unclear.[218] ZIKV can infect placental macrophages,[908] but the syncytiotrophoblasts, which form the interface between the placenta and maternal circulation, do not support viral replication.[68,214] ZIKV may access susceptible cytotrophoblasts at sites of placental implantation into the decidua,[1096] or the maternal immune response may compromise the integrity of the placental barrier.

The extensive antigenic cross-reactivity between ZIKV and DENV creates the possibility that prior DENV exposure could modulate the outcome of ZIKV infection. The emergence of ZIKV in regions with high DENV seroprevalence implies that prior DENV infection does not provide durable protection against ZIKV. However, cross-reactive immunity may provide short-term protection or reduce disease severity.[374,393,779,940] Although cross-reactive nonneutralizing antibody responses between different DENV serotypes can exacerbate DENV disease via ADE,[512] currently there is no

evidence that DENV antibodies enhance ZIKV infection in humans or nonhuman primates.[374,779,858] A greater risk may be that cross-reactive antibodies from a prior ZIKV infection could exacerbate subsequent DENV infection, which will become apparent now that the two viruses are coendemic in Latin America and Southeast Asia.

Pathological Features

Since ZIKV disease in adults typically is self-limited and benign, it is not generally associated with significant pathology beyond erythematous maculopapular lesions and petechiae.[271] Although the range of manifestations that constitute CZS is not fully known, pathological features have been described, particularly for severe presentations.[197,245,706] Overall, the pathological features of CZS are similar to other congenital infection syndromes, such as those caused by human cytomegalovirus or rubella virus. The brains of severely affected fetuses and infants exhibit lissencephaly, hypoplasia, calcifications, and ventriculomegaly, most often seen when ZIKV exposure occurred early in gestation. Other commonly reported lesions include microglial nodules, gliosis, neurodegeneration, and necrosis. Affected fetuses also may exhibit microphthalmia, and infants may present with ophthalmological disease including focal pigment mottling, chorioretinal atrophy, and optic nerve atrophy.[248,322,1151] The ophthalmological effects of ZIKV infection may not be limited to *in utero* exposure, as ZIKV-associated uveitis has been reported in adults, including chorioretinal lesions.[545,739] Congenital ZIKV infection is associated with placental damage, which likely is an additional source of fetal damage beyond direct viral-induced pathology.[197,245,706] Placental findings include chronic villitis, stromal fibrosis and calcifications, and chorionic vasculitis. In a subset of affected fetuses, ZIKV RNA and antigens have been detected by *in situ* hybridization and immunohistochemistry.

Yellow Fever Virus

History, Global Distribution, and Epidemic Cycle

Several reviews have described the historical details and epidemiology of YFV infection.[57,299,348] The causative agent of yellow fever (YF), YFV, was

first isolated (strain Asibi) in 1927 after inoculation of a rhesus monkey with the blood of a patient from Ghana.[1074] YFV originated in Africa, was imported into the Americas during the slave trade, and had the first reported epidemic in the Yucatan in 1648.[61] Historically, large epidemics of YF disease occurred beyond these regions and were described in the 17th through 20th centuries as far north in the Americas as Canada, as well as in parts of Europe including Spain, Italy, France, and England.[764] Despite the presence of an effective vaccine (17D strain), with more than 500 million doses administered to humans,[348] YFV infection has remained a public health threat in some parts of the world. Currently, YFV is endemic in tropical regions of Africa and the Americas, infects humans and nonhuman primates, and is transmitted by mosquitoes including *Aedes aegypti*. The WHO estimates an incidence of 200,000 YF cases per year, leading to approximately 30,000 to 60,000 deaths with the majority occurring in sub-Saharan Africa.[846] Overall, 47 countries in Africa and the Americas are considered within the modern YFV-endemic zone, with 600 to 700 million people at risk of infection.[299,348]

The sylvatic or jungle cycle of YFV in which transmission occurs between mosquitoes and monkeys explains why extensive vaccination campaigns have reduced but not eradicated infection. In East Africa, YFV infection is maintained in monkey transmission cycles in the jungle with the *Aedes africanus* mosquito vector. Periodically, infection may cross into humans during an intermediate savannah cycle, with transmission by several different *Aedes* mosquito species (e.g., *Aedes bromeliae*). Indeed, in the Americas, most cases appear to be a result of humans exposed to the jungle cycle of YFV.[63] Epidemic YFV infection (human–mosquito–human cycle) ensues in urban or domestic areas with *Aedes aegypti* as the principal mosquito vector. Rapid urbanization in Africa and the Americas with population shifts from rural to urban settings combined with the collapse of mosquito eradication programs has allowed the *Aedes aegypti* vector to repopulate many parts of the world and caused YFV to be classified as a reemerging threat.[348]

Unfortunately, dramatic increases in YFV incidence have occurred recently in areas that had been considered essentially free of YF.[59,350] In 2013, YFV infection resulted in 130,000 cases and 78,000 deaths in Africa.[350] In Uganda and Brazil in 2016, YFV infections and deaths were associated with a lack of vaccination and likely were due to sylvatic

transmission.[316,583] In 2016, urban YF occurred in Angola and the Democratic Republic of the Congo and was difficult to contain due to vaccine shortages.[1055]

YFV Diversity

YFV does not belong to an antigenic subgroup based on plaque reduction neutralization assays,[153] but shows greater genetic relationship to other African flaviviruses including Banzi, Wesselsbron, and Bouboui viruses. Indeed, cross-protection against YFV infection in monkeys has been shown after immunization with some of these related viruses.[456] Although there is only one serotype of YFV, there is significant diversity within the genus. Seven genotypes have been proposed including two West African genotypes, a single Central/South African genotype, two East African genotypes, and two South American genotypes.[299] These genotypes of YFV were originally defined based on nucleotide variation of greater than 9% in the prM, E, and 3′ UTR gene regions[810,1182] and have been confirmed with full-genome sequencing of YFV isolates.[1159] Phylogenic studies suggest that YFV originated in East or Central Africa and was introduced subsequently into West Africa and South America.[809,810] Beyond genotypes, sequence analysis of 135 YFV strains isolated from 1935 to 2016 in Brazil revealed further strain divergence into clades that differ at the nucleotide and amino acid level by up to 7% and 5%, respectively.[1146] The physiological basis for genotype-specific amino acid variation between YFV isolates remains uncertain although it is likely that selection confers a phenotypic advantage in a given host.

Clinical Features of YFV Infection

In humans, YFV infection causes a variable clinical syndrome ranging from no symptoms to mild febrile flu-like illness to fulminate and possibly fatal disease. Approximately 15% of people who become infected develop a severe visceral disease, and in this group, there is a 20% to 50% case fatality rate.[767] Symptoms occur within 3 to 6 days of mosquito inoculation and include an abrupt onset of fever, chills, myalgia, back pain, and headache during the initial period of infection, which usually lasts 3 days and corresponds to peak viremia. During this phase, individuals are infectious to

mosquitoes. In some, this stage may be followed by a short “period of remission,” with defervescence and improvement of clinical sign and symptoms. Shortly after, in a subset (20%) of patients, fever and symptoms worsen (“period of intoxication”) with vomiting, epigastric pain, and jaundice; this is associated with YFV replication in the liver, an absence of viremia, and measurable anti-YFV antibodies in serum. As time progresses, severe YFV infection evolves into a hemorrhagic fever characterized by severe hepatitis, renal failure, hemorrhage, shock, and multiorgan failure. A bleeding diathesis manifests with melena, hematemesis, epistaxis, ecchymosis, menorrhagia, petechial hemorrhages, and blood oozing from mucus membranes. Renal failure is associated with an abrupt decrease in urine output and albuminuria. Laboratory tests show leukopenia, thrombocytopenia, and a coagulopathy. Death occurs on the 7th to 10th day of illness and is preceded by hemodynamic and cardiovascular instability, acute liver failure, hypothermia, hypoglycemia, and coma. For those individuals surviving severe YFV infection, convalescence is prolonged with hepatitis and associated constitutional symptoms persisting sometimes for months.

Pathological Features of YFV Infection

Macroscopic gross pathology of tissues from YFV infection autopsy studies shows an enlarged and icteric liver and edematous and enlarged kidneys and heart. Microscopic pathologic analyses of the liver reveal six major features,[348,541,768] which occur primarily during the “period of intoxication”: (a) eosinophilic degeneration of hepatocytes and Kupffer cells; (b) midzonal hepatocellular swelling and necrosis, with sparing of the cells in the portal area; (c) the presence of Councilman bodies coincident with hepatocyte cell death; (d) absence of leukocyte inflammatory infiltrates; (e) microvesicular fatty changes and lipid accumulation, likely secondary to decreased apoprotein synthesis by hepatocytes; and (f) retention of the reticulin structure. YFV antigen and RNA are demonstrable in hepatocytes by immunohistochemistry or *in situ* hybridization,[244] and this, coupled with the absence of inflammation, suggests that cell death is mediated directly by virus infection, likely via an apoptotic mechanism.[768,905]

In the kidney, severe eosinophilic degeneration and a microvesicular fatty change of renal tubular epithelium are observed, analogous to that seen in the

liver. Viral antigen can be detected by immunohistochemistry in renal tubular cells.[244] Glomerular damage and albuminuria with changes in the basement membrane and degeneration of cells lining the Bowman capsule may be due to direct viral injury[768] or secondary to decreased blood flow during the sepsis syndrome.[348] The spleen shows an overall loss of lymphocytes, hyperplasia of the follicle, appearance of large mononuclear tissue histiocytes, and degeneration of cells with accumulation of fragmented nuclei.[542] In monkeys, necrosis of B-cell follicular areas of the spleen is more apparent.[769] In the heart, myocardial cells also undergo apoptotic changes as in other organs, in the absence of a significant cellular inflammatory response. Patchy lesions have been described in the sinoatrial (SA) node and bundle of His,[662] which could explain the paradoxical bradycardia and late cardiac death observed in some severe YFV cases.

Hemorrhagic manifestations and plasma leakage from capillaries are characteristic findings of severe YFV infection.[768] The bleeding manifestations are attributed to decreased synthesis of vitamin K–dependent coagulation factors by the injured liver, disseminated intravascular coagulation, and reduced platelet numbers and function. Beyond direct bleeding, there is additional vascular dysfunction, with pleural and peritoneal effusions, and edema of several other organs, including the brain. At present, the precise pathogenesis of the vascular leakage syndrome associated with YFV remains unknown, although highly elevated levels of proinflammatory and vasoactive cytokines are observed.[1108]

West Nile Virus

History, Global Distribution, and Epidemic cycle

WNV was first isolated in 1937 in the West Nile district of Uganda from a woman with an undiagnosed febrile illness.[1048] Historically, WNV caused sporadic outbreaks of a mild febrile illness in regions of Africa, the Middle East, Asia, and Australia. Indeed, in the 1950s, detailed studies of WNV showed recurrent outbreaks in Israel[83,366] and high levels of seroconversion in adults from Egypt[482,736]; these outbreaks and others in Africa generally were not associated with severe human disease. However, in the 1990s, the epidemiology of infection changed. New outbreaks in Eastern Europe were

associated with higher rates of neurological disease.[478] In 1999, WNV entered North America and caused seven human fatalities in the New York area as well a large number of avian and equine deaths. Since then, WNV has been present throughout the continental United States as well in parts of Canada, Mexico, the Caribbean, and South America. Because of the increased range, the number of human cases has continued to rise: in the United States between 1999 and 2019, 51,684 cases were confirmed (48% of which were neuroinvasive) and associated with 2,374 deaths (https://www.cdc.gov/westnile/statsmaps/index.html). The highest incidence (3.4 cases per 100,000 individuals) of WNV infection in the United States has occurred in South Dakota.

WNV cycles in nature between *Culex* mosquitoes and birds but also infects and causes disease in humans, horses, and other mammals (Fig. 9.8). Although its enzootic cycle is overwhelmingly between mosquitoes and birds, with mammals serving as "dead-end" hosts because of low-level and transient viremia, nonviremic transmission of WNV between cofeeding mosquitoes[462] suggests that mammals could act as reservoirs for mosquito infection. Most (~85%) human infections in the Northern Hemisphere occur in the late summer with a peak number of cases in August and September. This reflects the seasonal activity of *Culex* mosquito vectors and a requirement for virus amplification in the late spring and early summer in avian hosts. In warmer parts of the world, virtually year-round transmission is observed. Although more than 100 avian species are susceptible to WNV infection, in the United States, some are particularly vulnerable with a large number of deaths in crows, jays, and hawks. Ecology studies suggest that *Culex pipiens*, the dominant enzootic (bird-to-bird) and bridge (bird-to-human) vector of WNV in urbanized areas in the northeast and north central United States, shifts its feeding preferences from birds to humans during the late summer and early fall, coincident with the dispersal of its preferred host, the American robin (*Turdus migratorius*).[526]

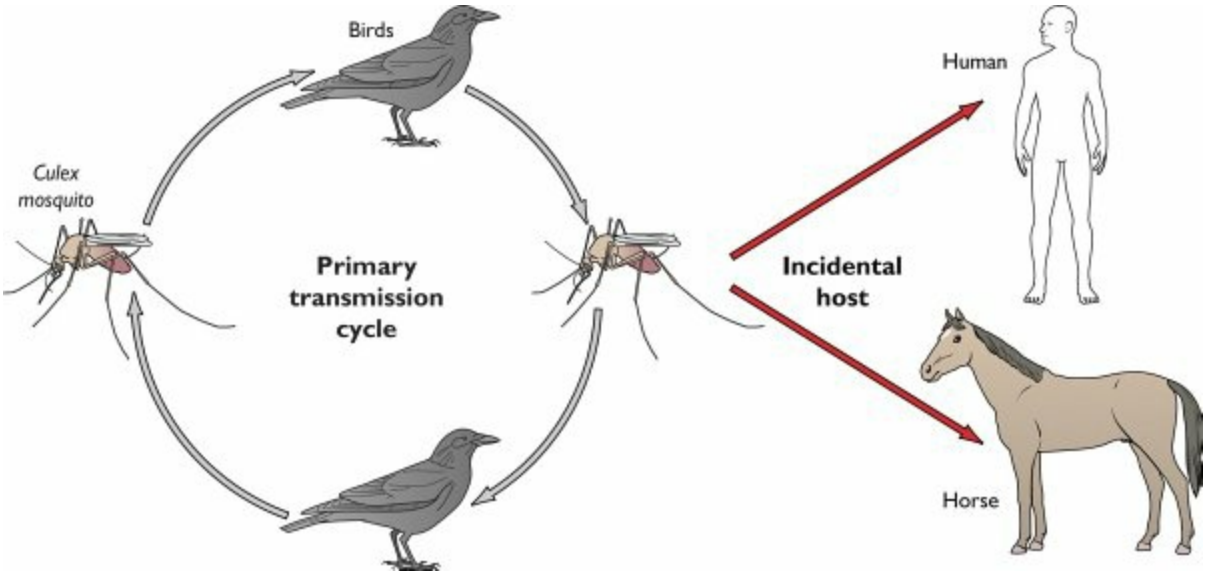

FIGURE 9.8 Transmission cycle of West Nile virus. WNV is maintained in nature in an enzootic transmission cycle between mosquitoes and birds. Many vertebrate species, including humans, may also be infected as "dead-end" hosts for WNV. The resulting transient low-level viremia in mammalian hosts does not support sufficient infection of the mosquito vector to continue the transmission cycle.

WNV Diversity

Sequencing and phylogenic analysis of full-length genomes have resulted in a division of WNV strains into four or more distinct lineages.[84,492,591,681] However, most severe neuroinvasive WNV infections are attributed to strains from lineages 1 and 2. Lineage 1 strains are separated into three clades (1a, 1b, and 1c). Clade 1a is composed of isolates from Europe, the Middle East, Russia, and the Americas and includes all strains from the United States and Canada. Clade 1b contains the naturally attenuated Australian variant, Kunjin virus, which forms a tight cluster with approximately 2% to 3% difference at the amino acid level from North American WNV strains.[985] Clade 1c is composed only of isolates from India, sometimes referred to as lineage 5 strains. Historically, lineage 2 isolates were isolated from sub-Saharan Africa and Madagascar and generally showed less ability to cause disease in humans

and animals[71,478]; lineage 2 isolates now circulate in parts of Eastern Europe[306] where they have caused severe neurological disease and fatalities.[111] There are fewer sequenced strains from lineage 3 and 4 WNV, with only one lineage 3 isolate from Austria in 1997[45] and several lineage 4 isolates[681] from Russia between 2002 and 2006. A putative 6th WNV lineage has been described from Spain and is based on a small gene fragment.[1150] Koutango virus, which was initially classified as a different virus, is now considered a 7th lineage of WNV; it is unusual, as it has been isolated from ticks and rodents.[313] Within a given ecological niche, possibly because of its enzootic cycle, WNV has remarkable genetic stability despite its error-prone RNA-dependent RNA polymerase; full-length sequencing analysis of North American isolates over the past decade has revealed a rate of approximately 5 nucleotide and less than 1 amino acid mutation per genome per year, with little geographic subdivision.[240,1102]

Clinical Features of WNV Infection

Seroprevalence studies suggest that most (~80%) cases are subclinical, without significant symptoms. Among clinical cases, many develop a self-limiting illness termed “WNV fever.” This syndrome begins after a 2- to 14-day incubation period and is characterized by fever accompanied with myalgia, arthralgia, headache, fatigue, gastrointestinal complaints (nausea, vomiting, and diarrhea), maculopapular rash, or lymphadenopathy. This nonneuroinvasive form of WNV infection can be severe as 38% of patients with WNV fever were hospitalized with a mean length stay of 5.4 days.[480] A subset of the symptomatic cases progress to the neuroinvasive forms of WNV infection, including acute flaccid paralysis, meningitis, encephalitis, and ocular manifestations[46,1010]; in many instances, a combination of these syndromes is present. Overall, about 1 in 150 WNV infections result in the most severe and potentially lethal form of the disease. During an epidemic, the seroconversion rate is approximately 3%,[792,1132] and the attack rate for severe disease during an epidemic is approximately 7 per 100,000.[480] The risk of severe WNV infection is greatest in the elderly.[201,814,1132] At least two studies have estimated a 20-fold increased risk of neuroinvasive disease and death in those over 50 years of age.[480,814] Persistent movement disorders, cognitive complaints, and functional disability may occur after West Nile

neuroinvasive disease. West Nile poliomyelitis-like disease may result in limb weakness or paralysis. Moreover, even patients with apparently mild cases of acute disease have sustained subjective and somatic sequelae following WNV infection. Thus, the neurological and functional disability associated with WNV infection represents a considerable source of morbidity in patients long after their recovery from acute illness.[1008–1011]

Although most human WNV infections occur after the bite of an infected *Culex* mosquito, other routes have been reported including via transfusion, organ transplantation, congenital, and breast milk transmission. In 2002, 23 cases of WNV infection were identified after transfusion of blood products.[864] These cases led to the development and implementation of nucleic acid amplification tests, which have been used to identify infected pools or individual blood product samples[143,871] and largely prevent transmission by transfusion. Nucleic acid screening of blood donors has not completely eliminated transfusion-transmitted WNV infections as "breakthrough" infections have occurred and were attributed to units that had levels of viremia below the sensitivity of the screening assay.[144] In addition to transfusion-associated WNV infection, organ transplantation–associated cases have been reported.[566,570] Because of the relatively low incidence of WNV infection in organ transplantation and risk of false positives that can occur with wide-scale testing, screening is not mandated.

Pathological Features of WNV Infection

WNV causes encephalitis in several vertebrate species including humans, horses, and birds, by virtue of its ability to infect and cause injury to neurons through direct (viral-induced) and indirect (immune response induced) mechanisms.[172] Pathologic observations in humans, however, are limited by the small number of autopsy studies on individuals succumbing to WNV infection. Gross macroscopic examination of organs (brain, lung, kidney, and spleen) tends to be unremarkable.[843] Microscopic examination of the brain in humans and other animals reveals histological changes that are consistent with the clinical disease.[298,843] This includes neuronal cell death, activation of resident microglia and infiltrating macrophages, perivascular and parenchymal accumulation of $CD4^+$ and $CD8^+$ lymphocytes and $CD138^+$ plasma cells, and the formation of microglial nodules. These lesions, which

tend to be patchy in distribution, occur in the brainstem, cerebral cortex, hippocampus, thalamus, and cerebellum.[843] Additionally, overt meningitis with cellular infiltrates in the meninges can be apparent. In some cases, destruction of vascular structures with focal hemorrhage is present, suggestive of a vasculitis; this may be associated with local compromise of the blood–brain barrier.[262,1180] Immunohistochemical analysis and *in situ* hybridization confirm that WNV antigen and RNA are present in neurons from multiple regions of the brain, although other cells (e.g., astrocytes or $CD11b^+$ myeloid cells) may be infected to lesser degrees.[228,270]

WNV infection also causes a poliomyelitis-like syndrome of acute flaccid paralysis.[365,613] Patients show markedly decreased motor responses in the paretic limbs, preserved sensory responses, and widespread asymmetric muscle denervation without evidence of demyelination or myopathy.[613] Microscopically, in the spinal cord, an intense inflammatory infiltrate around large and small blood vessels is observed with large numbers of microglia in the ventral horn. Anterior horn motor neurons are targeted by WNV,[613,1028] and studies suggest that axonal transport from peripheral neurons can mediate WNV entry into the spinal cord and induce acute flaccid paralysis.[964]

A recent study in mice suggested that WNV infection in pregnancy, similar to ZIKV, might have the potential to cause congenital anomalies in fetuses. WNV replicated efficiently in human placental explants and caused similar levels of placental infection, transplacental transmission, and fetal demise in immunocompetent mice.[885] Several prior studies examined small cohorts of women infected with WNV during pregnancy and their offspring,[838,893,1042] including one study of 77 pregnant women. Among infants born to WNV-infected mothers, two had microcephaly, one had lissencephaly, and eight exhibited abnormal postnatal growth, suggesting a microcephaly rate of 2.6% in this group of WNV-infected neonates. Although a statistically significant link between congenital WNV infection and microcephaly was not established given the small numbers, more study of this possibility may be warranted.

Although most mammalian WNV infections are cleared by the adaptive immune response, persistence in the kidney has been described, albeit infrequently. Hamsters experimentally infected with WNV developed chronic renal infection and viruria for up to 8 months despite clearance from blood

and the appearance of neutralizing antibodies. Although minimal histopathology was reported, WNV antigen staining was detected in the renal epithelium, interstitial cells, and tubules.[1110] Interestingly, these persistent viruses evolved genetically and no longer caused neuroinvasive disease on challenge of naïve animals.[1212] Analogous to the studies in hamsters, WNV RNA was demonstrated in 5 of 25 urine samples from convalescent humans 1.6 to 6.7 years after the initial infection, although infectious virus was not successfully isolated.[806] In separate studies, higher viral RNA copy numbers were measured in the urine samples compared with the serum sample from the same patient during the acute phase,[813] although only a small fraction tested positive approximately 5 months later.[67]

Persistent WNV infection in the CNS also has been suggested by experimental infection studies in monkeys, hamsters, and mice. In monkeys, WNV persisted at least 5.5 months after initial infection and was isolated in the cerebellum and cerebral subcortical ganglia but had lost its neurovirulence and cytopathic properties.[889] In hamsters, persistent WNV RNA and foci of WNV antigen–positive cells were identified in the CNS of hamsters between 28 and 86 days after infection,[1033] and this was associated with long-term neurological sequelae. In mice, infectious WNV persisted in the brains of wild-type animals up to 4 months, and viral RNA could be detected at 6 months in up 12% of mice, even in animals with subclinical infection.[30] Consistent with this observation, a model of persistent WNV disease was identified in a panel of genetically diverse mice, with virus in the brain observed for approximately 2 months.[386] The authors postulated that regulatory T-cell responses restrained the immune response, preventing clearance of the infection.

Japanese Encephalitis Virus

History, global Distribution, and Epidemic Cycle

JEV is a mosquito-transmitted flavivirus and the prototype virus of the JEV antigenic serocomplex. JEV causes severe neurological disease, primarily in Asia, where it accounts for approximately 35,000 to 50,000 cases and 10,000 to 15,000 deaths annually.[1129] JEV epidemics originally were described in Japan in the 1870s, and the virus initially was recovered in 1935 from the

brain of an infected human in Tokyo; this isolate was established as the prototype JEV strain (Nakayama).[615] While most human infections are asymptomatic, greater than 50% of the symptomatic cases are fatal or result in devastating long-term neurological sequelae.[1001] Moreover, as JEV-induced disease largely occurs in children living in rural areas, it is likely vastly underreported in most regions of Asia.[1001,1050]

The enzootic cycle of JEV is between waterbirds (e.g., egrets and herons) and mosquitoes, with pigs also serving as an amplifying host. JEV is transmitted primarily by *Culex* mosquitoes (principally *Culex tritaeniorhynchus*) that breed in rice fields and stagnant water. Humans are considered incidental targets and dead-end hosts, as they do not produce a viremia sufficient to infect mosquitoes. Two epidemiological patterns are observed: in northern temperate areas, JEV infections occur during the summer months, whereas as in tropical climates, year-round transmission of JEV has been described.[381]

Globally, despite the introduction of several inactivated and live attenuated vaccines (see below), JEV remains an important cause of arthropod-transmitted viral encephalitis. Disease caused by JEV is widely distributed in Asia with outbreaks occurring in Japan, China, Taiwan, Korea, the Philippines, India, parts of Southeast Asia, and the Far Eastern region of Russia. While cases in China appear to be declining, possibly due to vaccination campaigns, epidemic activity in India, Nepal, and other parts of Southeast Asia appears to be escalating. More recently, JEV has been described in Pakistan, Papua New Guinea, and Australia, suggesting that its geographic range may be expanding.[438,439]

JEV Diversity

Phylogenetic analysis suggests that JEV evolved from an ancestral flavivirus in Africa, within the last few centuries.[377] Based on sequence analysis primarily of the viral structural genes, JEV was initially classified into a single serotype with four genotypes (I–IV),[192,193,1134] with as much as 12% variation at the nucleotide level. These divisions have been confirmed by full-length genome sequencing on a subset of isolates. Genotype I includes isolates from Thailand, Cambodia, Korea, China, Japan, Vietnam, Taiwan, and Australia from 1967 to the present. Genotype II includes strains from

Thailand, Malaysia, Indonesia, Papa New Guinea, and Australia from 1951 to 1999. Genotype III includes isolates recovered from mostly temperate areas of Asia including Japan, China, Taiwan, the Philippines, and the Asian subcontinent between 1935 and the present. Finally, genotype IV includes strains from Indonesia that were isolated only in 1980 and 1981. A fifth, more divergent genotype (V) was defined based on full-genome sequencing of a 1952 isolate from a patient in the Muar region of Malaysia[760] and a second isolate from *Culex tritaeniorhynchus* mosquitoes from 2011.[621] Genotype V strains have approximately 20% and 9% nucleotide and amino acid divergence, respectively, and showed significant variation with respect to neutralization by JEV-specific monoclonal antibodies.[445] Additional sequence fragments of genotype V strains have been detected more recently in Korea,[527] suggesting the possible emergence of this more diverse JEV clade.

Because genotypes I and III largely were isolated in epidemic regions, and genotypes II and IV were associated with endemic transmission, differences in strain virulence were hypothesized to explain the epidemiological patterns of JEV.[193] However, as the geographic range of JEV has expanded, there are now several examples in which strains of individual genotypes cause either epidemic or endemic disease depending on the region or country.[1054]

Clinical Features of JEV Infection

In humans, JEV infection can be asymptomatic or produce a range of syndromes including a mild nonspecific febrile illness, aseptic meningitis, seizures, encephalitis, and poliomyelitis-like flaccid paralysis. Disease onset usually begins with a 1- to 2-week period of flu-like symptoms including headache, fever, cough, and upper respiratory symptoms as well as gastrointestinal complaints such as nausea, vomiting, and diarrhea. In infants and young children, the disease can progress rapidly as the virus invades the CNS and infects and injures neurons. CNS invasion is heralded by nuchal rigidity, photophobia, and altered mental status. JEV infection in the CNS can share features with Parkinson disease including mask-like facies, hypertonia, tremor, and cogwheel rigidity. Other CNS symptoms include seizures (more common in children than adults), ataxia, involuntary movements (e.g., choreoathetosis, facial grimacing, and lip smacking), and

cranial nerve palsies. Associated with this are elevated white blood cell counts and pressure in the CSF and abnormal EEG examinations. Imaging studies in the brain have revealed thalamic and basal ganglia abnormalities during the acute phase of the disease.[1050] Upper rather than lower extremity paralysis is more common, and lower motor neuron disease of the spinal cord can develop. Death can occur, especially in children, within 3 to 5 days of CNS symptoms or much later due to complications associated with hospitalization or cardiopulmonary status. A prospective study evaluated the clinical features and long-term prognosis of 118 children with encephalitis due to JEV in Malaysia.[845] Only 44% of patients had a full recovery, with 8% dying during the acute phase of the illness and 31% having persistent and severe neurological sequelae. These included chronic seizures, motor dysfunction, and neuropsychiatric symptoms such as mental retardation and psychiatric disorders.

Pathological Features of JEV Infection

JEV infection in the brain results in neuronal degeneration, necrosis, microglial nodule formation, and perivascular and parenchymal leukocyte infiltrates as well as focal hemorrhage. Parenchymal damage in the CNS is attributed to both direct cytopathic effect of the virus in nonrenewing populations of neurons and the resultant inflammatory state induced by activated microglia and infiltrating leukocytes. While these histological findings can occur throughout the brain, they usually are more restricted to the gray matter in the cortex, midbrain, and brainstem, providing anatomical correlates for the tremor and dystonias associated with CNS infection. Focal lesions are seen predominantly in the thalamus and cerebral peduncles but also are observed in the substantia nigra, cerebral and cerebellar cortices, and the anterior horn of the spinal cord,[1050] the latter of which is associated with a poliomyelitis-like acute flaccid paralysis.[1053] In patients that die rapidly, there may be little histological evidence of inflammation, but instead, high levels of JEV antigen can be detected in morphologically intact neurons.[494]

St. Louis Encephalitis Virus

History, Global Distribution, and Epidemic Cycle

St. Louis encephalitis virus (SLEV) is a mosquito-borne member of the JEV serocomplex capable of causing severe neurological disease in humans. SLEV was first discovered in 1933 following a large epidemic of encephalitis in St. Louis, Missouri (1,095 cases and 225 deaths).[242,679,919] More than 10,000 cases of severe illness and 1,000 deaths have since been attributed to SLEV infection, reflecting annual endemic transmission (~50 cases/year) punctuated by epidemic periods that occur every 5 to 15 years.[763] At least 41 epidemics of SLEV have occurred in the United States since 1933,[242] the largest of these in 1975.[220] During this epidemic, SLEV cases were reported in 29 states and the District of Columbia; the greatest number of illnesses occurred in Ohio, Mississippi, Indiana, and Illinois. Roughly 1,500 confirmed cases were reported, resulting in 171 fatalities. The most recent large outbreak of SLEV occurred in central Florida during 1990, resulting in 222 laboratory-confirmed cases and 14 deaths.[728] A more contemporary study reviewed the SLEV surveillance data in the United States for 2003 through 2017, including human disease cases and nonhuman infections.[225] Over the 15-year period, 198 counties from 33 states reported SLEV activity; 94 of those counties reported SLEV activity only in nonhuman species and 193 human SLEV infections were documented, including 148 cases of neuroinvasive disease. Among these cases, clusters of infections were reported in Arizona and California in 2015.[1198]

SLEV distribution ranges from Canada to Argentina and across North America.[919] SLEV is maintained in nature in enzootic cycles between *Culex* mosquitoes and birds (primarily songbirds and pigeons). The transmission cycle of this virus varies by region due to differences in the biology of the primary vector mosquitoes.[919] In the eastern and central United States, the principal vectors of SLEV are *Culex pipiens* and *Culex quinquefasciatus* mosquitoes. *Culex tarsalis* is the primary vector for SLEV in Western states, whereas *Culex nigripalpus* transmits SLEV in Florida. The avian hosts of SLEV in these transmission cycles include house finches, house sparrows, and mourning doves. The mechanism of virus transmission and amplification in South and Central America is less clear. SLEV has been isolated from 11 different mosquito genera, many of which feed primarily on mammals.

Both WNV and SLEV are antigenically related members of the JEV serogroup that share a similar transmission cycle between *Culex* mosquitoes and birds. How the introduction of WNV in North America has impacted the

epidemiology of SLEV is of significant interest. Analysis of the number of neuroinvasive cases attributed to SLEV reported to the CDC between 1999 and 2007 revealed a threefold reduction by comparison to data in the pre-WNV era.[918] Interpretation of this finding is complicated by changes in the intensity of surveillance and local testing for arboviral diseases in the years after the introduction of WNV. Because major epidemics of SLEV have occurred infrequently in the past, the modest number of clinical cases may simply reflect a nadir in the natural cycle of this virus. Alternatively, the existence of cross-reactive antibodies in WNV-immune avian reservoirs may disrupt the transmission cycle of SLEV via competition for avian hosts. While the infection of house finches with WNV has been shown to confer protection from subsequent infection by SLEV, the reciprocal is not true. Prior exposure of finches to SLEV prevents mortality following WNV infection but not the level of viremia that is sufficient for transmission of WNV.[314] Similar findings were reported in a golden hamster model of infection.[1111] The disappearance of SLEV from regions of California following the introduction of WNV is consistent with the notion that competition may allow for the local displacement of the virus from historically endemic areas.[920]

SLEV Diversity

Phylogenetic studies grouped SLEV isolates into seven genetic lineages (I–VII), many of which were divided further into clades of related genotypes.[558,717] These groups correspond roughly to the geographic distribution of each lineage of SLEV.[1126] For example, lineage I includes viruses isolated in the western United States, whereas lineage V contains South American strains and an isolate from Trinidad. However, the relationship between phylogenetic relatedness and geographic region is imperfect. SLEV strains vary considerably with respect to virulence in avian and mammalian hosts; these differences correlate roughly with geographic distribution.[114,772] In addition to regional persistence, sequence analysis reveals that SLEV may be transported between regions.[558]

Clinical and Pathological Features of SLEV Infection

As is the case for both WNV and JEV, the majority of SLEV infections of humans are clinically asymptomatic. The ratio of apparent to inapparent infections has been reported to range from 1:16 to 1:425.[763] Increasing age is a significant factor influencing susceptibility to severe illness. Symptomatic illness is noted after an incubation period of 5 to 15 days and is characterized by mild malaise, fever, headache, nausea, myalgia, sore throat, and cough.[128] Severe neurological manifestations including encephalitis and aseptic meningitis may occur and can be fatal. Case fatality rates for SLEV range from 5% to 20%, with fatalities increasing in the elderly.[919] While most SLEV cases resolve spontaneously and without sequelae, many patients (30%–50%) experience an extended convalescence lasting up to 3 years. This phase is characterized by headache, depression, memory loss, and weakness.[128,919]

Tick-Borne Encephalitis Viruses

History, Global Distribution, and Epidemic Cycle

TBEV causes a fatal neurological syndrome that primarily occurs in northern China and Japan, through Russia, to parts of Northern Europe.[698] TBEV infection was first described in 1931 after a pattern of seasonal meningoencephalitis cases in Austria.[992] In 1939, experiments confirmed that this seasonal encephalitis in humans was caused by a virus transmitted by the tick, *Ixodes persulcatus*.[1256] Although a highly effective formalin-inactivated vaccine has been implemented in some European countries (e.g., Austria) with marked reductions in case numbers,[451] TBEV-induced morbidity and mortality continue to rise.[1086] Between 1990 and 2012, over 65,500 cases of TBE were reported in 18 European countries.[1242] TBEV is believed to cause several thousand human cases per year, the majority of which occur in parts of Russia.[395] This increase is thought to be due to changes in climate, population dynamics and range of permissive ticks, and shifts in land usage. Seroprevalence in domestic animals in Eastern Europe has shown good spatial correlation with TBEV incidence in humans.[483] Within Russia, Siberia has the highest number of TBEV cases, whereas outside of Russia, the Czech Republic has the greatest incidence.[698] The relative virulence of TBEV increases with its eastward spread, with the Far Eastern subtype having a case

fatality rate of almost 40%.

In the enzootic cycle, TBEV is maintained between ticks and different vertebrate hosts, with humans as incidental hosts (Fig. 9.9). TBEV is primarily transmitted by the hard tick *Ixodes ricinus,* although in Eastern Europe and Russia, the principal vector is *Ixodes persulcatus*. Infection is seasonal, usually occurring between March and November,[504] and coincides with peaks of feeding activity of the particular tick vector. TBEV is endemic from Central Europe to Far East Asia with cases reported in 34 countries.[1085] Ticks can become chronically infected after ingesting viremic blood or by transstadial or transovarial transmission. In addition, infected ticks can transmit virus to uninfected ticks during cofeeding on rodents.[395,587] This is because the local skin environment supports TBEV replication, and migratory infected cells transport virus within the skin allowing for transmission in the absence of viremia.[586]

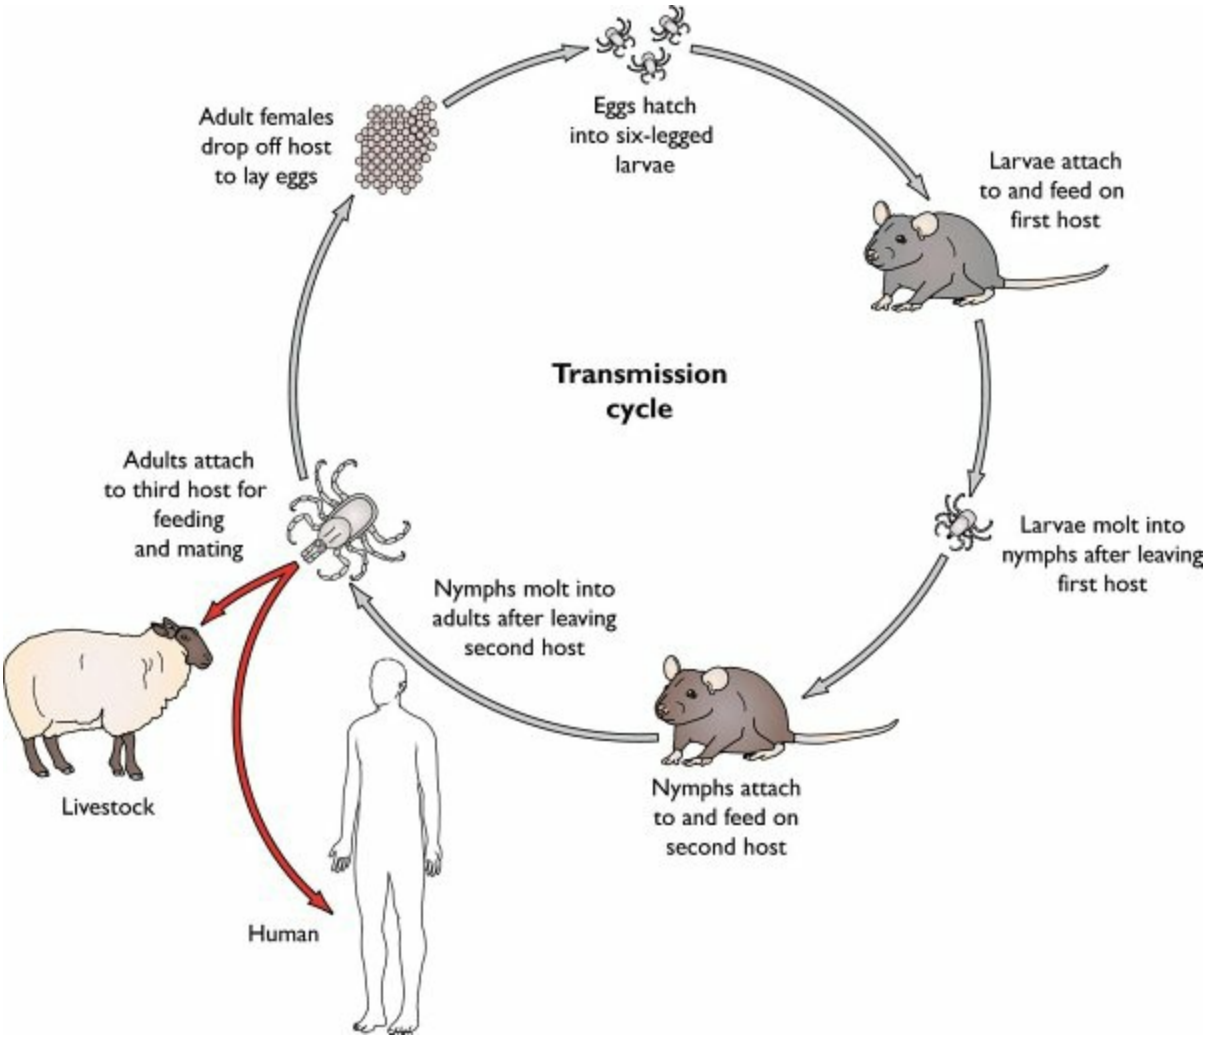

FIGURE 9.9 Transmission cycle of tick–borne encephalitis virus. TBEV transmission is connected to the life cycle of the vector due to a requirement for the tick to feed prior to transition through each of its developmental stage. Ticks are infected during this blood meal, molt, and then may infect a mammalian host. Nonviremic transmission between cofeeding ticks has also been shown to be an important mechanism of transmission and is not pictured.

One exception to TBEV transmission by tick inoculation is the syndrome of biphasic milk fever, which results from oral infection and was first identified in Russia between 1947 and 1951. During milk fever epidemics, whole families contracted TBEV infection, and this was associated with the

consumption of goat milk. Goats develop subclinical TBEV infection after tick bite and become the source of infectious virus after secretion into milk. Analogously, TBEV transmission to humans has been reported after consumption of unpasteurized cow or sheep milk or dairy products.[395] These findings are supported by experiments in mice in which TBEV infection was established after oral feeding.[888]

TBEV Diversity

Based on sequence similarity, three main subtypes of TBEV exist: the Far Eastern genotype 1 (previously Russian spring and summer encephalitis), European genotype 2 (previously Central European encephalitis), and Siberian genotype 3 (previously West Siberian). Within these three genotypes, there is approximately 1.2% to 1.7% difference at the amino acid level. The Far Eastern, European, and Siberian genotypes 1, 2, and 3 differ from each other by approximately 5% to 7% at the amino acid level. In addition to these three TBEV genotypes, two additional genotypes (4 and 5) have been described based on nucleotide and amino acid differences.[255] Other viruses that are antigenically related across Europe, Asia, and North America are classified as part of the TBEV serocomplex,[151] also termed the mammalian group of TBFVs. Besides TBEV, this group includes Omsk hemorrhagic fever virus (OHFV), louping-ill virus, Langat virus (LGTV), Powassan virus (POWV), Kyasanur Forest disease virus (KFDV), Kadam virus (KADV), Royal Farm virus (RFV), Gadgets Gully virus (GGYV), Alkhurma hemorrhagic fever virus (AHFV), and Karshi virus (KSIV). Of these viruses, TBEV, LIV, and POWV cause encephalitis in humans and animals, whereas OHFV, KFDV, and AHFV cause hemorrhagic fever.[396,952] LGTV is a naturally occurring avirulent virus (analogous to Kunjin virus among WNV strains), and no clinical disease has been reported for KSIV, RFV, or GGYV.

Clinical Features of TBEV Infection

About one-third of patients after inoculation by an infected tick will become symptomatic,[504] with men affected twice as frequently as women, although this could reflect exposure bias. The incubation period for TBEV infection in humans varies but for most individuals is approximately 1 to 2 weeks. A

prodrome of fatigue, musculoskeletal pain, and headache lasts a few days and is followed by an abrupt onset of fever, nausea, vomiting, and myalgia; this phase is associated with thrombocytopenia, leukopenia, and mildly elevated levels of liver enzymes in the serum. Subsequent to this, several clinical syndromes of TBEV infection develop, as reviewed previously[395,504]: (a) *Febrile syndrome*. This illness is characterized by high fever (39°C) with no evidence of neuroinvasion. It lasts from 1 to 5 days, and upon defervescence, patients recover completely; (b) *Meningitis*. This is the most common form of clinically apparent TBEV infection occurring in approximately 50% of individuals. After the onset of fever, symptoms worsen with progressive headache, nausea, vomiting, and photophobia. Patients exhibit cerebrospinal fluid leukocyte pleocytosis after lumbar puncture. Fever lasts 1 to 2 weeks, with gradual recovery; (c) *Meningoencephalitis*. This form occurs in approximately 10% of cases, is more severe, and is associated with damage to the CNS. Individuals become weak and lethargic and develop focal signs of disease including hemiparesis, hemiplegia, seizures, and autonomic instability. Up to 30% of these cases are fatal, and survivors have long-term neurological sequelae with slow convalescence; (d) *Poliomyelitis-like disease*. This is characterized by a prodrome of limb weakness or numbness that progresses to paralysis. Paralysis occurs more frequently in the upper limbs, with the proximal segments affected more often. Recovery is slow, is partial, and occurs in only one-half of patients, with the remainder showing progressive deterioration; (e) *Polyradiculitis*. This syndrome has a biphasic course with fever, headache, and myalgia followed by defervescence. Approximately one week later the second phase starts and is characterized by pain and damage in peripheral nerves, sometimes coupled with meningitis. Recovery from this form of TBEV infection is usually complete; (f) *Chronic or persistent infection*. This form has been described in Siberia and Far East Russia although not in Europe and is believed to associate uniquely with the Siberian subtype of TBEV. Chronic or persistent infection is characterized by a late phase (months or even years later) deterioration of the neurological sequelae that developed during the acute illness. Alternatively, chronic TBEV infection can begin with the acute phase of disease, such that neurological symptoms occur years after a tick bite. Clinical symptoms can include epilepsy, parkinsonian movement and cognitive disorders, and progressive muscle atrophy, ultimately with dementia and death ensuing. Although infectious virus has not been routinely recovered in autopsy studies, a TBEV

strain was isolated from a patient who died of a progressive (2-year) form of tick-borne encephalitis 10 years after experiencing a tick bite[394]; and (g) *Postencephalitic syndrome*. Both retrospective and prospective clinical trials have shown that TBEV infection is associated with a slow recovery period that has considerable long-term morbidity.[403,503,746] This postencephalitic syndrome occurs in approximately 40% to 60% of patients and includes memory disturbances, headache, and affective and gait disorders. The frequency of these symptoms was proportionately higher in more severe cases.

Pathological Features of TBEV Infection

Gross pathologic analysis of the brain of humans who succumb to lethal TBEV infection shows edema and hyperemia. Microscopic lesions occur in a patchy distribution throughout the CNS but are most prominent in the brainstem, basal ganglia, thalamus, cerebellum, and spinal cord. The cerebral and spinal meninges show a diffuse leukocyte infiltration, predominantly with lymphocytes. In the parenchyma of the brain and spinal cord, perivascular infiltrates, microglial nodules, and necrosis of neurons are observed. Notably, Purkinje cell neurons in the cerebellum and anterior horn motor neurons in the spinal cord are preferentially targeted and injured by TBEV.[504] Immunohistochemical analysis of brains from 28 autopsy cases[353] showed prominent TBEV antigen staining in Purkinje cells, neurons of the dentate gyrus, the brainstem, and basal ganglia, with T lymphocytes detected in direct apposition to TBEV-infected neurons.

Emergence of POWV in the United States

POWV is a tick-borne flavivirus that was first isolated from the brain of a child who died of encephalitis in Powassan, Ontario, in 1958.[719] Human cases of POWV have been reported in the United States, Canada, and Russia.[458] Although POWV infections are relatively rare, they can cause severe neuroinvasive disease including meningitis and encephalitis. Approximately 10% of neuroinvasive POWV cases are fatal, and 50% of survivors suffer long-term neurological sequelae.[458] POWV is emerging, as increasing numbers of cases have been diagnosed in the United States over the past decade[562] and up to 3% to 5% of *Ixodes scapularis* ticks isolated in

parts of the United States now test positive for POWV.[18,543]

Two genetic lineages of POWV circulate in North America, lineage I and lineage II (also called deer-tick virus [DTV]), that share at least 96% amino acid identity in their E proteins.[296] POWV lineage I strains are predominantly maintained in *Ixodes cookei* ticks and include isolates from New York and Canada, whereas lineage II strains are found in *Ixodes scapularis* deer ticks and include strains from regions infested by these ticks.[296] Although POWV has been found predominantly in north central and northeastern parts of the United States in *Ixodes* species ticks, POWV also has been isolated from *Dermacentor andersoni* ticks, indicating the vector and geographical range may be larger than estimated.

PATHOGENESIS AND IMMUNITY

Virus Attachment

Flavivirus entry into cells is mediated by the E proteins and can be considered in three discrete steps (Fig. 9.10). The first step involves the attachment of the virion to the target cell. Collisions between virions and target cells are not always productive. “Attachment factors” promote infection by increasing the duration of contact between the virion and cell surface and thereby increase the likelihood that subsequent steps in the virus entry pathway will occur. Attachment factors are not strictly required for infection. In contrast, interactions with viral “receptors” promote required events during virus entry. While the distinction between these two types of cellular factors is clear for some viruses (e.g., HIV), the cell biology of flavivirus entry remains poorly understood, as no cellular factor is required for fusion between the virion and membranes once exposed to an acidic environment.[215,369] Several cellular factors have been shown to function as attachment factors or receptors during the flavivirus entry as discussed below.

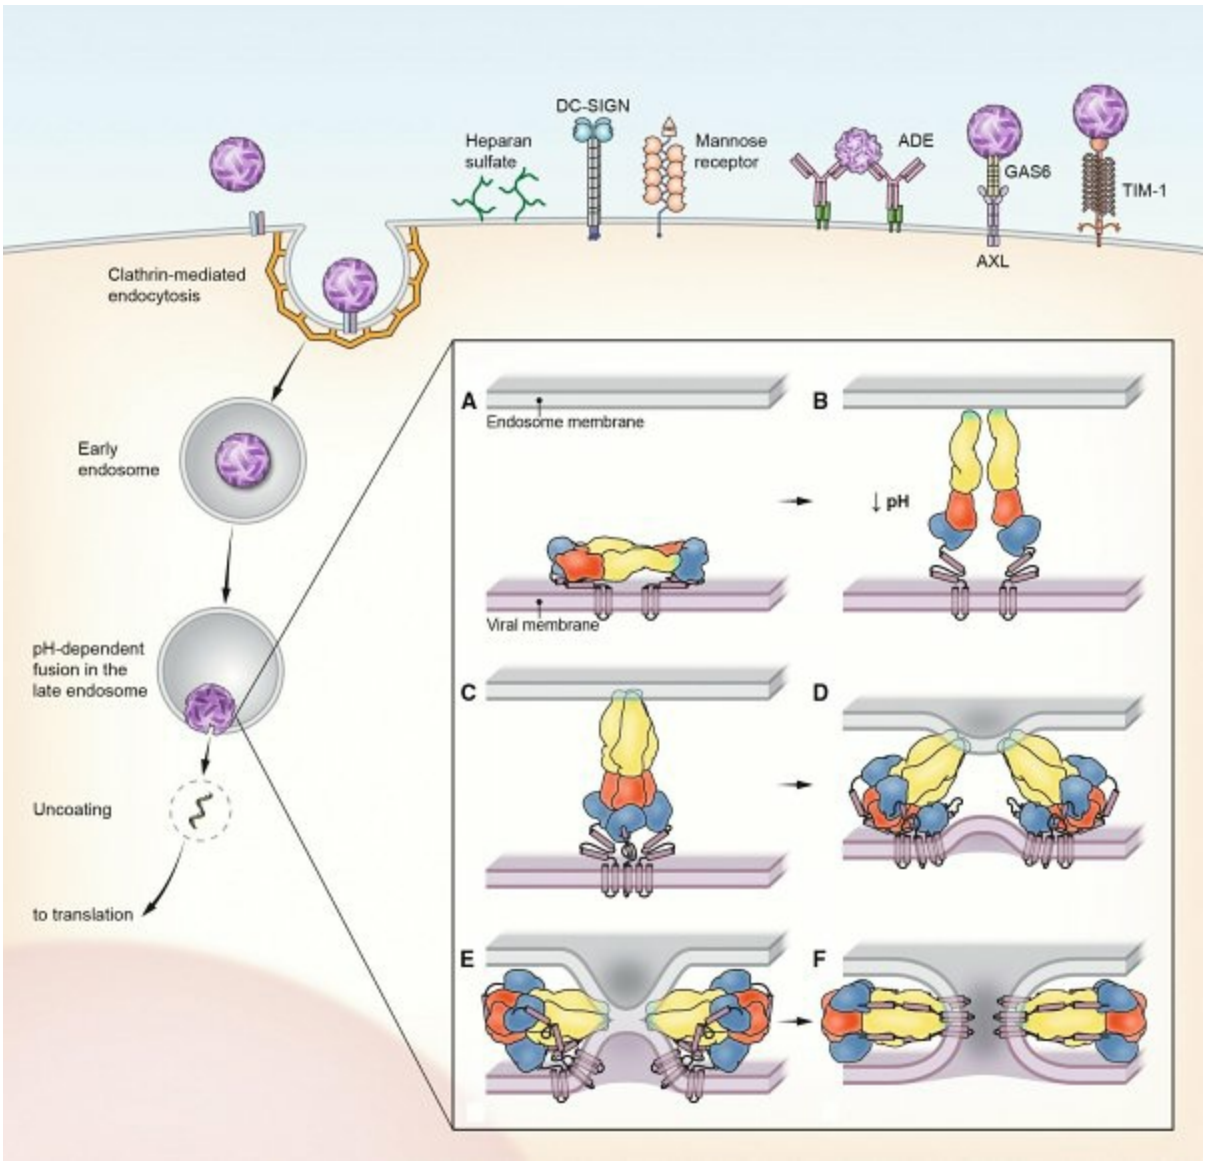

FIGURE 9.10 Flavivirus entry into cells. The entry of flaviviruses into mammalian cells is mediated by interactions with a variety of cell surface–expressed host factors. These include heparan sulfate, C-type lectins (DC-SIGN, DC-SIGNR, and mannose receptor), and members of the phosphatidylserine receptor family including TIM-1 and AXL. Viruses complexed with antibodies also efficiently attach to cells expressing Fc receptors. Flaviviruses enter cells via clathrin-mediated endocytosis and then traffic to endosomal compartments in which fusion occurs. The mechanism of fusion is depicted in the **inset**. Exposure of the E protein dimers present on

mature virions **(A)** to a mildly acid environment results in their disassociation and a conformational change that projects E-DII away from the virion membrane (**B**). This orients the E-DII-FL in a position where it may insert in the target cell membrane. E proteins in this extended conformation next form trimers **(C)**. The stem anchor packs into grooves of the core trimer **(D–F)** as the molecule folds back on itself and pulls viral and host membranes into proximity. Antibodies have the potential to block multiple steps in this virus entry pathway.
(This figure was modified from Pierson TC, Kielian M. Flaviviruses: braking the entering. Curr Opin Virol 2013;3:3–12.)

Glycosaminoglycans

The interactions between flaviviruses and glycosaminoglycans (GAGs) have been documented.[191,464,609,694] The binding site on the virion for these sulfated polysaccharides has been mapped to positively charged surfaces of the E protein.[191,694] GAGs promote more efficient attachment to cells via electrostatic interactions with the virus particle. Passage of virus in cell culture selects for variants that bind more efficiently to GAGs, although this adaptation appears to be associated with reduced fitness *in vivo*.[608,610,694] Treatment of cells with soluble heparin sulfate can inhibit infection.[191,612,647]

Lectins

The prM and E proteins of flaviviruses may be modified by the addition of one or two N-linked complex- or high-mannose–type sugars. Host lectins may contribute to more efficient virion attachment through interactions with these viral sugars. CD209 (DC-SIGN) is a calcium-dependent (C-type) lectin that serves as an attachment factor for several classes of viruses (reviewed in Ref.[1142]), including some flaviviruses.[241,817,1104] CD209 is expressed *in vivo* on a subset of dendritic cells (DCs) and macrophages.[1142] The infectivity of DCs by DENV correlates with CD209 expression; immature DCs express CD209 and are more permissive to infection than mature DCs expressing lower levels of CD209.[1104,1210] Antibodies against CD209 or soluble forms

of this lectin can block DENV infection of DCs.[817,1104] Experiments with truncated forms of CD209 suggest that internalization of CD209 is not required to increase the efficiency of virus attachment to selected cell types.[670] CD209L (DC-SIGNR)[241,1104] and the mannose receptor (MR)[747] also have been identified as attachment factors for flaviviruses. The genetic linkage between DENV disease severity and polymorphisms in the CD209 promoter is consistent with a role for this attachment factor in humans.[850]

Phosphatidylserine Receptor Family

Genetic complementation experiments first identified members of two phosphatidylserine receptor families as capable of enhancing interactions of flaviviruses with target cells.[729] These molecules bind negatively charged phosphatidylserine lipids incorporated into the inner leaflet of the plasma membrane that become exposed on the outer leaflet during the process of apoptosis.[310] Incorporation of phosphatidylserine into the lipid envelopes of viruses allows virions to hijack this pathway via a process referred to as apoptotic mimicry.[22] Many viruses exploit this pathway.[491] Molecules in the T-cell immunoglobulin domain and mucin domain (TIM) family of receptors bind phosphatidylserine directly and have been shown to facilitate virus entry, including TIM-1 and TIM-4. These molecules are expressed on lymphocytes and antigen-presenting cells (macrophages and dendritic cells) of the immune system and function as signaling molecules that coordinate immune functions. TYRO3 and AXL of the TAM (*T*YRO3, *A*XL, *M*ERTK) family of tyrosine kinases indirectly mediate virus attachment through interactions with phosphatidylserine-binding proteins Gas6 or protein S. AXL is expressed widely and plays multiple roles in immune regulation, and in human diseases, including cancer and autoimmunity, when dysregulated. The signaling functions of TAM receptors are required to promote more efficient virus infection, although virus binding remains unaffected.[729,870]

A role for host factors of the TIM/TAM family in flavivirus infection *in vivo* was studied extensively in the wake of the emergence of ZIKV. Multiple studies demonstrated that expression of AXL enhanced ZIKV infection *in vitro*,[433,730] and this molecule was expressed on target cells *in vivo* with the potential to contribute to the unique pathogenesis of ZIKV.[568,831] Studies in knockout mice demonstrated that AXL was not required for ZIKV infection

in mice deficient in interferon (IFN) receptor signaling[448,626,1181] or for WNV infection in mice with intact IFN signaling.[751] A role for AXL in pathogenesis may relate to its capacity to dampen the innate immune response in target cells or affect the blood–brain barrier.[194,751] It remains possible that human AXL may have a more significant role in flavivirus infectivity than its mouse ortholog.[926,975]

The Cell Biology of Flavivirus Entry

Flaviviruses enter cells via clathrin-mediated endocytosis.[3,202,368,560,1141] Single-particle tracking studies of DENV suggest that virions move across the surface of cells until they encounter preformed clathrin-coated pits. Virus particles are then internalized and traffic into endosomal compartments where viral fusion occurs. Fusion between viral and cellular membranes is triggered by the acidic environment of endosomes. The conformational changes in the E proteins that orchestrate membrane fusion have been studied using biochemical and structural approaches (reviewed in Ref.[877]).

Flavivirus Tropism

The molecular basis for the tropism of flaviviruses is incompletely understood. A wide variety of cell lines representing different lineages and species can be infected *in vitro*. This suggests that cellular factors involved in virus entry are either highly conserved (from arthropods to vertebrate hosts) or redundant. Alternatively, the adaptation of cell lines to continuous culture may select for expression of host factors used by virions *in vitro* distinct from those used *in vivo*. Targets for flavivirus infection *in vivo* appear more restricted. Target cell types infected by flaviviruses include monocytes, macrophages, DCs, hepatocytes, neurons, and endothelial cells.[51,963] Insights that followed emergence and unique pathogenesis of ZIKV identified the importance of placental cells and those of the male and female reproductive tract as important targets of infection.[149,382] Tropism may be regulated at a postentry level through the activities of IFN and IFN-stimulated genes (ISGs).[149,963]

Mechanisms of Dissemination

Viscerotropic Viruses

For both viscerotropic (e.g., DENV, ZIKV, and YFV) and encephalitic (e.g., WNV, JEV, and TBEV) flaviviruses, the skin is the likely initial infection site after vector inoculation, with resident dendritic cells[147,703] or epidermal keratinocytes[635] believed to be the primary target cells. Subsequently, recruitment of monocytes and monocyte-derived dendritic cells to the underlying dermis may provide additional targets for infection.[881,991] The dose of virus inoculated by mosquitoes under conditions of natural infection is not known precisely, but likely ranges from 10^3 to 10^5 plaque-forming units (PFU),[995,1076] depending on the flavivirus and vector species. Active WNV replication can be detected at the subcutaneous site of infection within one day of inoculation,[133] and viral spread to the lymph node occurs in animals infected by mosquitoes or with mosquito salivary extracts.[995,1077] Factors in mosquito saliva alter cytokine levels and other components of innate immunity, leading to local immunosuppression or dysregulation,[993] and enhanced viral spread and replication. One exception to this paradigm is the sexual transmission of ZIKV, where epithelial cells in the vagina (male-to-female) or rectum (male-to-male) likely are the initial targets of infection.

Flaviviruses disseminate to local lymph nodes either associated with migratory infected dendritic cells[900] or as free virus that transudates directly into lymphatic fluid.[501] Macrophages on the floor of the subcapsular sinus and in the medulla of lymph nodes capture viral particles, serving as additional targets of virus amplification and initiators of innate and adaptive immune responses.[501] Virus produced in the draining lymph nodes likely spreads to intravascular venous compartments via efferent lymphatic drainage. Virus in the bloodstream can directly infect blood cells or visceral tissues, which can result in further dissemination and secondary viremia.

The infectivity of flaviviruses in plasma, the fluid component of blood, appears remarkably short, with a half-life in mice ranging from 2 to 10 minutes for DENV and WNV, respectively.[339] The loss of infectivity is due in part to complement (C3 and C4 components) opsonization via mannose-binding lectin (MBL) recognition of N-linked glycans on the surface of virions[339] and binding by antibodies. The short half-life of an infectious flavivirus in plasma may also reflect sequestration and removal by different

visceral organs.[485] Alternatively, flaviviruses may transit rapidly into the cellular compartment of blood. One study of patients with DENV infections of different disease severity showed DENV antigen (prM and NS3) predominantly in cells of monocyte ($CD14^+$, $CD32^+$) lineage, with up to 80% to 90% of cells of expressing viral antigen.[292] Analogously, $CD14^+$ monocytes are principal targets of ZIKV infection in peripheral blood mononuclear cells.[332,745] The finding of DENV in blood monocytes is consistent with prior literature[699] but contrasts with studies in rhesus macaques suggesting that platelets become positive for dengue antigen during the course of infection.[844] Finally, another explanation for the rapid drop of plasma infectivity is that flaviviruses adhere readily to erythrocytes in whole blood.[934]

Neurotropic Viruses

Flavivirus neuropathogenesis requires neuroinvasiveness, the capacity to enter the CNS, and neurotropism, the ability to propagate efficiently within cells of the CNS. In classical studies, phenotypic distinctions were made among different arthropod-borne viruses on the basis of replication efficiency and pathogenic potential in peripheral versus CNS tissues.[13] A main principle was the relationship between peripheral viral burden and propensity for neuroinvasion. Viruses with a low capacity to replicate in the periphery generally had less neuroinvasive potential, regardless of their intrinsic neurovirulence. Aerosol-acquired infections are possible exceptions, as these may use alternate routes of CNS entry (e.g., accessing the olfactory bulb via the cribriform plate). Also, in the context of ZIKV vertical transmission, the viral burden in the mother likely facilitates infection of the maternal decidua, seeding of the fetally derived placenta, and dissemination to the fetal brain.[218]

Data from several studies indicate that the time of onset, magnitude, and duration of viremia, as well as the integrity of the host immune system, influences the risk of entry into the CNS. Thus, the neuropathogenic potential of most flaviviruses is a balance between replication efficiency and the effectiveness of early host defenses in clearing viremia. Neuroinvasiveness is affected by both viral and host factors. Based on genetic analysis of virulent and attenuated strains of JEV, TBEV, YFV, ZIKV, and WNV, viral determinants of neuroinvasiveness generally map to the E

protein.[71,73,173,724,826,827] However, NS1 also may contribute to neuroinvasiveness of certain flaviviruses by modulating endothelial barrier function in a tissue-specific manner and influencing virus dissemination across tissue barriers.[896] The precise mechanisms associated with these viral genetic determinants have not been determined but are believed to relate to increased viral infectivity of key target cells through enhanced binding and penetration or induction of proinflammatory cytokines and disruption of the endothelial glycocalyx-like layer.[361]

Animal models of infection of encephalitic flaviviruses have begun to define factors that govern virus entry into the CNS. Blood–brain barrier (BBB) crossing likely occurs through a hematogenous route, as increased viral burden in the serum correlates with earlier and enhanced neuroinvasion.[265] Accordingly, changes in endothelial barrier permeability may facilitate CNS entry; these may be triggered by vasoactive cytokines (e.g., TNF-α)[680,1180] or activation of matrix metalloproteinases that degrade the BBB extracellular matrix.[1152,1169] Nonetheless, other cytokines and signaling pathways, including type I and III IFNs and TAM receptors, can tighten the BBB and prevent virus and immune cell crossing.[236,599,751] Additional mechanisms may contribute to CNS infection of flaviviruses, including (a) direct infection of or passive transport through the endothelium[284,654,1153]; (b) infection of olfactory neurons and rostral spread from the olfactory bulb.[133] Access through the olfactory bulb is believed to occur after infection by aerosol or intranasal routes[812,828,909] as well as in the context of peripheral inoculation.[725] The olfactory bulb is vulnerable to direct infection because of the exposure of its nerve terminals within the olfactory mucosa; (c) virus is transported by infected immune cells trafficking into the CNS[1183]; (d) Access to the CNS after breakdown of BBB integrity[182,544]; and (e) Retrograde axonal transport from infected peripheral neurons.[481,786,964,1179] Although much has been learned from infection studies in mice and hamsters, the precise mechanisms of CNS entry of encephalitic flaviviruses in humans and other animals require additional study.

Mechanisms of Immune Control—Innate Immunity

Cellular Innate Immunity

Monocytes and macrophages

Monocytes and macrophages play key roles in orchestrating control of flaviviruses but also can become targets and reservoirs of infection. Recent studies of human patients infected with ZIKV showed that $CD14^{+}CD16^{+}$ monocytes are principal targets of infection in peripheral blood.[745] Because monocytes can infiltrate many tissues, they may act as "Trojan horses" for the spread of infection across tissue compartments. Analogously, after DENV infection, sorting of peripheral blood mononuclear cells revealed that $CD14^{+}$ monocytes were infected with DENV and produced the inhibitory cytokine IL-10.[1040] In a mouse model of primary infection, $Ly6C^{hi}$ monocytes were recruited to the DENV-infected dermis and differentiated to monocyte-derived DCs, which then became targets for DENV replication.[991] During secondary DENV infection, DENV can be opsonized with non- or subneutralizing antibody levels that augment entry and infection of monocytes through activating Fc-gamma receptors (FcγRs).[426,539] In this context of enhanced infection, DENV immune complexes activate Syk to mediate elevated secretion of proinflammatory cytokines including IL-1β.[154]

Macrophages can limit infection through direct viral clearance, enhanced antigen presentation to B and T cells, and production of proinflammatory or antiviral cytokines and chemokines.[564,700] The protective role of macrophages is highlighted by studies in mice, which demonstrated exacerbated WNV, TBEV, DENV, or YFV disease after selective macrophage depletion.[81,136,326,522,900,1257] Macrophages may control flaviviruses through the production of nitric oxide (NO) and other reactive oxygen intermediates after stimulation of inducible nitric oxide synthase (NOS2).[559,646,978,979] Activation of macrophages in response to flavivirus infection also promotes the release of type I IFN, TNF-α, IL-1β, IL-8, and other cytokines, some of which have antiviral activity.[1031] Despite their protective role in innate defense, macrophages and microglia also are targets of infection by some flaviviruses[548,584,936] and have the potential to contribute to pathogenesis through ADE mediated by Fcγ and complement receptors.[162,367,866] The macrophage cell-surface receptor CLEC5A has been reported to interact with DENV and JEV directly, resulting in DAP12

phosphorylation, activation of the NLRP3 inflammasome, and the release of proinflammatory cytokines.[189,190,1209] Anti-CLEC5A mAb inhibited JEV-induced proinflammatory cytokine release from microglia and prevented bystander damage to neuronal cells. Thus, in some circumstances, macrophages can contribute to flavivirus-induced disease, although the contribution to clearance versus pathogenesis may vary depending on the specific virus, the presence of preexisting nonneutralizing antibodies, and the specific proinflammatory molecules that are produced.

Neutrophils

Although neutrophils are among the first circulating leukocytes to respond to infection or inflammatory stimuli, their function in flavivirus infection remains uncertain. While some studies suggest a protective function, others indicate that neutrophils can contribute to flavivirus pathogenesis. A protective role was reported in the context of WNV infection, as macrophages produced neutrophil chemoattractive chemokines (CXCL1 and CXCL2), neutrophils rapidly migrated to the site of infection, and mice depleted of neutrophils 1 or 2 days after virus infection developed higher viremia and experienced earlier death.[43] Paradoxically, if neutrophils were depleted prior to infection, viremia was reduced and survival was enhanced.[43] Analogously, depletion of neutrophils resulted in prolonged survival and decreased mortality in Murray Valley encephalitis virus-infected mice, and neutrophil infiltration and disease correlated with iNOS expression within the CNS.[26] Moreover, WNV burden, proinflammatory cytokines, and apoptotic cells in the CNS of *Il22*$^{-/-}$ mice were reduced, and this was associated with decreased neutrophil migration into the brain.[1168] Finally, transcriptional gene signatures from whole blood showed a greater abundance of neutrophil transcripts in patients who progressed to severe dengue, a finding supported by higher plasma levels of proteins associated with neutrophil degranulation.[468] Although further studies are warranted, neutrophils may prevent or promote flavivirus disease, depending on the specific virus and immunological context.

Dendritic cells

Human peripheral blood contains two major classes of dendritic cells (DCs),

plasmacytoid DCs (pDCs) and myeloid DCs (mDCs), which can be distinguished based on function and surface markers. pDCs lack phagocytic capacity, are less efficient in capturing and presenting antigens to T cells, but produce extraordinarily high levels of type I IFN in the presence of viruses or bacteria,[1034] and are thus considered to have a crucial sentinel role in antiviral immunity.[1090,1091] In pDCs, flaviviruses can stimulate either TLR7 or RIG-I signaling in the same cell, depending on how its nucleic acid content is delivered (i.e., via internalization or active replication).[135]

Low levels of DENV replication are observed in pDC, but proinflammatory cytokines are produced rapidly and can accumulate to high levels. This cytokine response was not dependent on viral replication, but was dependent on endosomal TLR7, and could be induced by purified DENV RNA.[1083,1174] Immature virus particles, which carry viral RNA to the endolysosome-localized TLR7 sensor, may contribute to progression of dengue disease by eliciting a strong innate immune response in pDCs.[250] In prospective clinical studies, the absolute number of circulating pDC remained stable early in moderately ill children with dengue fever or other nondengue, febrile illnesses. However, there was an early decrease in circulating pDC in children who subsequently developed DHF, as a blunted blood pDC response was associated with an altered innate immune response, higher viremia levels, and severe disease.[874] Interestingly, the host origin of the flavivirus influences the response generated by pDC as WNV grown in mammalian cells was a potent inducer of IFN-α secretion in pDCs, whereas pDCs failed to produce IFN-α when exposed to WNV grown in mosquito cells.[1037]

mDCs reside and circulate throughout the body, enabling them to transport antigens from the periphery to lymphoid tissues. They are professional antigen-presenting cells that transmit incoming infectious signals to B and T cells, to orchestrate rapid and efficient adaptive immune responses.[1067] mDCs are more readily infected by flaviviruses *ex vivo* and are thought to contribute to viral spread and early immune system priming depending on the particular virus. For example, WNV efficiently infects mouse mDCs and induces a type I IFN and proinflammatory cytokine response through RIG-I–like pattern recognition receptors (PRRs) and MAVS-dependent signaling cascade.[231,1088] In comparison, JEV induced impaired responses in mice through MyD88-dependent and MyD88-independent pathways, with blunted costimulatory molecule expression and

production of the anti-inflammatory cytokine IL-10, which resulted in poor T-cell priming.[15] DENV productively infects human mDCs and induces the release of high levels of chemokines and proinflammatory cytokines, with the notable exception of type I IFN,[941,942] although this latter finding has not been observed with all strains of DENV.[47,630] As an example, DENV-4 replication peaks earlier and promotes stronger innate immune responses, with increased expression of DC activation and migration markers and increased cytokine production, compared with DENV-2.[434] Apart from this, mature mDCs were capable of supporting ADE of DENV, whereas immature DC, due to the expression of higher levels of DC-SIGN, did not support ADE.[110]

Despite an accumulating wealth of data on purified mDCs *ex vivo*, few studies have assessed their direct function *in vivo* in the context of flavivirus infection. Selective genetic deletion of *Batf3* or *Wdfy4*, which affect CD8α^+ mDC (DC1) homeostasis or function, resulted in defective cross presentation and virus-specific CD8$^+$ T-cell responses to WNV in mice.[463,1116] However, JEV infection appears to actively suppress *in vivo* cross presentation of soluble and cell-associated antigens, resulting in diminished CD8$^+$ T-cell responses.[17]

Natural killer cells

Natural killer (NK) cells are innate immune lymphocytes that serve as a first line of defense against a variety of infections.[95] NK cells mediate protection through the recognition and killing of target cells and the production of immunomodulatory cytokines, particularly IFN-γ, which enhances innate immunity and shapes the subsequent adaptive immune response.[213] Unlike adaptive T and B lymphocytes, NK cells do not rearrange their receptor genes somatically but rely on inhibitory and activating cell receptors that recognize MHC class I and class I–like molecules, as well as other ligands.[138] The function of NK cells in flavivirus infection remains uncertain. Some *in vitro* studies suggest that human NK cells can inhibit WNV infection through both cytolytic (ADCC) and noncytolytic (IFN-γ) activities.[1246] The activating human NK cell receptor, NKp44, has been reported to bind directly to domain III of DENV and WNV E proteins. This interaction induced IFN-γ secretion and lysis of WNV-infected targets by NK cells.[460] However,

flavivirus infection may inhibit NK cell killing by increasing the cell-surface expression of class I MHC molecules,[276,360,461,532] which sends an inhibitory signal to NK cells.[497] *In vivo*, the function of NK cells in flavivirus infection also remains unclear. While NK cells expand and become activated in YFV- and DENV-infected humans and mice,[183,820,1022] antibody depletion of NK cells in mice did not alter morbidity or mortality after WNV infection.[1029] In humans infected with TBEV, highly differentiated $CD57^+$ NK cells were activated, but this was associated with decreased expression of perforin and granzyme B, as well as diminished NK cell responses to target cells.[104] However, in *ex vivo* experiments, the combination of type I IFN, TNF-*α*, and cell-surface receptor engagement with DCs enabled NK cells to overcome immune evasion by DENV.[643]

γδ T cells

γδ T cells contribute to the innate defense against several viruses by virtue of their abundance in epithelial and mucosal tissues and ability to respond rapidly to nonpeptide antigens by secreting proinflammatory cytokines and chemokines. As they lack classical MHC restriction, γδ T cells can react with viral antigens in the absence of conventional antigen processing.[1065] γδ T cells are divided into functionally distinct subsets, which have disparate effects on host immunity to pathogen infection.[715] As an example, $Vγ4^+$ γδ T cells enhance Th1 cell activation through IFN-γ– and CD1-dependent mechanisms.[479] To date, much of the initial analysis of γδ T-cell function during flavivirus infection has focused on studies with WNV in mice, although recent studies confirm that human and monkey γδ T cells also are activated rapidly after YFV infection.[258,821] Mice deficient in γδ T cells were more susceptible to WNV infection,[1177] and this was in part due to their ability to produce IFN-γ, which has direct antiviral effects.[1030] Moreover, mice depleted of $Vγ1^+$ γδ T cells have enhanced viremia and higher WNV mortality, whereas the opposite is observed with depletion of $Vγ4^+$ γδ T cells.[1194] Subsequent work showed that γδ T cells also contribute to the development of a protective $CD8^+$ T-cell response against WNV as $TCRδ^{-/-}$ mice were more susceptible than wild-type mice to secondary WNV challenge.[1170] This priming effect may reflect DC maturation (increased expression of surface costimulatory and class II MHC molecules and

secretion of IL-12) that is promoted by γδ T cells after activation by WNV.[315]

Mast cells

Mast cells contribute to a variety of inflammatory reactions and host defense against pathogens by secreting chemokines, cytokines, and inflammatory lipid mediators and granule-associated products.[692] Mast cells express Fc receptors, reside primarily in tissues, and associate closely with vascular beds.[1012] Infection or activation of mast cells by DENV can promote viral clearance[1060] or have immunopathological consequences that contribute to the vasculopathy associated with secondary infection. DENV infection of mast cells *ex vivo* resulted in increased secretion of chemokines including CCL5 without inducing degranulation,[531] and production of vasoactive cytokines was enhanced in the presence of subneutralizing concentrations of antibody that promote ADE.[533] Mast cells also are targets of DENV in human skin, and this induces degranulation and alters cytokine expression profiles.[1128] Antibody-enhanced DENV infection of mast cells in culture also resulted in significant production of TNF-*α* that can stimulate endothelial cells[131] as well as massive mast cell apoptosis that occurs via global caspase activation.[132] Preexisting anti-DENV IgG can enhance both mast cell degranulation and vascular leakage during DENV infection.[1092] Thus, mast cells may contribute to a second mechanism of antibody-enhanced immune pathology during DENV infection that is dependent not on enhanced virus replication but on FcγR-mediated augmented degranulation responses. Drugs (e.g., ketotifen or leukotriene receptor antagonists) that stabilize mast cells diminished metabolic dysregulation, complement activation, and inflammation associated with DENV infection and pathogenesis in mice.[790,1059]

Cell-Intrinsic Immunity

Recognition and control of flaviviruses by host sensors

IFN responses are an essential host defense program against many viruses, including flaviviruses. IFNs are produced during the earliest stages of viral infection after recognition of pathogen-associated molecular patterns (PAMPs) by specific PRRs. Mammalian cells primarily detect and respond to

RNA virus infection by recognizing non-self viral RNA or viral RNA structural elements through several distinct PRRs including the cell-surface and endosomal RNA sensors toll-like receptors 3 and 7 (TLR3 and TLR7) and the cytoplasmic RNA sensors retinoic acid–inducible gene I (RIG-I) and melanoma differentiation–associated gene 5 (MDA5) (Fig. 9.11). Binding of single- and/or double-stranded viral RNA to PRRs results in downstream activation of transcription factors, such as IFN-regulatory factors 3 and 7 (IRF3 and IRF7) and NF-κB, and induction of IFN-α and β. Secretion of IFNs followed by engagement of the IFN-$\alpha\beta$ receptor (IFNAR) in an autocrine and paracrine fashion activates JAK–STAT-dependent and JAK–STAT-independent signal transduction cascades[622] that induce the expression of hundreds of ISGs, a subset of which have antiviral activity against flaviviruses (Fig. 9.12).[998]

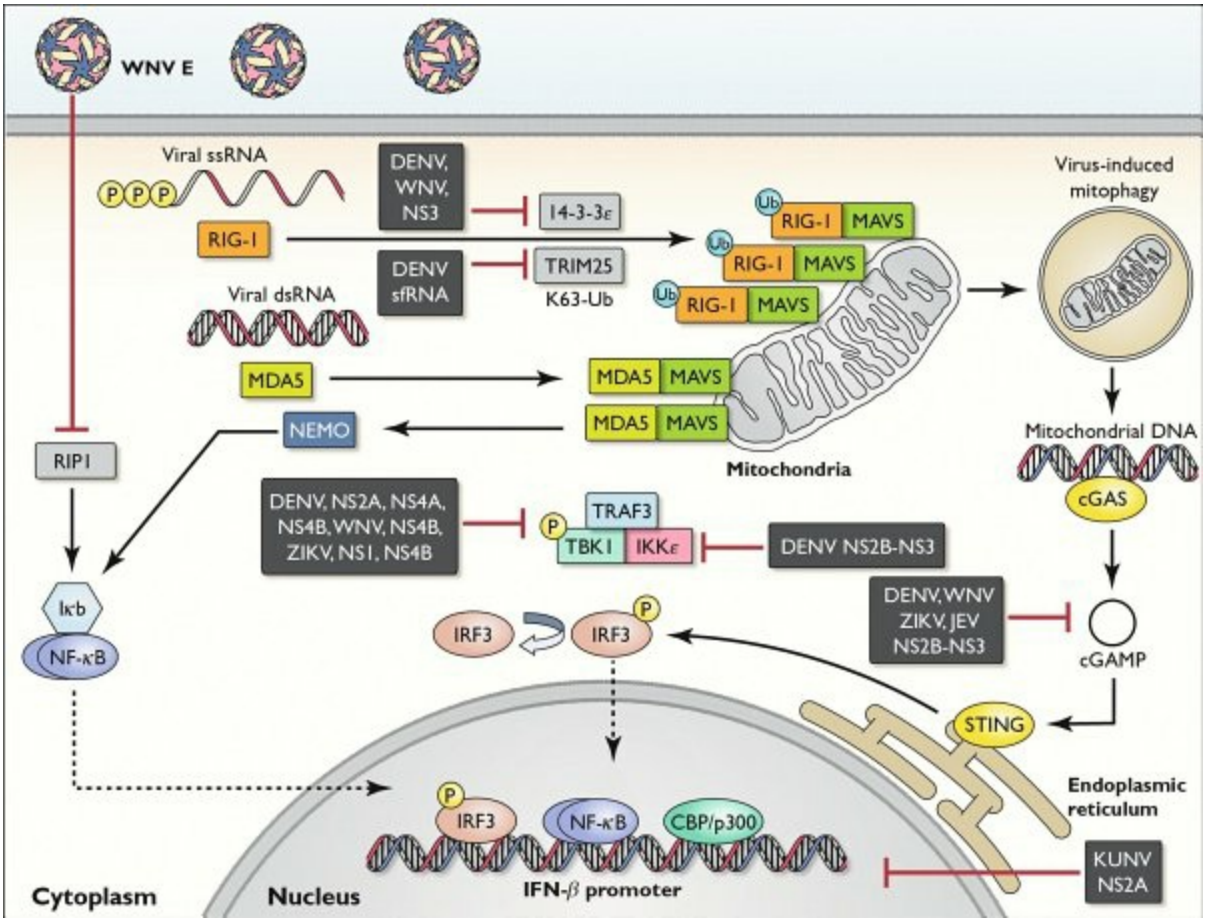

FIGURE 9.11 Detection of flavivirus RNA by cytosolic pathogen recognition receptors (PRRs) and mechanisms of viral evasion.

Cytoplasmic PRR and signaling cascade. Infection by flaviviruses produces dsRNA replication intermediates that display motifs recognized by RIG-I and MDA5. Binding of viral RNA promotes an interaction with MAVS that results in recruitment of signaling proteins (NEMO and TRAF3) that activate IRF3 and NF-κB. These transcription factors translocate to the nucleus and bind to the promoter region of the IFN-β gene leading to transcription and translation. Mechanisms of evasion by flaviviruses include the following: (a) a delay in recognition of WNV RNA by RIG-I; (b) impairment of RIP-1 signaling by high-mannose carbohydrates on the structural E protein; (c) reduction in IFN-β gene transcription by the KUNV NS2A protein; (d) reduction of type I IFN production by catalytically active DENV NS2B-NS3 protein; and (e) viral dsRNA intermediates localize to specialized membrane vesicles, which prevent rapid detection by intracellular sensors such as RIG-I.

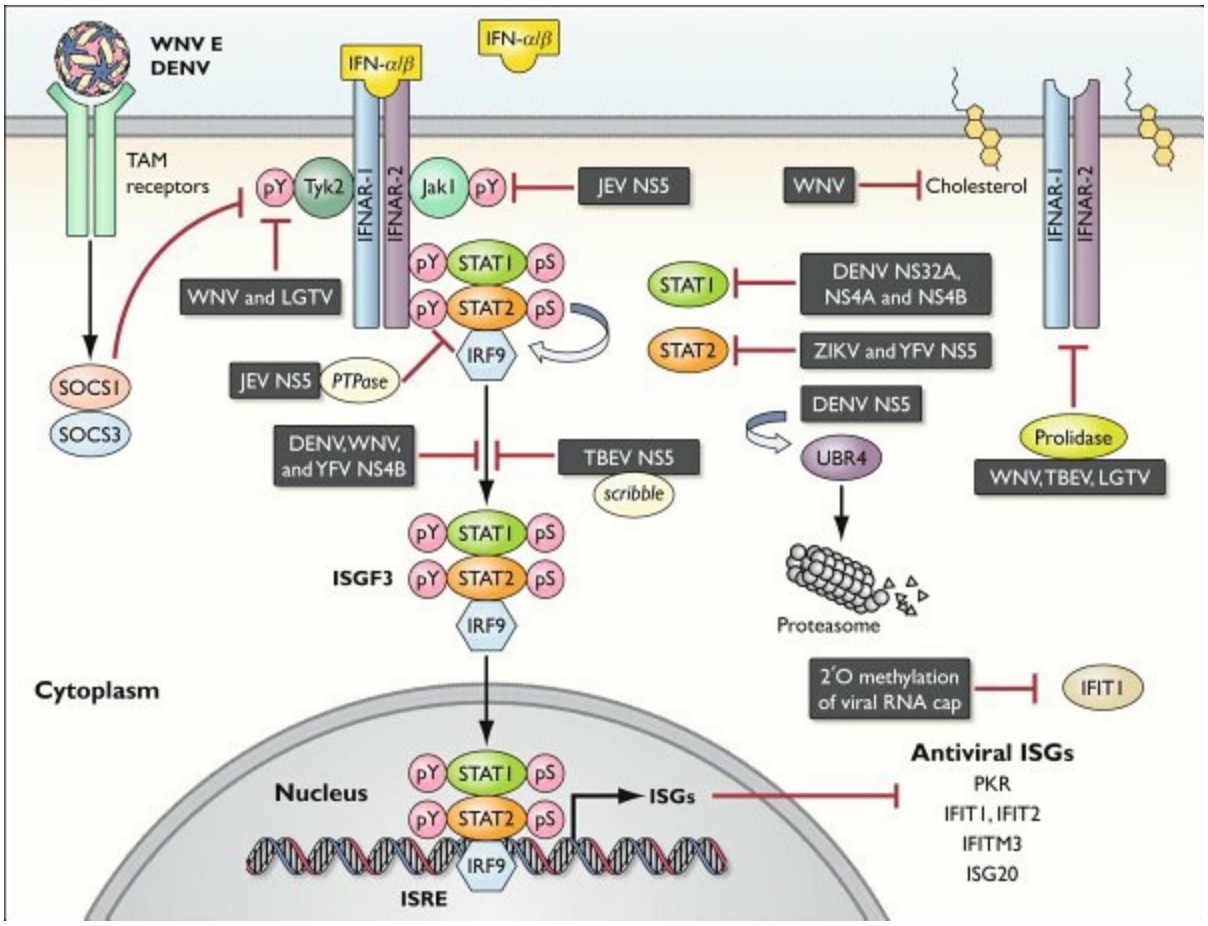

FIGURE 9.12 Type I interferon (IFN) signaling and mechanisms of disruption by flaviviruses. Secretion of IFN by a flavivirus-infected cell results in autocrine and paracrine signaling through the heterodimeric IFN-$\alpha\beta$ receptor (IFNAR). IFN binding results in activation and tyrosine phosphorylation of JAK family members (JAK1 and Tyk2) and the cytoplasmic tail of IFNAR. This promotes recruitment of STAT1 and STAT2, which themselves become phosphorylated by the JAKs. Phosphorylated STAT1 and STAT2 proteins heterodimerize, associate with IRF9, and translocate to the nucleus, where they bind ISRE sequences to induce expression of hundreds of interferon-stimulated genes (ISGs). Mechanisms of evasion by flaviviruses include the following: blockade of phosphorylation of (a) Tyk2 and (b) JAK1 by flavivirus NS5; (c) activation of a phosphotyrosine phosphatase

by JEV NS5; (d) reduction in STAT2 gene and protein expression by DENV and YFV NS5; (e) attenuation of STAT signaling by flavivirus NS4B; (f) down-regulation of IFNAR through virus-induced redistribution of cellular cholesterol; and (g) antagonism of IFIT family gene effector functions by 2'-*O*-methylation of flavivirus RNA.

RIG-I and MDA5 contribute to the induction of host IFN and antiviral response to flaviviruses. The highly structured 5′ region of the DENV and ZIKV genomes are recognized by RIG-I.[185] Fibroblasts deficient in RIG-I and MDA5 showed decreased IRF3 activation, delayed induction of IFN and ISG responses, and augmented WNV and DENV replication.[336,337,667,815] RIG-I primes the early type I IFN response, whereas MDA5 has a role in a second phase of ISG expression that occurs later in the course of infection, possibly due to accumulation of dsRNA replication intermediates. A genetic deficiency of MAVS, an essential RIG-I and MDA5 adaptor molecule that is anchored to mitochondria, completely disabled the IFN response in fibroblasts[231,337] and was associated with enhanced WNV lethality and dysregulated immune responses in mice.[1088] RIG-I–dependent signaling appears dominant in mice as animals deficient in RIG-I were more vulnerable to JEV infection,[510] and a deficiency of proteins that regulate the TRIM25-mediated ubiquitination and activation of RIG-I resulted in enhanced WNV replication and mortality.[1167] Consistent with this, JEV and DENV induce the type I IFN response through a mechanism involving RIG-I/IRF3 and NF-κB.[176] Nonetheless, higher mortality rates, altered $CD8^+$ T-cell responses, and increased viral infection in primary macrophages were observed after WNV infection in mice and cells lacking MDA5.[307,602] Despite data suggesting that RIG-I and MDA5 recognize flavivirus RNA and induce type I IFN responses, IFN-α and IFN-β production in some cell types appears independent of MAVS[1088] or the downstream transcription factor IRF3.[113,227,230]

TLR3, which is expressed on the surface of fibroblasts and in the endosomes of myeloid cells, promotes IRF3 phosphorylation after binding double-stranded viral RNA through a signaling cascade that includes

recruitment of TRIF and activation of the kinases TBK1 and IKKε.[714,999] Initial studies with TRIF-deficient fibroblasts suggested that TLR3 may be dispensable for recognition of flaviviruses in cells,[336] although subsequent cell culture studies showed a proinflammatory and protective effect of TLR3 after DENV infection.[815,1130] Experiments in *Tlr3*$^{-/-}$ mice have had conflicting results. *Tlr3*$^{-/-}$ mice injected by an intraperitoneal route paradoxically showed decreased WNV lethality despite higher peripheral viral titers, presumably because of blunted cytokine responses (e.g., TNF-α) that normally facilitate neuroinvasion.[1180] Consistent with a possible pathological role, preliminary studies suggest a functional TLR3 allele is a risk factor for severe human TBEV infection.[530] In comparison, other studies with *Tlr3*$^{-/-}$ mice and a different WNV strain or with JEV showed increased viral burden in the brain and enhanced lethality,[228,437] as might be anticipated for a PRR that triggers a protective host immune response. *Ex vivo* and *in vivo* experiments suggest a cell-specific role of TLR3, as it protected against WNV largely by restricting replication in neurons. More recent studies have defined a link between ZIKV-mediated TLR3 activation, perturbed cell fate, and a reduction in the volume of cerebral organoid cultures, which suggests TLR3 activation may lead to disrupted neurogenesis.[235]

Although TLR4 is a PRR best known for its ability to recognize lipopolysaccharide present in many gram-negative bacteria, it may functionally impact flavivirus infection, immunity, and pathogenesis. A possible pathogenic role of TLR4 was suggested in studies with JEV, as *Tlr4*$^{-/-}$ mice showed enhanced resistance to infection.[437] Genetic ablation of TLR4 resulted in enhanced type I IFN, humoral, and T-cell responses, which were mediated by increased numbers of pDCs and NK cells and reduced numbers of Tregs in lymphoid tissues. A second pathogenic role of TLR4 signaling was suggested when studies showed that DENV NS1 devoid of bacterial endotoxin activity directly activated human peripheral blood mononuclear and endothelial cells via TLR4, which induced the release of proinflammatory cytokines and chemokines. The importance of TLR4 activation *in vivo* was confirmed by the reduction in capillary leakage by a TLR4 antagonist in a mouse model of DENV infection[756,757] and suggested by analysis of *TLR4* gene polymorphisms in human DENV patients.[1019] However, a second group did not corroborate these findings and observed that DENV NS1 induced vascular leakage in Tlr4-/- mice at similar levels to

wild-type animals.[362]

TLR7 is an endosomal PRR that detects guanosine- and uridine-rich single-stranded RNA[268] and activates IRF7 via the adaptor molecule MyD88 IRF7 was identified as a primary regulator of antiviral gene induction after YFV infection,[351] with some of this activation occurring through TLR7 recognition of viral RNA.[906,907,1083,1174] Similarly, DENV stimulates IFN production in pDC in a TLR7-dependent manner after virus uncoating.[1174] The antiviral IFN-α response against WNV is primarily mediated by IRF7,[229] and at least some of this signal is attributed to recognition of viral RNA by TLR7. Indeed, both *Tlr7*$^{-/-}$ and *Myd88*$^{-/-}$ mice show increased susceptibility to WNV infection, and this was associated with increased local infection and yet decreased production of IL-1β, IL-6, IL-12 and IL-23 and several chemokines, which altered leukocyte trafficking and control in several tissues.[1094,1124,1195] Studies in aged mice showed that dysregulation of TLR7 signaling contributes to impaired innate and adaptive T-cell responses and an enhanced vulnerability in old mice during WNV infection.[1216]

In addition to using RNA sensors to detect flaviviruses, immune cells use the DNA-sensing machinery to detect intracellular damage generated early during infection by flaviviruses.[6] DENV infection induces mislocalization of mitochondrial DNA into the cytoplasm of infected cells.[7] The leaked mitochondrial DNA is detected by the DNA sensor cyclic GMP–AMP synthase (cGAS), which triggers the stimulator of IFN genes (STING) pathway and induction of type I IFN production. This mechanism likely explains why *cGAS*$^{-/-}$ and *STING*$^{-/-}$ mice and cells showed greater susceptibility to WNV infection.[997,1230]

Type I IFN signaling pathway

Type I IFNs induce an antiviral state by up-regulating genes with both direct and indirect inhibitory functions.[884] In humans and mice, there are multiple IFN-α genes (13 in humans, 14 in mice) and one IFN-β gene, in addition to multiple other subtypes.[1143] IFN-α and IFN-β are considered the dominant functional type I IFNs in humans and are secreted by many cell types following virus infection. Type I IFN primes adaptive immune responses through stimulation of DCs, through activation of B and T cells, and by

prolonging survival of recently activated T cells.[603,604,1068] Pretreatment of cells with IFN-α or IFN-β inhibits flavivirus replication *in vitro*,[87,264,649,673,1157] but treatment after infection is less effective.[25,219,264,963,1062] Although flaviviruses can antagonize IFN-induced responses after infection, IFN still restricts replication and spread *in vivo*. Mice lacking the type I IFN receptor (*Ifnar1*$^{-/-}$) or downstream signaling components (e.g., STAT1 or STAT2) show enhanced lethality and replication after WNV,[517,963] DENV,[1023] YFV,[735] ZIKV,[600,1127] or MVEV[663] infections. Increased replication occurred in normally resistant cell populations and tissues after flavivirus infection of *Ifnar1*$^{-/-}$ mice, suggesting that IFN acts in part to restrict viral tropism. The importance of type I IFN in controlling flavivirus infection has been confirmed in therapeutic disease models. Pretreatment of animals with IFN-α or inducers of IFN-α attenuates infection by SLEV, WNV, YFV, and Modoc viruses.[130,499,616,617,883,1105] The relevance of these pathways has been confirmed *in vivo*, as transcriptomic analyses show that animals or primary cells infected with flaviviruses produce a potent innate antiviral transcriptional signature characterized by ISGs.[47,468,906,970]

Type I IFN-induced genes that control flavivirus infection

Substantial progress has been made in defining the specific IFN-induced antiviral genes that limit flavivirus infection (reviewed in Ref.[996]) (Fig. 9.12). Initial studies showed that dsRNA-dependent protein kinase (PKR) and 2′-5′-oligoadenylate synthase (Oas) proteins mediate intrinsic cell resistance to WNV.[965] PKR is activated by binding dsRNA and phosphorylates the eukaryotic translation initiation factor 2 (eIF2-α) resulting in attenuation of protein synthesis.[743] PKR also may have independent antiviral effects by activating signaling pathways that augment type I IFN production[64,356] and directly regulating IFN-α mRNA stability.[1003] RNase L is activated by 2′-5′-linked oligoadenylates that are synthesized by Oas enzymes. RNase L inhibits viral infections by functioning as an endoribonuclease that cleaves viral RNA[1253,1254] and by generating small self-RNA PAMPs that amplify antiviral immunity through a RIG-I– and MDA5-dependent pathway.[690,691] *Rnasel*$^{-/-}$ fibroblasts and macrophages support increased WNV replication *in*

vitro,[965,983] and knockdown of RNase L enhanced infection in human cells.[651] Moreover, mice deficient in RNase L showed increased lethality following WNV infection, with higher viral loads in peripheral tissues at early time points after infection.[965]

Flavivirus resistance is one of the earliest examples of a genetic determinant of pathogen susceptibility defined in mice. In 1937, flavivirus resistance was shown to be inherited in a single-gene autosomal dominant manner.[1187] In 2002, susceptibility to flaviviruses in mice was mapped to a mutation in the gene *Oas1b* (found in most common laboratory mouse strains), resulting in the expression of a nonfunctional truncated Oas1b isoform.[709,868] Oas1b restricts flavivirus replication by a cell-intrinsic post-entry mechanism independent of RNase L[983] and the type I IFN signaling pathway.[129] Knock-in of the wild-type Oas1b allele into a flavivirus-susceptible mouse generated a resistant phenotype,[982] and murine cells that ectopically expressed Oas1b resisted WNV infection by preventing viral RNA accumulation inside infected cells.[505] While biochemical studies have shown that Oas1b itself is an inactive 2′-5′-Oas, other experiments suggest that Oas1b inhibits Oas1a activity resulting in reduced 2′-5′-oligoA production in response to poly(I:C).[297] Negative regulation of 2′-5′-Oas by inactive Oas1b proteins may tune the RNase L response that could cause significant damage in cells, if it were not tightly controlled. OAS orthologs in other species also restrict flavivirus replication, and *OAS1* polymorphisms are associated with WNV disease in humans[94,639] and horses.[639,869,935]

Ectopic expression and siRNA or knockdown or CRISPR-Cas9 gene editing have been used to identify novel ISGs that restrict infection of multiple different flaviviruses.[927,997,998] The ISG viperin has inhibitory activity against TBEV, WNV, DENV, and ZIKV (reviewed in Ref.[652]). Viperin inhibits flavivirus infection and virulence by diminishing RNA synthesis and replication,[1139] inducing assembly of defective virions,[1160] and targeting the NS3 protein for proteasomal degradation.[857] JEV appears to counteract the antiviral actions of viperin by targeting it for proteasomal degradation.[174] The interferon-inducible transmembrane (IFITM) proteins inhibit multiple enveloped viruses, including flaviviruses.[119] IFITM3 suppressed WNV replication in nonneuronal cells, and *Ifitm3*$^{-/-}$ mice were vulnerable to lethal WNV infection.[376] Cell culture studies have shown that

IFITM3 can restrict infection and cell death associated with ZIKV infection[776,976] and that IFITM3 contributed to both the baseline and IFN-induced inhibition of DENV infection and entry.[1255] Members of the IFI-6-16 family of ISGs (e.g., human *IFI-6*; mouse *Ifi27l2a*) also have antiviral activity against multiple flaviviruses. Ifi27l2a initially was identified in neuronal subsets as antiviral gene against SLEV and WNV.[199] Consistent with these data, *Ifi27l2a*$^{-/-}$ mice were more susceptible to lethal WNV infection and sustained higher viral burden in specific brain regions.[675] A CRISPR-Cas9 screen identified the human ortholog, IFI-6, as an inhibitor of WNV, ZIKV, YFV, and DENV infections by preventing the formation of virus-induced ER membrane invaginations required for replication.[927] Cholesterol 25-hydroxylase is an ISG that catalyzes the formation of 25-hydroxycholesterol (25-HC) from cholesterol and was shown to block entry of ZIKV, DENV, YFV, and WNV.[618] Studies in nonhuman primates and mice showed that 25-HC treatment suppressed ZIKV-induced viremia and infection and tissue damage in the embryonic brain of mice.[618] Although the field is rapidly advancing with respect to identifying antiviral ISGs against flaviviruses, definitive studies in genetically deficient animals may be required to establish the cell- and tissue-specific nonredundant effects of individual ISGs in controlling flavivirus infection in the context of a robust type I IFN response.

Type III IFN signaling pathway

Recent studies have identified important immunomodulatory and antiviral effects of the type III (IFN-*λ*) signaling pathway against flaviviruses. IFN-*λ* functions at barrier surfaces and is induced downstream of pathogen recognition receptor sensing and activation of MAVS.[601] IFN-*λ* binds to and signals through a selectively expressed heterodimeric receptor (IFNLR1/IL10R*β*), distinguishing it from type I IFNs, which bind to the more broadly expressed IFNAR1/IFNAR2 heterodimeric receptor. IFN-*λ* has antiviral functions against ZIKV in the context of infection of the maternally derived decidua and fetally derived placenta during pregnancy in mice and humans.[68,188,214,484] A K154E coding variant of human IFN-*λ*4, which is restricted to certain African populations, remarkably has greatly enhanced *in vitro* activity against ZIKV infection.[53] Apart from its direct antiviral

effects,[682] IFN-λ also inhibited neuroinvasion and infection of WNV and YFV by tightening the blood–brain barrier.[275,599]

Inflammasome

The NOD-like receptors (NLRs) detect danger signals within cells, leading to formation of the inflammasome signaling complex and secretion of proinflammatory cytokines of the IL-1β family.[972] Pathogens can be detected by NLRs NLRP3 or AIM2, which leads to activation of caspase-1 via multiprotein complexes known as inflammasomes. Activation of procaspase 1 enables processing of pro–IL-1β and pro–IL-18 and subsequent release of the proinflammatory cytokines IL-1β and IL-18 from cells.[707] WNV, DENV, and ZIKV infections of humans are associated with elevated levels of systemic IL-1β, suggesting that flavivirus infection can activate inflammasome signaling.[911,1171] In mice, IL-1β signaling and the NLRP3 inflammasome are involved in control of viral replication and CNS disease associated with WNV infection, and WNV infection triggers production of IL-1β from cortical neurons.[911] Consistent with these observations, mice deficient in the inflammasome adaptor protein ASC, which is essential for IL-1β production, showed reduced survival and enhanced WNV replication in peripheral tissues and the CNS.[571] Subsequent studies showed that IL-1R1 signaling promotes control of WNV infection within the CNS via modulation of local DC-mediated T-cell reactivation and T-cell localization.[294,295]

Inflammasome activation also has been implicated in enhancing protective immune responses or contributing to immunopathology of other flaviviruses including DENV and ZIKV. Type I IFNs and IL-18 regulate the antiviral response of primary human γδ T cells against DCs infected with DENV, and antagonizing inflammasome activation significantly inhibited the anti-DENV IFN-γ response of γδ T cells.[1131] In macrophages, the cell-surface signaling receptor, CLEC5a, appears to be important for DENV-induced inflammasome activation, which might contribute to the febrile syndrome in DENV patients.[1209] Platelets appear to enhance the vascular permeability associated with DENV infection through inflammasome-dependent release of IL-1β.[472] In the context of ZIKV infection, silencing of NLRP3 in cells and knockout of NLRP3 in mice inhibited IL-1β secretion, indicating an essential role for NLRP3 in ZIKV-induced IL-1β activation and inflammatory

responses in the brain and peripheral organs.[1171] ZIKV NS5 protein reportedly facilitates the assembly of the NLRP3 inflammasome complex, leading to IL-1β activation through interaction with NLRP3 and induction of reactive oxygen species production.[449] ZIKV NS1 recruits the host deubiquitinase USP8 to cleave polyubiquitin chains from caspase-1 to inhibit its degradation by the proteasome.[1252] An analysis of the neural parenchyma from ZIKV-positive microcephaly cases found higher expression levels of NLRs NLRP1, NLRP3, and AIM2; cytokines IL-1β, IL-18, and IL-33; and enzymes caspase-1, iNOS, and arginase 1 compared to healthy controls. These results suggest that inflammasome activation might cause damaging neuroinflammatory responses that contribute to CZS.[249]

Chemokines

Depending on the specific flavivirus infection, individual chemokines and cytokines can either protect or contribute to pathogenesis. For encephalitic flaviviruses, production of inflammatory chemokines in the brain by neuronal and nonneuronal cells coordinates recruitment of lymphocytes for clearance of viral infection. Chemokines that have been detected in the brain or CSF after WNV, JEV, or TBEV infection of mice include CXCL9 (MIG), CXCL10 (IP-10), CXCL11 (I-TAC), CCL2 (MCP-1), CCL3 (MIP-1α), CCL4 (MIP-1β), and CCL5 (RANTES).[347,406,537,1021,1121] WNV infection in the brain is associated with the early expression of the T-cell chemoattractant CXCL10 by infected neurons[537]; this expression proceeds in a caudal to rostral direction with higher levels detected in the cerebellum. This regional heterogeneity in CXCL10 expression is due to differential regulation by WNV-infected cortical versus cerebellar granule cell neurons and leads to enhanced trafficking of WNV-specific T cells that express the CXCL10 receptor CXCR3 into the cerebellum.[1243] Loss of CXCL10 or CXCR3 via targeted deletion or neutralizing antibody administration leads to decreased recruitment of WNV-specific $CD8^+$ T cells into the CNS, especially within the cerebellum, increased viral loads, and enhanced mortality.[537,1243] In contrast, antagonism of polarized CXCR4–CXCL12 interactions along the BBB improved survival from lethal WNV infection through enhanced intraparenchymal migration of WNV-specific $CD8^+$ T cells within the brain, leading to reduced viral loads and decreased immunopathology.[721]

A genetic deficiency in CCR2, a chemokine receptor on inflammatory monocytes and other leukocyte subtypes, resulted in markedly increased WNV-induced mortality in mice[642] and was associated with a selective reduction of monocyte accumulation in the brain. Subsequent experiments showed that CCR2 mediates selective peripheral blood monocytosis in the context of WNV infection, and this is critical for accumulation of protective monocytes in the brain. While a protective role for CCL2–CCR2 interactions was observed with a virulent WNV strain, an opposing phenotype was seen after infection with an attenuated strain; neutralization of CCL2 reduced the number of microglia in the brain during WNV infection but prolonged the life of infected animals.[355] Thus, depending on the virulence of the strain, CCL2-CCR2-dependent monocyte accumulation and migration may differentially affect disease outcome after WNV infection. Although both CCR2 ligands CCL2 and CCL7 are required for monocytosis and monocyte accumulation in the CNS, only CCL7 deficiency resulted in increased WNV burden in the brain and enhanced mortality. The enhanced susceptibility in *Ccl7*$^{-/-}$ mice was associated with the delayed migration of neutrophils and CD8^{+} T cells into the CNS.[56]

Additional studies have established that the chemokines CCL3, CCL4, and CCL5, all of which bind to the chemokine receptor CCR5, are strongly induced within the brain after WNV infection.[363,537,1021] Moreover, targeted deletion of CCR5 is associated with depressed leukocyte trafficking, increased viral burden, and enhanced mortality.[363] In humans, homozygosity for a defective CCR5 allele (*CCR5Δ32*) correlates with an increased risk of symptomatic WNV and TBEV disease.[364,529,640,641] Because the mouse studies examined the entire brain with regard to expression and leukocyte trafficking and the human studies did not report on specific neurological symptoms, it remains unclear whether CCR5-expressing leukocytes also exhibit regional specificity during CNS recruitment.

For viscerotropic flaviviruses such as DENV, the function of chemokine interaction with their receptors remains less certain. Although DENV-infected wild-type mice produce high levels of chemokines CCL2, CCL3, and CCL5 in their spleen and liver, Ccr1$^{-/-}$ mice had a phenotype similar to wild-type mice, whereas infection of Ccr2$^{-/-}$ or Ccr4$^{-/-}$ mice showed attenuated lethality, liver damage, leukocyte activation, and levels of IL-6 and IFN-γ without significant differences in viral load.[398] Thus, chemokine–

chemokine receptor interactions in the context of DENV infection appear to contribute to the development of disease. Nevertheless, in an encephalitic mouse model of DENV infection, CXCL10 interaction with CXCR3 was required for clearance and resistance to infection.[473] Finally, a case of YFV vaccine-associated viscerotropic disease was associated with polymorphisms in both CCR5 and CCL5 genes.[899]

Complement Activation and Flaviviruses

The complement system is a family of serum and cell-surface proteins that recognize PAMPs, altered-self ligands, and immune complexes. Although complement activation inhibits infection of many viruses (reviewed in Refs.[40,1072]), it has both protective and pathogenic roles in flavivirus infection depending on the specific virus, phase of the infection, and immune status of the host.[40,211] Activation of the complement cascade triggers several antiviral functions including pathogen opsonization and/or lysis and priming of adaptive immune responses. Complement is activated through the classical, lectin, and alternative pathways depending on specific recognition molecules.[1165,1166] Classical pathway activity is triggered by C1q binding to antigen–antibody complexes on the surface of pathogens. The lectin pathway is initiated by MBL or ficolin recognition of carbohydrate structures on the surface of microbes or apoptotic cells. The alternative pathway is constitutively active at low levels through the spontaneous hydrolysis of C3 and also amplifies activation of the classical and lectin pathways. Deposition of C3 and C4 fragments (C3b and C4b) on a pathogen facilitates binding and phagocytosis by complement receptors (CR1, CR3, CR4, and CRIg), a process called opsonization, which helps to clear microbial infections.[164]

Protective activity of complement on flavivirus infection

Complement can limit flavivirus infection by stimulating adaptive immune responses or by directly neutralizing infection. In support of an immune-priming role for complement, *C3*$^{-/-}$ mice are more susceptible to lethal WNV infection and show greater viral burden and reduced antiviral antibody titers.[734] Infection studies with mice lacking C1q, MBL, C4, or factor B establish that all complement activation pathways protect against WNV

infection.[340,732] However, each activation pathway exerts distinct effects in response to WNV infection. Humoral IgM responses to WNV depend upon activation of C3 by the lectin recognition pathway. In contrast, both the lectin and alternative pathways appear necessary for efficient T-cell priming as *C4*$^{-/-}$, factor B$^{-/-}$, and factor D$^{-/-}$ mice exhibited reduced WNV-specific CD8^{+} T-cell responses.[732] The T-cell defects in C4$^{-/-}$ mice may be indirect as depressed IgM responses could affect viral opsonization and antigen presentation. The terminal lytic complement components (C5–C9) do not appear to serve a major function in protection, as C5 neither contributed to protection against WNV pathogenesis nor augmented the neutralizing efficacy of complement-fixing anti–WNV-neutralizing antibodies in mice.[733] Flaviviruses directly trigger complement activation, which can inhibit infectivity. Increasing concentrations of serum complement neutralize WNV or DENV in cell culture and *in vivo* in the absence of antibody, and this depends on recognition of N-linked glycans on the surface of the virion by MBL.[339] Complement activation by flaviviruses occurs *in vivo* as C3 and C4 consumption occurs prior to the induction of a specific antibody response.[732] Complement augments antibody-mediated neutralization of flaviviruses, including YFV, DENV, and WNV.[254,734,1057] The C1q component of complement is sufficient to enhance the potency of antibody neutralization as it reduces the number of antibodies that must bind the virion to neutralize infectivity.[733] The protective efficacy of flavivirus-neutralizing antibodies *in vivo* correlates with IgG subclasses that efficiently fix complement.[733,989]

Pathologic effects of complement on flavivirus infection

In myeloid cells that express complement receptors, antibody-dependent complement activation paradoxically may enhance viral infection.[162,163] Blockade of complement receptor-3 (CD11b/CD18) abrogated the complement-dependent enhancement of WNV infection in this model system. Thus, under certain circumstances, antibody and complement-dependent opsonization of flaviviruses may increase infection in myeloid cells. During WNV infection, a complement-microglial axis promoted synapse loss in brain neurons and was associated with memory impairment in mice.[1147] C1q was up-regulated and localized to microglia, infected neurons, and

presynaptic terminals during WNV neuroinvasive disease. Microglial engulfment of presynaptic terminals in hippocampal neurons in the context of acute and subacute WNV infection occurred through a complement-dependent process.[1147] A pathological role for complement activation has been proposed for the vascular leakage syndrome that accompanies severe dengue.[41,107] In early clinical studies, reduced levels of C3, C4, and factor B and increased catabolic rates of C3 and C1q were observed, particularly in patients with severe DENV disease.[107] Additionally, C3 breakdown products and anaphylatoxins accumulated in the circulation of severely ill patients and peaked at the day of maximum vascular leakage.[206,689] Circulating immune complexes formed by virions and DENV-specific antibodies have been hypothesized to cause pathological complement activation.[107] One alternative hypothesis is that infected cells express sufficient amounts of DENV antigens (E or NS1 proteins) on their surface facilitating immune complex formation and complement deposition.[88] Indeed, in DENV-infected endothelial cells, lower factor H compared to factor B production and greater C3b and C5b-9 deposition was observed, which might contribute to enhanced vascular permeability.[39,41,148] In some human populations, factor H gene polymorphisms and haplotypes with higher levels of expression are associated with protection against severe DENV disease.[557,862]

Humoral Immunity

Humoral immunity contributes significantly to the protective host response to flavivirus infection (reviewed by Ref.[1044]). Passive administration of flavivirus-reactive monoclonal antibodies (mAbs), purified polyclonal γ-globulin, or immune sera confers significant protection in animal models of flavivirus infection.[303,358,516] Moreover, the administration of γ-globulin has been used therapeutically.[80,915] Advances in antibody sequencing and isolation techniques enabled isolation of potently neutralizing human antibodies with therapeutic potential.[320,839] Although neutralizing antibody titers correlate with protection by several flavivirus vaccines,[78,451,711,774] this relationship is imperfect.[99,1106] Antibodies also exert protective effects via effector functions coordinated by the Fc portion of the immunoglobulin heavy-chain molecule, including complement fixation, antibody-mediated cellular cytotoxicity, and facilitating virus clearance.[733,989,990] Furthermore,

anti-flavivirus antibodies may be protective even when targeting nonstructural proteins, such as NS1.[44,282,513]

Mechanisms of Neutralization

Antibody-mediated neutralization is defined as a reduction in the ability of viruses to productively infect cells as a direct result of antibody occupancy of the virion. Antibody-mediated neutralization of flaviviruses occurs when individual virions are engaged by antibody with a stoichiometry that exceeds a required threshold (reviewed in Ref.[282]). The number of antibodies decorating the virion at any antibody concentration is controlled by the functional avidity of antibody binding and epitope accessibility on the virion. As detailed above, the dense arrangement and dynamics of E proteins on the virus particle, combined with structural heterogeneity arising from incomplete prM cleavage, define the accessibility of viral surfaces for antibody recognition and neutralization.[279,818] While some antibodies target poorly accessible epitopes with limited or no capacity to neutralize infection, other classes recognize quaternary epitopes displayed on the surface of infectious virions, as detailed below. Advances in defining structure–function relationships of antibodies elicited by flavivirus infection or vaccination have improved understanding of neutralization mechanisms, potency, and vaccine antigen design.

Antibodies block infection via mechanisms that act at distinct steps in the flavivirus replication cycle (Fig. 9.10). Antibodies can block flavivirus attachment to host cells.[223,450,833] At present, it is unknown whether antibodies that block attachment to cells do so by interfering with specific receptor interactions on the target cells or via a general steric hindrance mechanism. Flavivirus-reactive antibodies also block infection after the virus attachment step. Seminal studies by Gollins and Porterfield demonstrated that antibodies could block the uncoating and infectivity of WNV even when added after virions attached to cells. Furthermore, they demonstrated that antibodies could directly block fusion of virions to synthetic liposomes.[370] These observations have been expanded greatly to include other flaviviruses and antibodies.[944,1119] Analysis of the ability of a large panel of TBEV-reactive antibodies to block liposomal fusion revealed mAbs capable of blocking fusion completely (25% of antibodies tested), partially (58% of

antibodies tested), or not at all (17% of antibodies tested).[1070] These results suggest an ability to block fusion is a relatively common functional property of neutralizing antibodies. Structural studies illustrate different ways in which antibodies block fusion. Experiments with anti-WNV mAb E16 suggest this antibody blocks the radial expansion of the virus particle and traps it in an intermediate step of the fusion process following exposure of the virus to acidic pH conditions (Fig. 9.10).[514] Alternatively, some antibodies prevent the disassociation of E protein dimers at the onset of fusion through the recognition of epitopes composed of features on more than one E protein. Multiple antibodies that inhibit fusion via this type of quaternary recognition have been described including those targeting WNV, DENV, and ZIKV.[323,325,443,515,1107] Individual mAbs may be capable of blocking infection at more than one step of the virus entry pathway. Factors with the potential to impact neutralization mechanism include antibody concentration, virion maturation state, and host immune factors such as C1q and Fc receptors.[254,733,734,1057]

Antibody-Dependent Enhancement of Infection

ADE of infection describes the marked increase in the efficiency of infection of cells expressing Fc receptors by viruses–antibody complexes.[429,430] While ADE has been demonstrated for several families of viruses *in vitro*, a role for enhancing antibodies in the pathogenesis of human disease has been demonstrated in limited contexts, including secondary DENV infection.[538,539] Aspects of the complex pathogenesis of secondary DENV infection have been recapitulated in animal models. Passive transfer of DENV-reactive antibodies increases viral burden and exacerbates disease in an IFN-$\alpha\beta\gamma$ receptor-deficient mice[52,1240] and increases viremia in primates.[371,418] A recent study of serum collected from a longitudinal cohort identified a narrow range of pre-existing anti-DENV antibody titers as a predictor of risk for severe dengue.[512] ADE has also been suggested as a cause for adverse outcomes in the context of the Dengvaxia® tetravalent vaccine in children, as detailed below.

The mechanism of ADE has been studied extensively. The phenomenon of ADE is controlled by the number of antibody molecules, which serve to more efficiently attach viral immune complexes to cells expressing Fcγ or

complement receptors.[421] Almost all antibodies have the capacity to support ADE, although exceptions have been reported.[922] Antibody concentrations that support ADE are bounded at the upper end by the neutralization threshold and at lower concentrations by the minimal number of antibodies required for durable attachment to Fcγ receptors. This window of enhancing concentrations is modulated by antibody isotype, Fc receptor subtype, and complement.[731,1221] Interactions between viral immune complexes and Fcγ receptors are determined by the constant region of the antibody heavy chain and influenced by the single conserved N-linked glycan at position N297 of the IgG heavy chain. ADE can be inhibited by antibodies that block Fcγ–receptor interactions,[865] enzymatic removal of the heavy chain of the antibody molecule,[1240] and removal of the N-linked glycan on IgG molecules.[52,371,878] A recent study suggested the composition of the N-linked sugar on anti-DENV antibodies correlated with disease outcome,[1178] providing a new mechanistic link between antibody effector activities and DENV pathogenesis. Two Fc receptor–independent mechanisms of ADE have also been described. Haslwanter and colleagues demonstrated that the binding of an antibody at the TBEV E protein dimer interface of mature virions caused displacement of the E-DII-FL resulting in more efficient binding to lipid membranes.[446] A DENV-reactive antibody that is cross-reactive with a cell-surface–expressed host protein has been shown to promote ADE in the absence of Fc receptors because it is capable of simultaneously binding both the virion and target cell.[477]

The mechanisms of ADE also may promote more efficient viral replication and spread at a postentry step. The ligation of monocyte or macrophage Fcγ receptors by IgG immune complexes, rather than aiding host defenses, has been hypothesized to suppress innate immunity, increase production of IL-10, and bias T-helper cell responses, leading to increased infectious output by infected cells.[427,791] Initial studies with the unrelated Ross River alphavirus in RAW 264.7 macrophage-like cells showed that infection by ADE suppressed expression of CXCL10, NOS2, IRF1, TNF-*α*, and IFN-γ.[633,688] Subsequent experiments with DENV in the THP-1 monocytic cell line confirmed that ADE attenuated innate immune responses by down-regulating the RIG-I/MDA5 signaling pathway and decreasing production of type I IFN and ISGs.[1138] However, more recent experiments with DENV infection and primary human monocytes[109,555] did not

demonstrate suppressed production of inhibitory or immunomodulatory cytokines in the context of ADE. One caveat to this concept of intrinsic ADE is that enhanced viral entry and infectivity (via DENV immune complex interaction with Fcγ receptor) yield higher levels of viral nonstructural proteins in a cell, which themselves independently suppress innate immunity[259,260] irrespective of Fcγ receptor signaling. Although the idea that intrinsic ADE of infection suppresses innate immunity and modulates disease severity of DENV infection is appealing,[427] it remains to be distinguished from the enhanced infectivity *per se* and confirmed in a physiologically relevant setting.

The Antigenic Structure of Flaviviruses

Flaviviruses were first classified according to serological reactivity by arbovirus-immune sera.[168,246] Flavivirus-reactive antibodies continue to be classified with respect to their capacity to discriminate between the antigens of viruses within and between related serological groups of viruses.[1125] For example, mAbs that react with DENV may be type-specific (one DENV serotype), sub–complex-specific (more than one DENV serotype), complex-reactive (all DENV viruses), or flavivirus group–reactive (multiple flaviviruses).[454] The extensive cross-reactivity among flaviviruses complicates the use of serological diagnostics to manage flavivirus outbreaks and disease. Large panels of murine and human mAbs against DENV, WNV, ZIKV, TBEV, and JEV have been developed and characterized.[1044] These efforts reveal that virtually every exposed surface of the flavivirus virion may be targeted by antibodies.

E protein epitopes recognized by neutralizing antibodies

The majority of neutralizing antibodies bind epitopes on the E protein.[1044] Early studies distinguished epitopes on the E protein based on the biochemical and functional properties of mAbs, including a capacity to bind and compete for viral antigens, neutralize virus, and inhibit hemagglutination of red blood cells. Epitopes are now cataloged using structural methods, saturation mutagenesis, and neutralization escape studies. A nonexhaustive catalogue of well-characterized flavivirus epitopes is detailed below:

1. *DIII-LR*. The DIII-LR epitope is an accessible surface of DIII composed of three discontinuous loops and the amino-terminal region. Multiple DIII-LR–reactive neutralizing antibodies have been described. As an example, mAb E16 is a type-specific WNV-reactive MAb that neutralizes at picomolar concentrations *in vitro* and protects mice from lethal challenge when administered 5 days after infection.[783,784,839] The molecular basis for E16 recognition on E-DIII and mature virions has been detailed using structural and functional approaches.[611,833] Type-specific mAbs that bind the DIII-LR of DENV, JEV, TBEV, and ZIKV have been described.[124,321,516,938,1079,1222,1251] While antibodies of this specificity are common in the repertoire of murine antibodies elicited by infection, their contribution to the human repertoire of antibodies elicited by WNV or DENV is limited.[79,818,1120,1163] In contrast, the contribution of DIII-reactive antibodies to the neutralizing activity of ZIKV-immune sera is significant.[938,1233]
2. *DII-FL*. Antibodies that bind the E-DII-FL are highly cross-reactive.[221,224,841,1071] The accessibility of this epitope is very sensitive to the maturation state of the virion; antibodies that bind this conserved structure have a limited capacity to bind mature virions.[841,1071] Passive transfer of E-DII-FL antibodies in mice reveals they may be protective, have limited potency, and may be dependent on Fc-dependent mechanisms.[1080,1158] While mutation of E-DII-FL residues reduces antibody binding, other adjacent structures also may contribute to the fine specificity of binding and the functional properties of these antibodies.[233,372,841] The structure of the E-DII-FL antibody mAb E53 bound to soluble E proteins was solved.[196] Residues shown to be important antibody contacts for this antibody include those of the fusion loop (residues 104–107 and 109–110) as well as residues of the BC loop of E-DII.[841] The DENV 1C19 mAb binds a similar epitope, including the BC loop, and was remarkably potent *in vitro* and in murine models.[1046] Other modes of E-DII-FL recognition have been documented. DII-FL antibodies are common in humans.[79,252,840,1069,1120]
3. *Quaternary epitopes*. Many antibodies have been described that recognize quaternary epitopes unique to the surface of mature virions (reviewed by Ref.[1044]). Antibodies with these properties typically are

identified by their inability to bind soluble E proteins despite efficient recognition of the virus particle. One well-studied example is the E-dimer epitope (EDE).[253,320,950] Antibodies that bind the EDE interact with residues on E-DI and E-DIII of one E protein subunit and a conserved patch of E-DII on the opposing E protein of the dimer, including the E-DII-FL. Some EDE antibodies also contact the N-linked sugar of E-DII.[950] The EDE footprint largely overlaps the surface contacted by prM on immature virions at low pH.[950] EDE antibodies potently neutralize infection and are cross-reactive; antibodies elicited by DENV infection have been shown to neutralize both ZIKV and SPOV and are cross-protective in animal models[960] Unexpectedly, EDE antibodies bind virions in a manner insensitive to the presence of uncleaved prM, despite the quaternary nature of the epitope, and overlap between the EDE and prM binding footprints.[950] These data suggest partially mature virions exist in a dynamic equilibrium that allows antibody to displace uncleaved prM and trap E proteins in antiparallel dimers.

Antibodies that bind the prM protein

Antibodies that bind prM protein have been described. [79,155,251,311,1047,1149] Generally, these antibodies are characterized by limited neutralizing activity *in vitro*. Studies of the memory B-cell antibody repertoire indicated that DENV prM-reactive antibodies are relatively common.[243,251] These antibodies are typically cross-reactive among DENV viral serotypes. prM-specific antibodies have been hypothesized to contribute to the pathogenesis of DENV infection due to their capacity to readily support ADE.[251,939] A recent demonstration that DENV-1 circulates as mature virions *in vivo* raises questions about the role of partially mature viruses in the pathogenesis of DENV.[914]

NS1-reactive antibodies

The nonstructural protein NS1 of some flaviviruses is secreted at high levels into the extracellular environment during flavivirus infection, predominantly as a hexamer,[330] with significant accumulation (up to 50 μg/mL) in the sera of DENV-infected patients.[14,41,631,1231] NS1 plays multiple roles in flavivirus

pathogenesis including the inhibition of complement by binding the negative regulator factor H or by promoting C4 degradation.[37,203] NS1 has been hypothesized to play a mechanistic role in severe dengue (reviewed by Ref.[361]). NS1 interactions with the vascular endothelium increase permeability by disrupting tight junctions.[897] NS1 also promotes dysregulated cytokine production following TLR4-dependent interactions with mononuclear cells, indirectly contributing to vascular leakage.[757] Autoreactive NS1-binding antibodies may contribute to pathogenic features of secondary DENV infections through multiple mechanisms including the activation and complement-mediated opsonization of platelets, decreasing anticoagulation factors, and promoting inflammation and apoptosis.[1082,1084] Many NS1-reactive mAbs have been characterized. Passive transfer of mAbs against NS1 can protect mice against lethal infection by DENV, WNV, YFV, and ZIKV,[44,204,588,987] and this requires an intact Fc moiety.[204,205,989,990] Protective anti-NS1 MAbs have been shown to recognize cell-surface–associated NS1 and trigger Fcγ receptor-dependent phagocytosis and clearance of WNV-infected cells.[205] NS1 has been developed as a vaccine target for multiple flaviviruses with promising results.[74,120,257,312,902,986,988] Because NS1-reactive antibodies do not bind virus particles, a conceptual advantage of this vaccine platform is that antibodies are incapable of contributing to ADE.

The Repertoire of Antibodies Elicited In Vivo

The composition of the polyclonal antibody response elicited by infection has been studied using multiple techniques, yielding many important insights (reviewed in Refs.[343,1044]). Analysis of the specificity of antibodies in the memory B-cell compartment provided insight into surfaces recognized by antibodies, antibody ontogeny, and identified the importance of quaternary modes of recognition. Biochemical studies with recombinant proteins and virus particles incorporating mutations in the fusion loop suggest antibodies that bind the E-DII-FL are a considerable portion of circulating antibodies.[221,222,590,650,840] Cross-reactive human E-DII-FL mAbs are frequently isolated from the memory B-cell compartment.[79,251,252,1120] Serum antibody depletion experiments using intact virions or soluble dimeric E proteins suggest the majority of circulating neutralizing antibodies bind

epitopes contained within and/or among E protein dimers on mature virions.[488,1161] Numerous human mAbs that bind complex quaternary epitopes have been described (reviewed by Ref.[343]). The use of molecular clone technology to transplant selected quaternary epitopes recognized by type-specific DENV antibodies among DENV strains has provided insight into the specificity of the neutralizing antibody response to infection and vaccination.[343,344]

T-Cell–Mediated Control

$CD8^+$ T Cells

$CD8^+$ T cells, by virtue of their ability to lyse infected target cells and produce inflammatory cytokines (e.g., IFN-γ and TNF-*α*), can have either protective or pathologic effects depending on the context. Depending on the flavivirus strain and experimental system, beneficial or adverse functions of $CD8^+$ T cells have been reported. Experiments in small animal models and *in vitro* demonstrate that $CD8^+$ T lymphocytes can be an essential component of protection against infection by several flaviviruses, including WNV, DENV, YFV, ZIKV, and JEV.[97,125–127,655,802,803,901,917,1026,1043,1196,1223,1225] Consistent with this, individuals with hematologic malignancies and impaired T-cell function have an increased risk of neuroinvasive WNV infection.[804,895] Upon recognition of a flavivirus-infected cell that expresses class I MHC molecules, antigen-restricted cytotoxic T lymphocytes (CTL) proliferate, release proinflammatory cytokines,[126,276,520,564,901] and lyse cells directly through the delivery of perforin and granzymes A and B, or via Fas–Fas-ligand interactions. In WNV infection, mice deficient in $CD8^+$ T cells have higher and sustained WNV burdens in the spleen and CNS and increased mortality.[1026,1175] $CD8^+$ T cells require perforin and Fas ligand interactions to control infection of virulent WNV strains as mice deficient in these molecules had increased CNS viral burdens and lethality.[1027,1029] Moreover, adoptive transfer of wild-type but not perforin- or Fas-ligand–deficient $CD8^+$ T cells decreased CNS viral burden and enhanced survival. The net function of $CD8^+$ T cells in infection by other encephalitic flaviviruses (e.g., JEV or MVEV) also varies. Initial reports showed that JEV-specific cytotoxic $CD8^+$ T cells could reduce production of infectious virus from infected macrophage

and neuronal-like cells *in vitro*.[802] Moreover, adoptive transfer of anti-JEV $CD8^+$ T cells by an intracerebral route protected adult but not newborn or suckling BALB/c mice against lethal JEV challenge.[803] However, in vaccine immunization studies, challenge experiments in mice deficient in $CD8^+$ T cells indicate that $CD8^+$ T cells are dispensable, and immune antibody was the most critical component of protection.[856] $CD8^+$ T cells may have a lesser role *in vivo* in JEV infection because of active subversion of the antigen-presentation pathway by the virus; JEV infection can lead to active depletion and impairment of $CD8\alpha^+CD11c^+$ dendritic cells,[15,16] which are the cells that dominantly mediate cross presentation of antigen and priming of $CD8^+$ T-cell responses *in vivo*.[463] With MVEV infection, effector $CD8^+$ T cells in the brain appear pathological as mice deficient in granule exocytosis (perforin or granzyme B) or Fas-mediated cytotoxicity showed delayed and reduced mortality.[632]

For DENV, which generally does not cause encephalitis, the protective or pathologic function of $CD8^+$ T cells still is not fully resolved. During primary infection of mice, depletion of $CD8^+$ T cells before infection resulted in significantly higher viral loads. DENV-specific $CD8^+$ T cells produced IFN-γ and TNF-*α* and exhibited cytotoxic activity *in vivo*.[1225] In comparison, a pathogenic role of $CD8^+$ T cells has been reported during secondary DENV infection. Due to the significant amino acid sequence homology among the four serotypes, there is a high potential for T-cell cross-reactivity during secondary heterologous DENV infection. Serotype cross-reactive $CD8^+$ T cells are preferentially activated during secondary infection in humans in a phenomenon termed “original antigenic sin”.[777] These cross-reactive $CD8^+$ T cells exhibit altered cytokine production and reduced cytolytic activity.[65,75,695,778] Aberrant cytokine production by T cells could contribute to severe DENV disease, as higher levels of proinflammatory mediators may contribute to endothelial cell dysfunction or damage, leading to plasma leakage.[713]

More recent studies that have profiled antigen-specific $CD8^+$ T-cell responses against DENV have suggested that immune imprinting contributes to a protective response. An analysis of $CD8^+$ T-cell responses from human subjects in Sri Lanka challenges the original antigenic sin theory.[1189]

Although skewing toward primary infecting DENV was detected, this was not associated with qualitative or quantitative impairment of responses. Higher magnitude and more polyfunctional responses for HLA alleles were associated with decreased susceptibility to severe disease, suggesting that $CD8^+$ T cells are protective against DENV disease.[1189,1191] Consistent with these results, in studies with HLA transgenic mice although cross-reactive DENV $CD8^+$ T-cell responses were lower than responses elicited by serotype-specific T cells, immunization with either serotype-specific or variant peptide epitopes enhanced viral clearance, demonstrating that both serotype-specific and cross-reactive $CD8^+$ T cells can contribute to *in vivo* protection against DENV infection.[300] Finally, primary DENV infection induces antigen-specific $CD8^+$ T cells that are highly activated and proliferating, exhibit antiviral effector functions, and home to the skin.[937]

In the context of the intensive study of ZIKV pathogenesis, much has been learned about $CD8^+$ T-cell responses to ZIKV from animal and human studies, which suggest these immune cells are largely protective. In mice, polyfunctional, cytotoxic $CD8^+$ T cells become activated and can reduce ZIKV burden, whereas their depletion or genetic absence resulted in greater ZIKV infection and mortality,[301] and adoptive transfer of ZIKV-immune $CD8^+$ T cells protects against ZIKV infection.[476] Another study showed that both ZIKV-specific and ZIKV/DENV cross-reactive $CD8^+$ T cells can protect against ZIKV infection,[1196] and prior DENV immunity can protect against ZIKV infection during pregnancy in mice, and $CD8^+$ T cells mediate this cross protection.[917] Whereas in most cases, $CD8^+$ T cells have conferred protective activity against ZIKV in mice, pathological consequences in the CNS have been described as well.[502,693]

Less is known about human $CD8^+$ T-cell responses to ZIKV. Initial studies showed that $CD8^+$ T cells were highly activated during the viremic phase, and tetramer-positive ZIKV-specific $CD8^+$ T cells could be detected in blood.[589,925] More recent studies have shown that ZIKV-specific $CD8^+$ T cells have a polyfunctional IFN-γ signature with up-regulation of TNF-α, cell activation markers (e.g., CD69), and cytotoxic proteins.[392]

$CD4^+$ T Cells

$CD4^+$ T cells can restrict or contribute to pathogenesis depending on the flavivirus and whether the response is primary or anamnestic. Studies in mice have shown that $CD4^+$ T cells restrict pathogenesis of primary WNV infection. A genetic or acquired deficiency of $CD4^+$ T-cell function resulted in protracted WNV infection in the CNS that culminated in uniform lethality by 50 days after infection. $CD4^+$ T cells protect against primary WNV infection by providing help for antibody responses, sustaining WNV-specific $CD8^+$ T-cell responses in the CNS that enable viral clearance, producing antiviral cytokines, and directly killing cells.[127,1043] A protective role for $CD4^+$ T cells against lethal JEV infection in mice was observed as depletion reduced and adoptive transfer promoted survival.[97] Moreover, in humans, impaired JEV-specific $CD4^+$ T-cell function (e.g., IFN-γ secretion) was seen preferentially in patients with encephalitis and neurological sequelae,[572] and a high-quality, polyfunctional $CD4^+$ T-cell response was associated with recovery from JEV.[1136] Consistent with these data, $CD4^{-/-}$ mice also showed greater susceptibility to CNS infection by a neuroadapted strain of YFV.[655] In comparison, depletion of $CD4^+$ T cells prior to DENV infection in mice had no effect on tissue viral burden, DENV-specific antibody titers or neutralizing activity, or $CD8^+$ T-cell responses.[1223]

Memory $CD4^+$ T cells can have protective or pathological consequences depending on the context. For DENV, immunization schemes that elicit antigen-specific $CD4^+$ T cells prior to infection of mice resulted in significantly lower viral burden after challenge with homologous DENV.[1223] Moreover, in humans, highly polarized cytotoxic $CD4^+$ T cells were associated with protective immunity.[1190] A megapool of 180 different peptides has been developed to effectively measure *ex vivo* $CD4^+$ T-cell responses irrespective of DENV serotype or geographical location.[391] Under certain conditions, induction of $CD4^+$ T cells can contribute to viral clearance and reduced pathogenesis. However, during heterologous secondary DENV infection, cross-reactive $CD4^+$ memory T cells may be stimulated by antigen from the secondary infection. These $CD4^+$ T cells then augment the response of memory $CD8^+$ T cells, which can result in an overexuberant production of inflammatory cytokines and an increased risk for severe DENV disease.[75]

Experiments with ZIKV also have established protective functions of

$CD4^+$ T cells. In studies with *Ifnar1*$^{-/-}$ mice, a neutralizing antibody response was dependent on $CD4^+$ T cells and associated with reduced viral load in the brain and mortality. Adoptive transfer of purified $CD4^+$ T cells prevented infection-associated weight loss and protected all animals against a lethal ZIKV infection.[447,674] A polyfunctional and polyclonal $CD4^+$ T-cell response can prevent ZIKV neuroinvasion and infection within the CNS. Moreover, DENV-specific memory $CD4^+$ T cells display antiviral effector capacity toward ZIKV, suggesting a potential beneficial effect in humans of preexisting T-cell immunity to DENV upon ZIKV infection.[638]

$CD4^+CD25^+FoxP3^+$ Regulatory T Cells

Regulatory $CD4^+$ T cells (Tregs) are a subset of $CD4^+$ T cells that can suppress effector T cells to control reactivity to self-antigens and pathogens.[959,1089] These cells blunt inflammation and maintain antigen-specific T-cell homeostasis.[565,836] Tregs control the development of symptomatic WNV infection in humans and mice.[594] Symptomatic WNV-infected mice and humans had lower Treg frequencies compared with asymptomatic cohorts, and Treg-deficient mice developed lethal WNV infection at a higher rate than controls. Using the genetic variation of mice from the Collaborative Cross, one group established a model of chronic, persistent WNV infection, and this was associated with a strong immunoregulatory signature upon infection that correlated with restraint of the WNV-directed cytolytic responses.[386] Moreover, Treg-dependent production of TGF-β shaped the resident memory $CD8^+$ T-cell response in the brain after WNV infection.[383] Interestingly, in severe DENV infection in humans, although Tregs expand and function normally, their relative frequencies are insufficient to control the immunopathology of severe disease.[676] Indeed, a separate study showed that although $FoxP3^+$ Tregs expand in acute dengue, they predominantly consist of naïve Tregs, with poor suppressive capacity.[489] A more detailed study is needed to clarify the role of Tregs in preventing or promoting flavivirus pathogenesis.

Flavivirus Immune Evasion

Evasion of the Type I IFN Pathway

Flaviviruses have evolved several strategies to avoid and/or attenuate induction of type I IFN and its effector responses. In cell culture, flaviviruses are largely resistant to the antiviral effects of IFN once infection is established.[264] This may explain, in part, the relatively modest therapeutic window for IFN-*α* administration that has been observed clinically in animal models or humans infected with JEV, SLEV, and WNV.[178,507,910,1052] Experiments by several groups have demonstrated that individual flaviviruses attenuate IFN signaling at distinct and multiple steps in the cascade. Excellent recent reviews can be accessed for further mechanistic detail.[86,342,753]

Inhibition of IFN-β gene induction

Three mechanisms have been described by which flaviviruses minimize the induction of IFN-*β* (Fig. 9.11):

1. *PRR detection*. Highly pathogenic WNV strains evade IRF3-dependent recognition pathways without actively antagonizing the host defense signaling pathways.[336] Virulent WNV strains delay activation of PRR, such as RIG-I, through uncertain mechanisms to provide the virus with a kinetic advantage in the infected cell to elude host detection during replication at early times after infection.[518] In contrast, less pathogenic strains of WNV induce greater levels of IFN at early time points.[517] One strategy that DENV and WNV likely use to prevent RLRs from accessing viral RNA in the cytoplasm is the formation of separate replication compartments. Flaviviruses replicate in ER-convoluted membrane vesicles, also called viroplasm-like structures,[357,1193] which may function as a physical barrier to conceal dsRNA from cytoplasmic RLR sensors and delay IFN induction. As a second strategy, DENV and ZIKV NS4B induces elongation of mitochondria, which physically contact the ER-associated membranes that are sites of replication. This restructuring attenuates RIG-I–dependent activation of IFN responses.[181]
2. *PRR signaling*. Individual flaviviruses interfere with specific steps in PRR signaling pathways to inhibit IFN-*β* induction. DENV sfRNA, a noncoding RNA derived from the 3′ UTR of viral genomic RNA that

contributes to pathogenicity and evasion of the type I IFN response,[1000] can inhibit TRIM25-dependent activation of RIG-I.[696] Multiple flavivirus NS3 proteins (e.g., DENV and WNV) can compete with RIG-I for 14-3-3ε binding to inhibit the translocation of RIG-I to mitochondria.[175] The strong binding affinity of NS3 for 14-3-3ε was attributed to a highly conserved 4–amino acid motif 64-R-X-E-P-67, in which the central E66 glutamic acid residue mimics the phosphorylated Ser/Thr residue of cellular 14-3-3–binding motifs. ZIKV, DENV, WNV, and JEV, but not YFV NS2B/3 proteases, cleave STING, thereby preventing type I IFN induction mediated by cGAS, possibly downstream of virus-induced DNA damage or mitophagy.[8,269,1232] As the cleavage sites for DENV and ZIKV NS2B/3 are present in human STING, but not in the murine ortholog, STING likely functions as a species-specific restriction factor for these viruses.

3. *Downstream of PRR signaling*. The NS2B/3 protease of DENV can bind to IKKε and block its kinase activity, thereby inhibiting IRF3 phosphorylation and its nuclear translocation.[27] Ectopic expression of NS2A and NS4B from DENV-1, DENV-2, and DENV-4, as well as NS4B of WNV, inhibited the autophosphorylation-dependent activation of TBK1.[234] The NS4A protein from DENV-1, but not other DENV serotypes, also inhibited TBK1, suggesting that DENV-1 contains additional IFN-regulating virulence determinants. ZIKV NS1 and NS4B also appear to inhibit IFN-β induction at the level of TBK1 activation.[1213] The high-mannose carbohydrates on the E protein may independently block the production of IFN-β, IL-6, and TNF-α that is induced by dsRNA in macrophages. This effect was not directly dependent on TLR3 but instead occurred downstream at the level of the signaling intermediate and NF-κB activator, receptor-interacting protein (RIP)-1.[31] Based on studies with macrophages from different age cohorts, this E protein–dependent inhibitory pathway may be dysregulated in elderly humans, leading to a pathogenic cytokine response.[548] Although the mechanistic basis for how specific forms of the E protein alter antiviral signaling programs remains uncertain, glycosylated E proteins can potentially signal through multiple cell-surface lectins including the mannose receptor[747] and CLEC5a.[189]
4. *IFN-β gene transcription and translation*. Studies with KUNV have

identified the nonstructural protein NS2A as an inhibitor of IFN-*β* gene transcription.[656,660] Incorporation of an A30P mutation of NS2A into a KUNV genome resulted in a virus that elicits more rapid and sustained synthesis of type I IFN; infection of this mutant virus *in vitro* and *in vivo* was highly attenuated. The exact cellular target of NS2A and its mechanism of inhibition remain unknown. More recent studies with ZIKV suggest that flaviviruses also may independently inhibit IFN-*β* translation in human dendritic cells and neuroprogenitor cells through an as yet uncharacterized mechanism that may depend on motifs in the viral NS4B protein.[116,375]

Impaired IFNAR pathway signaling

In addition to antagonizing induction of IFN-*β*, several flaviviruses target the JAK–STAT signaling pathway for evasion to prevent the induction of antiviral ISGs (Fig. 9.12). Thus, even when type I IFN is produced, it may not achieve its optimal inhibitory effect because of attenuated signaling capacity. As the nonstructural proteins NS2A, NS3, NS4A, NS4B, and NS5 mediate many of the viral evasion mechanisms described below, these countermeasures are largely intrinsic to infected cells.

1. *Phosphorylation of JAKs*. Studies with LGTV and WNV found interference with phosphorylation of both JAK1 and Tyk2.[87,405] A variation on this was observed with JEV, which showed complete inhibition of phosphorylation of Tyk2 with little effect on JAK1 phosphorylation.[649] Expression of a subgenomic replicon or infection of cells with DENV also inhibited Tyk2 phosphorylation and had no effect on IFNAR expression.[467] However, there may be cell- or virus-specific effects, as JEV also inhibits STAT1 and STAT2 activation in the setting of normal levels of Tyk2 phosphorylation.[645]
2. *STAT1 and STAT2 protein expression and function*. Another important evasion strategy employed by several different flaviviruses is the direct antagonism of STAT1 and/or STAT2. Ectopic expression studies in A549 cells with DENV showed that NS2A, NS4A, or NS4B enhanced replication of an IFN-sensitive virus by blocking nuclear localization of STAT1.[800] Subsequent experiments showed that NS4B of DENV, WNV, and YFV partially blocks STAT1 activation and ISG

induction.[799] Mutagenesis studies have identified a sequence determinant on WNV NS4B (E22/K24) that controls IFN resistance in cells expressing subgenomic replicons.[308]

The nonstructural proteins of WNV, DENV, ZIKV, and YFV potently block STAT2 activation through different mechanisms.[34,388,567,596,661,718] The NS5 protein of DENV recruits the host factor UBR4, which induces the proteasomal degradation of STAT2.[789] Although ZIKV similarly promoted proteasomal degradation of STAT2, it did not require UBR4.[388] Both DENV and ZIKV NS5 interact with human STAT2, but not mouse Stat2,[35,388] indicating that STAT2 also contributes to the species-specific restriction of DENV and ZIKV infection. Introduction of either the structural (capsid and E proteins) or nonstructural (NS1–5) proteins from a pathogenic WNV strain (Texas 2002) into an attenuated strain (Madagascar 1978) led to more potent IFN-antagonistic activity and pathogenesis, suggesting that both structural and nonstructural proteins of WNV contribute to efficient STAT1/2 inhibition.[1087] Antagonism of STAT2 by YFV has some unique features. For example, the binding of YFV NS5 to STAT2 depends on stimulation of cells with type I or III IFNs.[597] Type I IFN signaling promotes TRIM23-dependent K63-linked ubiquitination of YFV NS5 that enables its association with STAT2.[597] Unlike DENV or ZIKV, STAT2 binding by YFV NS5 does not promote degradation but rather inhibits interaction of ISGF3 to promoter elements to prevent ISG transcription.

While NS5 attenuates JAK–STAT signaling after TBEV, LGTV, and JEV infection, the mechanism of NS5 inhibition appears to have virus-specific characteristics. For TBEV, a sequence in the methyltransferase domain of NS5 binds the PDZ protein scribble to inhibit JAK–STAT signaling.[1197] For LGTV, the JAK–STAT inhibitory domain was mapped to sites within the RNA-dependent RNA polymerase domain.[861] For JEV, the N-terminal 83 residues of NS5 inhibit JAK–STAT signaling through a protein tyrosine phosphatase–dependent mechanism.[644]

3. *Cholesterol redistribution*. Flavivirus infection can promote relocalization of cholesterol to intracellular membranous sites of replication. This redistribution diminishes the formation of cholesterol-

rich lipid rafts in the plasma membrane and attenuates the IFN antiviral signaling response.[686]

4. *Up-regulating negative regulators*. WNV, JEV, and TBEV can block IFNAR-dependent signal transduction by up-regulating the expression of suppressors of cytokine signaling (SOCS) 1 and 3,[574,697] which dampen JAK1 activity. Subsequent mechanistic studies showed that WNV and also other enveloped viruses that incorporate phosphatidylserine lipids into their virions induce SOCS1/3 gene expression by binding to inhibitory TAM (Tyro3/Axl/Mer) receptors on dendritic cells, thereby blunting the antiviral IFN response.[91]
5. *IFNAR expression*. TBEV and WNV antagonize type I IFN signaling by inhibiting surface expression of IFNAR1. Loss of IFNAR1 was associated with binding of the viral NS5 protein to prolidase, a cellular dipeptidase. Prolidase was required for IFNAR1 maturation and accumulation, activation of IFN-*β*–stimulated gene induction, and type I IFN-dependent control of viral infection.[672]

Impaired IFN effector functions

Although flaviviruses devote a significant segment of their genome to inhibiting JAK–STAT signaling, they also target individual downstream antiviral effector molecules. Viperin is a an antiviral ISG that inhibits hepatitis C, influenza, HIV, and Sindbis viruses, possibly because of its ability to alter lipid raft formation. JEV, however, counteracts viperin by promoting rapid proteasome-dependent degradation.[174] The mechanism of this inhibition remains unclear, as transfection of individual JEV proteins failed to explain the phenotype suggesting a combined effect of viral proteins or replication is required. Viperin also restricts WNV pathogenesis[1093] and inhibits replication of TBEV and ZIKV by targeting NS3 for proteasomal degradation.[857] Viperin also attenuates flavivirus replication by catalyzing the production of a chain-terminator ribonucleotide.[359]

All pathogenic flaviviruses (e.g., WNV, DENV, JEV, ZIKV, TBEV, and YFV) encode methyltransferases as part of their NS5 proteins to modify the 5′ cap structure of their viral mRNAs, thereby mimicking eukaryotic cap 1 (m7GpppNm) structures. Flavivirus 2′-*O*-methyltransferase activity evades viral RNA detection by IFIT proteins,[232,1259] which can block viral protein

synthesis by binding preferentially to non–2′-*O*-methylated cap 0 (m7GpppN-RNA) structures and competing for eIF4e binding.[413,528] A recombinant WNV encoding an NS5 E218A mutant protein that is defective in 2′-*O*-methyltransferase activity was more sensitive to the antiviral action of IFIT family members.[232,1095] Similarly, ablation of the 2′-*O*-methyltransferase activity from JEV and DENV led to growth attenuation of the mutant viruses in the context of cellular innate immune responses.[620,1260] Recent studies have suggested that in addition to enhanced recognition by IFIT1, flavivirus RNA lacking 2′-*O*-methylation also may act as a PAMP for induction of multiple innate immune genes.[620,1259]

Evasion of the Complement Pathway by NS1

To minimize recognition and/or destruction by complement, viruses have evolved strategies to evade or exploit complement to establish infection.[40,1072] Flavivirus NS1 is expressed on cell surfaces, secreted from infected cells, and accumulates in the serum of infected individuals, with high circulating levels correlating with severe DENV disease.[41,629] WNV NS1 attenuates complement activation of the alternative pathway by enhancing the cofactor activity of factor H for factor I–mediated cleavage of C3b to iC3b, which decreases deposition of C3b and the C5b to C9 membrane attack complex on cell surfaces.[203] As an additional mechanism by which flaviviruses can evade complement, NS1 also binds to C4 and C1s, which enhanced the cleavage of C4 to C4b and reduced C4b and C3b deposition on cell surfaces.[37] NS1 also protects DENV from neutralization in solution by binding to MBL and inhibiting complement deposition.[1118] Soluble NS1 has also been reported to bind the complement regulatory factors C4bp,[38] vitronectin, and clusterin, the latter two of which inhibit the formation of the C5b to C9 membrane attack complex.[210,581]

Class I MHC and NK Cell Evasion

Because of their capacity to directly kill virally infected cells or produce inflammatory cytokines that control early stages of infection, NK cells are an important initial defense against many viruses. NK cells lyse infected cells by releasing cytotoxic granules that contain perforin and granzymes or by binding to cell death–inducing receptors on target cells. NK cell activation is

finely regulated through a balance of activating (Ly49D, Ly49H, and NKG2D) and inhibitory cell-surface receptors (killer cell immunoglobulin-like receptors [KIR], immunoglobulin-like inhibitory receptors [ILT], and CD94-NKG2A). To control the consequences of untoward activation of NK cells, inhibitory receptors are expressed constitutively, some of which bind to host MHC class I molecules on opposing cells and transmit inhibitory signals through intracellular tyrosine-based inhibitory motifs in their cytoplasmic domains. A decrease in expression of class I MHC molecules on a cell may prompt NK cell activation by attenuating the inhibitory signals. Thus, NK cell target recognition occurs after ligation of activating receptors and repression of inhibitory receptors on the cell surface.

Although many DNA viruses attempt to avoid NK responses by a variety of mechanisms including expressing MHC class I homologs, flaviviruses may evade NK cell cytotoxicity by increasing surface expression of class I MHC molecules.[532,657,658] Expression of class I MHC molecules is stimulated by increasing the transport activity of TAP[762,798] and by NF-kB–dependent transcriptional activation of MHC class I genes.[521] The rapid increase in expression of MHC class I suggests that early in the course of infection, flaviviruses may overcome susceptibility to NK cell–mediated lysis, even if it is at the expense of later recognition by an adaptive $CD8^+$ T-cell response. Consistent with this, splenocytes from WNV-immunized mice had poor NK cell lytic activity,[762] and mice with acquired deficiencies in NK cells demonstrated no increased morbidity or mortality compared to wild-type controls.[1029]

ANIMAL MODELS OF FLAVIVIRUS PATHOGENESIS AND DISEASE

Animal models of viral infections are used to address fundamental questions that are difficult to answer in human studies. These investigations are often directed toward defining basic mechanisms of viral pathogenesis (tropism, dissemination, and virulence) and host immune responses (protective and pathologic), but also are important for determining relative efficacy of candidate vaccines and antiviral agents. In general, the most useful surrogate models mimic features of human disease, are reproducible, and have the

capacity for high-throughput experimentation. The weakness of many animal models is they often do not fully recapitulate human disease with respect to kinetics, viral replication and spread, or disease phenotype, and thus restraint is required in applying these results to the human condition. Animal models of flavivirus infection are varied in their fidelity to human disease and, thus, utility in providing basic insight into pathogenesis, immune control, and likely efficacy of vaccines or antiviral agents. This section will review the strengths and weaknesses of key animal models and what investigators in the field have learned by using them.

Dengue Virus

One of the major limitations in identifying and working with animal models of DENV infection is that humans are the only known host to develop disease after infection. A second consideration is that severe dengue and its plasma leakage syndrome are associated with preexisting maternal antibody in infants and secondary infection in children and adults, suggesting an immunopathogenesis mechanism, which has been difficult to recapitulate in animals. While each of the animal models described below has been informative for understanding DENV infection, their inability to mimic human disease has limited the insight on human DENV infection.

Nonhuman Primate Model of DENV Infection

Although humans are the natural host for DENV, serological data support the existence of a sylvatic cycle between mosquitoes and nonhuman primates (NHPs).[1176] Several species of NHP (e.g., chimpanzees and rhesus macaques) have been infected experimentally with DENV and develop viremia and adaptive immune responses,[431,432,984] although in most cases, there is limited evidence of the severe disease seen in humans. One study in macaques showed thrombocytopenia, transiently reduced complement levels, and enhanced peak viremia after secondary infection with heterologous DENV serotype although only 1 of 44 animals developed a syndrome that shared features of severe human disease.[432] Features of severe dengue were observed in six rhesus macaques after high-dose (10^7 PFU per animal) intravenous infection with a DENV-2 strain including neutropenia, thrombocytopenia, clotting abnormalities, and petechial hemorrhage.[844]

NHPs also have been used as a model to study ADE and its consequences. Enhancement of viremia was observed in juvenile rhesus monkeys after passive transfer of antibody and heterologous DENV challenge.[418] Analogously, an approximately 100-fold increase of DENV-4 viremia was demonstrated in juvenile rhesus monkeys that received a cross-reactive mAb recognizing the fusion loop in DII.[371] In neither model, however, was evidence of severe vascular leakage observed despite the increase in DENV replication. NHPs also have been used to evaluate adaptive immune response and protection of live attenuated or subunit-based DENV vaccine candidates.[207,289,551]

Mouse Models

The utility and clinical features of individual mouse models of DENV infection have been described in great detail.[1224,1241] Below, we describe some features of the more commonly used models in the field. In general, there are several hurdles to establishing mouse models of DENV disease pathogenesis: (a) the majority of models are not ideal because most mice do not develop the same clinical disease as humans; (b) it has been difficult to infect mice reliably and reproducibly with low passage clinical and mosquito isolates. Hence, many studies are performed with laboratory- or mouse-adapted strains that have uncertain relevance to the strains that cause human disease; and (c) DENV is virulent in humans because it has evolved specific countermeasures to evade the human immune response.[260] In mice, these evasion mechanisms do not function, resulting in rapid control.

IFN signaling–deficient mice

Because of the importance of STAT2 and the IFN response in restricting DENV infection, mice lacking receptors for both type I (IFN-α/β) and type II (IFN-γ) (e.g., AG129) were tested and shown vulnerable to intraperitoneal (IP) infection with a mouse-adapted (New Guinea C) DENV-2 strain[495] or intravenous (IV) infection with a laboratory-adapted (PL046) DENV-2 strain.[1023] In these studies, however, mice succumbed to DENV infection because of rapid spread to the CNS, resulting in encephalitis and paralysis, which are not common features of human disease. Similar results were observed in Stat1$^{-/-}$ and Stat2$^{-/-}$ mice,[35,1025] although in some cases

hemorrhage was observed after inoculation at multiple sites.[189] Other studies identified mouse-adapted (DENV-2 D2S10) and nonadapted strains (DENV-2 Y98P) that cause rapid death of AG129 mice associated with some characteristics of human disease, including cytokine storm, vascular leakage, and high TNF-α levels[1024,1098] after IV or IP infection.

AG129 mice have been used as a model to test antiviral candidates[195,1002,1066] or to explore the role of ADE in disease severity. Preexisting cross-reactive monoclonal or polyclonal antibodies facilitate ADE *in vivo* and promote more severe DENV disease including vascular leakage.[52,1240] Importantly, when the Fc fragment was eliminated by proteolysis or modified genetically, enhanced replication and disease were no longer observed, thus confirming that ADE via Fcγ receptor engagement can cause severe disease in an animal.[420,1205] Cellular and tissue tropisms have been examined in the ADE model in AG129 mice[52,1240]; the virus targets are similar to that described in human autopsy studies with antigen present in the lymph node, spleen, and bone marrow, with infection in myeloid cells, and possibly with sinusoidal endothelial cells in the liver. Although the comparative data are intriguing, the absence of IFN in mice independently broadens cellular and tissue tropism of flaviviruses,[963] and thus, some caution in interpretation is warranted. Some of this concern was mitigated through the use of mice with cell-type–specific gene deletions of IFNAR1. For example, *LysM* Cre^{+} *Ifnar1*$^{\text{fl/fl}}$ mice, which lack Ifnar1 expression only in myeloid cells, sustained high levels of DENV infection and disease, including plasma leakage, hypercytokinemia, liver injury, hemoconcentration, and thrombocytopenia.[882]

Immunocompetent mice

The successful infection of immunocompetent mice with DENV strains would allow more detailed analysis of the kinetics and function of protective immune responses. Although most DENV strains replicate poorly in wild-type laboratory strains of mice, recent reports suggest that infection may be possible, with the development of a spectrum of disease. Subcutaneous and systemic hemorrhage was induced in wild-type C57BL/6 mice after intradermal (ID) infection with a laboratory-passaged DENV-2 16681 strain.[186] With this strain, C57BL/6 and BALB/c mice also developed

thrombocytopenia, elevated levels of systemic TNF-α, and liver damage.[187,852] These experiments did not show evidence of vascular leakage, the hallmark of severe DENV disease in humans. However, wild-type mice experimentally inoculated with a DENV clinical isolate (DENV-2, Eden strain) experienced a rise in hematocrit values that remained increased over naïve mice for 4 days postinfection, demonstrating some evidence of increased vascular permeability.[1059]

Mouse–human chimeras

Because most mouse strains do not sustain DENV replication after infection, mouse–human chimeras have been developed. Early studies using severe combined immunodeficient (SCID) mice engrafted with human peripheral blood lymphocytes showed marginal infection with a DENV-1 strain.[1211] Subsequent studies engrafted human tumor cells (K562, HepG2, Huh-7),[23,98,648] which supported DENV replication but caused CNS disease and not a vascular leakage syndrome. Nonobese diabetic (NOD)/SCID or NOD/SCID IL2Rγ$^{-/-}$ mice have been engrafted with CD34^{+} human cord blood hematopoietic progenitor cells. After infection with DENV-2, these chimeric mice developed some of the signs of severe human disease including fever, rash, and thrombocytopenia.[82,487,793] In an analogous model, Rag2$^{-/-}$ x γ chain$^{-/-}$ mice engrafted with CD34^{+} human fetal liver stem cells and inoculated with DENV-2 developed viremia and fever and produced human specific anti-DENV antibody responses.[582] While engraftment of human cells is advantageous as the response of human cells, pathogenesis, and possibly tropism can be analyzed, the chimeric models have limitations: (a) the disease phenotype recapitulates only some of the features of severe DENV; (b) the mouse-to-mouse level of chimerism is variable, making phenotypic analysis challenging; (c) the throughput of experiments is low, making these models less practical for vaccine or antiviral testing; and (d) the immune cross talk between human and mouse cells within an animal may be altered, limiting interpretation of effects on immunity.

Zika Virus

Prior to the emergence of ZIKV in Latin America, few studies had evaluated ZIKV pathogenesis in animals.[77,266,1185] However, the explosive growth of

ZIKV research since 2015 has spurred the development of new animal models, revealing pathogenic mechanisms and providing systems for evaluating therapeutic interventions. The most significant models of ZIKV infection are nonhuman primates and mice (reviewed in Ref.[788]), but ZIKV disease also has been studied in guinea pigs, hamsters, tree shrews, and swine.[93,237,238,256,569,748,1032,1200,1250] Early ZIKV isolates were maintained by serial passage in suckling mouse brains, which likely selected variants with improved replication in this tissue. Thus, historical studies (as well as contemporary studies using historical strains) may overestimate the neurotropism of ZIKV relative to strains circulating in humans and mosquitoes.

Nonhuman Primate Models

Rhesus macaques serve as valuable models for ZIKV pathogenesis research, owing to their physiological similarity to humans and a significant preexisting research infrastructure resulting from their use in models of other infectious diseases. Rhesus macaques recapitulate key features of ZIKV infection in humans including transient viremia; fever and rash; viral RNA in saliva, urine, and semen; viral replication in tissues such as the eye and testis; susceptibility via subcutaneous, intravenous, or intravaginal inoculation; and commonly asymptomatic infection.[165,285,414,466,619,849] Experimental ZIKV infection in cynomolgus and pigtail macaques is similar to rhesus.[42,256,414,546,834,849] ZIKV also infects baboons, which may better represent the sylvatic reservoir of ZIKV as they are African monkeys and have been found to be ZIKV seropositive in nature.[139,407] Marmosets, squirrel monkeys, and owl monkeys also are susceptible to experimental ZIKV infection, which may be relevant to the establishment of a sylvatic reservoir in New World primates.[198,1144]

Mouse Models

Mice offer advantages in terms of cost, scale, speed, and genetic tractability, enabling mechanistic studies that are not feasible in nonhuman primate models. A disadvantage of mouse models is that ZIKV replicates poorly in immunocompetent mice and thus does not exhibit the tissue tropism and disease phenotypes characteristic of human infection. Mice lacking type I

interferon (IFN-$\alpha\beta$) production or responses succumb to ZIKV infection and exhibit broad tissue tropism, implying that the innate antiviral response is a key barrier to ZIKV replication and pathogenesis in mice.[600,947] Mice lacking the IFN-$\alpha\beta$ receptor (alone or also lacking the IFN-γ receptor) have provided models for studying ZIKV disease phenotypes including congenital infection (below), sexual transmission, and ocular infection, as well as for evaluating vaccines and antivirals.[288,382,723,752,928,1103,1251] The restriction of ZIKV replication in mice results in part from an inability of ZIKV NS5 to degrade murine Stat2, and therefore ZIKV cannot inhibit IFN signaling in mice by the same mechanism used in human cells.[388,567] Indeed, *Stat2*$^{-/-}$ mice succumb to ZIKV infection, and transgenic wild-type mice expressing human STAT2 can develop disease in the context of ZIKV strains with additional mouse-adaptive mutations.[375,1127] In addition, the ZIKV NS2B-NS3 protease targets human but not murine STING, resulting in sustained IFN production and diminished viral replication in mouse cells.[269] However, mice lacking STING were not more susceptible to ZIKV than wild-type mice,[269,600] implying that STING is a contributing but not dominant factor restricting ZIKV infection in mice.

Human Tissue Models

ZIKV replicates in a variety of human cell types in culture, with monocytes being key targets in humans and macaques.[332,466,745,834,849] Recent advances in brain organoid culture systems, as well as studies of neural progenitor cells in culture and in mice, have revealed a tropism for neuronal subsets in the developing brain that likely contributes to the neurodevelopmental defects caused by ZIKV infection *in utero*.[235,346,440,625,903, 904,1101] Cellular mechanisms that may contribute to ZIKV neuropathogenesis include neural progenitor death and dysregulated proliferation,[1101] the ability of Musashi-1 to bind the 3′ UTR of the ZIKV genome and promote viral replication in neural progenitors,[184] and the ability of ZIKV sfRNA to antagonize fragile X mental retardation protein, which has important functions in neurodevelopment.[1056] The mechanisms of ZIKV congenital disease also have been advanced by *ex vivo* culture systems that model infection at the maternal–fetal interface. These systems include cultures of syncytiotrophoblasts from term placentas as well as explants of midgestation

chorionic villi, both of which have revealed that syncytiotrophoblasts are resistant to ZIKV infection whereas cytotrophoblasts are susceptible, and suggest that constitutive cytokine production contributes to antiviral immunity in the placenta.[68,214,484,1096]

Pregnancy and Vertical Transmission Models

Physiological similarity to humans, including in placental architecture, has made nonhuman primate systems the most faithful models of ZIKV vertical transmission and congenital disease. ZIKV infection in pregnant macaques recapitulates key features of CZS in humans including placental inflammation and calcifications, disrupted brain development, ophthalmological pathology, and fetal demise.[4,5,209,286,465,687,708,761,823] ZIKV infection in pregnant macaques also produces sustained maternal viremia similar to that observed in pregnant women.[687,708,823] As in humans, only a subset of ZIKV-exposed macaque pregnancies develops CZS and the manifestation of disease is variable, making it challenging to design studies with a feasible number of animals. Baboons offer advantages as pregnancy models because they breed year-round and their estrous phase is externally evident, facilitating timed infection experiments, though research facilities for baboons are more limited.[408] Marmosets provide an interesting system for studying congenital ZIKV infection because their pregnancies typically are dizygotic twins, allowing assessment of independent transplacental transmission events in each infected dam[1007]; such studies support observations in humans finding concordant CZS outcomes in monozygotic twins and discordant outcomes in dizygotic twins exposed to ZIKV *in utero*.[150,969]

While NHPs have provided valuable systems for understanding the manifestations of CZS, limitations in terms of experimental size and cost have meant that mice have emerged as a key model for studying the mechanisms that control transplacental transmission and fetal pathology. Mouse and human placentas are both hemochorial, although other anatomic differences as well as developmental differences between 3-week mouse and 40-week human pregnancies require caveats when translating effects in mouse pregnancy systems to humans.[24] Most ZIKV congenital infection models use dams with impaired IFN-$\alpha\beta$ signaling, commonly transgenic mice

lacking the IFN-$\alpha\beta$ receptor or administration of an IFN-$\alpha\beta$ receptor-blocking monoclonal antibody. In these systems, fetuses become infected and exhibit growth restriction or demise, with infection at earlier gestational stages associated with more severe fetal pathology.[484,750,1229] IFN-$\alpha\beta$ signaling plays a key role in restricting ZIKV replication and thereby controlling transplacental transmission, but this antiviral response itself also elicits placental and fetal pathology, pointing to immune pathology as a potential contributing factor to CZS.[1228]

Yellow Fever Virus

Despite the fact that YFV was isolated in 1927 and that a vaccine was developed 10 years later, our understanding of the mechanisms underlying the pathogenesis of virulent YFV remains limited. Analogous to DENV, part of this stems from the lack of a small animal model that recapitulates the viscerotropism of human infection. Given the reemergence of YFV, an improved understanding of its pathogenesis and a vehicle for testing novel vaccines and antiviral agents through the use of existing and new animal models of disease is now a research priority.

Human Vaccine Model

Vaccination with the attenuated 17D strain of YFV has conferred protection on hundreds of millions of humans worldwide. Recent prospective analyses have examined the interaction of 17D YFV with the innate immune system and how this might be important for triggering long-term protective adaptive immunity.[898] A systems biology approach defined early gene signatures that predicted immune responses in humans vaccinated with yellow fever vaccine YFV-17D. Computational analyses identified induction of genes (e.g., complement protein C1qB, TNFRS17, and eukaryotic translation initiation factor 2 alpha kinase 4) that correlated with and predicted protective B- and T-cell responses with high accuracy in an independent, blinded trial.[906]

Nonhuman Primate Model of Severe YFV Infection

YFV cycles in nature as part of a sylvatic cycle between *Aedes* mosquitoes and wild monkeys. Rhesus and cynomologus monkeys develop viscerotropic disease, analogous to humans, ranging from mild to fulminant hepatitis,

whereas African and New World NHPs generally have milder or silent infections,[768] with some exceptions.[781] The pathogenesis of YFV infection in rhesus monkeys resembles severe human disease with the development of jaundice, acute renal failure, coagulopathy, and shock,[769] although the course is more severe, not biphasic, produces markedly higher viral burden, and is also associated with severe necrosis of lymphoid tissue.[542,769] The coagulopathy in monkeys is associated with a global decrease in synthesis of clotting factors secondary to direct hepatic damage and impaired hemostasis associated with abnormalities of platelet function.[768]

In contrast to that described for DENV, preexisting immunity to heterologous flaviviruses results in protection rather than enhanced pathogenesis of YFV in NHP. Rhesus monkeys that were infected previously with DENV were protected against YFV challenge, and recipients of anti-DENV antibodies by passive transfer showed no evidence of enhanced disease.[768,1112] Monkeys immunized with other flaviviruses,[456] similar to humans with prior exposure to flaviviruses,[771] manifest a lower incidence of severe YFV disease.

Rodent Models of YFV Infection

Historical infection studies in mice and hamsters with nonadapted YFV did not cause viscerotropic disease. Syrian golden hamsters, however, did develop disease more closely resembling human YFV infection (hepatitis, hepatic necrosis, splenic necrosis), but this phenotype requires serial passage of YFV *in vivo*, and renal disease was not observed.[720,1215] In comparison, peripheral infection of wild-type mice does not cause viscerotropic disease. However, YFV-induced encephalitis can be induced in suckling mice after IP or IC inoculation, in adult mice if the blood–brain barrier is disturbed, or if mouse-adapted strains are used.[60,328,329,768,977] Because these models do not cause viscerotropism, they are of limited relevance to understanding the pathophysiology of human YFV infection and have been largely restricted to vaccine and antiviral testing. Subcutaneous infection studies of mice deficient in IFN signaling revealed viscerotropic YFV infection and disease (liver and spleen necrosis) without a requirement for virus adaptation.[735] This study suggests that nonadapted YFV has little ability to evade the antiviral activity of IFN-α/β in mice, whereas species-specific antagonism of IFN-α/β antiviral

activity in primate hosts may contribute to infection outcome.

West Nile Virus

WNV and other encephalitic flaviviruses are generally more promiscuous in their ability to infect and cause disease in different species of animals. Beyond its endemic cycle in multiple species of birds, WNV causes severe disease in horses and occasionally can infect other mammals sometimes with severe consequences.[115] Although the molecular basis for its broad animal tropism remains uncharacterized, as a result of this, it has been easier to develop small animal models of infection that recapitulate features of human disease using low passage field isolates. However, the frequency of neuroinvasive disease may vary significantly among animal species, making some models preferred for studying pathogenesis and disease outcome.

Nonhuman Primate Model of WNV Infection

Nonhuman primate models of WNV infection are important because of their potential for use in evaluating vaccine and therapeutic candidates. In one study of five intradermally infected rhesus macaques, the clinical course, level and duration of viremia, and antibody response were similar to that occurring in uncomplicated human WNV infection, although it was unclear whether virus entered the brain in these animals.[913] This model of sustained viremia and measurable immune responses has been used to evaluate the efficacy of WNV vaccine candidates.[1201] Analogously, in baboons, after intradermal infection, WNV accumulated to high levels in blood and was associated with a transient macular rash, but failed to cause encephalitis or other severe clinical signs.[1208] Although these NHP models do not develop WNV encephalitis, it remains possible that the frequency of neuroinvasive disease parallels human infection (1:150) and thus would require much larger studies to identify severe cases. In contrast to infection via a peripheral route, intracerebral inoculation of rhesus monkeys with different African and Asian WNV strains results in persistent viral infection in the CNS and other organs.[889] These animals sustained a prolonged infection course and showed evidence of fatal encephalitis with diffuse neuronal degeneration and necrosis and inflammation. Similar severe clinical manifestations (fever, tremors, and spasticity) were observed in rhesus macaques challenged via a frontal lobe

injection with the New York 1999 strain of WNV.[32]

Hamster Model

Syrian golden hamsters are an excellent small animal model for studying WNV pathogenesis, vaccine efficacy, and antiviral screening. Intraperitoneal or even oral infection of WNV results in viremia of 5 to 6 days in duration, followed by the development of virus-specific antibodies.[980,1214] Clinical signs of encephalitis (weakness, tremor, ataxia, and paralysis) were apparent within 6 to 7 days of infection with an approximately 50% mortality rate. WNV disease correlated with the detection of viral antigen and neuronal degeneration in several regions of the brain including the cerebral cortex, basal ganglia, hippocampus, cerebellum, and brain stem. Because of their larger size relative to mice, hamsters have been used to elucidate particular aspects of neuropathogenesis. WNV spread to the CNS can occur through a retrograde axonal transport mechanism, as the virus moves from peripheral motor neurons into the spinal cord.[964,1179] Electrophysiology studies have shown that respiratory distress associated with WNV infection is caused by diaphragmatic suppression through lesions in the brain stem and cervical spinal cord or altered vagal afferent function.[785]

In the hamster model, infectious WNV can be cultured from the brains of hamsters up to 53 days after initial infection,[1214] suggesting that persistent replication occurs. Persistent WNV infection in the spinal cord causes continued neuronal dysfunction, chronic neuropathological lesions, and poliomyelitis-like disease and can be measured using electrophysiological approaches.[1033] Hamsters also develop persistent viruria, as infectious WNV can be cultured from urine for several weeks.[1122]

The hamster model has been used to evaluate candidate therapeutics or vaccines against WNV disease. Studies with small molecule inhibitors,[787] antiviral cytokines,[782] synthetic oligonucleotides,[1123] and humanized monoclonal antibodies[783] have been performed with varying efficacy, especially when administered as postexposure therapy.[261] Analogously, immunization with single-cycle,[1202] recombinant subunit,[1036] or live attenuated[1109] vaccines has elicited durable protective immunity and, thus, has provided a robust preclinical small animal model for assessment and comparison of the surrogate markers of protection.

Mouse Models

Infection studies in several inbred laboratory strains of mice have provided insight into the fundamental mechanisms of WNV dissemination, pathogenesis, and immune system control. Most studies have been performed with North American WNV strains and wild-type and immunodeficient C57BL/6 mice. The strengths of this particular model include (a) depending on the dose of virus and age of mice, a subset of wild-type mice develop neuroinvasive disease, whereas the remainder are infected with minimal or limited spread to the CNS. Thus, the mechanisms by which the immune system restricts viral entry or facilitates viral clearance can be studied; (b) many features of pathogenesis and neuropathology appear remarkably similar to that observed in humans; (c) non-adapted low passage WNV isolates cause disease in wild-type mice. Thus, this model can be used to define the genetics of virus attenuation; (d) there are many transgenic, knockout, and conditional knockout mice available from academic laboratories and public consortia to study the role of specific genes or cells in pathogenesis; and (e) genes (e.g., CCR5 and OAS1b) that predict susceptibility in mice have been corroborated as risk factors for human WNV disease.[263] Nonetheless, there are limitations to the model including the compressed disease time course, the difficulty in obtaining CSF samples in live animals because of size, and a rather flat virus dose–response curve after peripheral infection.

Following peripheral inoculation of mice, initial WNV replication is thought to occur in skin Langerhans dendritic cells,[147] with mosquito saliva modulating the local proinflammatory cytokine response.[994] Dendritic cells migrate to and seed draining lymph nodes, resulting in a primary viremia and subsequent infection of peripheral tissues such as the spleen and, occasionally, the kidney. By the end of the first week, WNV is largely cleared from the serum and peripheral organs, and infection in the CNS is observed in a subset of immunocompetent animals. Mice that succumb to infection develop CNS pathology similar to that observed in human WNV cases, including infection and injury of brain stem, hippocampal, and spinal cord neurons.[1028] WNV infection is detected in at much lower levels in nonneuronal CNS cell populations, such as $CD11b^{+}$ cells[228,1124] or astrocytes.[270] In most surviving wild-type mice, infectious WNV is cleared from all tissue compartments within 2 to 3 weeks after infection. However,

persistent WNV infection in the brains of class II MHC,[1043] $CD8^+$ T-cell,[1026] or perforin-deficient mice[1029] was routinely observed. Analogously, a small subset of wild-type mice sustained WNV persistence in the CNS even in the setting of a robust antibody response and inflammation.[30] More recent studies in mice of the Collaborative Cross with greater genetic heterogeneity have described a larger range of clinical phenotypes and their associations with particular genes and immune signatures.[385–387]

FLAVIVIRUS VACCINES

Successful vaccination programs have reduced the clinical impact of flavivirus infections dramatically. More than 500 million doses of vaccine to prevent YFV infection have been administered since its development in 1937.[348] This landmark achievement effectively blunted the impact of this virus on global health. However, decades later, limited vaccine availability to combat the emergence of YFV in Africa and South America highlights a need for continued innovation in vaccine design and manufacturing.[816] Furthermore, safe and effective vaccines are not yet available for many flaviviruses with a sustained or emergent potential to significantly impact public health. This section will provide a noncomprehensive overview of flavivirus vaccine platforms and vaccine development efforts, focused principally on efforts that have yielded licensed vaccines or those in advanced clinical trials.

Flavivirus Vaccine Platforms

Numerous vaccine strategies have been evaluated in preclinical and clinical studies to protect against flaviviruses (Fig. 9.13). While most vaccines seek to present the E protein to the immune system, several approaches employing the nonstructural protein NS1 as an antigen also have been utilized.[120,628]

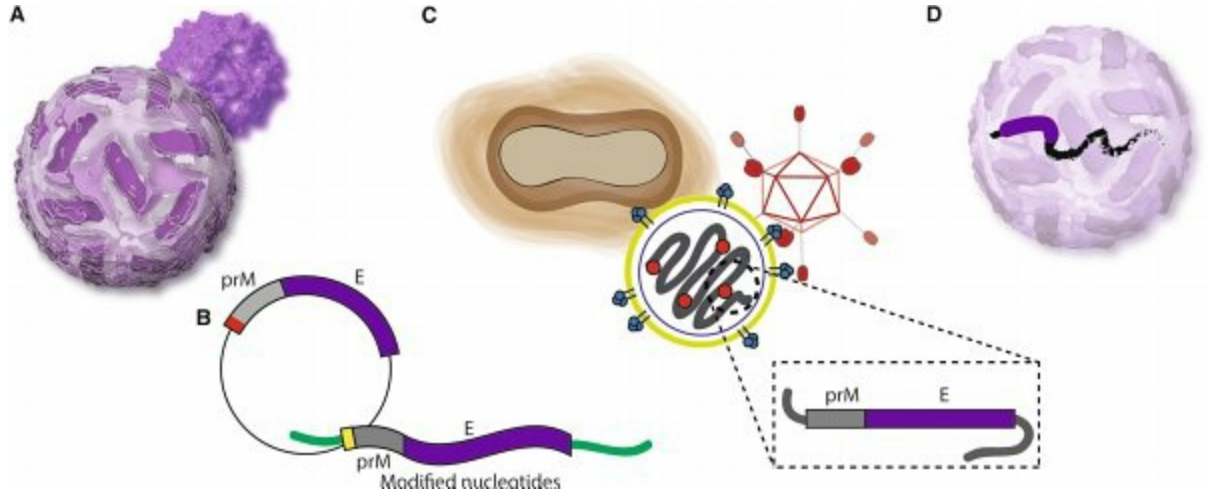

FIGURE 9.13 Flavivirus vaccine platforms. Multiple vaccine platforms have been evaluated in preclinical and clinical studies as vaccine candidates to protect against flaviviruses. These include subunit and subviral particle vaccines **(A)**, nucleic acid vaccines **(B)**, viral vectors **(C)**, and live attenuated viruses **(D)**.

Live Attenuated Vaccines

Live attenuated flavivirus vaccines have been created by extensive passage, including the earliest efforts to produce a vaccine against DENV by Sabin and colleagues.[957] Multiple licensed vaccine products have been created using this approach including countermeasures for YFV and JEV, as detailed below. The development of molecular clone technology for flaviviruses enabled the design and evaluation of multiple strategies to rationally attenuate infectious viruses, including deletions in the 3′-untranslated region,[737,1015] inhibiting the activity of the 2′-*O*-methyltransferase involved in modulating the host response to viral RNA in the cytoplasm,[1261] and removing N-linked sugars on the NS1 protein.[930] Furthermore, noninfectious self-replicating RNAs derived from the genome designed to express SVPs have also shown promise in preclinical studies.[177,819,1201,1202]

Inactivated Vaccines

Virus inactivation is a proven approach to create safe and protective vaccines. Vaccines produced from JEV-infected mouse brains have been effective at

controlling JEV in many parts of Asia, including Japan, South Korea, Taiwan, and Thailand.[327] Inactivated TBEVs are also successful vaccines.[921] This conceptually straightforward pathway to vaccine design and production prompted several groups to create inactivated vaccine candidates for ZIKV.[1,759] Inactivation of live attenuated vaccine candidates has also been evaluated as new vaccine products, conferring an additional layer of safety.[327]

Subunit Vaccines

Subunit vaccines have been evaluated in preclinical and clinical studies. Soluble forms of the E protein have been proposed for several viruses.[607] Soluble DIII and E proteins can be relatively straightforward to express at high levels, manufacture, combine with increasingly powerful adjuvant technologies, and optimally dose. However, the discovery that many potently neutralizing and protective antibodies recognize complex epitopes that include features of multiple E proteins on the virion may limit the utility of this approach.[950] To address this limitation, several groups have designed stabilized E protein dimers as immunogens.[742,949] Numerous approaches to immunize with recombinant SVPs have been reported and show promise in animal models.[550,738,961]

Nucleic Acid Vaccines

Nucleic acid vaccines have several desirable features as vaccine platforms including a completely synthetic manufacturing process, rapid ability to design antigens, capacity to simultaneously deliver multiple antigens, and, in the case of DNA vaccines, a well-established safety profile in humans. DNA vaccine constructs have been developed and evaluated in the clinic for several flaviviruses, including WNV, DENV, and ZIKV.[76,352,606,704,1106]

Nucleoside-modified mRNAs (mRNAs) are synthetic RNA molecules delivered as lipid nanoparticles or complexed with lipids of varied composition.[1192] This technology is capable of producing protein at high level *in vivo* and is being evaluated as a vaccine platform for several unrelated virus families, cancer, and as a therapeutic to address other human diseases. mRNA design includes multiple features thought to avoid recognition by host sensors including a 5′ cap, modified nucleosides, and

optimized UTR.[1192] mRNAs expressing ZIKV antigens were evaluated as part of the rapid response to the 2015 epidemic and subsequently as a potential countermeasure to the increased prevalence of POWV in North America.[496]

Yellow fever virus

The live attenuated YF-17D vaccine is considered among the most safe and effective vaccines ever developed, an achievement for which Max Theiler was awarded the Nobel Prize in 1951 (the only one awarded for the development of a viral vaccine).[770] The current YFV vaccine was derived from a virus isolated in 1927 from a West African man suffering from a mild febrile illness (the Asibi strain).[1074] The Asibi strain was passaged 176 times in the embryonic tissue of mice and chickens to yield the YF-17D virus with considerably reduced neuro- and viscerotropic properties.[766,1114] Vaccines currently in use are substrains of YF-17D; strain YF-17DD is used in vaccines produced for South America (passage 287–289), whereas the YF-17D-204 strain (passages 235–240) is distributed elsewhere, including the United States.[62,1063] The consensus sequence of the vaccine strains differs from the parent Asibi strain by approximately 20 amino acids as well as four nucleotide changes in the 3′ UTR.[766] Vaccine is produced in chicken embryos, lyophilized, and administered by subcutaneous injection following reconstitution in saline. A single dose of YFV vaccine contains roughly 10^4 to 10^6 PFU,[62] but administration of a 1/5 fractional dose confers similar protection and allows vaccine supplies to be extended during an outbreak.[58]

The Immune Response to YF-17D Infection

The host response to YF-17D infection involves both the innate and adaptive arms of the immune system.[770] Multiple studies highlight the significance of the innate immune response to YF-17D in shaping the adaptive immune response to vaccination.[351,898,907] YF-17D activates mDC and pDC through multiple TLR proteins, including TLR2, TLR7, TLR8, and TLR9, resulting in the induction of proinflammatory cytokines and IFN-α.[906,907] Of interest, a capacity to interact with multiple TLR pathways does not appear redundant; these interactions tune the adaptive response by influencing the balance of Th1 and Th2 cytokines and the quality of the anti-YFV T-cell response.[907]

Indeed, YF-17D infection induces a mixture of Th1 and Th2 cytokines *in vivo*,[351,968] and YF-17D–infected DCs present viral antigen to T cells despite inefficient replication in these cells.[54,854]

YF-17D vaccination induces a low transient viremia that peaks 5 days postvaccination.[766] Defervescence is coincident with a reduction in viremia and the detection of cellular and humoral responses. YF-17D infection induces a polyfunctional $CD8^+$ T-cell response of considerable magnitude (2%–13% of $CD8^+$ T cells) that peaks roughly 2 weeks postimmunization.[9] Analysis of the breadth of this response demonstrates that all 10 viral proteins contain epitopes recognized by $CD8^+$ T cells; reactivity with epitopes in E, NS3, and NS5 proteins was most common.[12,351] The virus-specific $CD8^+$ T-cell response contracts at approximately day 30 postinfection to a size that corresponds to approximately 5% to 10% of the magnitude of the original response, with memory $CD8^+$ T cells persisting for years.[12,749]

Vaccination with YF-17D also elicits a neutralizing antibody response in virtually all recipients.[78,873] Kinetic analysis of vaccinated adults revealed that approximately 87% had neutralizing antibodies at 2 weeks postvaccination, with virtually 100% of subjects developing neutralizing antibody by day 28.[593] YFV-reactive IgM can be detected by day 9, peaks between days 14 and 17, and persists for more than 1 year. YFV-specific IgG is detected between days 10 and 17 and peaks approximately 1 month postvaccination.[770] Neutralizing antibodies that correlate with protection persist for decades.[78,711,770,774] More than 90% of vaccinated subjects had neutralizing antibody when examined 16 to 19 years postimmunization.[946] Indeed, neutralizing antibody was detected in 80% of vaccinated US military personnel when assayed 30 to 35 years after receiving YF-17D.[890]

Adverse Events Arising from YF-17D Vaccination

More than 500 million doses of YF-17D have been administered to humans with a high track record of safety.[348] The most common side effects from YF-17D vaccination are transient headache, myalgia, and low-grade fever.[1063] Severe adverse events (SAE) following vaccination have been reported, albeit at a very low frequency. The risk of SAE following vaccination increases with age; the incidence of SAE in vaccine recipients

greater than 70 years of age is roughly 10-fold higher than that for individuals aged 19 to 29.[523] Three main classes of SAE have been reported: (a) anaphylactic reactions are infrequent (1 in 135,000) and likely are a result of allergic responses to components of the vaccine including egg and chicken proteins, gelatin, and latex.[519,1063] (b) Yellow fever vaccine–associated neurological disease (YEL-AND) is associated with invasion of the CNS by the vaccine strain. This SAE was most commonly reported prior to the establishment of the vaccine seed system (in 1945) and in infants prior to changes in the recommendations for vaccination of children less than 6 months old (in 1960).[766] The mechanism underlying the increased risk of YEL-AND in infants remains uncertain, but may reflect differences in the level or duration of viremia, the integrity of the BBB, or a failure to mount an effective immune response.[770] Twenty-nine cases of YEL-AND have been reported since 1990 with a case fatality ratio of 6.9%[770] with an incidence of 0.4 to 0.8 per 100,000 doses.[653,1063] (c) Yellow fever vaccine–associated viscerotropic disease (YEL-AVD) is a SAE that mimics aspects of naturally acquired YFV infection. It is characterized by high fever (within 2–5 days of vaccination), malaise, and myalgia that is followed by jaundice, oliguria, cardiovascular instability, and hemorrhage. Analysis of the sequence of viruses recovered from vaccine recipients with YEL-AVD failed to identity mutations associated with this SAE.[62] Risk factors for YEL-AVD include advanced age and a history of thymus disease or thymectomy. As of 2010, 57 cases of YEL-AVD have been reported with a case fatality rate of 64%. In the United States, the incidence is estimated as 0.3 to 0.5 per 100,000 doses.[1063]

Dengue Virus

Three live attenuated tetravalent DENV vaccines have been evaluated in advanced clinical trials. Two methods of attenuation were employed to create the four replicating viruses used in combination with each vaccine candidate. The 3′ UTR of flaviviruses folds into RNA structures that regulate genomic RNA replication, translation, and cytopathic properties.[208,879] The introduction of a 30-nucleotide deletion into the 3′ UTR yielded a markedly attenuated virus *in vivo*, which still elicited a robust humoral response in monkeys and humans.[289,737] Vaccination of humans with a DENV-4Δ30

virus resulted in low-level viremia (~1.6 logs) in 70% of recipients,[289] which is not sufficient for blood meal transmission of the vaccine to mosquito vectors. Similar results have been reported with a DENV-1Δ30 virus constructed from the Western Pacific 1974 strain.[291] While introduction of this deletion was not sufficient for attenuating all DENV strains,[100,101] further iterations of this concept, including additional deleted regions, were successful.[102] ZIKV was attenuated using similar strategies, as detailed below. The attenuating mechanism of deletions in the 3′ UTR was mapped to changes in the abundance of the sfRNA involved in modulating the host innate immune response.[145,1045]

The creation of chimeric flaviviruses encoding the structural genes of heterologous viruses is a second attenuation approach that has yielded promising vaccine candidates. The first chimeric viruses were constructed by introducing the C, prM, and E genes of DENV-1 or DENV-2 into the genetic background of DENV-4.[121] These viruses were immunogenic and attenuated as immunization of monkeys elicited neutralizing antibodies and reduced viremia following challenge with a homologous wild-type strain.[122] These early studies established that the structural proteins conferred the serological specificity of chimeric DENV. Chimeric vaccine candidates encoding the heterologous C-prM-E and prM-E cassettes have been characterized; viruses constructed using the latter replicated more efficiently than those encoding all three structural genes, perhaps due to a requirement for interaction between RNA elements in the capsid gene and the 3′ UTR.[122] Three tetravalent chimeric flavivirus vaccine candidates in advanced stages of clinical development are detailed below.

NIAID Tetravalent Vaccine Candidate

A tetravalent DENV vaccine consisting of live viruses bearing a combination of both full-length and chimeric genomes is being developed by the National Institute of Allergy and Infectious Diseases and National Institutes of Health.[1199] At the core of this vaccine platform are viruses attenuated by a Δ30 deletion in the UTR. Chimeric viruses were constructed using the DENV-4Δ30 background and prM-E cassettes from the other DENV serotypes. While a large number of different configurations were evaluated in preclinical studies, nine were tested as monovalent vaccine candidates in

phase I clinical studies. Testing individual components in healthy subjects confirmed the infectivity of each candidate and simplified the optimization of a tetravalent formulation in humans.[290] The original combination of this vaccine is called TV003 and dosing includes 10^3 PFU each of a DENV-1Δ30 virus, a chimeric DENV-2/DENV-4Δ30 virus encoding DENV-2 prM-E, a DENV-3Δ30/31 virus containing both a Δ30 and Δ31 deletions, and a DENV-4Δ30 virus.[534] An additional combination, TV005, also was prepared and included an increased dose (10^4 PFU) of the chimeric DENV-2/4Δ30 virus component. Administration of TV003 or TV005 is safe and immunogenic; at 90 days postvaccination, 90% of the TV005 recipients had circulating antibody capable of neutralizing all four DENV serotypes. Of interest, administration of a second dose of vaccine 6 months later does not result in the mild rash associated with primary TV005 vaccination nor an anamnestic neutralizing antibody response (defined by an increase in titer by more than fourfold). These data suggest TV005 is capable of eliciting sterilizing immunity and the possibility that a single vaccine dose may be sufficient.[534] A controlled human challenge study has demonstrated the protective capacity of TV003 against DENV-2,[535] and additional studies are underway with TV005 and DENV-3. Phase III clinical studies are ongoing.

Takeda Tetravalent Vaccine Candidate

A second chimeric tetravalent DENV vaccine candidate has been developed using an attenuated DENV-2 strain as the backbone.[474,475] This vaccine, called TDV, includes three chimeric viruses encoding the prM-E of DENV-1, DENV-3, and DENV-4 as well as the highly passaged DENV-2 strain PDK-50. Three mutations in this DENV-2 backbone contribute to the attenuation of each component of the vaccine. Preclinical studies revealed TDV elicited a balanced neutralizing antibody response that was protective in mouse and NHP challenge models.[848] Clinical studies of TDV administered via a subcutaneous or intradermal route in two doses 90 days apart revealed 90% to 93% of volunteers were capable of neutralizing at least three DENV serotypes.[354,847] A phase II study of a high-dose formulation confirmed the immunogenicity of this vaccine in a DENV-endemic setting, with the highest responses observed after the second vaccine dose.[958] Phase III clinical studies are underway.

Sanofi Pasteur Tetravalent Vaccine Candidate

Because of the well-established safety profile of the YF-17D vaccine, a tetravalent chimeric DENV vaccine, Dengvaxia®, was constructed by replacing prM-E of YF-17D with those of four low passage primary DENV strains.[400,409] Three doses of vaccine are administered in humans at 6-month intervals. The immunogenicity and efficacy of CYD-TVD have been evaluated in multiple advanced clinical studies (reviewed in Ref.[410]). Multiple phase III clinical trials demonstrated Dengvaxia® confers protection in DENV-experienced subjects 9 to 45 years of age. Dengvaxia® was the first anti-DENV vaccine licensed. However, the use of Dengvaxia® in DENV-seronegative individuals is not recommended, as discussed below.

Complications Associated with DENV Vaccine Deployment

The severe clinical outcomes that occurred following some secondary DENV infections highlighted a risk that vaccine-elicited antibodies might contribute to pathogenesis under some circumstances. While the goal of tetravalent vaccine development efforts was to create a balanced tetravalent response protective against all four DENV serotypes, uniform immunogenicity has been difficult to achieve. In the phase IIb study of Dengvaxia® in approximately 4,000 healthy Thai schoolchildren, three doses of vaccine failed to protect against DENV-2 challenge, whereas efficacy against other DENV serotypes ranged from 56% to 100%.[953] Changes to the formulation of tetravalent vaccine to adjust the dose of individual components to achieve a more balanced response were only straightforward in instances where each monovalent component was tested independently in clinical trials, as reflected by the evolution of the NIH vaccine candidate from the TV003 to TV005 formulation.[534]

The clinical development of Dengvaxia® identified possible disease enhancement in vaccine-elicited immunity, reinforcing a need for greater insight into the complexities of immunity to DENV. Two large phase III studies of this vaccine conducted in Asia[161] or Latin America[1156] revealed an overall efficacy of 56% to 60.8% against virologically confirmed symptomatic dengue. These studies noted that the vaccine was most effective

in individuals with prior exposure to DENV and less so in younger age groups. Long-term follow-up revealed that the protection conferred by Dengvaxia® was restricted to individuals greater than 9 years of age.[416] Dengvaxia® was subsequently licensed for use in 20 countries for individuals 9 years of age and older. This recommendation was based in part on the finding that vaccinated children aged 2 to 5 in the Asia study detailed above were at greater risk of hospitalization as compared to controls.[29] Serological studies later demonstrated that DENV-immune status was an important predictor of vaccine efficacy.[1058] Individuals who were DENV seropositive at the time of vaccine administration experienced benefit from Dengvaxia® for at least 5 years, whereas DENV-naïve individuals were at increased risk over this interval, independent of age.[423] Recommendations for vaccine use were changed to exclude DENV-seronegative subjects. It has been suggested that Dengvaxia® sensitizes an immune response to secondary infections in a manner analogous to the primary exposure to authentic DENV.[318] Further follow-up is required to evaluate the public health impact of the use of this vaccine candidate on children since its licensure.

While antibody cross-reactivity among flaviviruses is common, more severe disease following a secondary infection in humans has been limited to DENV infections. The unusual pathogenesis of ZIKV in DENV-endemic settings led to the hypothesis that antibodies elicited by DENV might play a role in exacerbating ZIKV disease. The infection of ZIKV can be enhanced *in vitro* by cross-reactive antibodies in some circumstances.[252] However, ADE can be demonstrated in cell culture with virtually all flaviviruses and has not proven to correlate with clinical disease outcomes. Several studies have shown the passive transfer of antibodies into mouse models of ZIKV infection can exacerbate disease.[55,134,912] The relevance of these models to human disease remains to be established; passive transfer of mAbs into mice also exacerbates disease caused by YFV, MVEV, and JEV.[378,1164] Studies of DENV in similar murine models demonstrate that the presence of T cells limits ADE in similar circumstances.[1239] Enhanced ZIKV disease in DENV convalescent mice was not observed, although more severe DENV following ZIKV challenge was possible.[333] Ultimately, a role for prior DENV in ZIKV pathogenesis will be addressed by epidemiological studies in the field. So far, two large studies suggest prior DENV was protective against ZIKV in the 2015 outbreak.[374,940]

Japanese Encephalitis Virus

JEV is a principal cause of pediatric encephalitis in Asia and has been a focus of vaccine development efforts since before World War II.[424] Inactivated suspensions of JEV-infected mouse brains were administered to military personnel in response to an outbreak of Japanese B virus (now recognized as JEV) on Okinawa in 1945.[954] While circumstances did not permit a complete evaluation of efficacy, this vaccine elicited neutralizing antibodies in a subset of vaccinated subjects at titers that protected mice from lethal infection.[955] Since that time, considerable progress has been made toward developing a safe and effective JEV vaccine. Multiple vaccination approaches have reduced the incidence of JEV in countries with the means to utilize them.

Mouse Brain–Derived JEV Vaccines

Vaccines produced from JEV-infected mouse brains have been effective at controlling JEV in many parts of Asia, including Japan, South Korea, Taiwan, and Thailand.[327] The Research Foundation for Microbial Diseases of Osaka University (BIKEN) produced the majority of mouse brain–derived JEV vaccine licensed for international use between 1954 and 2005. This vaccine platform uses genotype III Nakayama or Beijing-1 strains for different markets.[70] Brain tissue from intracranially infected mice is homogenized, and virus is purified by ultracentrifugation and filtration steps and inactivated by formalin.[469] These vaccines were used primarily in Japan, Korea, Thailand, Malaysia, Sri Lanka, and Vietnam to protect against endemic JEV.[70] The BIKEN vaccine was licensed for travelers in the United States and elsewhere and marketed as JE-VAX™.[327] Efficacy studies of mouse brain–derived JEV vaccines suggest they are modestly immunogenic and require multiple boosts. A placebo-controlled, double-blinded evaluation of monovalent (Nakayama strain) or bivalent (Nakayama and Beijing strains) formulations of JE-VAX conducted in Thailand revealed an efficacy of 91% in children receiving two doses of vaccine 7 days apart.[469] However, interpretation of these studies is complicated by the prevalence of individuals with prior flavivirus experience in JEV-endemic regions. Studies of the immunogenicity of two doses of JE-VAX in flavivirus-naïve subjects revealed only 33% seroconversion at 26 weeks post vaccination; however,

near-complete seroconversion was achieved using a third dose.[891,966] Attempts to measure the durability of antibody responses elicited by mouse brain–derived vaccine in endemic regions have been complicated by the potential boosting by naturally acquired flavivirus infection. Studies of military vaccine recipients suggest that neutralizing antibodies may persist for at least 3 years.[345] Vaccine is typically administered in two doses separated by 1 to 4 weeks, followed by a booster 1 to 2 years later. Travelers require a rapid three-dose vaccination regimen (days 0, 7, and 30).[327] Although mouse brain–derived JEV vaccines have efficacy in humans, roughly 20% of JE-VAX recipients experience local adverse events including swelling, redness, and pain at the injection site and mild systemic symptoms. Severe allergic and neurological complications of vaccination have been observed (10–260 and 0.1–2 per 100,000 vaccinees, respectively).[70,327] Vaccine-related fatalities resulted in cessation of production of JE-VAX in 2005 in favor of newer vaccines with more favorable safety profiles.

Live Attenuated JEV Vaccines

SA14-14-2 is a live attenuated JEV vaccine that has been administered to more than 300 million individuals.[424] The parental SA14 strain was isolated from the larvae of *Culex pipiens* mosquitoes collected in China in 1954 and causes lethality when inoculated into weanling mice via the intracranial route. The attenuated strain was developed after extensive passaging of the SA14 strain in cell culture and in hamsters and suckling mice.[824,1218] A single dose of SA14-14-2 induces a neutralizing antibody response in 85% to 100% of nonimmune recipients.[1049,1133,1218] Case-controlled studies demonstrated that a single dose of SA14-14-2 vaccine provided considerable protection (80%–99%),[96,457,573,837] which was durable even after 5 years.[1100] SA-14-14-2 was licensed for use in China in 1988 and subsequently distributed in Nepal, South Korea, Sri Lanka, Thailand, and India.

ChimeriVax-JE (also known as JE-CV or IMOJEV) is a promising live attenuated vaccine constructed using the YF-17D backbone described above (reviewed in Ref.[72]). ChimeriVax-JE was constructed by replacing the prM-E genes of YF-17D with SA-14-14-2 prM-E. Vaccination with ChimeriVax-JE elicits a protective response in mice and primates.[72,402,775] Clinical studies in humans reveal the vaccine is well tolerated and elicits a durable neutralizing

antibody response (reviewed in Ref.[200]). This vaccine is licensed in 14 countries including Australia and Thailand.

Inactivated JEV Vaccines Produced in Cell Culture

The IC51 (or IXIARO) vaccine is a formalin-inactivated vaccine produced in Vero cells under serum-free conditions and adjuvanted with aluminum hydroxide.[327] IC51 uses the SA14-14-2 JEV strain[547] and is administered in two doses 28 days apart, each containing approximately 6 mg of purified virus. Licensure was granted based on a noninferiority immunogenicity study comparing the response of recipients receiving IC51 to those vaccinated with a three-dose regimen of JEVAX. While a single dose of IC51 was poorly immunogenic (41% seroconversion), 4 weeks after the second dose, 96% of recipients had detectable neutralizing antibodies, and these persisted in most subjects 6 months after vaccination.[547] No significant local or systemic adverse events were associated with vaccination; rare events await a more detailed analysis of larger populations of vaccine recipients. IC51 was licensed for use in the United States as a traveler's vaccine in 2009 for individuals over 17 years of age. An inactivated JEV vaccine derived from the genotype III P3 strain and produced in hamster cell cultures also has been used extensively in China, with as many as 70 million doses of this vaccine administered each year.[424]

Tick-Borne Encephalitis Virus

Two inactivated TBEV vaccines are used to prevent infection in Europe, but are not licensed in the United States.[921] Kunz and colleagues developed the first licensed vaccine in 1973 using the Austrian Neudörfl strain of TBEV grown in chick embryo fibroblasts, after inactivation with formalin and adjuvanting with aluminum hydroxide.[578,579] Today, this vaccine is distributed as FSME-IMMUN by Baxter Biosciences. A second vaccine, produced by Novartis and marketed as Encepur,[105,540] was licensed in 1991. It is produced using similar methods except the German K23 strain of TBEV is substituted. Both inactivated TBEV vaccines are administered in three doses and require boosting. The conventional schedule requires three vaccinations at 0, 1 to 3 months, and 9 to 12 months, a booster at 3 years, followed by additional booster vaccinations every 5 years. These vaccines are

immunogenic; virtually, 100% of vaccinated subjects develop neutralizing antibody titers following their third dose,[578] and antibodies persist for at least 5 years.[886,1206] The effectiveness of current TBEV vaccines in the field has been estimated at approximately 99%.[1070] Despite the availability of effective vaccine, TBEV incidence in parts of Europe has increased, coincident with poor vaccine coverage.[580]

Zika Virus

The emergence of ZIKV in the Americas and its linkage to congenital disease in 2015 prompted vaccine development efforts using multiple vaccine platform technologies detailed below.

Inactivated Vaccines

The first ZIKV vaccine development efforts were initiated even before the epidemic in the Americas. A formalin-inactivated adjuvanted vaccinate candidate using an African strain of ZIKV was shown to be protective in mice and advanced to clinical trials in India; the results of these studies are not yet available.[1081] The Walter Reed Army Institute of Research (WRAIR) developed a ZIKV-purified inactivated vaccine (ZPIV) using a Puerto Rican ZIKV isolate that was highly successful in animal models[1] and subsequently evaluated in multiple clinical studies.[759] The ZPIV vaccine was licensed by Sanofi Pasteur but not developed further. The development of similar vaccine products by the Takeda Pharmaceuticals[48] and Emergent BioSolutions is ongoing.

Nucleic Acid Vaccines

Numerous DNA vaccine candidates encoding ZIKV prM-E have been developed and evaluated in preclinical studies.[280,349,811,1227] The sequence of these vaccine candidates differed with respect to the plasmid background, codon optimization method, strain selection, signal sequence of prM, and presence of an N-linked glycosylation site. A DNA vaccine candidate that lacks the “pr” peptide of prM (called M-E) also showed promise in animal models despite being incapable of SVP production.[1,595] Three prM-E encoding DNA vaccine candidates were evaluated in phase I clinical

studies.[352,1106] These studies revealed a varying capacity to elicit neutralizing antibodies. For example, the administration of three doses of vaccine VRC5283 by needle-free injection elicited antibodies with a geometric mean titer of 1/304 12 weeks after administration of the first dose. In contrast, while most recipients of the vaccine candidate GLS-5700 generated ZIKV E protein–binding antibodies in response to vaccination, only a fraction of the vaccine-immune sera from these individuals showed neutralizing activity. Of interest, passive transfer of these antibodies into a lethal mouse model was protective, highlighting a need for a more detailed understanding of the protective mechanisms of vaccine-elicited antibodies. VRC5283 is currently being evaluated in a placebo-controlled phase II clinical trial at multiple sites in the Americas. ZIKV mRNA vaccines encoding prM-E were shown to be highly immunogenic and protective in mice and NHP models.[860,929,930] mRNA vaccine candidates are being evaluated in clinical studies, but data describing these vaccine development efforts have not yet been published. The short timeline (>4 months) between the identification of an appropriate vaccine candidate sequence and the initiation of clinical trials highlights the potential for synthetic vaccines as a rapid first response to emerging threats.

Live Attenuated Vaccines

Multiple live attenuated vaccines for ZIKV are being developed and have been evaluated in mice and NHP models.[1014,1016,1217] These platforms protect against viremia in animal models, prevent damage to the male reproductive tract, and inhibit congenital disease. These constructs employ multiple modes to attenuate the viruses using information obtained from both vaccine development programs for other flaviviruses[737,1015] and more fundamental studies of flavivirus biology.[930] A chimeric DENV-2 virus encoding ZIKV prM-E genes is being evaluated in phase I clinical studies by scientists at NIAID.

Viral Vectors

Numerous viral vectors have constructed to express ZIKV genes as vaccine candidates and shown to confer immunity.[120,894,986] Multiple adenovirus-based vectors, using different rhesus and human adenovirus strains, have been evaluated as ZIKV vaccine platforms.[140,404,1219] Adenovirus vectors

expressing ZIKV M-E have been studied extensively and this antigen and vaccine platform is being evaluated in clinical trials.[1,217] Administration of a rhesus adenovirus 52 vaccine candidate elicited neutralizing antibodies and a protective immune response in mice and NHP models. Subsequent studies revealed remarkably durable protection from viremia in NHPs 1-year postadministration of a single vaccine dose.[1,2,595] A ZIKV vaccine utilizing a live attenuated measles strain to express prM and a soluble form of the E protein has been described.[832] Administration of this vaccine candidate reduced viral loads and protected against congenital disease in a mouse model.

West Nile Virus

While there is no WNV vaccine licensed for use in humans, several platforms have been developed (reviewed in Ref.[69]). Live attenuated flavivirus chimeras were developed for WNV using the strategies described above. ChimeriVax WNV vaccine candidates were constructed by replacing the prM-E genes of the YF-17D virus with those of WNV.[409] ChimeriVax-WN01 encodes unmodified prM-E sequence of the NY99 strain and was developed as a veterinary vaccine that has been used in horses since 2006.[665,666] ChimeriVax-WN02 differs from the veterinary vaccine by three amino acid substitutions in the E protein introduced to reduce neurovirulence and a fourth adventitious substitution that arose during adaptation of the vaccine lot to growth on Vero cells.[409] ChimeriVax-WN02 was safe and immunogenic in phase I and II clinical trials in humans.[92,773] In addition, a third chimeric WNV vaccine candidate was developed using the DENV-4Δ30 backbone included in the TV-005 DENV vaccine and shown to be safe and immunogenic in clinical studies.[293,875]

DNA vaccination has also shown promise for WNV vaccination. DNA vaccine constructs typically express genes encoding prM-E. Two phase I clinical studies of a WNV nucleic acid vaccine have been performed.[239,606,704] These trials demonstrated that three doses of vaccine were well tolerated and capable of eliciting both a T-cell and neutralizing antibody response. A similar construct has proven to be efficacious at reducing WNV incidence in horses and a variety of birds.[69]

Acknowledgments

We thank Mr. Ethan Tyler and Mrs. Erina He (OD, NIH) for preparation of Figures 9.2, 9.4, and 9.6 to 9.13. HISTORY

Coronaviruses are enveloped RNA viruses that are broadly distributed among humans, other mammals, and birds, causing acute and persistent infections. Members of this family were isolated as early as the 1930s as the causative agents of infectious bronchitis in chickens, transmissible gastroenteritis in pigs, and severe hepatitis and neurologic disease in mice. It was not until the 1960s, however, that these viruses and certain human respiratory viruses[10,285] were recognized to share characteristics that merited grouping them together. Their most notable common feature, revealed by electron microscopy, was a fringe of widely spaced, club-shaped spikes that were morphologically distinct from similar surface projections of ortho- and paramyxoviruses. The halo of spikes, giving the viral particle the appearance of the solar corona, prompted the name that was adopted for this virus group.[404]

Over the next 40 years, coronaviruses were studied mainly because they cause economically significant respiratory and gastrointestinal diseases in domestic animals and because they provide unique models for viral pathogenesis. The only two recognized human coronaviruses (HCoVs) were found to be responsible for a substantial fraction of common colds, particularly those that circulate in winter months. This situation changed dramatically in 2002 with the emergence and worldwide spread of a devastating new human disease, severe acute respiratory syndrome (SARS), which was caused by a previously unknown coronavirus.[127,222,334] Although

the SARS epidemic was extinguished within a year, research stimulated by the outbreak led to great strides in our understanding of coronaviruses. By 2005, two additional, widespread human respiratory coronaviruses were discovered.[425,455] Moreover, searches for animal virus reservoirs have nearly tripled the number of identified coronaviruses and defined an entire new genus,[289,457,459] although most of the recently discovered species are known only as genomic sequences and have yet to be isolated or propagated experimentally. This increased comprehension of coronaviruses bore fruit in 2012, when another zoonotic coronavirus crossed species from camels to cause the often-fatal human disease, Middle East respiratory syndrome (MERS),[474] which currently persists on the Arabian peninsula. The etiological coronavirus, its genome sequence, and its host cell receptor were all identified within 6 months, based on knowledge gained from the SARS epidemic.

CLASSIFICATION

The coronaviruses are the largest group within the *Nidovirales* (Fig. 10.1), a taxonomic order that comprises the families *Coronaviridae*, *Arteriviridae*, *Roniviridae*, and *Mesoniviridae*. The arteriviruses[225] consist of five genera of mammalian pathogens. The roniviruses,[99] which infect shrimp, and the mosquito-borne mesoniviruses[313] are the only members of the order that have invertebrate hosts. Nidoviruses are membrane-enveloped, nonsegmented positive-strand RNA viruses that are set apart from other RNA viruses by certain distinctive characteristics.[152] Their most significant common features are (a) an invariant general genomic organization, with a very large replicase gene upstream of the structural protein genes; (b) the expression of the replicase–transcriptase polyprotein by means of ribosomal frameshifting; (c) a collection of unique enzymatic activities contained within the replicase–transcriptase protein products; and (d) the expression of downstream genes via transcription of multiple 3′-nested subgenomic mRNAs. It should be noted that the replicative similarities among the four nidovirus families are offset by marked differences in the numbers, types, and sizes of their structural proteins and great variation among the morphologies of their virions and nucleocapsids.

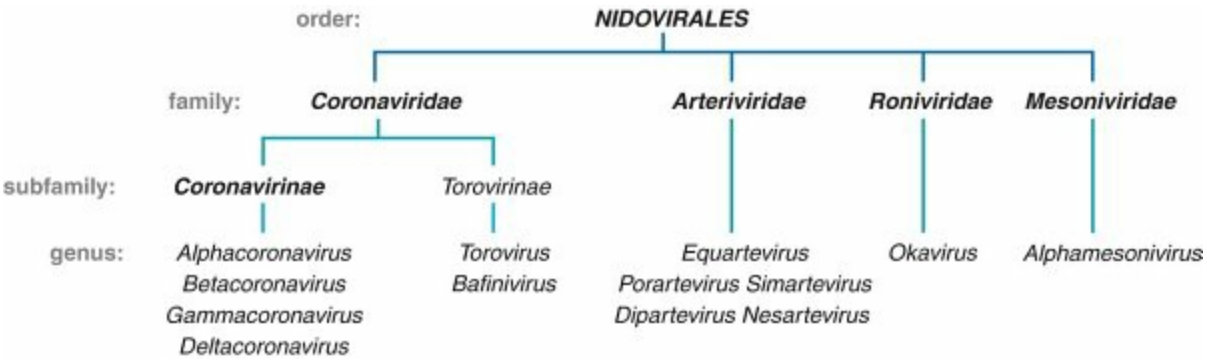

FIGURE 10.1 Taxonomy of the order *Nidovirales*.

Coronaviruses are classified as one of two subfamilies (*Coronavirinae*) in the family *Coronaviridae* (Fig. 10.1). The other subfamily, *Torovirinae*, contains the toroviruses, which are pathogens of cattle, horses, and swine,[398] and the bafiniviruses, the only nidoviruses currently known to infect fish.[375] This chapter will concentrate almost exclusively on the *Coronavirinae*.

Coronaviruses were originally divided into three serological groups. More recently they have been arranged into four genera: the alpha-, beta-, gamma- and deltacoronaviruses (Fig. 10.1). This sorting is based on rooted phylogenetic clustering and pair-wise evolutionary distances in seven key domains of the replicase–transcriptase polyprotein.[106,152,188] Within a genus, viruses are classified as the same species if they share more than 90% amino acid sequence identity in the conserved replicase domains. As a consequence, some viruses historically considered to be separate species are currently recognized as a single species, for example, alphacoronavirus 1 or betacoronavirus 1 (Table 10.1).

TABLE 10.1 Classification of coronaviruses

Species[a]	GenBank Accession[b]	Viruses Included Within Species
Genus *Alphacoronavirus*		
Alphacoronavirus 1	AJ271965	Transmissible gastroenteritis virus (TGEV)
	EU186072	Feline coronavirus type I (FCoV-I)
	AY994055	Feline infectious peritonitis virus (FIPV)
	GQ477367	Canine coronavirus (CCoV)
Human coronavirus 229E (HCoV-229E)	AF304460	
Human coronavirus NL63 (HCoV-NL63)	AY567487	
Porcine epidemic diarrhea virus (PEDV)	AF353511	
Mink coronavirus 1 (MCoV 1)	HM245925	
Wénchéng shrew virus (WESV)	KY967735	
Lucheng Rn rat coronavirus (LRNV)	KF294380	
Rhinolophus bat coronavirus HKU2 (*Rh*-BatCoV HKU2)	EF203067	
Scotophilus bat coronavirus 512 (*Sc*-BatCoV 512)	DQ648858	
Miniopterus bat coronavirus 1 (*Mi*-BatCoV 1)	EU420138	
Miniopterus bat coronavirus HKU8 (*Mi*-BatCoV HKU8)	EU420139	
Bat coronavirus HKU10 (BatCoV HKU10)	JQ989266	
Bat coronavirus CDPHE15 (BatCoV CDPHE15)	KF430219	

Species[a]	GenBank Accession[b]	Viruses Included Within Species
Genus *Betacoronavirus*		
Betacoronavirus 1	U00735	Bovine coronavirus (BCoV)
	EF446615	Equine coronavirus (EqCoV)
	AY903460	Human coronavirus OC43 (HCoV-OC43)
	DQ011855	Porcine hemagglutinating encephalomyelitis virus (PHEV)
	KF906249	Dromedary camel coronavirus HKU23 (DcCoV HKU23)
Murine coronavirus	AY700211	Mouse hepatitis virus (MHV)
	FJ938068	Rat coronavirus (RCoV)
Human coronavirus HKU1 (HCoV-HKU1)	AY597011	
Severe acute respiratory syndrome–related coronavirus (SARSr-CoV)	AY278741	Human SARS coronavirus (SARS-CoV)
	DQ071615	SARS-related *Rhinolophus* bat coronavirus Rp3 (SARSr-*Rh*-BatCoV Rp3)
Middle East respiratory syndrome–related coronavirus (MERS-CoV)	JX869059	
Hedgehog coronavirus (EriCoV)	KC545383	
Tylonycteris bat coronavirus HKU4 (*Ty*-BatCoV HKU4)	EF065505	
Pipistrellus bat coronavirus HKU5 (*Pi*-BatCoV HKU5)	EF065509	
Rousettus bat coronavirus HKU9 (*Ro*-BatCoV HKU9)	EF065513	
Genus *Gammacoronavirus*		
Avian coronavirus	AJ311317	Infectious bronchitis virus (IBV)
	EU022526	Turkey coronavirus (TuCoV)
Cetacean coronavirus	EU111742	Beluga whale coronavirus SW1 (BWCoV SW1)
	KF793824	Bottlenose dolphin coronavirus HKU22 (BdCoV HKU22)
Genus *Deltacoronavirus*		
Porcine deltacoronavirus (PDCoV)	JQ065042	
Munia coronavirus HKU13 (MuCoV HKU13)	FJ376622	
Bulbul coronavirus HKU11 (BuCoV HKU11)	FJ376620	
Thrush coronavirus HKU12 (ThCoV HKU12)	FJ376621	
White-eye coronavirus HKU16 (WECoV HKU16)	JQ065044	
Common-moorhen coronavirus HKU21 (CMCoV HKU21)	JQ065049	
Widgeon coronavirus HKU20 (WiCoV HKU20)	JQ065048	
Night heron coronavirus HKU19 (NHCoV HKU19)	JQ065047	

[a]Only viruses for which there are complete genome sequences are listed.

[b]Representative GenBank accession numbers are given; in most cases, multiple genomic sequences for a given virus are available.

Although they have tremendous potential for interspecies transmission, coronaviruses are generally confined to a single host or a small set of related hosts. The alpha- and betacoronaviruses almost exclusively infect mammals. In contrast, the gamma- and deltacoronaviruses, with few exceptions, have avian hosts. Many of the viruses listed in Table 10.1 have been studied for decades, specifically those included in the species alphacoronavirus 1, betacoronavirus 1, murine coronavirus, and avian coronavirus. The focus of research on these viruses came about largely because they were amenable to isolation and growth in tissue culture.

However, since 2004, molecular surveillance and metagenomics efforts initiated in the wake of the SARS epidemic have led to the discovery of a multitude of previously unknown coronaviruses in a variety of hosts. Notably, most of the newly recognized species were identified in bats, which form one of the largest orders of mammals. Diverse alpha- and betacoronaviruses have been described in bats from every continent except Antarctica; these viruses include the likely immediate predecessors of SARS-CoV,[179,287] as well as more distant relatives of ancestors of other HCoVs.[92,94,272] Birds have also proven to be a rich source of novel coronaviruses that are so highly divergent as to constitute a separate genus—the deltacoronaviruses.[238,457] It has been proposed that bats and birds are ideally suited as reservoirs for the incubation, spread, and evolution of coronaviruses, owing to their common ability to fly and their propensity to roost and flock.[456]

Six of the viruses in Table 10.1 are associated with human disease. The most categorically harmful of these, SARS-CoV, is not currently present in the human population but has the unabated potential to reemerge from animal sources. By contrast, MERS-CoV, which is discussed at length later in this chapter, continues to cause human infections with an alarmingly high case fatality rate. To date, however, this virus has remained geographically confined and has not evolved the high ability that SARS-CoV had for human-to-human transmission. The remaining four HCoVs, the alphacoronaviruses HCoV-229E and HCoV-NL63 and the betacoronaviruses HCoV-OC43 and HCoV-HKU1, typically cause common colds. Remarkably, HCoV-NL63 and HCoV-HKU1 were discovered in the post-SARS era,[425,455] despite the fact that each was subsequently found to be prevalent worldwide and to have been in circulation for a long time. Although generally associated with upper respiratory tract (URT) infections, the four endemic HCoVs can cause lower respiratory tract infections and have more serious consequences in the young, the elderly, and immunocompromised individuals.

VIRION STRUCTURE

Virus and Nucleocapsid

Virions of coronaviruses are roughly spherical and moderately pleomorphic. In early investigations, viral particles were reported to have average diameters of 80 to 120 nm but ranged from extremes of 50 to 200 nm.[284] Some of the variation in particle size and shape was likely attributable to distortions introduced by virion purification or negative staining of samples for electron microscopy. The characteristic spikes of coronaviruses, typically described as club-like or petal-shaped, were seen to emerge from the virion surface as stalks with bulb-like distal termini. More recent studies, employing cryoelectron microscopy and cryoelectron tomography,[28,36,307,310] have produced images, such as those shown in Figure 10.2A, in which virion size and shape were observed to be far more regular, although still pleomorphic. These studies, which examined a number of alpha- and betacoronaviruses, converge on mean particle diameters of 118 to 136 nm, including the contributions of the spikes, which protrude some 16 to 21 nm from the virion envelope.

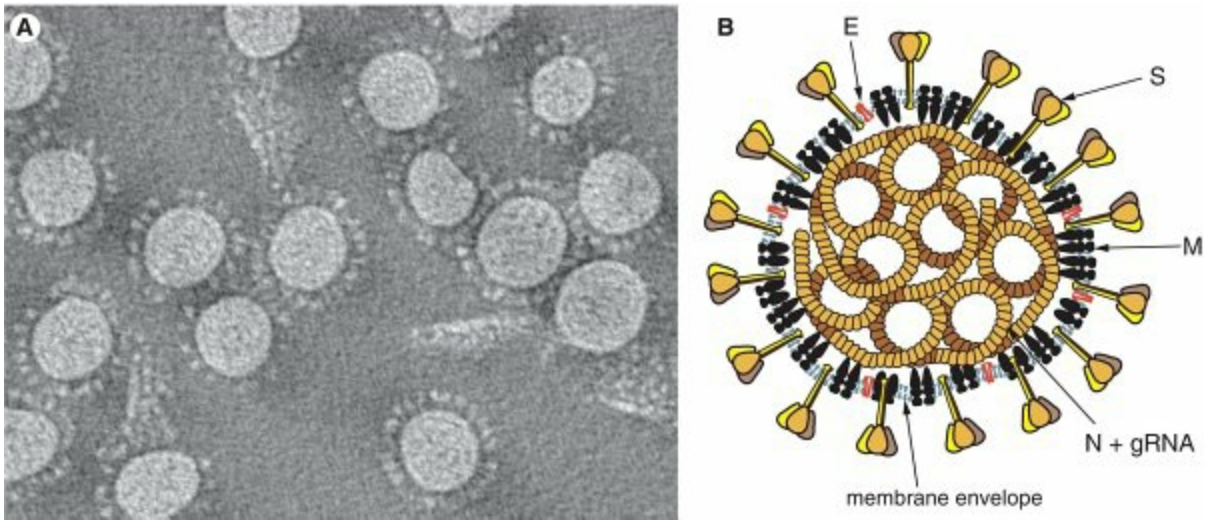

FIGURE 10.2 Coronavirus structure. **A:** Cryoelectron tomographic image of purified virions of mouse hepatitis virus (MHV), reconstructed as described in Neuman BW, Kiss G, Kunding AH, et al. A structural analysis of M protein in coronavirus assembly and morphology. *J Struct Biol* 2011;174:11–22. (Image provided by Benjamin Neuman, David Bhella, and Stanley Sawicki.) **B:** Schematic showing the major structural

proteins of the coronavirus virion: S, spike protein; M, membrane protein; E, envelope protein; and N, nucleocapsid protein.

Enclosed within the virion envelope is the nucleocapsid, a ribonucleoprotein containing the viral genome. The structure of this component is relatively obscure in whole virions, but its makeup can be discerned in some electron micrographs of virions spontaneously disrupted or solubilized with nonionic detergents.[57,104,144,205,277] Such studies revealed another distinguishing characteristic of coronaviruses: they have helically symmetric nucleocapsids. While helical symmetry is the rule for nucleocapsids of negative-strand RNA viruses, it is highly unusual for positive-strand RNA animal viruses, almost all of which have icosahedral capsids. The best-resolved images of a coronavirus nucleocapsid, that of HCoV-229E, showed filamentous structures with a diameter of 9 to 13 nm and a 3- to 4-nm-wide central canal[57]; these filaments were noted to be narrower and less sharply segmented than paramyxovirus nucleocapsids. However, varying and sometimes discrepant parameters have been reported for the nucleocapsids of other coronaviruses,[281] emphasizing the need for much further work to clearly define the dimensions, symmetry, and protein–RNA stoichiometry of this virion component in isolation. More recent coronavirus ultrastructural studies suggest that, when packaged within the virion envelope, the helical nucleocapsid is quite flexible, forming coils and other structures that fold back on themselves.[28,307]

Virion Structural Proteins

Coronaviruses contain a canonical set of four major structural proteins: the spike (S), membrane (M), and envelope (E) proteins, all of which are located in the membrane envelope, and the nucleocapsid (N) protein, which is found in the ribonucleoprotein core (Fig. 10.2B).

The distinctive surface spikes of coronaviruses are composed of trimers of S molecules[36,119] that bind to host cell receptors and mediate the earliest steps of infection.[86] In some cases, S protein can also induce cell–cell fusion late in infection. S is a class I viral fusion protein,[46] in common with several RNA virus spike proteins, of which the influenza HA protein is the best-

studied example.[168] The S monomer is a transmembrane protein containing a very large ectodomain and a tiny endodomain. Its mass ranges from 126 to 168 kDa, with glycosylation increasing this by some 40 kDa. The roughly equal-sized amino-terminal and carboxy-terminal subunits of the molecule are denoted S1 and S2, respectively (Fig. 10.3). S1 subunits display extremely low sequence homology across the four genera and often diverge considerably among different isolates of a single species.[326,441] By contrast, S2 subunits are more highly conserved.[107] High-resolution cryoelectron microscopic (EM) structures have recently been determined for the S protein ectodomains of at least one representative virus from each genus: SARS-CoV (Fig. 10.3),[473] MHV,[436] HCoV-HKU1,[214] HCoV-NL63,[437] MERS-CoV,[473] PDCoV,[379,465] and IBV.[380] These exhibit a remarkable unity in their architecture. S ectodomains extend 130 to 160 Å in length, from the base at the membrane envelope to the top of the spike. Viewed from above, the S trimer has a triangular cross section, tapering from a diameter of 115 to 140 Å at the membrane-distal head to 50 to 70 Å at the membrane-proximal base. In the S protein trimer, the S1 subunits make up the bulbous, receptor-binding portion of the spike. Despite the high amino acid sequence variability of S1, all of the bulb structures are quite similar. S1 subunits each consist of an amino-terminal and a carboxy-terminal domain (NTD and CTD), as well as one to three smaller subdomains at differing locations. S1 NTDs have a fold like that of galectins, a family of cellular *β*-galactoside–binding proteins. Particular variations in the packing arrangements of S1 NTDs and CTDs within the trimer suggest that alpha- and deltacoronavirus S proteins are more closely related to each other than to other S proteins[379,465]; likewise, the beta- and gammacoronavirus S proteins bear more of a resemblance to each other than to S proteins of the other two genera.[380] The S2 subunit trimers constitute the narrower stalk of the spike, distancing the bulb from the membrane. S2 structures are highly similar across all four genera and are principally composed of multiple long *α*-helices, including those within two heptad repeat regions (HR1 and HR2).

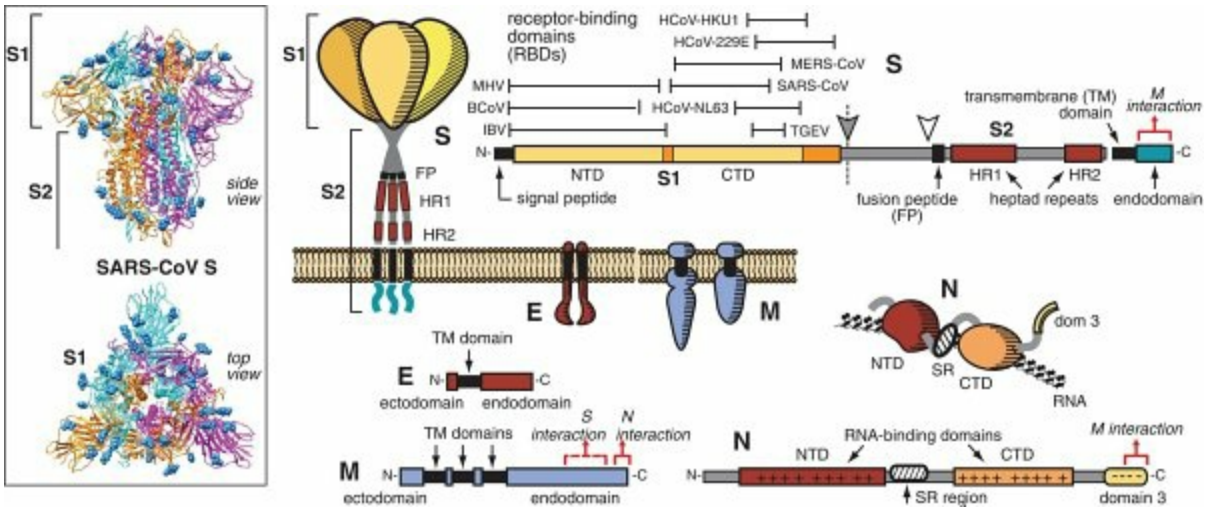

FIGURE 10.3 Virion structural proteins. Folded and linear representations of the spike (S), membrane (M), envelope (E), and nucleocapsid (N) proteins. Also shown (*boxed*) are side and top views of a cryo-EM model of the SARS-CoV S protein ectodomain. (From Yuan Y, Cao D, Zhang Y, et al. Cryo-EM structures of MERS-CoV and SARS-CoV spike glycoproteins reveal the dynamic receptor binding domains. *Nat Commun* 2017;8:15092.) In the model, each S monomer is colored differently; *blue spheres* represent N-linked glycans. The size scale for the linear diagram of S is half of that for the other proteins. In the linear diagram of S, *solid* and *open arrowheads* indicate the S1/S2 and S2′ cleavage sites, respectively. In the linear diagrams of S, M, and N, *red brackets* indicate mapped regions involved in assembly interactions (see *Assembly and Release of Virions*).

During synthesis, the S protein is inserted, via a cleaved signal peptide,[59] into the endoplasmic reticulum (ER), where it becomes modified by N-linked glycosylation.[175,363] Comprehensive mapping of glycosylation sites has been carried out for the S proteins of HCoV-NL63[437] and PDCoV,[465] revealing that N-linked glycans occupy nearly all of the consensus NXS/T sites in the S1 and S2 subunits. The early steps of glycosylation occur cotranslationally, and this alteration assists monomer folding and proper oligomerization;

terminal glycosylation is then completed subsequent to trimerization.[119] The shield formed by glycans covers a significant fraction of the surface of the S trimer and may mask epitopes, thereby contributing to evasion of immune surveillance.[437] S protein monomer folding is also accompanied by the formation of intrasubunit disulfide bonds among a subset of the cysteine residues of the ectodomain.[321] Most of the disulfide linkages have been mapped for the S trimer structures of MHV[436] and PDCoV.[465]

In many coronaviruses, the S protein is partially or completely cleaved by a furin-like host cell protease,[59,275] separating the S1 and S2 subunits (Fig. 10.3). This cleavage is a late event in virion assembly and release from infected cells. Another type of S protein cleavage (S2′), thought to be essential for all coronaviruses, takes place during the initiation of infection and activates the molecule for membrane fusion.[34] Generally, each type of S proteolytic processing occurs immediately downstream of a highly basic peptide motif.[290] The differing functions of S1 and S2, and the role of proteolysis, are discussed later (see *Viral Entry and Uncoating*).

The most abundant structural protein in coronaviruses, the M protein,[405] gives the virion envelope its shape. The M monomer, which ranges from 25 to 30 kDa, is a polytopic membrane protein that is embedded in the envelope by three transmembrane domains.[174,362] At its amino terminus is a very small ectodomain; the carboxy-terminal endodomain of M accounts for the major part of the molecule and is situated in the interior of the virion or on the cytoplasmic face of intracellular membranes (Fig. 10.3). Although it is inserted cotranslationally into the ER membrane, the M protein generally does not bear an amino-terminal signal peptide.[59,362] For IBV and MHV, it was found that either the first or the third transmembrane domain of M alone sufficed as a signal for insertion and anchoring of the protein in its native membrane orientation.[174,267,276] Anomalously, M proteins of the alphacoronavirus 1 species do contain cleavable amino-terminal signal peptides, but it is not clear whether these are necessary for membrane insertion.[201] The ectodomain of M is modified by glycosylation, which is usually N-linked.[174,195,300] However, a subset of betacoronavirus M proteins, and possibly some deltacoronavirus M proteins, exhibit O-linked glycosylation.[111] Glycosylation of M has been shown to influence both organ tropism and the interferon (IFN)-inducing capacity of certain

coronaviruses.[109,240]

M proteins are moderately well conserved within each coronavirus genus, but they diverge considerably across genera. The most variable part of the molecule is the ectodomain. By contrast, a 22–amino acid endodomain segment immediately downstream of the third transmembrane domain exhibits a high degree of sequence conservation. As yet, the M protein has been refractory to crystallization, but cryo-EM and tomographic reconstructions have provided a glimpse of the structure of this protein within the virion envelope.[28,307,310] These studies reveal that the large carboxy terminus of M extends some 6 to 8 nm into the viral particle and is compressed into a globular domain, consistent with early work showing that the endodomain is very resistant to proteases.[58,362] The observed M structures are likely to be dimers, the monomers of which are associated through multiple interacting regions. M dimers appear to adopt two different conformations: a compact form that promotes greater membrane curvature and a more elongated form that contacts the nucleocapsid.[310]

The E protein is a small polypeptide, of 8 to 12 kDa, that is found in limited amounts in the virion envelope.[174,281] Despite its minor presence, no wild-type coronavirus has been discovered to lack this protein. Engineered knockout or deletion of the E gene has effects ranging from moderate,[115] to severe,[228,232] to lethal.[7,322] Thus, although E is not always essential, it is critical for coronavirus infectivity (see *Assembly and Release of Virions*). E proteins have widely divergent sequences, but all share a common architecture: a short hydrophilic amino terminus, followed by a large hydrophobic region and, lastly, a large hydrophilic carboxy-terminal tail (Fig. 10.3). E is an integral membrane protein, but it does not have a cleavable signal peptide and is not glycosylated.[96,174,432] Beta- and gammacoronavirus E proteins have been shown to be palmitoylated on cysteine residues downstream and adjacent to the hydrophobic region.[44,97,268] The membrane topology of E is not completely resolved.[97,174,364,432] Most evidence indicates that this polypeptide transits the membrane once, with an amino-terminal exodomain and a carboxy-terminal endodomain. Contrary to this are reports that E has a hairpin conformation, with both termini on the cytoplasmic face of membranes, or that E can have multiple membrane topologies. E protein has been observed to assemble into homo-oligomers, ranging from dimers

through hexamers,[174,452] and a pentameric α-helical bundle structure has been solved for the hydrophobic region of SARS-CoV E.[339] Oligomerization is consistent with the ion channel activity of this protein, but the monomeric form of E may also play a separate role[446] (see *Assembly and Release of Virions*).

Residing in the interior of the virion, the N protein is the sole protein constituent of the helical nucleocapsid.[174] Monomers of this 38- to 52-kDa protein bind along the RNA genome in a beads-on-a-string configuration common to other helical viral nucleocapsids (Fig. 10.2B). However, unlike the nucleoproteins of rhabdo- and paramyxoviruses, the coronavirus N protein provides little or no protection for its genome against the action of ribonucleases.[277,304] The bulk of the N protein monomer is made up of two independently folding domains, which are called the N-terminal domain (NTD) and the C-terminal domain (CTD), although neither includes its respective terminus of the N molecule (Fig. 10.3). With the exception of a highly conserved stretch of 30 amino acids within the NTD,[282] there is only a moderate degree of primary sequence homology among N proteins across all genera. However, high structural homology is evident among the crystal or solution structures that have been determined for the NTDs and CTDs of multiple coronaviruses.[68,73,137,157] Flanking the NTD and CTD are three spacer segments, the central one of which contains a serine- and arginine-rich tract (the SR region). The remaining functionally distinct region of N, the carboxy-terminal domain 3, has been defined genetically.[186,219] The spacer segments and domain 3 are each likely to be intrinsically disordered polypeptides.[68,69] Most of the N molecule, including the NTD and CTD, is highly basic; by contrast, domain 3 is acidic.

The N protein is a phosphoprotein,[174] modified at a limited number of serine and threonine residues. Phosphorylation sites have been mapped for TGEV, IBV, and MHV (representing three of the four genera), and collectively, targeted sites can fall in any domain or spacer region of the N molecule.[51,74,447] Thus, a general pattern for N protein phosphorylation cannot yet be discerned, nor have all responsible kinases been identified, although there is evidence linking glycogen synthase kinase-3 to phosphorylation of the SR region of MHV N.[460] The role of phosphorylation is not clearly established, but it has long been thought to have regulatory

impact. Phosphorylation has been suggested to trigger a conformational change in N protein,[402] and it may modulate RNA-binding affinity, transcription elongation, or N oligomerization.[68,460]

The most salient function of the N protein is to bind to viral RNA. Nucleocapsid formation must involve both sequence-specific and nonspecific modes of RNA binding. Specific RNA substrates that have been identified for N protein include the transcription-regulating sequence (TRS)[157,281] (see *Viral RNA Synthesis*), polyadenylate,[421] and the genomic RNA packaging signal (PS)[87,293] (see *Assembly and Release of Virions*). The NTD and the CTD are each separately capable of binding to RNA ligands *in vitro*, and the (unbound) structures of these domains offer some clues as to how this is accomplished. The NTD consists of a U-shaped *β*-platform with an extruding *β*-hairpin, which presents a putative RNA-binding groove rich in basic and aromatic amino acid residues.[68,137,157] The tightly interconnected CTD dimer forms a rectangular slab, one face of which exhibits a potential RNA-binding groove lined by basic *α*-helices.[68,73] Some work suggests that, in the intact N protein, optimal RNA binding requires concerted contributions from both the NTD and the CTD, as well as other regions of the molecule.[69,184] In addition to RNA binding, a significant component of nucleocapsid stability results from interactions among N monomers.[304] A major part of this is generally attributed to dimerization and higher-order oligomerization of the CTD,[67,68,137] but additional regions of N–N association have been mapped to the NTD and to domain 3.[89,137,184] Another crucial interaction of the N protein is to bind to M protein.[136,405] This capability is provided by the carboxy-terminal domain 3 of N.[186,231,433]

A fifth prominent structural protein, the hemagglutinin–esterase (HE) protein, is found only in lineage A betacoronaviruses, which include MHV, BCoV, HCoV-OC43, and HCoV-HKU1. In virions of these species, HE forms a secondary set of short projections, of some 5 to 10 nm, arrayed beneath the canopy of S protein spikes.[105,162] The 48-kDa HE monomer is made up almost entirely of an amino-terminal ectodomain, which acquires an additional 17 kDa of N-linked glycosylation during synthesis. The mature protein is a disulfide-linked homodimer.[173] As its name indicates, the HE protein is a hemagglutinin; that is, it is able to bind to sialic acid moieties found on cell-surface glycoproteins and glycolipids.[105] Further, HE possesses

acetylesterase activity, specific for either 9-*O*- or 4-*O*-acetylated sialic acids. These characteristics are thought to allow HE to act as a cofactor for S protein, assisting attachment of virus to host cells, as well as expediting the travel of virus through the extracellular mucosa. Consistent with this notion, the presence of HE in MHV dramatically enhances neurovirulence in the mouse host.[203] Conversely, in HCoV-OC43, which had a relatively recent zoonotic origin, the hemagglutinin activity of HE was lost by counterselection as the virus evolved to accommodate the sialoglycan composition of the human respiratory tract.[26] The two activities of the HE protein are strikingly similar to the receptor-binding and receptor-destroying activities found in influenza C virus. Remarkably, the coronavirus HE gene is clearly related to the influenza C virus HEF gene.[273] Moreover, toroviruses also possess a homolog of the HE gene,[95] raising the possibility that all three of these virus groups evolved from a common ancestor.[273,394] This kinship is further corroborated by the crystal structure of the BCoV HE protein, which reveals separate receptor-binding and acetylesterase domains perched atop a truncated membrane-proximal region.[476] The coronavirus HE protein thus resembles a squat version of its influenza virus counterpart.

GENOME STRUCTURE AND ORGANIZATION

Basic and Accessory Genes

The coronavirus genome, which ranges from 25 to 32 kb, is among the largest of those of all RNA viruses, including RNA viruses that have segmented genomes. This exceptional RNA molecule acts in at least three capacities[152]: as the initial mRNA of the infectious cycle (see *Expression of the Replicase–Transcriptase Complex*), as the template for RNA replication and transcription (see *Viral RNA Synthesis*), and as the substrate for packaging into progeny viruses (see *Assembly and Release of Virions*). Consistent with its role as an mRNA, the coronavirus genome has a canonical eukaryotic 5′-terminal cap 1 structure and a 3′ polyadenylate tail.[153] The genome comprises a basic set of genes in the invariant order 5′-replicase-S-E-M-N-3′, with the huge replicase gene occupying two-thirds of the available

coding capacity (Fig. 10.4). The replicase–transcriptase is the only protein translated from the genome; the products of all downstream open reading frames (ORFs) are derived from subgenomic mRNAs. The 5′-most position of the replicase gene is dictated by the requirement for expression of the replicase to set in motion all subsequent events of infection. The organization of the other basic genes, however, does not seem to reflect any underlying principle, since engineered rearrangement of the downstream gene order is completely tolerated.[113]

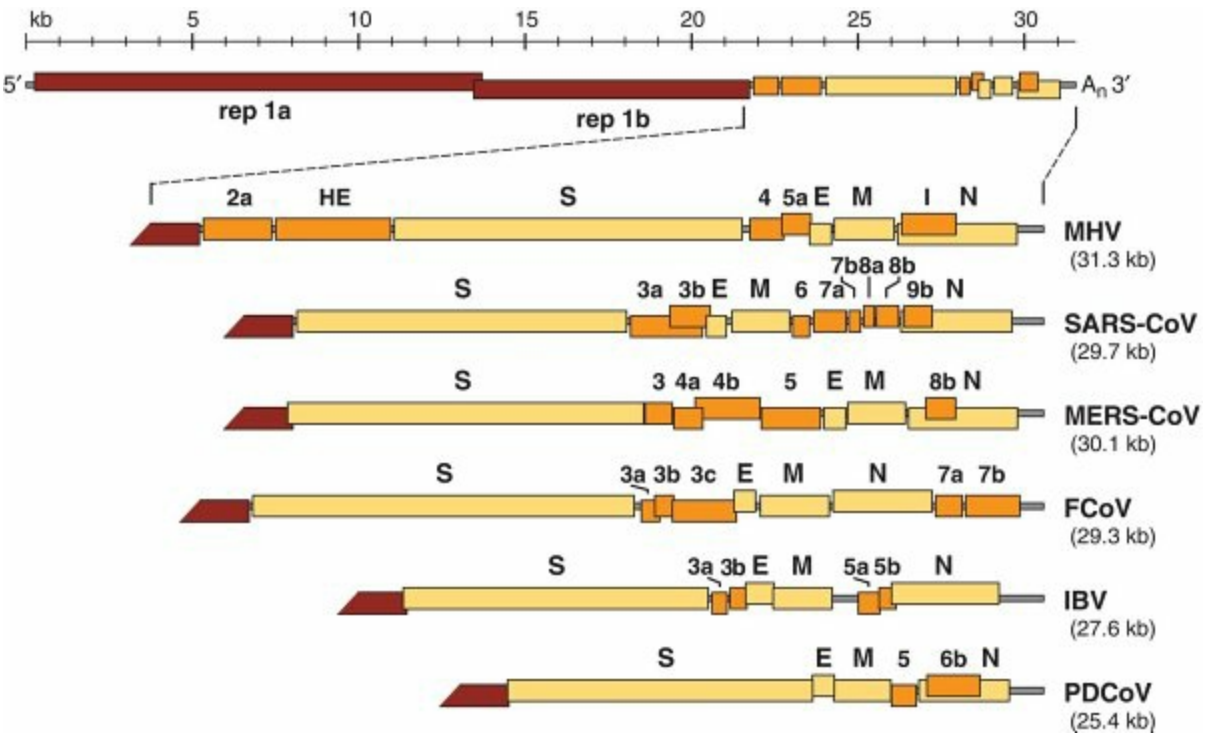

FIGURE 10.4 Coronavirus genome organization. A schematic of the entire genome of MHV is shown at the top. The replicase gene constitutes two ORFs, rep 1a and rep 1b, which are expressed by a ribosomal frameshifting mechanism (see *Expression of the Replicase–Transcriptase Complex*). The expanded region shows the downstream genes of three betacoronaviruses (MHV, SARS-CoV, and MERS-CoV), an alphacoronavirus (FCoV), a gammacoronavirus (IBV), and a deltacoronavirus (PDCoV). The total genome size is given for each virus. The sizes and positions of

accessory genes are indicated, relative to the basic genes S, E, M, and N.

Dispersed among the basic genes, there are from one to as many as eight additional ORFs, designated accessory genes, which tend to be specific to various lineages within each genus[281,303] (Fig. 10.4). These can fall in any of the intergenic intervals downstream of the replicase gene,[456] except, curiously, never between the E and M genes. In some cases, an accessory gene can be partially or entirely embedded as an alternate reading frame within another gene, for example, the internal (I) gene of MHV or the 3b gene of SARS-CoV. By convention, accessory genes are numbered according to the smallest transcript in which they fall. Consequently, there is usually no relatedness among identically named accessory genes in coronaviruses of different genera, for example, the 3a genes of SARS-CoV, FCoV, and IBV (Fig. 10.4). Some of these extra ORFs are thought to have been acquired through ancestral recombination with RNA from host or heterologous viral sources. The HE gene is the best supported example of this type of horizontal gene transfer.[273] Two other such candidates are the 2a gene found in MHV and HCoV-OC43, which encodes a 2′,5′-phosphodiesterase,[151] and gene 10 of beluga whale coronavirus, which encodes a putative uridine–cytidine kinase.[289] Notably, the 2a protein is structurally and functionally homologous to the MERS-CoV 4b protein,[416] to a module of the torovirus replicase,[394] and to the mouse AKAP7 protein.[151] This strongly suggests that the ancestral 2a gene was captured from a host mRNA. The origins of most accessory genes, however, remain an open question, as most have no identifiable orthologs in protein databases. Some others have ORFs with multiple disruptions and are likely to be relics of genes lost during evolution.

Almost all intact accessory genes that have been examined are expressed during infection, although the functions of only a handful are well resolved. The protein products of most accessory genes are nonstructural, but the HE protein is a clear exception to this rule,[173] and a few other accessory proteins have been shown to be components of virions.[303] Mutational knockout or deletion of accessory genes has not yet revealed any that are essential for viral replication in tissue culture. Conversely, accessory gene ablation,[101,110,203] or transfer to another virus,[411] can have profound effects

on viral pathogenesis. In some cases, the basis for this is understood to result from interactions with host defenses, particularly innate immune mechanisms (see *Immune Response and Viral Evasion of the Immune Response*). For other accessory genes, though, potential *in vivo* functions have not been elucidated.

Coronavirus Genetics

Classical coronavirus genetics focused principally on two types of mutants: first, naturally arising viral isolates, particularly deletion mutants, which offered clues to the genetic basis of different pathogenic traits, and second, temperature-sensitive mutants isolated from MHV by chemical mutagenesis.[235] Some of the latter proved valuable in analyses of the functions of structural proteins.[219,274,282] However, owing to the large target size of the replicase gene, the majority of such randomly generated mutants had conditional–lethal, RNA-negative phenotypes. These are currently sorted into five complementation groups, yielding one approach to examining the multiplicity of functions encompassed by the viral replicase–transcriptase.[29,371,403]

The development of coronavirus reverse genetics proceeded in two phases.[120] Initially, a method called targeted RNA recombination was devised at a time when it was uncertain whether the construction of full-length infectious cDNA clones of coronavirus genomes would become technically feasible. With this scheme, a synthetic donor RNA bearing mutations of interest is transfected into cells that have been infected with a recipient parent virus possessing some characteristic that can be selected against.[219] In its current form, for manipulation of MHV, the technique uses a chimeric recipient parent virus designated fMHV. The fMHV chimera is a mutant of MHV that contains the S protein ectodomain from feline infectious peritonitis virus (FIPV), a feline coronavirus, and can therefore only grow in feline cells (see *Virion Attachment to Host Cells*). The restoration of its ability to grow in murine cells, via recombination with donor RNA containing the MHV S gene, enables a powerful selection for viruses bearing site-specific mutations.[227,283] Analogous chimeras have been generated for construction of recombinants of FIPV, IBV, and PEDV. However, the utility of targeted RNA recombination is restricted to the 3′ third of the genome.

To obtain access to the coronavirus replicase gene, it was necessary to

create full-length cDNAs. Three innovative strategies were developed to overcome the inherent barriers presented by the huge size of the replicase gene and the high instability of its various regions when propagated in bacterial clones.[9,120] In the first strategy, a full-length cDNA copy of a coronavirus genome is assembled downstream of the CMV promoter in a bacterial artificial chromosome (BAC) vector, which is stable by virtue of its low copy number.[8] The BAC can be manipulated by standard cloning techniques or, more recently, by λ phage–based homologous recombination in bacteria[140] or homologous recombination in yeast.[316] Viral infection is then launched from transfected BAC DNA, through transcription of infectious coronavirus RNA by host RNA polymerase II. This method of initiating infection obviates potential limitations of *in vitro* capping and synthesis of genomic RNA. In the second strategy, a full-length genomic cDNA is assembled by *in vitro* ligation of smaller cloned cDNA fragments, some of the boundaries of which have been chosen so as to interrupt regions of instability.[120,471] The ligation occurs in a directed order that is dictated by the use of asymmetric restriction sites. Infectious genomic RNA is then transcribed *in vitro* and used to transfect susceptible host cells. An extension of this method has demonstrated the construction entirely from synthetic cDNAs of the genome for a hypothetical progenitor of an extant coronavirus.[33] In the third strategy, the genome of vaccinia virus is used as the cloning vector for a full-length coronavirus cDNA that is generated by long-range RT-PCR.[415] The cDNA is then amenable to manipulation by the repertoire of techniques available for poxvirus reverse genetics.[9] Infections are launched from *in vitro*–synthesized RNA or, alternatively, from transfected cDNA transcribed *in vivo* by T7 RNA polymerase encoded by fowlpox helper virus.[54] Collectively, these systems developed for complete reverse genetics have provided an essential pathway toward unraveling the complexities of the coronavirus replicase.

CORONAVIRUS REPLICATION

Virion Attachment to Host Cells

Coronavirus infection is initiated by virion binding to a cellular receptor (Fig.

10.5). There then follows a series of events culminating in the delivery of the nucleocapsid to the cytoplasm, where the viral genome becomes available for translation. Individual coronaviruses usually infect only one or a few closely related hosts. The interaction between the viral S protein and its cognate receptor constitutes the principal determinant governing coronavirus host species range and tissue tropism. This has been most convincingly shown in two ways. First, the expression of a particular receptor in nonpermissive cells of a heterologous species renders those cells permissive for the corresponding coronavirus.[117,130,253,258,355,420,442,470] Second, the engineered replacement of the S protein ectodomain changes the host cell species specificity or tissue tropism of a coronavirus in a predictable fashion.[165,227,341,368,424] The more variable subunit, S1, is the part of the spike protein that binds to receptor. Binding leads to large conformational changes, mediated by the more conserved S2 subunit, that result in the fusion of virion and cell membranes. The region of S1 that contacts the receptor, the receptor-binding domain (RBD), has been mapped to the CTD of S1 for SARS-CoV,[453] MERS-CoV,[270,443] HCoV-HKU1,[352] HCoV-NL63,[262] TGEV,[147] and HCoV-229E.[40] By contrast, the RBD for MHV maps to the NTD of its S1 subunit[224]; this galectin-like domain of S1 is often reserved by other coronaviruses for binding to carbohydrate attachment factors.[249,335,348] The RBD is usually found in a “lying” state, buried in the S trimer structure, and it must undergo a transition to a “standing” state to become accessible to the receptor.[380,473] It is not yet clear what governs this conformational change.

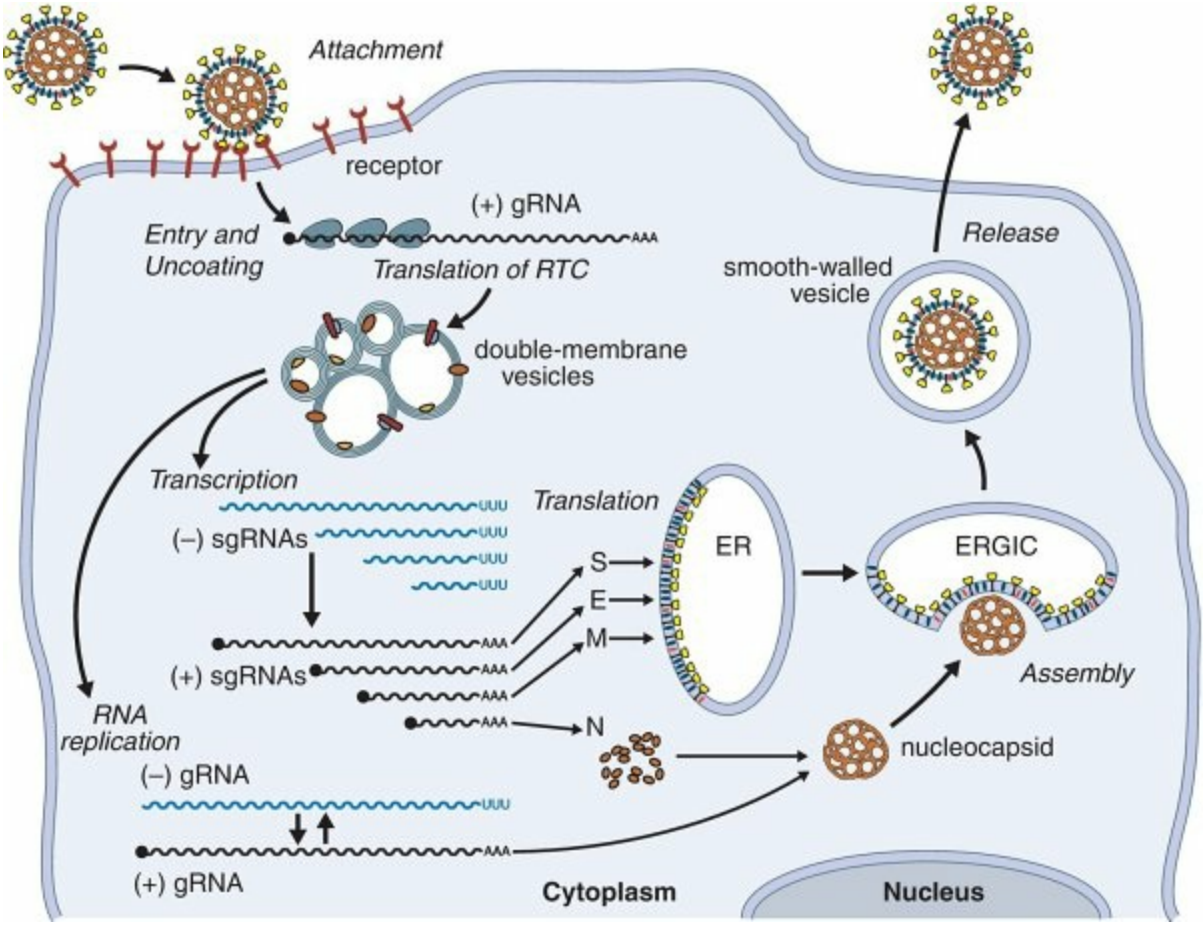

FIGURE 10.5 Overview of coronavirus replication (see text for details).

The known cellular receptors for coronaviruses are listed in Table 10.2. The MHV receptor, mCEACAM1, was the first discovered coronavirus receptor (as well as one of the first receptors defined for *any* virus).[450,451] That this molecule is the only biologically relevant receptor for MHV was made clear by the demonstration that homozygous *Ceacam1*$^{-/-}$ knockout mice are totally resistant to infection by high doses of MHV.[170] CEACAM1 is a member of the carcinoembryonic antigen (CEA) family within the immunoglobulin (Ig) superfamily, and, in its full-length form, CEACAM1 contains four Ig-like domains.[130] A diversity of two– and four–Ig domain isoforms are generated by multiple alleles and alternative splicing variants of *Ceacam1*.[129] The wide range of pathogenicity of MHV in mice is thus thought to be strongly affected by the interactions of S proteins of different

virus strains with the array of receptor isoforms that are expressed in mice of different genetic backgrounds.[408] The solved structure of the MHV RBD-mCEACAM1 complex has allowed the identification of key residues at the S protein–receptor interface and has also revealed why the closely related S protein of BCoV cannot bind the MHV receptor.[248]

TABLE 10.2 Coronavirus receptors

Virus[a]	Receptor	References
Alphacoronaviruses		
TGEV	Porcine aminopeptidase N[b] (pAPN)	117
PRCoV	Porcine aminopeptidase N (pAPN)	118
PEDV	(Unknown, but *not* pAPN)	386,257
FCoV-II, FIPV	Feline aminopeptidase N (fAPN)	420
FCoV-I	(Unknown, but *not* fAPN)	131
CCoV	Canine aminopeptidase N (cAPN)	35
HCoV-229E	Human aminopeptidase N (hAPN)	470
HCoV-NL63	Angiotensin-converting enzyme 2 (ACE2)	172
Betacoronaviruses		
MHV	Murine carcinoembryonic antigen–related adhesion molecule 1 (mCEACAM1)	450
BCoV	*N*-Acetyl-9-*O*-acetylneuraminic acid[e]	374
HCoV-OC43	*N*-Acetyl-9-*O*-acetylneuraminic acid[e]	226
SARS-CoV	Angiotensin-converting enzyme 2 (ACE2)[c]	258
MERS-CoV	Dipeptidyl peptidase 4 (DPP4)[d]	355
Gammacoronaviruses		
IBV	Alpha-2,3-linked sialic acid[e]	348
Deltacoronaviruses		
PDCoV	Porcine aminopeptidase N (pAPN)	253,442

[a] All virus abbreviations are as given in Table 10.1.

[b] Mammalian aminopeptidase N is also known as CD13.

[c] Human CD209L (L-SIGN), a lectin family member, can also act as a receptor for SARS-CoV but with much lower efficiency than ACE2.[197]

[d] DPP4 is also known as CD26.

[e] It is not yet known whether BCoV, HCoV-OC43, and IBV also have protein receptors.

Many alphacoronaviruses and one deltacoronavirus use aminopeptidase N (APN) of their respective hosts as a receptor (Table 10.2).[117,118,253,420,442,470] APN (also called CD13) is a cell-surface, zinc-binding protease that is resident in respiratory and enteric epithelia and in neural tissue. The APN molecule is a heavily glycosylated homodimer. In general, the alphacoronavirus receptor activities of APN homologs are not interchangeable among species.[35,116] In line with this specificity, structures of RBD–APN complexes show that PRCoV and HCoV-229E have evolved to bind to different sites on pAPN and hAPN, respectively.[35,357,454] By contrast, the deltacoronavirus PDCoV is able to exploit as a receptor APN homologs from multiple mammalian and avian species.[253] This suggests that the S protein of this virus recognizes highly conserved determinants on APN, in accord with its postulated recent switch from an avian to a mammalian host.

The receptor for SARS-CoV, angiotensin-converting enzyme 2 (ACE2), was rapidly discovered following the isolation of the virus.[258] ACE2 is a cell-surface, zinc-binding carboxypeptidase involved in regulation of cardiac function and blood pressure. It is expressed in epithelial cells of the lung and the small intestine, the primary targets of SARS-CoV, as well as in heart, kidney, and other tissues. The crystal structure of the SARS-CoV S protein RBD in complex with ACE2 shows the RBD cradling one lobe of the claw-like catalytic domain of its receptor.[248,255] The cryo-EM structure of the complete S trimer bound to ACE2 indicates that receptor binding induces a conformational change in the RBD and may trigger the release of S1 subunits from S2 subunits.[396] Remarkably, ACE2 also serves as the receptor for the alphacoronavirus HCoV-NL63,[172] and the corresponding structural complex for that virus reveals that the HCoV-NL63 RBD binds to the very same motifs of ACE2 as are contacted by the SARS-CoV RBD.[248] Since the SARS-CoV and HCoV-NL63 RBDs have neither sequence nor structural

homology, this finding strongly supports the notion that they have independently evolved to bind to the same hot spot on the ACE2 surface. Analysis of the SARS-CoV RBD–ACE2 interface and structure-guided mutational investigations demonstrated the basis for the final jump of SARS-CoV from palm civets to human hosts (see *Epidemiology*). These studies found that mutation of merely two key RBD residues facilitated civet-to-human transmission and subsequent human-to-human transmission.[248]

Shortly following the isolation of MERS-CoV, its receptor was found to be dipeptidyl peptidase 4 (DPP4, also called CD26).[355] DPP4 is a membrane-bound exoprotease with a wide tissue distribution; it cleaves dipeptides from hormones, chemokines, and cytokines and carries out multiple other physiological functions. The DPP4 molecule comprises a carboxy-terminal catalytic domain and an amino-terminal eight-blade β-propeller domain. The structure of the MERS-CoV RBD–DPP4 complex shows that the interacting surface of the RBD is a four-stranded β-sheet that contacts blades 4 and 5 of the DPP4 propeller domain.[248,270] Notably, critical residues in this region of the receptor are well conserved between DPP4 of humans and camels, the source of zoonotic transmission of MERS-CoV.[248] While it is intriguing that DPP4, like APN and ACE2, is a protease, catalytic site mutational analyses and inhibitor studies of all three of these molecules have shown that their enzymatic activities are not required for receptor function.[116,248,258,355]

Viral Entry and Uncoating

The entry of virions into cells results from large-scale rearrangements of the S protein that lead to the fusion of viral and cellular membranes.[46] Coronaviruses can enter cells either by an “early” pathway of fusion at the plasma membrane or by a “late” pathway of receptor-mediated endocytosis followed by fusion with membranes of acidified endosomes. The rearrangements of S are triggered by some combination of proteolytic cleavage, receptor binding, and possibly also exposure to acidic pH.[169,290] Upon synthesis, S protein initially folds into a stable configuration, to prevent its premature activation prior to contacting target cells. Thus, during the entry steps of infection, S requires at least one encounter with a protease in order to separate the receptor-binding and fusion components of the spike and to expose its fusion peptide. There are two main types of proteolytic cleavage of

S. The first is a preliminary activation at the S1/S2 junction, which occurs in many coronaviruses but is not obligatory. This cleavage often takes place as virions exit from cells (in the previous round of infection), but it can also occur at the cell surface during receptor binding. The second type of cleavage happens at a locus (S2′) within the S2 subunit, upstream of the fusion peptide (Fig. 10.3).[34] This event can take place either at the cell surface or in endosomes. It is enhanced by prior S1/S2 cleavage and likely follows conformational changes in S that result from receptor binding. The gathering consensus is that S2′ cleavage occurs in all coronaviruses and is essential for fusion.[290] The exact assignment of the S2 fusion peptide is not agreed upon[46,290,323]; however, the best candidate is a region containing a highly conserved motif, IEDLLF, immediately downstream of the S2′ cleavage site.[291] High-resolution structures show that this putative fusion peptide is accessible on the periphery of the S trimer[214,436]; accordingly, S2′ cleavage would free its amino terminus for host cell membrane insertion.

The details of proteolytic activation are still incompletely understood but have been best studied for SARS-CoV. In most tissue culture cell types, entry of this virus is dependent upon cathepsins, which are acid-activated endosomal proteases. The infectivity of SARS-CoV, as well as many other coronaviruses, is thus suppressed by cathepsin inhibitors or by lysosomotropic agents.[388] It remains unresolved, however, whether neutralization of lysosomal pH prevents some required S protein conformational change or if its sole effect is to forestall the activation of endosomal proteases. Alternatively, cell-bound SARS-CoV can be activated by treatment with extracellular proteases, such as trypsin or elastase, greatly enhancing its infectivity and allowing the virus to enter from the cell surface.[290] This diversity of mechanisms of activation raises the question of which best reflects conditions during host infection. Recent studies suggest that for the SARS-CoV S protein, the most biologically relevant protease is TMPRSS2.[291,387] This transmembrane serine protease, which is expressed in pneumocytes, colocalizes with and binds to ACE2. In cells expressing TMPRSS2, SARS-CoV enters at the cell surface and is insensitive to cathepsin inhibitors and lysosomotropic agents. Similarly, there is evidence that “early” entry at the cell surface is also the most pertinent mechanism for initiation of MERS-CoV infection *in vivo*. In this case, it was found that TMPRSS2 is linked to the receptor DPP4 by a scaffold protein, tetraspanin

CD9.[132] Likewise, TMPRSS2-dependent “early” entry appears to be the main pathway followed by clinical (rather than cell culture-adapted) isolates of HCoV-229E, HCoV-OC43, and HCoV-HKU1.[384,385]

The coronavirus S protein is a class I viral fusion protein with domains structurally and functionally homologous to those of the fusion proteins of phylogenetically distant RNA viruses, such as influenza virus, HIV, and Ebola virus, but on a much larger scale.[46,47,168,249] As in those other viral fusion proteins, the coronavirus S2 moiety contains two separated heptad repeats, HR1 and HR2, with the fusion peptide upstream of HR1 and the transmembrane domain immediately downstream of HR2 (Fig. 10.3). Conformational changes brought about by receptor binding and S2′ cleavage release the fusion peptide, allowing its insertion into the host cell membrane. Concomitant dissociation of the S1 subunit effectively unlocks the S2 trimer, triggering major rearrangements.[250] The result is an irreversible folding that brings together the heptad repeats to form a six-helix bundle, juxtaposing viral and cellular membranes in sufficient proximity to allow lipid bilayer mixing and deposition of the virion nucleocapsid into the cytoplasm. The six-helix bundle is an extremely stable, rod-like complex. Highly similar crystallographic structures for this complex from the S proteins of MHV, SARS-CoV, MERS-CoV, and HCoV-NL63 all show the three longer HR1 helices forming a central, coiled-coil core. Arrayed around this, in an antiparallel orientation, the three shorter HR2 helices pack into the grooves between the HR1 monomers via hydrophobic interactions.[249] The high-resolution cryo-EM model of the MHV postfusion S2 trimer[438] depicts a 180-Å-long cone-shaped structure (taller than the entire prefusion S1/S2 ectodomain) with the six-helix bundle at its apex. Notably, the multiple *α*-helices that make up HR1 and adjacent regions in each monomer of the prefusion structure[436] have refolded into unusually long single helices in the central coiled coil of the postfusion structure.

Expression of the Replicase–Transcriptase Complex

Following delivery of the viral nucleocapsid to the cytoplasm, the next event of infection is the translation of the replicase gene from genomic RNA. This gene consists of two large ORFs, rep 1a and rep 1b, which share a small region of overlap (Fig. 10.4). Translation of the entire replicase depends upon

a mechanism called ribosomal frameshifting, whereby, with some probability, a translating ribosome shifts one nucleotide in the –1 direction, from the rep 1a reading frame into the rep 1b reading frame.[281] This repositioning is programmed by two RNA elements (Fig. 10.6A), embedded near the region of overlap, which were discovered in studies of IBV.[49] The first element is a heptanucleotide slippery sequence, 5′-UUUAAAC -3′, which is identical for all known coronaviruses and has apparently been selected as optimal for its role.[344] The second element, located a short distance downstream of the slippery sequence, is an extensively characterized RNA pseudoknot structure.[50] This latter component was initially thought to be a classic H-type pseudoknot, but analyses of SARS-CoV frameshifting support a more elaborate structure that includes a third stem-loop (SL) within pseudoknot loop 2.[343]

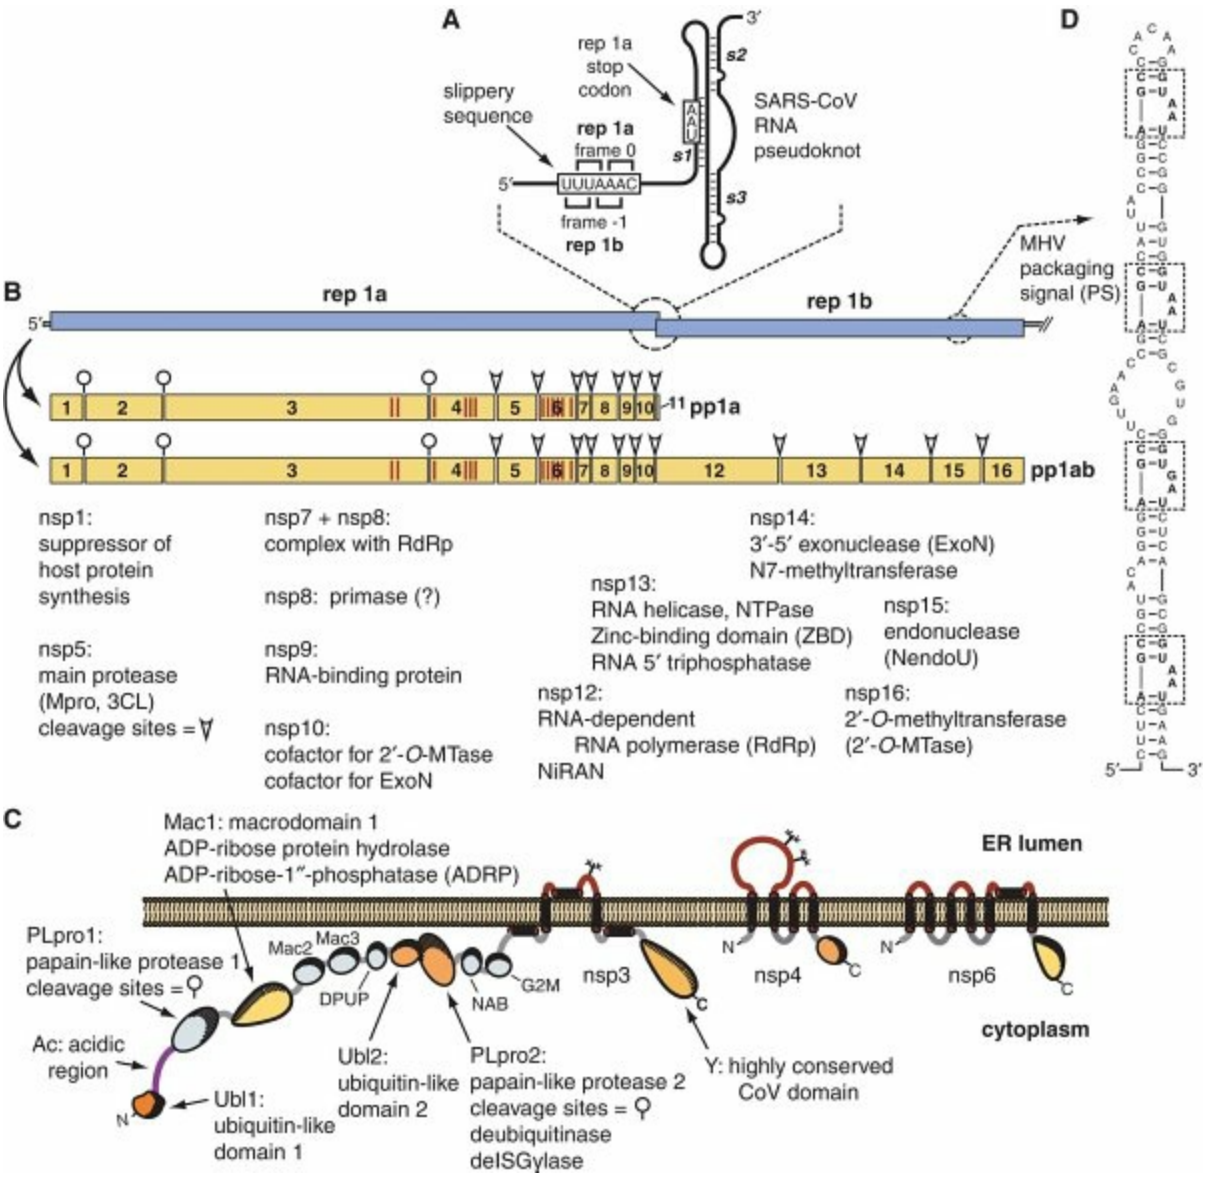

FIGURE 10.6 Coronavirus replicase gene and protein products. **A:** Ribosomal frameshifting elements of the SARS-CoV replicase gene.[343] Pseudoknot stems are indicated as s1, s2, and s3. **B:** Polyprotein pp1a and pp1ab processing scheme for alpha- and betacoronaviruses. The gammacoronavirus processing scheme is identical, except for the absence of nsp1. Known functions and properties of nsp1 to nsp16 are listed; nsp11 is an oligopeptide generated when ribosomal frameshifting does not occur. Transmembrane domains in nsp3, nsp4, and nsp6 are indicated by

red vertical lines.[200,320] **C:** Schematic of the three membrane-bound replicase components. Known functions of modules of nsp3 are listed.[309] Modules not found in all coronaviruses are shown in *gray*; in coronaviruses with a single PLpro, its position is that of PLpro2. **D:** The RNA packaging signal (PS) located in the nsp15-encoding region of the MHV genome.[77] This element is found only in a subset of the betacoronaviruses (MHV, betacoronavirus 1, and HCoV-HKU1); repeat units are *boxed*.

The two elements act together to produce the coterminal polyproteins pp1a and pp1ab. During most rounds of translation, the elongating ribosome unwinds the pseudoknot, and translation terminates at the rep 1a stop codon, yielding the smaller product, pp1a. In some fraction of the time, however, the pseudoknot blocks the mRNA entrance channel of the ribosome.[301] This allows the simultaneous slippage of the P- and A-site tRNAs into the rep 1b reading frame, resulting in the synthesis of pp1ab. It is not clear whether slippage is brought about by pausing required for the ribosome to melt out the mRNA structure[49] or without pausing, by mechanical deformation of the P-site tRNA.[190,301] Studies of reporter gene expression suggest that the incidence of coronaviral ribosomal frameshifting is as high as 25% to 30%[281] and an estimate of the *in vivo* frequency in infected cells accords with this high rate.[190] The role of programmed frameshifting is thought to be to provide a fixed ratio of translation products for assembly into a macromolecular complex.[344] It is also possible that frameshifting frequency is regulated to forestall expression of the enzymatic products of rep 1b until a suitable environment for RNA synthesis has been prepared by the products of rep 1a.

Polyproteins pp1a (402–502 kDa) and pp1ab (700–811 kDa) are autoproteolytically processed into mature products that are designated nsp1 to nsp16 (except in the gamma- and deltacoronaviruses, which do not have a counterpart of nsp1)[486] (Fig. 10.6B). Processing also generates many long-lived partial proteolytic products, which may have functional importance. There are two types of polyprotein cleavage activity. One or two papain-like

proteases (PLpro), which are situated within nsp3, carry out the relatively specialized separations of nsp1, nsp2, and nsp3.[288] Many PLpro also have deubiquitinase activity, which can block some host antiviral defenses. The main protease (Mpro), nsp5, performs the remaining 11 cleavage events.[15,399] Mpro is often designated the 3C-like protease (3CLpro) to point out its distant relationship to the 3C proteins of picornaviruses. Because of their pivotal roles early in infection, PLpro and Mpro present attractive targets for antiviral drug design.[288,467]

The processed nsps assemble to form the coronavirus replicase, which is also called the replicase–transcriptase complex (RTC).[308] The challenge of defining the roles of the many nsp components of the RTC was initially addressed by foundational studies in bioinformatics,[154,487] a discipline that continues to inform the analysis of this intricate molecular machinery.[244,309,392] Besides PLpro and Mpro, the products of rep 1a contain several activities that establish cellular conditions favorable for infection. Some of these are directly linked to RNA synthesis. Others are nonessential for viral replication in tissue culture, but they can have major effects on virus–host interactions (see *Immune Response and Viral Evasion of the Immune Response*). The very first polyprotein product, nsp1, exhibits a broad set of antagonistic activities that selectively inhibit host gene expression.[305] For different viruses, this is accomplished by diverse mechanisms, some of which operate by nsp1 associating with the small ribosomal subunit and recruiting a cellular endonuclease that cleaves host mRNAs. As yet, no function has been demonstrated for the next polyprotein product, nsp2.[308]

Nsp3 is by far the largest of the RTC proteins. It consists of a concatenation of individual structural modules that are arranged as globular domains separated by flexibly disordered linkers[246,309] (Fig. 10.6C). At the amino terminus of nsp3 are a ubiquitin-like domain (Ubl1) and a hypervariable acidic region (Ac). Ubl1 interacts with the SR region of the N protein,[185,187,204] and it is proposed that this interaction tethers the genome to the assembling RTC, in order to allow formation of the initiation complex for RNA synthesis. Also located within nsp3, as noted above, are one or two PLpro modules. Downstream of the Ac region or PLpro1, all coronaviruses contain a conserved macrodomain (Mac1). Mac1 exhibits ADP-ribose-1″-phosphatase (ADRP) activity, but recent work suggests that its

physiologically relevant role is as an ADP-ribose-protein hydrolase.[251] Although Mac1 is nonessential for viral replication, it is critical for *in vivo* pathogenesis.[140] At the carboxy terminus of nsp3 is a highly conserved region, designated the Y domain, containing three metal-binding clusters of cysteine and histidine residues.[309,487] The functions of other domains of nsp3 (Mac2, Mac3, DPUP, NAB, and G2M),[246,309,392] which appear only in various subsets of coronaviruses, remain to be elucidated.

Notably, the rep 1a products nsp3, nsp4, and nsp6 each contain multiple transmembrane helices that anchor the RTC to intracellular membranes (Fig. 10.6C).[200,320] These proteins are responsible for remodeling membranes to form organelles that are dedicated to viral RNA synthesis.[306] Cryoelectron tomographic imaging has revealed an extensive network of convoluted membranes, double-membraned vesicles (DMVs), and vesicle packets, all continuous with the ER, that are induced by coronavirus infection[216] (Fig. 10.7). Formation of these structures requires expression of nsp3, nsp4, and possibly also nsp6.[16,324] Apposition of paired membranes in DMVs may be promoted by interactions between the lumenal loops of nsp3 and nsp4.[164] Anchorage and compartmentalization of the RTC is thought to provide a scaffold for recruitment of soluble nsps, to offer protection from ribonucleases, and to sequester double-stranded viral RNA intermediates and other molecular signatures that can activate host innate immunity (see *Immune Response and Viral Evasion of the Immune Response*).

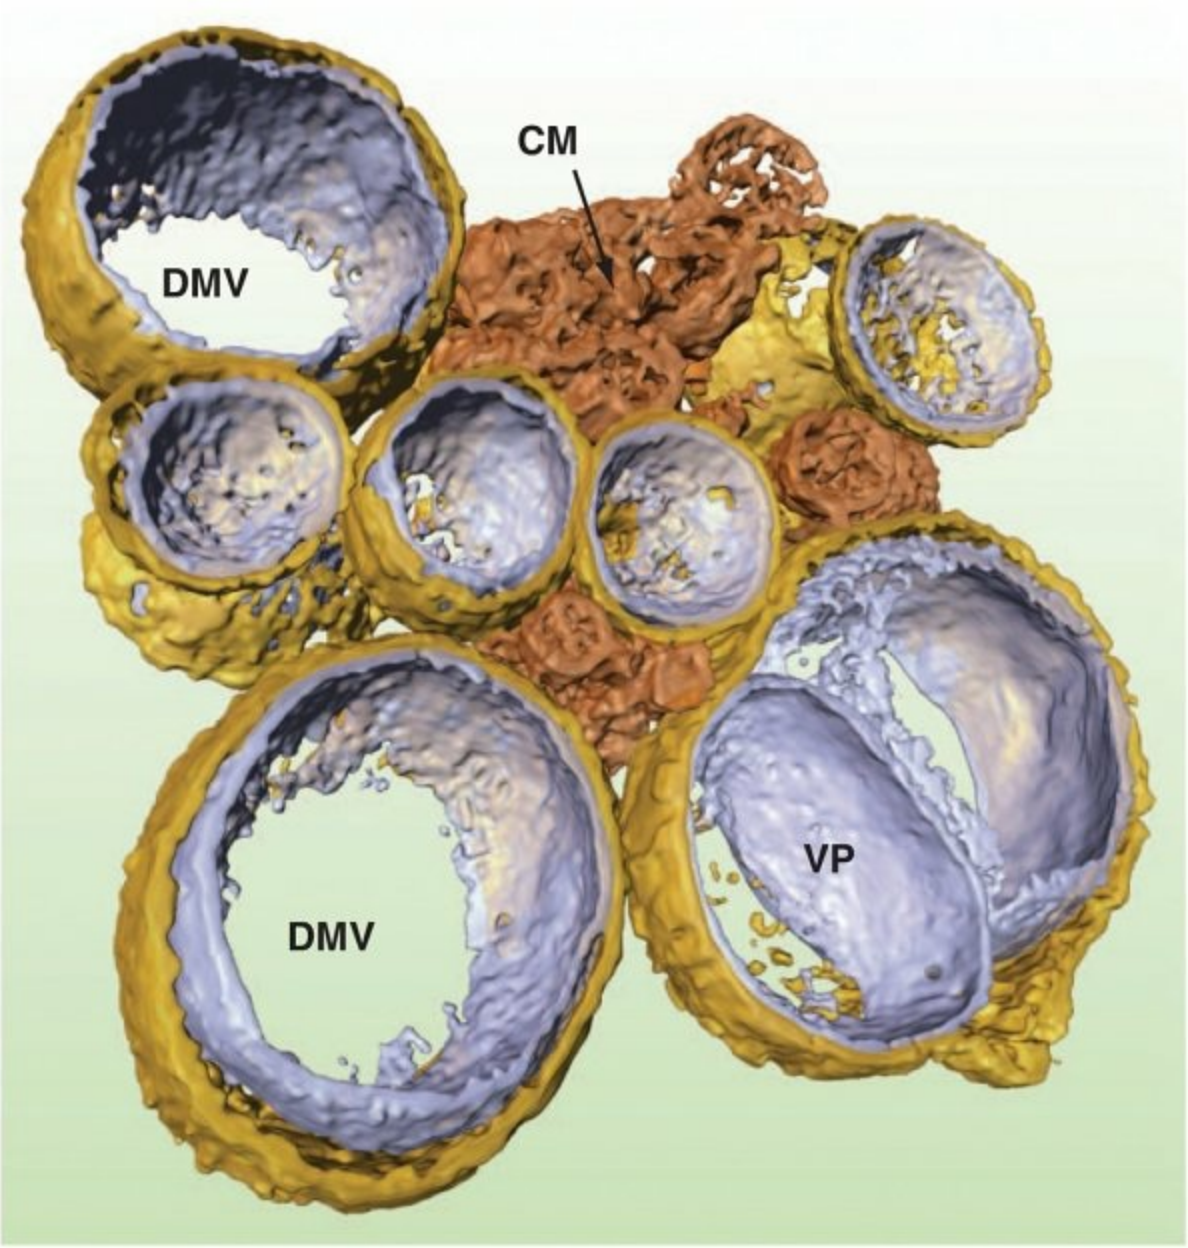

FIGURE 10.7 Membranous compartments for RNA replication and transcription induced by coronavirus infection. Shown is a cryoelectron tomographic reconstruction of the network of intracellular membrane rearrangements found in SARS-CoV–infected Vero cells. The three types of structures are convoluted membranes (CM), which are the major sites of nsp accumulation; double-membraned vesicles (DMVs), which appear to be the sites of active RNA synthesis; and vesicle packets (VP), which are

formed by the merger of DMV. (From Knoops K, Kikkert M, Worm SH, et al. SARS-coronavirus replication is supported by a reticulovesicular network of modified endoplasmic reticulum. PLoS Biol 2008;6:e226.)

The most carboxy-terminal products of pp1a are a cluster of essential small proteins, nsp7 to nsp10,[121,393] that act as regulatory subunits for components generated further downstream. The processed products encoded by rep 1b contain a collection of well-studied enzymatic activities, including many that are common to all positive-strand RNA viruses. Most prominent in the latter class is the coronavirus RNA–dependent RNA polymerase (RdRp), which is contained in nsp12. *In vitro* expression and characterization of nsp12 RdRp activity has been difficult, and there is not complete agreement among the results of different biochemical studies of this enzyme.[347] Addition of nsp7 and nsp8 has been shown to greatly enhance RNA binding by nsp12 and to potentiate its polymerase activity and processivity.[407] Consistent with this, a structure of nsp12 in complex with nsp7 and nsp8 has very recently been determined.[215] The coronavirus RdRp contains the finger, palm, and thumb domains characteristic of many viral polymerases and most closely resembles the RdRps of picornaviruses. In this model, a heterodimer of nsp7 and nsp8 is seen to bind to the RdRp thumb domain, forming interfaces with nsp12 that are supported by previous mutagenesis studies.[407] Additionally, nsp12 has an unusually large amino-terminal domain, unique to the order *Nidovirales*, named nidovirus RdRp–associated nucleotidyltransferase (NiRAN), which appears able to form monophosphate adducts with either GTP or UTP.[244] Evidence has been presented both for primer-dependent and de novo initiation of RNA synthesis by nsp12 alone or by the nsp12-nsp7-nsp8 complex.[393] A strong candidate for a prospective primase is nsp8, which, in some reports, possesses independent RdRp activity capable of synthesizing short RNA oligomers.[347] Alternatively, protein priming is one speculative role for the nsp12 NiRAN activity.

Another enzyme crucial to RNA synthesis is nsp13, a helicase falling in superfamily 1.[154] *In vitro*, nsp13 has RNA-stimulated NTPase activity and unwinds RNA duplexes in the 5′-to-3′ direction,[193] but its exact *in vivo* role

remains to be established.[393] A multinuclear zinc-binding domain (ZBD) at the amino terminus of nsp13 governs helicase activity[245] and may also mediate interactions with other molecular partners.[167] Like the NiRAN domain of nsp12, the ZBD of nsp13 is a unique marker of nidoviruses.

In common with many RNA viruses, coronaviruses produce machinery to catalyze multiple steps of the pathway for synthesis of the 5′-terminal cap structure of mRNA.[378,393] RNA 5′-triphosphatase, required for the first step of capping, is likely provided by nsp13, which possesses this in addition to its helicase and NTPase activities.[193] Intriguingly, the guanylyltransferase needed for the next step has thus far not been identified among the nsps, and it cannot be ruled out that this enzyme is appropriated from the host. For the final cap modifications, the nsp14 carboxy terminus and nsp16, respectively, harbor N7-methyltransferase and 2′-*O*-methyltransferase activities.[72,114] These enzymes operate in an obligatory sequential manner, with guanosine N7 methylation preceding ribose 2′-*O*-methylation. Activation of the nsp16 methyltransferase requires nsp10 as a cofactor, and the crystal structure of a heterodimer of these two proteins suggests that nsp10 serves as a platform to stabilize nsp16.[378]

Finally, there are two rep 1b–encoded activities that are not found outside the order *Nidovirales*[152,392,393]; surprisingly, both are ribonucleases. The first is an endonuclease, designated NendoU, which resides in nsp15. NendoU hydrolyzes both single- and double-stranded RNA and specifically cleaves downstream of uridylate residues, producing 2′-3′ cyclic phosphates.[122,192] Although it bears homology to XendoU, an enzyme involved in snoRNA processing and remodeling of the ER, the role of NendoU in coronavirus RNA synthesis, if any, is far from clear. However, NendoU catalytic mutants are profoundly attenuated due to activation of host innate immunity.[122] The second atypical activity is ExoN, a 3′-5′ exonuclease that is contained in the amino-terminal portion of nsp14.[292] Interestingly, the ExoN activity of nsp14 (but not the N7-methyltransferase) is stimulated by nsp10, and the nsp10-nsp14 complex is most active on a double-stranded RNA substrate with a 3′-end mismatch.[48] Moreover, nsp14 associates *in vitro* with the nsp7-nsp8-nsp12 RNA polymerase complex.[407] ExoN is not essential for viral replication, but nsp14 mutants have a greatly enhanced mutation rate.[133] All of these properties support the model that ExoN provides a proofreading

function for the coronavirus RdRp. Such a corrective activity may be essential for maintenance of the stability of the exceptionally large coronavirus genome.

Viral RNA Synthesis

Expression and assembly of the RTC sets the stage for viral RNA synthesis (Fig. 10.5), a process resulting in the replication of genomic RNA and the transcription of multiple subgenomic RNAs (sgRNAs).[281] The latter species serve as mRNAs for the genes downstream of the replicase gene. Each sgRNA consists of a leader RNA of 70 to 100 nucleotides, which is identical to the 5′ end of the genome, joined to a body RNA, which is identical to a segment of the 3′ end of the genome. The fusion of the leader RNA to body RNAs occurs at short motifs called TRSs, examples of which are listed in Figure 10.8. Like the genome, the sgRNAs have 5′ caps and 3′ polyadenylate tails. Together, these transcripts form a 3′-nested set, the single most distinctive feature of the order *Nidovirales*.[152] Synthesis of both genomic RNA and sgRNAs proceeds through negative-strand intermediates.[31,377] The negative-sense RNAs, which possess 5′ oligouridylate tracts[462] and 3′ antileaders,[376] are roughly a 10th to a 100th as abundant as their positive-sense counterparts.

	Virus	TRS
α-CoV	TGEV, FIPV, HCoV-NL63	5′-AACUAAAC-3′
β-CoV	MHV, BCoV, HCoV-HKU1	5′-AAUCUAAAC-3′
	SARS-CoV	5′-AAACGAAC-3′
	MERS-CoV	5′-AACGAACU-3′
γ-CoV	IBV	5′-CUUAACAA-3′
δ-CoV	PDCoV	5′-ACACAA-3′

FIGURE 10.8 Coronavirus RNA synthesis. Shown are a schematic of MHV genomic RNA and the nested set of transcribed subgenomic RNA (sgRNA) species that are a defining feature of the order *Nidovirales*. The leader and body copies of the transcription-regulating sequence (TRS-L and TRS-B, respectively) are denoted by *green boxes*. At the left are listed examples of consensus TRSs for representative viruses of each genus. Expanded regions above the genome depict *cis*-acting RNA structures at the genome termini. The structures shown are those characterized for MHV. Homologous structures exist in the BCoV and SARS-CoV genomes, and counterparts of some of these elements appear in other coronaviruses.[278,466] The 5′ expanded

region represents the 210-nt 5′ UTR and the first 281 nt of the rep 1a gene.[466] The elements shown are eight stem–loops (SL); TRS-L is denoted in *green*; the start codon of rep 1a is *boxed* in SL5a. The 3′ expanded region represents the 301-nt 3′ UTR.[493] The elements shown are the bulged stem–loop (BSL), the pseudoknot (PK), the hypervariable region (HVR), and the conserved coronavirus octanucleotide motif (*oct*); the stop codon for the upstream N gene is *boxed*.

At their 5′ and 3′ termini, coronavirus genomes contain *cis*-acting RNA elements that allow their selective recognition as templates for the RTC and play essential roles in RNA synthesis (Fig. 10.8). The initial localization of these elements was carried out in studies of defective interfering (DI) RNAs, which are extensively deleted genomic variants that propagate by competing for the viral RNA synthesis machinery. Manipulations of natural and artificially constructed DI RNAs, evaluated by transfection into helper virus–infected cells, made possible the mapping of sequences that are critical for the replication and transcription of DI RNA and, presumably, also for genomic RNA.[281] More recently, *cis*-acting RNA elements have been dissected through reverse genetics of the intact viral genome, complemented by *in vitro* biochemical and structural analyses.[278,466]

The most completely characterized 5′-terminal structures are those of the betacoronaviruses MHV and BCoV (Fig. 10.8), although structural and functional counterparts of some of these are found in SARS-CoV and in the alphacoronaviruses HCoV-229E and HCoV-NL63.[278,279] For MHV and BCoV, the elements that participate in viral RNA synthesis extend beyond the 5′ untranslated region (5′ UTR) into the replicase coding region, making up a series of at least eight SL.[160,466] One of these sequesters the start codon of the rep 1a gene within its stem and joins with two other SLs in a four-way junction formed by a long-range interaction between the 5′ UTR and the nsp1-coding region.[159] Mutations or deletions in many of these elements have been found to debilitate or kill the virus or to abrogate DI RNA replication. Many, but not all, of these structures can be exchanged among the genomes of different betacoronaviruses.[160,199] Significantly, functional analyses have

shown that either the stability[159,160] or the instability[254] of a given RNA stem can be critical for viral fitness, suggesting that these structures operate in a dynamic manner during RNA synthesis.

At the 3′ end of the genome, *cis*-acting RNA structures are confined entirely to the 3′ UTR[148] and, again, have been most thoroughly studied in MHV and BCoV. These elements consist of a bulged stem-loop (BSL)[281] and an adjacent pseudoknot[449] (Fig. 10.8) that have each been demonstrated to be essential for viral replication. The identical structures appear in other betacoronaviruses and are functionally interchangeable between MHV and either BCoV[281] or SARS-CoV.[150] The same structures are also found in the 3′ UTRs of the deltacoronaviruses; however, alpha- or gammacoronaviruses possess only counterparts of the pseudoknot or the BSL, respectively.[150,278] Further downstream in the betacoronavirus 3′ UTR is a hypervariable region, which is completely dispensable for viral replication but yet harbors an octanucleotide motif, 5′-GGAAGAGC-3′, that is almost universally conserved in coronaviruses.[149] Notably, the BSL and the pseudoknot partially overlap, and they therefore cannot fold up simultaneously. The two structures are thus thought to constitute a molecular switch between different steps of RNA synthesis.[148] In addition, the first loop of the pseudoknot forms a duplex with the extreme 3′ end of the genome and genetically interacts with the RTC subunits nsp8 and nsp9.[493] On this basis, a model has been proposed in which alternate RNA conformations of the 3′ UTR facilitate the transition between initiation of negative-strand RNA synthesis by the nsp8 primase and elongation by the nsp12 RdRp. However, this scheme does not yet incorporate potential cross talk between the 5′ and 3′ ends of the genome,[254] and much remains to be learned about how *cis*-acting RNA elements are recognized by, and cooperate with, the RTC.

A central issue in coronavirus RNA synthesis is how the leader RNA becomes attached to the body segments of the sgRNAs. It became clear from early work that transcription involves a discontinuous process.[281] UV transcriptional mapping demonstrated that sgRNAs are not processed from a genome-length precursor, and mixed infections with two different strains of MHV showed that leader RNAs could reassort between separate sgRNA body segments. It was also clearly established by DI RNA studies, and later confirmed by genomic reverse genetics,[490] that the TRSs play key roles in

sgRNA formation. The efficiency of fusion at an individual body TRS (TRS-B) is, in part, governed by how closely it conforms to the leader TRS (TRS-L).[395] Nonetheless, factors such as the local sequence context of the TRS, the position of the TRS relative to the 3′ end of the genome, and long-distance RNA–RNA interactions can also profoundly influence transcription levels.

It is now recognized that the leader-to-body fusion event takes place through a mechanism of discontinuous extension of negative-strand RNA synthesis.[370,490] In this model, both genomic and subgenomic negative-strand RNAs are initiated by the RTC at the 3′ end of the (positive-strand) genome template (Fig. 10.9). A pause in RNA synthesis occurs when the RdRp crosses a TRS-B. At this point, the RdRp may continue to elongate the growing negative strand. Alternatively, it may switch to the leader at the 5′ end of the genome template, guided by the complementarity between the 3′ end of the nascent negative strand and the TRS-L of the genome. The resulting negative-strand sgRNA, in partial duplex with positive-strand gRNA, then serves as the template for synthesis of multiple copies of the corresponding positive-strand sgRNA.

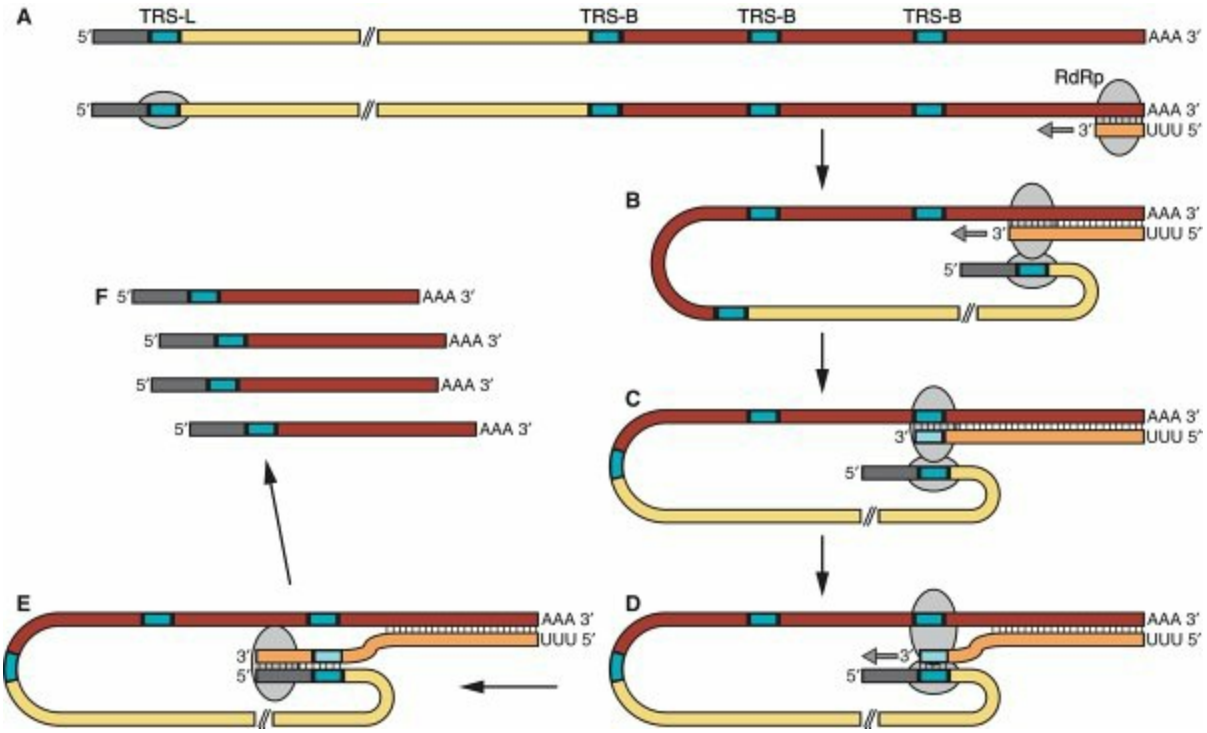

FIGURE 10.9 Coronavirus transcription through discontinuous

extension of negative-strand RNA synthesis. **A, B:**Negative-strand sgRNA synthesis initiates at the 3′ end of the positive-strand genomic RNA template. In the version of the model shown here, the genomic template loops out in such a way as to allow a component of the RTC to constantly monitor the potential complementarity of the 3′ end of the nascent negative-strand RNA with the TRS-L. **C:** Transcription pauses at a TRS-B. At this point, elongation may resume, thereby bypassing the TRS-B. **D:** Alternatively, the nascent negative strand may switch templates, binding to the TRS-L. **E:** Resumption of elongation results in completion of synthesis of an antileader-containing negative-strand sgRNA. **F:** The resulting complex of genome and negative-strand sgRNA acts as template for the synthesis of multiple copies of the corresponding positive-strand sgRNA. (Adapted from Zúñiga S, Sola I, Alonso S, et al. Sequence motifs involved in the regulation of discontinuous coronavirus subgenomic RNA synthesis. J Virol 2004;78:980–994.)

Leader-to-body fusion during negative-strand synthesis is amply supported by accumulated experimental results both with coronaviruses and the closely related arteriviruses. First, as necessitated by the model, negative-strand sgRNAs contain antileaders at their 3′ ends.[376] Second, in infected cells, there exist transcription intermediates containing negative-strand sgRNAs in association with the genome. These complexes actively participate in transcription[31,369] and can be biochemically separated from replication intermediates containing genome-length negative-strand RNAs.[372] Finally, as would be predicted for discontinuous negative-strand synthesis, engineered (or naturally occurring) variant nucleotides incorporated into the TRS-B, rather than the TRS-L, end up in the leader–body junction of the resulting sgRNA.[329,428,490] There remains, however, considerable further work to be done to elucidate the details of the model. It is not clear how the transcribing RdRp might continuously monitor the ability of its nascent product to base-pair to the TRS-L. Additionally, the synthesis of genome-length negative

strands would require the RdRp to bypass all of the TRS-B sites in the genome template. This may come about through a stochastic process, or it may be actively promoted by some RTC component or by N protein[460] under certain conditions. These and other questions will need to be addressed, possibly with the aid of a robust *in vitro* viral RNA synthesizing system.[427] Such a system would also be decisive in assessing the potential roles of host factors in transcription and replication. A number of cellular proteins that bind *in vitro* to genomic RNA segments, including hnRNP A1, polypyrimidine tract–binding protein, and polyadenylate-binding protein, have been proposed to take part in coronavirus RNA synthesis.[281,347,395] However, it has been difficult to convincingly demonstrate their specific involvement in viral processes. As yet, only a single candidate host factor has been shown to be required for *in vitro* viral RNA synthesis.[427]

In addition to its central role in sgRNA formation, template switching is also at the heart of RNA recombination, another prominent feature of coronavirus RNA synthesis. Significant rates of both homologous and nonhomologous RNA recombination have been found among selected and unselected markers during the course of infection.[281] It is presumed, but remains to be formally demonstrated, that coronavirus RNA recombination results from a copy-choice mechanism. In MHV, recombination has been shown to take place at an estimated frequency of 1% per 1.3 kb (almost 25% over the entire genome), the highest rate observed for any RNA virus.[29] On a fine scale, the sites of crossover are random,[27] although selective pressures can generate the appearance of local clustering of recombinational hot spots. This facility for RdRp strand-switching may make a major contribution to the ability of the huge coronavirus genome to circumvent the accumulation of deleterious mutations. It may also serve as a driver of evolution by horizontal gene transfer[182,273] (see *Basic and Accessory Genes*).

Assembly and Release of Virions

The immediate outcome of transcription is to enable translation of the proteins that build progeny viruses. The membrane-bound proteins M, S, and E are initially inserted into the ER, and from there, they transit to the site of virion assembly, the endoplasmic reticulum–Golgi intermediate compartment (ERGIC). Here, nucleocapsids composed of progeny genomes encapsidated

by N protein coalesce with the envelope components to form virions, which bud into the ERGIC[112,174] (Fig. 10.5).

Coronavirus assembly occurs through a network of cooperative interactions, most of which involve M protein. However, despite its central role, M is not assembly-competent by itself. Expression of M protein alone does not result in virion-like structures, and M traverses the secretory pathway beyond the budding site, as far as the *trans*-Golgi.[174,276,423] The first virus-like particle (VLP) systems developed for coronaviruses led to the key finding that coexpression of E protein with M protein is sufficient to yield the formation of particles that are released from cells and appear morphologically identical to coronavirus envelopes.[43,432] More recently, it has been shown that the additional coexpression of N protein substantially increases the efficiency of VLP formation[44,390] and can even compensate for mutational defects in M.[23] Other viral structural proteins, in particular S protein, are gathered into virions but are not specifically required for the assembly process. Since virions and VLPs contain very little E protein, this indicates that lateral interactions between M molecules provide the driving force for envelope morphogenesis. Investigations of the ability of M protein mutants to support VLP assembly concluded that M–M interactions occur via multiple contacts throughout the molecule, especially between the transmembrane domains.[112] Cryoelectron tomographic reconstructions of whole virions suggest that the M protein forms dimers that are maintained through multiple monomer–monomer contacts, while dimer–dimer interactions occur among the globular endodomains.[310]

It is incompletely understood how E protein critically assists M in envelope formation. E protein localizes to the ERGIC and *cis*-Golgi[96,315,430] and somehow secures localization of M protein at the budding site. Some evidence suggests that E protein promotes assembly by inducing membrane curvature.[174,432] Other work indicates a role for E in maintaining M protein in an assembly-competent state by preventing its nonproductive aggregation, a function that is crucially dependent on palmitoylation of E.[44] Such a chaperone-like role would be consistent with demonstrations that diverse heterologous E proteins, and even truncated versions of M protein, can functionally replace E protein in MHV.[228,233] Additionally, there are reports that point to a need for E protein to facilitate the release of virions from

infected cells.[365] These multiple roles are not mutually exclusive, and mutational studies have begun to assign individual functions to various regions of the E molecule. The carboxy-terminal endodomain of the IBV E protein has been shown to govern Golgi localization[96,97] and, when linked to a heterologous transmembrane domain, can support VLP and virion assembly.[365] Conversely, the transmembrane domain of IBV E disassembles the Golgi complex in a manner that promotes release of infectious virus, but it is unclear whether this is a general property of other coronavirus E proteins.[364] It is also presently unresolved which roles of E protein correlate with its state of oligomerization or require its function as an ion channel.[417,446]

The dispensability of S protein for VLP formation is consistent with earlier observations that spikeless (noninfectious) virions were formed by infected cells treated with the glycosylation inhibitor tunicamycin[175,363] or by cells infected with particular S mutants.[274] S protein thus appears to play a passive role in assembly, but during its passage through the secretory pathway, it is captured by M protein for virion incorporation.[112] For some S proteins, localization at or near the budding compartment is abetted by targeting signals contained in the endodomain.[423] The cysteine- and charge-rich S endodomain is also the region of the protein that interacts with M during assembly[45,469] (Fig. 10.3). The locus of M protein that reciprocally interacts with S has yet to be precisely mapped.[174]

Virion assembly is completed by condensation of the nucleocapsid with the envelope components. This is brought about principally by N and M protein interactions, which have been mapped, respectively, to the carboxy-terminal domain 3 of N[186,433] and to the carboxy terminus of the M endodomain[136,231] (Fig. 10.3). These interacting regions likely account for the thread-like connections that have been visualized between the M protein endodomain and the nucleocapsid in virion reconstructions.[28,310] Nucleocapsid formation is presumed to be concomitant with genome replication, but the details of how the nucleocapsid traffics to the budding compartment are not known. It is also only partially understood how coronaviruses selectively package genomic RNA from among the many positive- and negative-strand viral RNA species that are synthesized during infection. For MHV, DI RNA analyses mapped the genomic PS to a small

span of RNA sequence embedded in the region of the replicase gene that encodes a surface loop of nsp15[281] (Fig. 10.6D). Highly homologous structures exist in the genomes of the related betacoronaviruses BCoV and HCoV-HKU1.[77,87] However, the PSs for most coronaviruses, including the betacoronaviruses SARS-CoV and MERS-CoV, are clearly not situated at the same locus.[234] The only other mapped PS, that of the alphacoronavirus TGEV, falls near the 5′ end of the genome.[135,295] The mechanism by which MHV packaging operates is undetermined. Some work demonstrates that M protein, in the absence of N, acts as the discriminatory factor for PS recognition.[281,302] Other studies have shown that the MHV PS is specifically bound by N protein *in vitro*[87,293] and that PS recognition during infection requires a coordinated interaction of both the CTD and domain 3 of the N protein.[229,230] Unexpectedly, it has also been found that selective genomic RNA packaging is required for MHV evasion of the innate immune response.[24]

Following assembly and budding, progeny virions are exported from infected cells by transport to the plasma membrane in smooth-walled vesicles and are released by exocytosis. This is currently a poorly characterized stage of the replication cycle. It remains to be more clearly defined whether coronaviruses follow the constitutive pathway for post-Golgi transport of large cargo or, alternatively, if specialized cellular machinery must be diverted for their exit.[174] The ion channel property of E protein has been implicated in this process, but many further details await elucidation.[365]

For some coronaviruses, contingent upon the nature of S endodomain intracellular retention signals,[423] a fraction of S protein that has not been assembled into virions transits to the plasma membrane. Here, S can mediate fusion between infected cells and adjacent, uninfected cells. This cell–cell fusion depends upon S1/S2 cleavage late in infection (see *Viral Entry and Uncoating*) and occurs by a mechanism distinct from that of virus–cell fusion.[169] The resultant formation of large, multinucleate syncytia enables the rapid spread of infection by a route that does not rely on an extracellular phase of completely assembled virions.

PATHOGENESIS AND PATHOLOGY OF

CORONAVIRUS INFECTIONS

General Principles

Most coronaviruses spread to susceptible hosts by respiratory or fecal–oral routes of infection, with replication first occurring in epithelial cells (Table 10.3). Some, including HCoV-OC43, HCoV-229E, HCoV-NL63, HCoV-HKU1, and PRCoV, replicate principally in respiratory epithelial cells, where they produce virus and symptoms confined to the URT. Other coronaviruses, including TGEV, BCoV, PHEV, CCoV, FCoV, and enteric strains of MHV, infect epithelial cells of the enteric tract. Some of these viruses, such as TGEV, PEDV, and porcine deltacoronavirus (PDCoV), cause diarrhea that is particularly severe, and sometimes fatal, in young animals.[198,243] Inapparent enteric infection of adult animals maintains the virus in the population.[88] In addition to local infection of the upper respiratory or enteric tracts, several coronaviruses cause severe disease. For example, SARS-CoV and MERS-CoV spread from the upper airway to cause a severe lower respiratory tract infection, while FIPV spreads systemically to cause a generalized wasting disease in felines.[20,183,414] Rat coronavirus strains cause respiratory infection or sialodacryoadenitis due to infection of the salivary and lacrimal glands[337] but can also interfere with reproduction by infecting the female urogenital tract. PHEV of swine predominantly causes enteric infection but is also neurotropic.[252] Infection spreads to nerves that innervate the stomach of infected piglets and prevents gastric emptying, resulting in vomiting and wasting disease. The ability to cause localized versus systemic disease is mirrored in polarized tissue culture cells. Thus, coronaviruses such as mouse hepatitis virus, which can cause systemic disease, enter the apical side of cells and exit the basolateral side, whereas others, like HCoV-229E or SARS-CoV, which cause infection largely localized to the respiratory tract, enter and exit the cell apically.[90] In contrast, MERS-CoV enters and exits via both the apical and basolateral sides even though it causes mostly respiratory tract disease.[412]

TABLE 10.3 Representative coronaviruses and associated diseases

Virus[a]	Host Species	Sites of Infection	Clinical Disease
Alphacoronaviruses			
CCoV	Canine	GI tract	Gastroenteritis
FeCoV	Felidae	GI tract, respiratory	Gastroenteritis
FIPV	Felidae	Systemic disease	Peritonitis, wasting disease
HCoV-229E	Human	Respiratory	Upper respiratory tract infection
HCoV-NL63	Human	Respiratory	Upper respiratory tract infection, croup
PEDV	Swine	GI tract	Gastroenteritis
TGEV	Swine	GI tract, respiratory	Gastroenteritis
BatCoV	Bat	GI tract, respiratory	Unknown
Rabbit CoV	Rabbit	Heart, GI tract, respiratory	Enteritis, myocarditis
SADS-CoV	Swine	GI tract	Gastroenteritis
Betacoronaviruses			
BCoV	Bovine, ruminants	GI tract, respiratory	Enteritis, upper and lower respiratory tract infection
HCoV-OC43	Human	Respiratory	Upper respiratory tract infection
HCoV-HKU1	Human	Respiratory	Upper and lower respiratory tract infection
MHV	Mouse, rat	GI tract, liver, brains, lung	Gastroenteritis, hepatitis, encephalitis, chronic demyelination
PHEV	Swine	Respiratory, brain	Vomiting, wasting, encephalomyelitis
RCoV	Rat	Respiratory, salivary and lachrymal glands, urogenital tract	Respiratory tract infection, metritis, sialodacryoadenitis
SARS-CoV	Human	Respiratory, GI tract	Pneumonia (SARS)
MERS-CoV	Camel, human	Respiratory tract	Pneumonia (MERS)
BatCoV	Bat	GI tract, respiratory tract	Unknown
Gammacoronaviruses			
IBV	Chicken	Respiratory, kidney	Bronchitis, nephritis
TuCoV	Turkey	GI tract	Gastroenteritis
BWCoV	Beluga whale	Respiratory tract	Pneumonia, hepatitis
Deltacoronaviruses			
ThCoV	Thrush	Respiratory, GI tract	Unknown
PDCoV	Swine	GI tract	Gastroenteritis

[a]All virus abbreviations as in Table 10.1.

Animal Coronavirus Infections

Several coronavirus infections have been extensively studied in their natural hosts. Here, we will focus on murine and feline coronavirus infections.

Mouse Hepatitis Virus

MHV, which until the advent of SARS and MERS was the most widely studied coronavirus, causes enteric, hepatic, and neurological infections of susceptible strains of rodents. Remarkably, closely related strains of MHV, all of which use the same host cell receptor for entry,[450] infect different organs. Enteric strains, such as MHV-Y and MHV-RI, are a major problem in

animal research facilities.[88] These viruses spread within infected colonies to young, uninfected animals. They do not generally cause symptomatic disease but may subtly impair the host immune response to other pathogens and immunological stimuli.[88] Studies of MHV pathogenesis predominantly use the neurotropic JHM and A59 strains of virus (JHMV and MHV-A59), in part because they cause a demyelinating encephalomyelitis with similarities to the human disease multiple sclerosis (MS). Originally isolated from a mouse with hind limb paralysis,[25] JHMV became progressively more virulent on passage in mice, resulting in widespread neuronal infection.[445] Subsequently, most studies have used either attenuated JHMV variants or the mildly neurovirulent MHV-A59 strain for studies of demyelination. Infection with these viruses results in minimal infection of neurons, with oligodendrocytes, microglia, and astrocytes commonly infected.[401] Myelin destruction is largely immune-mediated, occurring during virus clearance from infected glia.[444,461] Thus, irradiated mice or congenitally immunodeficient mice (mice with severe combined immunodeficiency [SCID] or with a disrupted recombination activation gene 1 [$RAG1^{-/-}$]) do not develop demyelination after JHMV infection. When these mice are reconstituted with virus-specific T cells, demyelination rapidly develops[444,461] (Fig. 10.10). Demyelination is accompanied by infiltration of macrophages and activated microglia into the white matter of the spinal cord. Both CD4 and CD8 T cells are required for virus clearance from the central nervous system (CNS), with CD8 T cells considered most important in this process. CD8 T cells eliminate virus from infected astrocytes and microglia by perforin-dependent pathways, while clearance from oligodendrocytes is IFNγ-dependent.[264,327] However, T-cell–mediated virus clearance is not complete, and antivirus antibody is required to prevent virus recrudescence.[263] Coronaviruses may become persistent. In one example, viruses mutated in an immunodominant CD8 T-cell epitope are selected, resulting in evasion of the cytotoxic T-cell immune response and persistence.[340] Further, antivirus CD4 T cells, while critical for virus clearance, may also be immunopathogenic. Thus, infection with MHV mutated in an immunodominant CD4 T-cell epitope causes attenuated clinical disease, while enhancement of the antivirus CD4 T-cell response increases disease severity.[17]

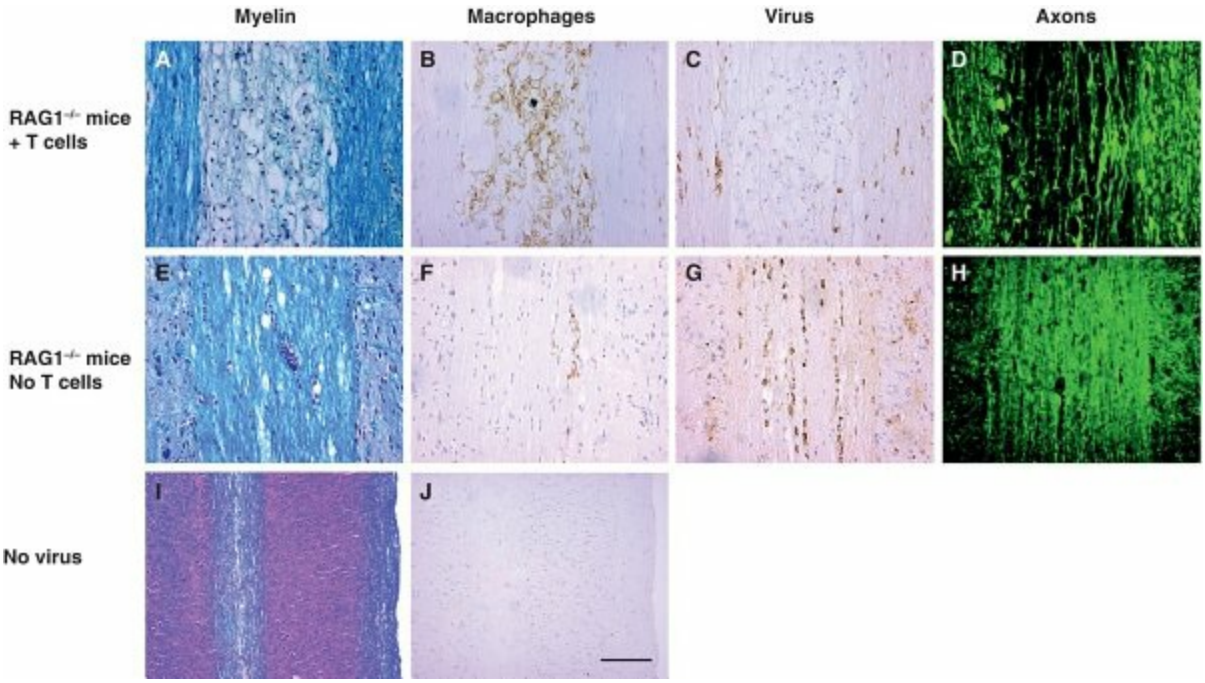

FIGURE 10.10 Immune-mediated demyelination in mice infected with a neurotropic MHV. RAG1$^{-/-}$ mice, lacking T and B cells, were either infected with a neurotropic coronavirus[461] (**A–H**) or uninfected (**I,J**). Four days later, some mice received adoptively transferred spleen cells from a wild-type C57Bl/6 mouse that was previously immunized intraperitoneally with MHV (**A–D**). All mice were sacrificed 8 days later and analyzed for demyelination (**A,E,I**), macrophage infiltration (**B,F,J**), viral antigen (**C,G**), and intact axons (**D,H**). Demyelination, macrophage infiltration, and axon destruction (**A,B,D**) were observed only in mice that received transferred MHV-immune cells showing that myelin destruction is largely mediated by T cells during the process of virus clearance (**C**).

Other strains of MHV, including MHV-A59, MHV-2, and MHV-3, infect both the liver and the CNS. Most notably, MHV-3 causes a fulminant hepatitis in susceptible strains of mice and chronic neurological infections in semi-susceptible strains.[401] In susceptible strains, MHV-3 infects

macrophages, resulting in upregulation of several proinflammatory cytokines, including IL-1β and fibrinogen-like protein 2 (FGL2), a transmembrane procoagulant molecule. Expression of FGL2 results in prothrombin cleavage, with consequent disseminated intravascular coagulation (DIC) and hepatic hypoperfusion and necrosis.[280] Levels of FGL2 are better predictors of a fatal outcome than are virus titers. Like JHMV, MHV-3 also infects the CNS, but infection of this organ occurs only in strains that do not develop a fulminant hepatitis. MHV-3 does not cause a demyelinating disease, but rather, ependymitis, hydrocephalus, encephalitis, and thrombotic vasculitis.[401] The pathogenesis of these entities is not well studied but appears to be immune-mediated. Unlike most other strains of MHV, MHV-3 directly infects T and B cells, resulting in lymphocyte apoptosis and lymphopenia. Lymphopenia, with consequent immunosuppression, facilitates virus persistence and its immunopathological consequences.

Feline Enteric Coronaviruses (FCoV) and FIPV

FCoV commonly cause mild or asymptomatic infections in domestic cats and other felines. Two serotypes of FCoV are recognized, with serotype II strains arising by recombination of serotype I FCoV with canine coronavirus in dually infected animals.[414] In some cats infected persistently with FCoV, mutations in the virus occur, resulting in the development of a lethal disease called feline infectious peritonitis (FIP); the virulent strain of FCoV is termed FIPV. Virulence correlates with the ability of the virus to replicate in macrophages. The nature of the mutations required for transition from FCoV to FIPV is not well understood, although for serotype II viruses, virulence maps in part to the surface glycoprotein.[414] This was shown using reverse genetics, in which S proteins from virulent and avirulent strains were swapped and tested for their ability to cause severe disease in cats. FIPV causes a multiphasic disease with relapses that result, ultimately, in immunosuppression, weight loss, and death (Fig. 10.11). Each episode is characterized by increased virus replication, fever, and lymphopenia.[108] FIPV does not directly infect lymphocytes. Rather, lymphopenia is believed to be a consequence of infection and activation of macrophages and dendritic cells. Subsequent lymphocyte depletion occurs when cells are exposed to high levels of proinflammatory cytokines, such as tumor necrosis factor, released by these infected cells. Virus dissemination occurs when infected

macrophages traffic throughout the body and are deposited in the vasculature. Infected macrophages provoke a pyogranulomatous reaction, which is responsible for many disease manifestations of FIP, such as peritonitis and serositis. Another consequence of immune dysregulation is hypergammaglobulinemia. Antibody–antigen complex formation commonly occurs in FIPV-infected cats and may contribute to vascular injury.[196] However, its precise role in pathogenesis remains uncertain because it is a late manifestation of disease and may make only a minor contribution to disease progression. Infection of macrophages by FIPV is enhanced by neutralizing antibody directed against the S glycoprotein. Enhanced macrophage infection is mediated by virus entry through Fcγ receptors. This phenomenon has been demonstrated *in vitro* using isolated macrophages and in cats that were previously immunized with vectors that express the S glycoprotein.[431] Although the potential occurrence of antibody-enhanced disease has hindered vaccine development, it has never been demonstrated in the natural feline infection. In fact, cats infected with FCoV often develop only low antivirus neutralizing antibody titers.[176]

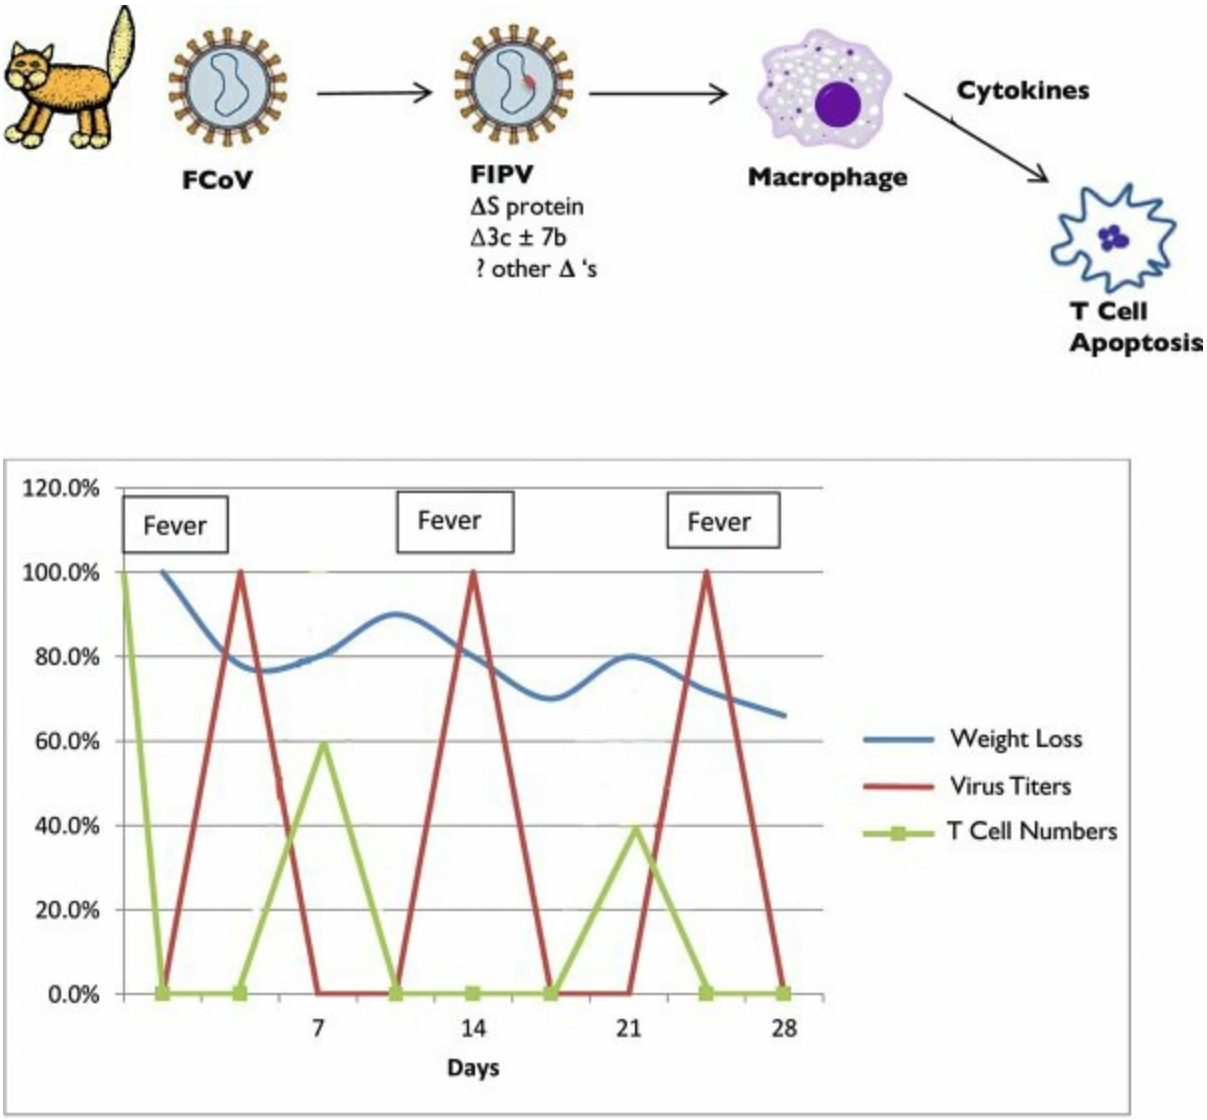

FIGURE 10.11 Recurrent feline infectious peritonitis (FIP). FIPV, the etiologic agent of FIP, occurs in felines persistently infected with feline coronaviruses. *Upper panels*: Mutations in the S glycoprotein and the ORF3b and 7b proteins occur as virus gains the ability to replicate in macrophages. Infected macrophages serve to transport the virus to sites in the host distant from the initial infection. These infected cells also express several cytokines that are believed to contribute to T-cell apoptosis. *Lower panel*: Clinical disease is characterized by recurrent bouts of virus replication accompanied by fever and clinical disease. Lymphopenia subsequently occurs as disease progresses. The pattern of disease

shown in the figure is representative of progressive disease, but the rate and extent of recurrence of virus replication and the rate of weight loss and of development of lymphopenia are variable from animal to animal. (Adapted from de Groot-Mijnes JD, van Dun JM, van der Most RG, et al. Natural history of a recurrent feline coronavirus infection and the role of cellular immunity in survival and disease. J Virol 2005;79:1036–1044.)[108]

Human Coronavirus Infections

Human Coronaviruses, Other Than SARS-CoV and MERS-CoV, Associated with Respiratory and Enteric Disease

Prior to 2003, HCoVs were primarily considered to be agents of URT disease and to cause little mortality. In general, while coronaviruses were readily isolated from infected birds and other animal species, and serially propagated in continuous cell lines, isolation of HCoVs from infected individuals was only rarely achieved. HCoV-229E and HCoV-OC43 were isolated from patients with URT infections in the 1960s.[284] There are striking differences in extent of genetic variability when isolates of HCoV-OC43 and HCoV-229E are compared. HCoV-229E isolated at geographically distinct locations show little evidence of variability.[79] In contrast, isolates of HCoV-OC43 from the same geographic area but isolated in different years show considerable sequence variations with emergence of novel recombinants.[237] The ability of HCoV-OC43 to tolerate mutations probably accounts for its ability to grow in mouse cells and infect the mouse brain as well as its ability to cross species (see *Epidemiology*). In contrast, HCoV-229E does not readily cross species and does not infect mice. Even in mice that are transgenic for expression of the HCoV-229E host cell receptor (hAPN), the virus does not readily grow or cause clinical disease.[236]

Two new HCoVs were isolated from the respiratory tracts of patients in the post-SARS era. HCoV-NL63, which causes mild respiratory disease,

displays homology with HCoV-229E. Phylogenetic analyses suggest that HCoV-NL63 and HCoV-229E diverged approximately 1,000 years ago.[350] A novel feature of HCoV-NL63 is that, unlike HCoV-229E, HCoV-NL63 does not use hAPN as a receptor. Rather, infection of cells is mediated by angiotensin-converting enzyme 2 (ACE2), the same molecule that is used by SARS-CoV, an unrelated betacoronavirus.[172,258] However, unlike SARS-CoV, HCoV-NL63 does not use cathepsin L or require endosomal acidification to infect ACE2-expressing cells[180] and does not cause severe respiratory disease. HCoV-HKU1, isolated from an adult patient in Hong Kong with pneumonia, also generally causes mild respiratory disease.[458]

A role for HCoVs in the etiology of the human disease MS was postulated, based on the ability of murine coronaviruses to cause chronic demyelinating diseases. Coronavirus-like particles have occasionally been detected in the CNS of patients with MS. HCoV-229E RNA was detected in about 44% (40 of 90) of human brains tested, with similar frequencies in brains from MS patients and patients who died from other neurological diseases or normal control subjects.[22] HCoV-OC43 sequences were detected in 23% (21 of 90) of the brains tested, with 36% incidence in brains from MS patients and 14% in that of controls. HCoV-OC43 has been associated with fatal encephalitis in a severely immunodeficient 11-month-old patient.[296] Together, these results are intriguing, but the role of non–SARS-CoV HCoVs in diseases outside the respiratory tract, especially in CNS diseases such as MS, requires further investigation.

SARS-CoV Infections

SARS-CoV, which causes severe respiratory disease, infects both upper airway and alveolar epithelial cells, resulting in mild to severe lung injury.[332] Virus or viral products are also detected in other organs, such as the kidney, liver, and small intestine, and in stool. Although the lung is recognized as the organ most severely affected by SARS-CoV, the exact mechanism of lung injury is controversial. Levels of infectious virus appear to diminish as clinical disease worsens, consistent with an immunopathological mechanism.[331] However, this conclusion must be tempered because specimens were obtained from nasopharyngeal aspirates, not from the lungs or other organs. The SARS-CoV spike protein may also directly contribute to

disease severity. Administration of the SARS-CoV S protein to mice with preexisting lung injury enhanced disease severity.[223] ACE2 appears to have a protective role in animals with lung injury, and S protein may exacerbate disease by causing its downregulation.

Pathological findings in patients who died from SARS were nonspecific. Cells in the upper airway were initially infected, resulting in cell sloughing but relatively little epithelial cell damage. However, virus rapidly spread to the alveoli, causing diffuse alveolar damage. This was characterized by pneumocyte desquamation, alveolar edema, inflammatory cell infiltration, and hyaline membrane formation (Fig. 10.12). Over time, alveolar damage progressed, eventually resulting in pathological signs of ALI (acute lung injury) and, in the most severe cases, ARDS (acute respiratory distress syndrome). Most notably, multinucleated giant cells, originating either from macrophages or respiratory epithelial cells, were detected in autopsy specimens. Although virus could be cultured from infected patients for several weeks, viral antigen was rarely detected in lung autopsy samples after 10 days postinfection.[314]

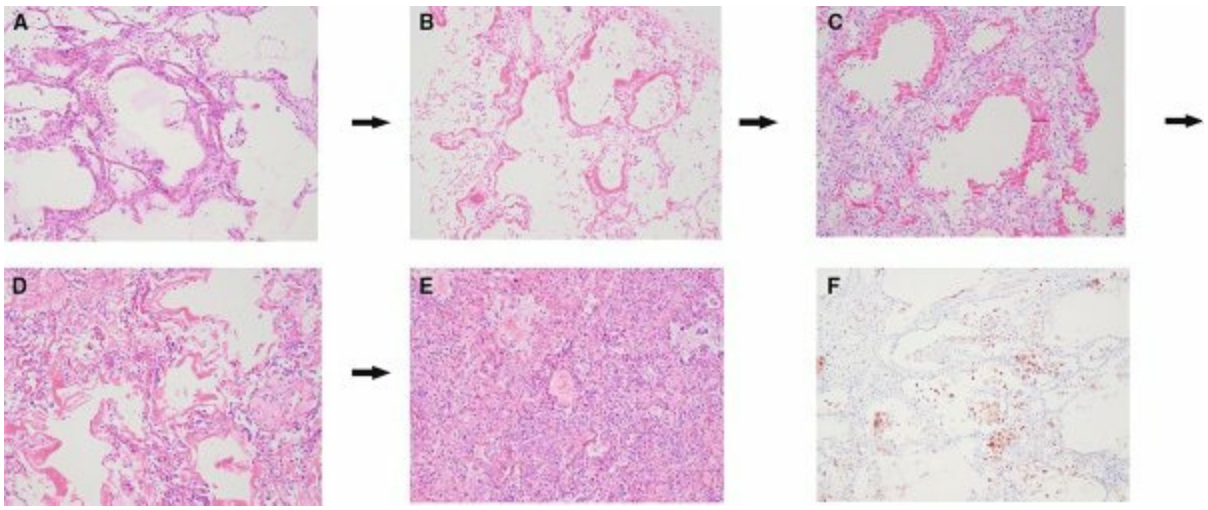

FIGURE 10.12 Pathological changes in lungs of patients with SARS. Lung samples obtained on autopsy were examined for pathological changes following SARS-CoV infection. **A–E:**Hematoxylin and eosin stain showing the progression of SARS pneumonia. Early stages of the SARS infection show edema and

early hyaline membrane formation (**A**), hyaline membrane formation (**B**), and increased inflammatory cell infiltration and pneumocyte hyperplasia (**C**). As the disease progresses, fibrotic changes become apparent (**D**). Late manifestations include obliteration of the alveolar volume by fibrous tissue, reactive pneumocytes, and inflammatory cells (**E**). **F:** Viral antigen is detected most prominently during early stages of the infection in macrophages and alveolar pneumocytes. (Figure kindly provided by Dr. John Nicholls, University of Hong Kong. Magnification: ×100.)

Like other coronaviruses, such as MHV and FIPV, SARS-CoV infects macrophages and dendritic cells, but unlike these two animal coronaviruses, it causes an abortive infection in these cells.[76,242,397] Several proinflammatory cytokines and chemokines, such as IP-10 (CXCL10), MCP-1 (CCL2), MIP-1a (CCL3), RANTES (CCL5), MCP-2 (CCL8), TNF, and IL-6, are expressed by infected dendritic cells; many of these molecules were also expressed at elevated levels in the serum of SARS-CoV–infected patients.[76] Lymphopenia and neutrophilia were detected in infected patients and were likely to be primarily cytokine driven.[76] A potentially confounding factor is that many SARS patients were treated with corticosteroids,[400] and steroids are a well-known cause of lymphopenia.

Understanding the mechanism of SARS-CoV–mediated human lung disease is impossible to address in patients since SARS has not recurred since 2004, necessitating the use of animal models. SARS-CoV infects several species of animals, including mice, ferrets, hamsters, cats, and monkeys,[406] but most of these animals develop either mild or no clinical disease, making them not useful for studies of lethal SARS. More useful for these studies was the isolation of rodent-adapted strains that cause severe disease in some strains of mice and rats.[359] Importantly, rodent-adapted strains cause an age-dependent increase in clinical severity,[360,480] paralleling the age-dependent severity observed in infected patients.[126] Animals with severe disease show pathological signs of ALI, increased levels of proinflammatory chemokines and cytokines, and diminished T-cell responses. These observations suggest

that immune dysregulation contributes to severe disease, paralleling pathological changes observed in infected humans. Elevated levels of type I interferon (IFN-I) were found in SARS patients with poor outcomes in the 2003 epidemic,[52] but its role in outcomes was not clear. However, mice infected with a lethal dose of SARS-CoV were protected if IFN-I expression was genetically deleted or if IFN signaling was blocked with antibody, suggesting that IFN-I contributed to severe disease.[70]

MERS-CoV Infections

MERS-CoV was first isolated in 2012 from a patient in the Kingdom of Saudi Arabia (KSA) with severe human respiratory disease.[474] MERS cases are confined to the Arabian peninsula and to travelers from the Middle East. In a notable example of the latter, a single patient who contracted MERS on the Arabian peninsula returned to South Korea, infecting 186 patients.[81] In endemic areas, MERS-CoV appears to be periodically introduced into human populations from infected camels, which are considered the major if not the only zoonotic source of infection.[366] Similar to SARS, the infection begins in the URT with spread to the lower airway. Patients are most contagious after developing pneumonia. Less is known about pathological changes in MERS patients when compared to those with SARS, in large part because only a few autopsies have been performed.[12,311] Like SARS, the mortality rate in MERS is very high, but unlike SARS, a fraction of infected patients develop subclinical disease.[20,183] As in the SARS epidemic, health care workers taking care of MERS patients are at high risk of developing infection. The number of cases decreased substantially as improved infection control measures were introduced in hospitals and emergency rooms.[183]

MERS-CoV primarily infects airway and epithelial cells and poorly infects human macrophages and conventional and plasmacytoid dendritic cells (pDCs). Infection of macrophages and dendritic cells results in a strong inflammatory molecule response.[373,422,482] Furthermore, MERS-CoV actively replicates in activated human T cells,[84] which may contribute to poor immune responses and severe outcomes. Because of the small number of autopsy specimens, animal models of MERS are required for pathogenesis studies. MERS-CoV causes mild disease in experimentally infected camels, macaques, and rabbits but does not infect mice or rats.[65] Notably,

experimentally infected camels develop rhinitis with high virus titers,[2] consistent with their role in camel–camel and camel–human transmission. Mice become susceptible to MERS-CoV infection if the human receptor is provided exogenously, either by transfection with adenovirus expressing hDPP4,[479] by transgenic expression of hDPP4,[4] or by replacement of mouse DPP4 with human DPP4 or a chimeric molecule.[85,259,328] Serial virus passage resulted in a lethal disease, making these mice useful for pathogenesis studies.[85,259] Similar to SARS-CoV–infected mice, mice with MERS developed pathological evidence of ALI, proinflammatory molecule expression, and diminished T-cell responses.

Immune Response and Viral Evasion of the Immune Response

As in most viral infections, both the innate and adaptive arms of the immune response are required for successful virus clearance and must be appropriate to minimize bystander immunopathological damage. One of the first steps in the host immune response to a coronavirus infection is the production of type 1 IFN (IFN-α/β). pDCs are the source for most IFN-α/β produced in coronavirus-infected hosts, although other cells, such as macrophages, also express IFN.[62,361] pDC expression of IFN is mediated by signaling through a TLR7- and IRF7-dependent pathway. The importance of IFN signaling in the initial immune response to coronaviruses was shown using mice defective in expression of the IFN-α/β receptor (IFNAR$^{-/-}$).[61,189] Infection of IFNAR$^{-/-}$ mice with mildly virulent strains of MHV results in rapid and uniformly fatal diseases. Additionally, the importance of the IFN response is also evidenced by the multiple IFN evasive mechanisms that coronaviruses employ, as described below. While the importance of the IFN response is well established, less is known about which specific IFN-stimulated genes (ISGs) are most critical for protection. RNase L, a well-described ISG, has a protective role in mice infected with MHV[478] or MERS-CoV.[416]

Once the initial IFN response is induced, virus clearance requires expression of proinflammatory cytokines and chemokines and their receptors, such as CCL2, CXCL9, CXCL10, and CCL3, to mediate T-cell and macrophage trafficking to sites of infection.[37] Infection of the CNS also requires breakdown of the blood–brain barrier, which is partially neutrophil-

dependent. In the absence of neutrophils or of neutrophil chemoattractants, such as CXCL1 and CXCL2, breakdown does not occur, resulting in more severe disease. A robust T-cell response is required for destruction of infected cells and clearance of infectious virus. T-cell responses are poor in felines with progressive FIP (Fig. 10.11) and in mice with severe SARS or MERS.[108,259,481] Virus is not cleared in MHV- or SARS-CoV–infected mice that lack T cells, again demonstrating the importance of the response in clearance.[381,461] Both CD4 and CD8 T-cell epitopes have been identified in mice infected with MHV, SARS-CoV, and MERS-CoV and in SARS patients. The vast majority of epitopes are located on the N, M, and S proteins.[75,266,336,338,479] Once virus has been cleared, the proinflammatory response must be controlled to prevent immunopathology. In MHV-infected mice, regulatory CD4 T cells, characterized by Foxp3 expression, are important for dampening a potentially pathogenic immune response.[418] IL-10, another anti-inflammatory factor important for minimizing immunopathological changes in MHV-infected mice, is expressed predominantly by virus-specific CD4 and CD8 T cells in the infected brain.[419] T cells are responsible for initial virus clearance, but an effective antivirus antibody response is required to prevent virus recrudescence.[263] Similarly, a robust neutralizing antibody response was detected in survivors during the 2002–2003 SARS outbreak[52] and in MERS survivors who had severe disease.[13]

Coronaviruses use several approaches, both active and passive, to evade the host IFN response and thereby establish a productive infection (Table 10.4). Coronaviruses replicate in double-membraned vesicles (DMVs) (Fig. 10.7), which may shield viral RNA from recognition by intracellular sensor molecules, such as RIG-I, MDA5, and TLR3. Thus, in fibroblasts or conventional DCs infected with MHV or SARS-CoV, no IFN is induced.[434,484] However, the IFN response does not appear to be actively blocked in these cells, because infection with *Sendai virus* or exposure to poly I–C induces IFN. In some cells, such as macrophages, microglia, and oligodendrocytes, coronaviruses induce an IFN response by signaling through MDA5 and, in oligodendrocytes, RIG-I.[256] To counter IFN induction through activation of MDA5, all coronaviruses express a 2′-*O*-methyltransferase (nsp16, see *Expression of the Replicase–Transcriptase Complex*). In the absence of 2′-*O*-methylation, viral RNA induces a potent MDA5-dependent

IFN response, which limits replication in wild-type animals but not in those deficient in IFNAR expression[491] (Table 10.4). Additionally, SARS-CoV, but not MHV PLpro inhibits, inhibits IFN induction by antagonizing IRF3 and NF-*k*B function.[124,142] Another component of nsp3, ADP-ribose-1″-monophosphatase (also termed macrodomain 1), prevents IFN induction by countering host-derived ADP ribosylation.[141] Nsp15, an endoribonuclease encoded by all coronaviruses, probably has a role in virus replication but also inhibits MDA5 induction and IFN expression.[123,212]

TABLE 10.4 Coronavirus proteins with immunoevasive properties

Protein	Virus Source[a]	Function	References
nsp1	MHV, SARS-CoV, SARSr-BatCoV Rp3, BatCoV HKU4, BatCoV HKU9, TGEV, MERS-CoV	1. Suppresses host protein expression through direct inhibition of translation or by promoting degradation of host mRNA, including IFN mRNA	213,298
		2. Inhibits IFN induction and signaling	492
nsp3 (PLpro)	SARS-CoV, HCoV-NL63, MHV	Blocks IRF3 activation and NF-κB signaling	246
nsp3 (Mac2, Mac3, PLpro)	SARS-CoV, HCoV-NL63, MERS-CoV	Blocks p53 action	246
nsp3 (ADRP)	SARS-CoV, HCoV-229E, MHV	1. Interferes with IFN-induced antiviral activity 2. Enhances host proinflammatory cytokine expression	246,141
nsp5	PDCoV	Inhibits IFN induction	485
nsp14	MHV, TGEV	Interferes with IFN-induced antiviral activity	32,55
nsp15	MHV, HCoV-229E	Evades RNA sensing	123,212
nsp16	MHV	Evades MDA5 activation, evades IFIT recognition	491,103
ORF 3b protein	SARS-CoV	Inhibits IFN synthesis and signaling	220
ORF 6 protein	SARS-CoV	Inhibits STAT1 nuclear translocation	143
ORF 5a protein	MHV	Interferes with IFN-induced antiviral activity	218
ORF 7 protein	TGEV	Interferes with PKR and 2′-5′ OAS/RNase L activities	100
ORF 4a protein	MERS-CoV	Binds dsRNA and inhibits IFN induction, inhibits stress granule formation	391,299,353
ORF 4b protein	MERS-CoV	Inhibits NF-κB signaling, IFN induction, and RNase L activation	416,53,468
ORF 5 protein	MERS-CoV	Modulates NF-κB signaling	286
NS6 protein	PDCoV	Inhibits IFN induction	138
N protein	MHV, SARS-CoV, MERS-CoV	Inhibits IFN induction; interferes with 2′-5′ OAS/RNase L activity	213,125,178
M protein	SARS-CoV, MERS-CoV	Inhibits IRF3 activation	271,389
ORFX protein	SARSr-CoV WIV1	Inhibits IFN induction	475

[a]All virus abbreviations as in Table 29.1.

Once IFNs are expressed, they bind to IFNAR, resulting in the upregulation of a large number of ISGs. Several coronaviral proteins inhibit either IFN signaling or specific ISGs (Table 10.4). In addition to inhibiting IFN

induction, the nsp16 2′-*O*-methyltransferase counters the ability of IFN-induced proteins IFIT1 and IFIT2 (also called ISG56 and ISG54) to inhibit translation of viral mRNA.[103] N protein inhibits IFN signaling, as do SARS-CoV, MHV, TGEV and MERS-CoV nsp1, and SARS-CoV ORF3b and ORF6 proteins. MERS-CoV ORF4a and ORF4b inhibit IFN expression.[213] The mechanism of action of some of these proteins has been elucidated. Nsp1 enhances host cell mRNA degradation and inhibits host cell protein synthesis, with specific effects on IFN signaling.[213] The karyopherin complex is required for nuclear import of STAT1, a critical component of the IFN signaling pathway, as well as the import of many other host proteins. SARS-CoV ORF6, by binding karyopherin-α2, sequesters karyopherin-β1 in the cytoplasm, indirectly inhibiting nuclear translocation of STAT1.[213] MERS-CoV 4b, by binding karyopherin-α4, inhibits NF-kB transport into the nucleus,[53] whereas ORF 4a binds to PACT, inhibiting MDA5 and RIG-I activation.[391] It should be noted that the role of some of these proteins in the natural infection requires additional study because many of them were analyzed as isolated proteins in transient expression assays. Further, in MERS-CoV–infected camels and humans, some of these immunoevasive genes are deleted without apparent changes in virulence.[83,330,463]

EPIDEMIOLOGY

Human Coronaviruses Other Than SARS-CoV and MERS-CoV

Four known coronaviruses, HCoV-OC43, HCoV-229E, HCoV-NL63, and HCoV-HKU1, are endemic in human populations. HCoV-OC43 and HCoV-229E cause up to 30% of all URT infections, based on several prospective studies.[208,284,429] The variable range of detection reflects year-to-year variability, detection methods, season, and age of subjects. These studies also suggest that peak activity occurs every 2 to 4 years.[145,294] In temperate climates, infections occur predominantly in the winter and early spring. HCoV-OC43 and HCoV-229E have also been associated with severe pneumonia in neonates and aged populations, especially those with underlying illnesses, such as chronic obstructive pulmonary disease or those

requiring intensive care.[155,429,439] The high rate of human coronavirus infections early in life and the pattern of infections during outbreaks demonstrate that HCoVs are efficiently transmitted in human populations, most likely via large and, to a lesser extent, small droplets. Infection may also occur via contact with contaminated surfaces.[41] Serologic studies suggest that infection with HCoV-229E and HCoV-OC43 frequently occurs in young children and then repeatedly throughout life.[191,202] Neutralizing antibodies against HCoV-OC43 or HCoV-229E have been detected in about 50% of school-age children and up to 80% of adults.[202,284,345]

HCoV-NL63 and HCoV-HKU1 also have worldwide distributions, causing up to 10% of respiratory tract infections.[1,349] Initial reports suggested that HCoV-NL63 was associated with severe respiratory disease but subsequent population-based studies showed that most patients developed mild disease, similar to those infected with HCoV-229E or HCoV-OC43.[429] HCoV-NL63 is also an important etiological agent of acute laryngotracheitis (croup).[349] HCoV-HKU1 was initially identified in an elderly patient with severe pneumonia, but subsequent studies indicated that it is associated with both mild and severe respiratory infections.[349,458] HCoV-NL63 and HCoV-229E may have evolved from bat coronaviruses.[413]

Severe Acute Respiratory Syndrome

During the 2002–2003 epidemic, SARS-CoV was isolated from several exotic animals, including Himalayan palm civets (*Paguma larvata*) and raccoon dogs (*Nyctereutes procyonoides*), in wet markets in Guangdong Province in China[161] (Fig. 10.13). Subsequent investigations showed that SARS-CoV could not be detected in these animals in the wild but SARS-related coronaviruses (SARSr-CoV) could be isolated from wild bats in China[146,179] (Table 10.1). Bats are now considered to be the ultimate source for SARS-CoV, with probable infection of human populations occurring after initial adaptation to animals in Chinese wet markets. The isolation of bat SARS-like coronaviruses that use ACE2, the same receptor as used by SARS-CoV, provides strong support for this conclusion.[146]

FIGURE 10.13 SARS-CoV spread from infected bats to infect humans in wet markets in Guangdong Province, China. SARS-related coronaviruses were detected in horseshoe bats and other bat species in China. The virus spread to human populations, likely animal handlers, in wet markets in Guangdong Province. Spread occurred either indirectly, via infection of exotic animals such as Himalayan palm civets, or directly, with subsequent human transmission to Himalayan palm civets and other exotic animals. This transmission occurred more than once, because a fraction of

the animal handlers was positive for anti–SARS-CoV antibody.[161] In one episode, a physician taking care of an animal handler became infected. He then flew to Hong Kong and stayed at Hotel M, where he inadvertently infected several other people staying at the hotel, probably via superspreading events. These infected individuals then flew to other countries, resulting in the international outbreak.

Serologic studies demonstrated that SARS-CoV did not circulate to a significant extent in humans prior to the outbreak in 2002–2003.[66,247] However, some persons working in wild animal wet markets in China had serologic evidence of a SARS-CoV–like infection acquired before the 2003 outbreak but reported no SARS-like respiratory illness.[161] Thus, virus may have circulated in these wild animal markets for a few years, with the SARS outbreak occurring only when a confluence of factors facilitated spread into larger populations. Although non-primate animals were the original source of SARS, its global spread occurred by human-to-human transmission. Transmission occurred through close contact, that is, direct person-to-person contact, fomites, or infectious droplets, and probably aerosols in some instances.[332] Because transmission usually only occurred after onset of illness and most efficiently after the patient was sufficiently ill to be hospitalized, most spread occurred in household and health care settings but infrequently in other settings.[334] A large number of susceptible persons were infected in superspreading events, but only a minority of infected individuals were involved in this type of spread[265,358] (Fig. 10.14). Superspreading events, which occur when a single individual infects multiple susceptible contacts, may have resulted from high virus burdens or a tendency for these individuals to aerosolize virus more efficiently than most infected persons. Most infected individuals spread the virus to only one or a few susceptible persons, suggesting that virus spread was relatively inefficient. Since the SARS outbreak was controlled in June 2003, only 17 cases of SARS were subsequently confirmed, and none of these occurred after June 2004.[260,261] Thirteen of these 17 cases resulted from laboratory exposures, including 7 secondary cases associated with one of the cases.

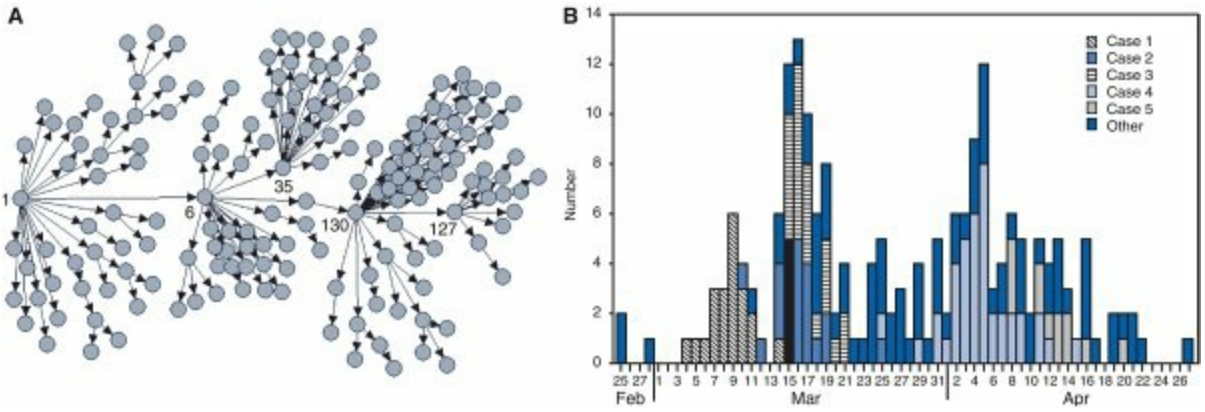

FIGURE 10.14 Role of superspreading events in SARS-CoV epidemics. SARS-CoV spread in Singapore in 2003, illustrated here, via superspreading and non-superspreading events. Most infected persons transmitted virus to less than five susceptible contacts. However, in a few instances, infected individuals were highly contagious, resulting in infection of larger numbers of contacts. The basis for superspreading events is not known but likely is a manifestation of larger virus burdens in a few infected patients. **A:** Probable cases of SARS by reported source of infection. **B:** Number of probable cases of SARS, by date of onset of fever and probable source of infection. (Originally published in Morbidity and Mortality Report, CDC, Atlanta, GA.)

Middle East Respiratory Syndrome

MERS-CoV has been isolated from the majority of camels in the Arabian peninsula, Africa, and parts of Asia[139] (Fig. 10.15). In addition, banked camel sera from the early 1980s show evidence of prior MERS-CoV infection. However, human infections have been identified primarily, if not solely, on the Arabian peninsula and even at this location, only since 2012. This difference in prevalence of camel and human infection remains unexplained and may relate to differences in human–camel interactions in countries on the Arabian peninsula compared to elsewhere. MERS-CoV likely originated in bats since MERS-like CoV have been detected in bats in Africa and elsewhere.[94,319] MERS-CoV itself has not been isolated yet from any bat

species, reflecting, perhaps, its transmission to camels several years ago and evolution within camel populations. MERS-CoV may be continuing to evolve in camels, since there are distinct clades of MERS-CoV isolated in Africa and the Arabian peninsula.[83,366] Most strikingly, MERS-CoV isolated from camels in West Africa are variably deleted in ORFs3, 4a and 4b,[83] indicating that these genes, which are believed to encode proteins involved in immune evasion, are not required for virulence in camels. Camels in the KSA are largely seropositive for MERS-CoV, with virus maintained by infection of juvenile camels, which become susceptible after maternal antibody has waned. High antibody titers in adult camels suggest that they are periodically exposed to MERS-CoV, boosting antibody titers. Humans in contact with camels have higher MERS-CoV–specific antibody titers than the general population but do not have clinical signs of MERS.[297] In the early years of the KSA outbreak and in the 2016 Korean outbreak, a majority of patients acquired MERS in nosocomial settings.[20,183] This was particularly striking in the Korean outbreak, in which a single traveler from the Middle East sought medical attention in several hospital emergency rooms before a diagnosis of MERS was made.[81] The delay in diagnosis resulted in infection of 186 individuals, with a 20% mortality. Increased recognition of the infection and better infection control measures have decreased the number of hospital-acquired infections so that at least 30% of patients are now considered primary.[91] However, only 50% of these patients have a history of camel contact. MERS-CoV is not very contagious in community settings ($R_0 < 1$) but spreads readily in hospitals to patients with underlying conditions such as chronic pulmonary or cardiac disease, renal failure, or an immunocompromised state.[56,82] One possible explanation for these disparate results is that MERS-CoV is circulating at low levels in some populations and that clinical cases occur occasionally, most often if patients with comorbidities become infected. Although not proven, this would be consistent with the lack of camel contact described by many primary cases. Within hospitals, virus is transmitted via contact and during aerosol-generating procedures.[11] Fomite or aerosol spread may also occur since MERS-CoV RNA (and virus in some studies) can be detected in the air and on environmental surfaces in hospitals for several days.[38,209]

FIGURE 10.15 Global distribution of human and dromedary camel MERS cases.[139] *Black asterisks*—countries with human and camel MERS cases. *Red asterisks*—countries with camel cases only. *Green asterisks*—countries with only human MERS cases. Note that MERS-CoV was detected in camels in the Canary Islands, not in mainland Spain.

Remarkably, given the recent transmission to humans, there is little evidence for evolution of MERS-CoV in human populations, unlike SARS-CoV, which underwent extensive mutation as it adapted to humans.[80,98] Additionally, deletions in ORFs 3, 4a, 4b, and 5 have been detected in patients,[330,463] suggesting that these immune evasion genes are not critical for human disease. Further, viruses isolated from some patients in Korea were mutated in the S glycoprotein, resulting in lower binding affinity for the DPP4 receptor.[210] Surprisingly, decreased affinity did not appear to affect clinical disease severity.

Genetic Diversity of Coronaviruses

The SARS and MERS outbreaks demonstrated the ability of coronaviruses to

cross species. Initially predicted from studies of coronavirus-infected cultured cells,[30] the ability of coronaviruses to cross species was also demonstrated when the betacoronaviruses HCoV-OC43, porcine hemagglutinating encephalomyelitis virus (PHEV), and BCoV were analyzed[435] (Fig. 10.16). It is estimated that PHEV diverged from HCoV-OC43 and BCoV 100 to 200 years ago, while HCoV-OC43 and BCoV diverged about 100 years ago. More recently, BCoV has crossed species to infect many ruminants, including elks, giraffes, and antelopes.[5] Other phylogenetic studies suggest that the porcine alphacoronavirus TGEV resulted from cross species transmission of a canine coronavirus.[269] In other examples, a bat coronavirus, HKU2, was shown to cross species to cause gastroenteritis in pigs (swine acute diarrheal syndrome [SADS]),[483] and a virus similar to HCoV-229E was isolated from camels.[93] PDCoV, a cause of swine diarrhea, is classified as a deltacoronavirus, a genus comprised of avian viruses. PDCoV appeared to cross from avian to mammalian species, using APN as a receptor and raising the possibility that it could similarly cross species to infect a variety of species, including humans.[253]

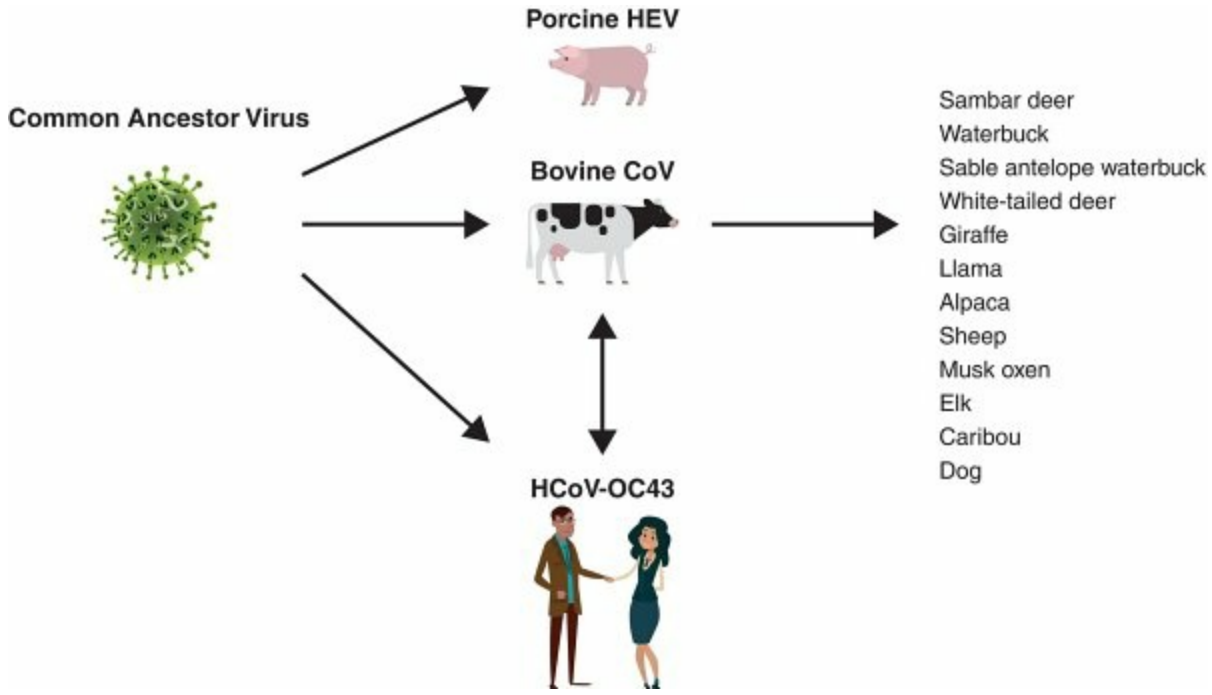

FIGURE 10.16 Coronaviruses mutate and recombine to cross species barriers. Phylogenetic analyses indicate that HCoV-OC43,

BCoV, and porcine hemagglutinating encephalomyelitis virus (PHEV) shared a common ancestor and diverged about 200 years ago. More recently (100–130 years ago), HCoV-OC43 and BCoV diverged, but it is not known whether BCoV infected human populations or HCoV-OC43 crossed species barriers to infect bovids. BCoV then spread to many ruminants and to dogs, probably via contact with infected domesticated cows.

In addition to their ability to cross species, coronaviruses readily undergo recombination (see *Viral RNA Synthesis*). Recombination events between canine (CCoV-I) and feline (FCoV-I) coronaviruses and an unknown coronavirus resulted in the appearance of two novel viruses (CCoV-II and FCoV-II).[269] In another illustration, new strains of IBV have been detected in chicken populations and appear to have resulted from recombination between circulating vaccine and wild-type IBV strains.[221] This propensity for recombination has raised concerns about the use of live attenuated coronavirus vaccines (see *Prevention*).

CLINICAL FEATURES

Human Coronaviruses Other Than SARS-CoV and MERS-CoV

HCoVs cause respiratory disease, including its most severe manifestations, SARS and MERS. Coronaviruses have occasionally been implicated in human enteric disease, particularly in newborns, with virus identified using electron microscopy because culture of infectious virus has been unsuccessful.[206] EM detection of coronavirus particles is not considered conclusive because other particles in stool specimens can have similar morphology to coronaviruses. However, RT-PCR assays designed to detect coronavirus RNA sequences in pathological specimens should clarify the role of coronaviruses in enteric diseases.

Clinical features of respiratory infections in humans follow two distinct

patterns, one for non–SARS-CoV/MERS-CoV (i.e., HCoV-229E, HCoV-NL63, HCoV-OC43, HCoV-HKU1) and one for the zoonotic coronaviruses, SARS-CoV and MERS-CoV. HCoV-229E and HCoV-OC43 were extensively characterized in volunteer studies in the 1960s.[284] Human volunteers inoculated intranasally with respiratory coronaviruses developed symptoms that included fever, headache, malaise, chills, rhinorrhea, sore throat, and cough with peak infection observed 3 to 4 days following infection. About half of the volunteers challenged with virus developed illness, and approximately 30% were asymptomatically infected, as indicated by detection of virus in the URT. Symptoms lasted for a mean of 7 days, with a range of 3 to 18 days. Natural infection in both adults and children is also usually associated with a common cold–like illness.[284] Natural infection is probably acquired in a fashion similar to that for many other respiratory viruses (i.e., inoculation of infectious secretions from infected persons or fomites onto mucous membranes of the URT or inhalation of infectious droplets), with primary infection of ciliated epithelial cells in the nasopharynx.[3] Destruction of these cells, combined with exuberant production of chemokines and cytokines by resident and infiltrating cells, results in signs and symptoms of clinical illness.

Non–SARS-CoV/MERS-CoV infections are occasionally associated with lower respiratory tract disease in children and adults.[155,409,429,439] One caveat is that coronaviruses are also sometimes detected in well, control patients, and, thus, the presence of virus may not be etiologically related to the illness. Studies using polymerase chain reaction (PCR) to detect viral RNA in middle ear fluids suggest that coronaviruses, like other respiratory viruses, can cause otitis media.[342] HCoV-NL63 and HCoV-HKU1 have also been detected in persons with acute upper and lower respiratory tract illness,[1,166,349] and HCoV-NL63 is associated with croup in children under the age of 3.[426] Studies of natural infection and volunteer studies showed that reinfection with coronaviruses is common, indicating that infection does not induce stable protective immunity.[191,284] For example, previously infected volunteers developed symptomatic disease if infected 1 year later with the same strain of HCoV-229E.[356]

SARS-CoV Infections

In contrast to the mild illness usually associated with human coronavirus infections, SARS-CoV nearly always resulted in a serious lower respiratory tract illness that required hospitalization, often in an intensive care unit (up to 20% of infections)[332] (Fig. 10.17). In the 2002–2003 epidemic, approximately 8,000 individuals were infected, with an overall mortality rate of 10%. Disease severity increased proportionally to age. Thus, no mortality occurred in patients less than 24 years old, but about 50% of infected individuals greater than 60 years succumbed to the infection. Mortality was also greater in patients with underlying disease. No clinical manifestations distinguished SARS from other severe respiratory diseases.[42,334] Illness usually had an onset of 4 to 7 days, although occasionally an incubation period of 10 to 14 days was observed. Disease was characterized by systemic symptoms such as fever, malaise, and myalgias. Unlike many other respiratory tract infections, URT signs and symptoms were not common. The first lower respiratory tract symptoms (usually a nonproductive cough and shortness of breath) and concomitant abnormalities on radiological examination developed several days after onset of systemic symptoms.[331] Respiratory symptoms were often accompanied by evidence of involvement of other organ systems. Virus particles and RNA were detected in several organs including the gastrointestinal tract, kidneys, and brain.[158] Thus, while diarrhea occurred at disease onset in less than 25% of patients, up to 70% developed gastrointestinal disease during the course of the illness. Most patients developed abnormal liver function tests and lymphopenia with a substantial drop in both CD4 and CD8 T-cell numbers.[102] Patients, generally those greater than 50 years of age or who had underlying disease, often had progressive respiratory failure leading to ARDS and death.[334,354] In these patients, lymphocyte and platelet counts remained abnormally low, while neutrophilia, presence of infectious virus or viral RNA in clinical specimens, and elevated proinflammatory cytokines for prolonged periods of time were common features. Asymptomatic or mild illness was uncommon.[171] Most survivors of SARS-CoV infection achieved full recovery, although pulmonary function abnormalities sometimes took months to subside,[464] and some had persistently abnormal pulmonary function.

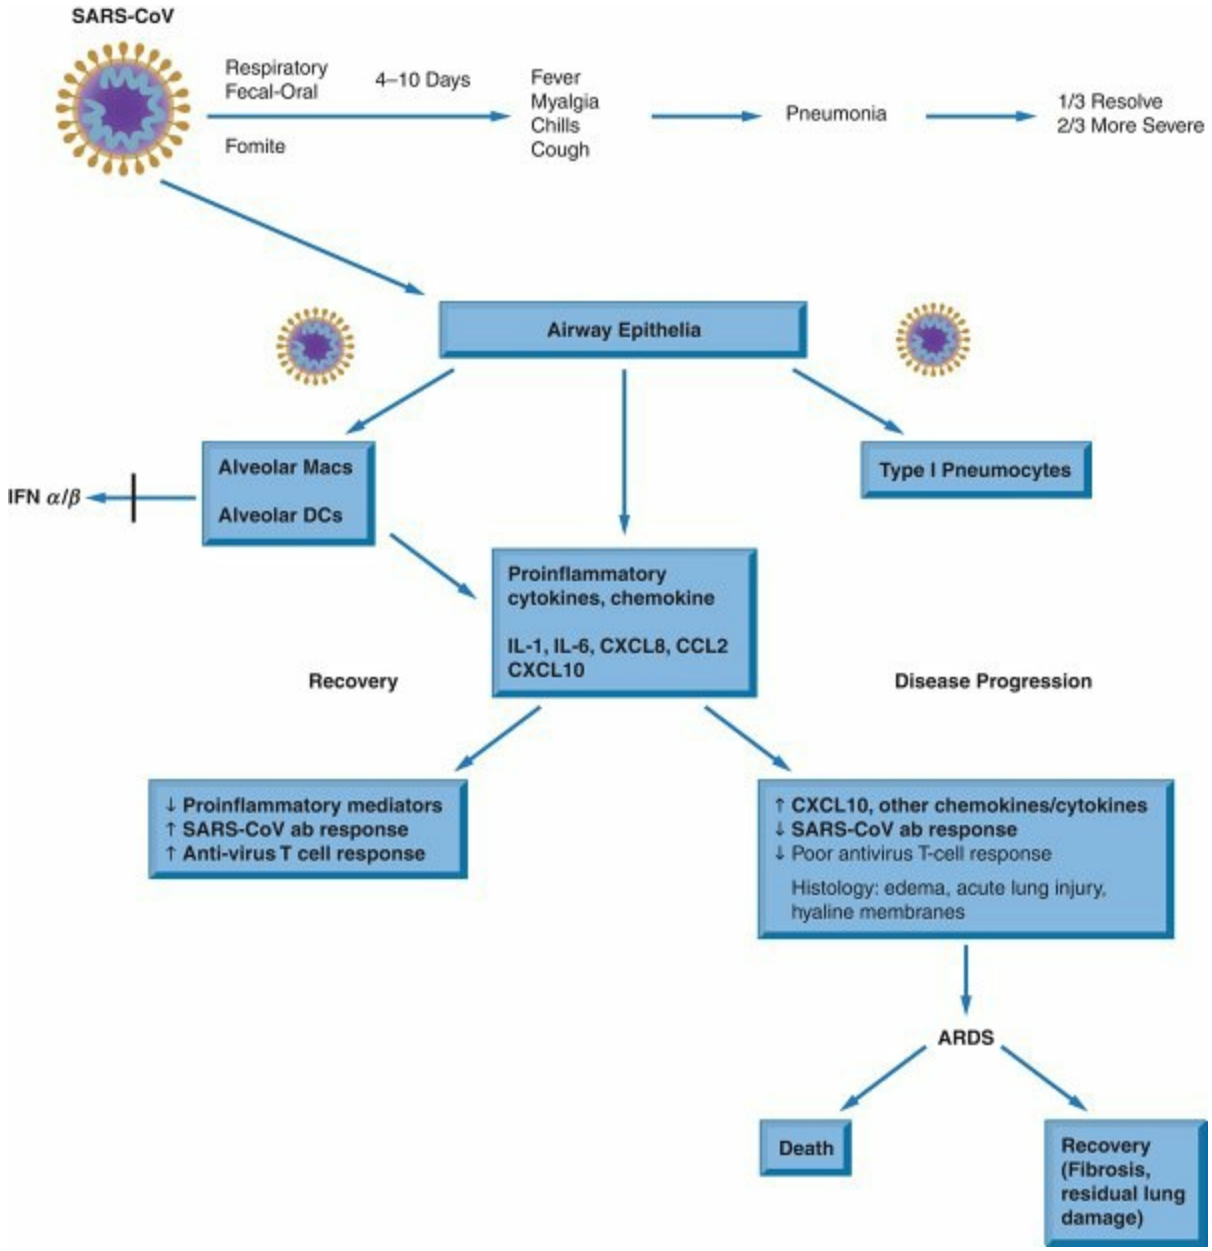

FIGURE 10.17 Clinical disease in patients infected with SARS-CoV. SARS-CoV spread to susceptible individuals via respiratory and fecal–oral routes and, less commonly, if at all, via fomites. Virus replication was initiated in the upper airway epithelial cells, based primarily on animal studies and *in vitro* studies using primary cultures of airway epithelial cells. Virus subsequently spread to the lower respiratory tract, with infection of type 1 pneumocytes and macrophages and dendritic cells most prominent.

The infection of the latter two cell types was abortive, resulting in production of proinflammatory cytokines and chemokines such as CXCL10 and CXCL8 but not type I IFN. In patients who recovered, expression of proinflammatory cytokines diminished, and robust antivirus antibody responses were detected. In patients who developed progressively more severe disease, cytokine production continued, and patients remained lymphopenic without developing an effective anti–SARS-CoV antibody response. Some of these patients died and significant long-term morbidity was found in many of the survivors.

MERS-CoV Infections

Like SARS-CoV, MERS-CoV initiates infection via the respiratory tract. The spectrum of human disease caused by MERS-CoV ranges from asymptomatic to severe, with an overall mortality of approximately 36%.[183] Older individuals and those with underlying conditions develop the most severe disease. Patients with severe disease develop respiratory failure and multiorgan dysfunction.[19] No specific clinical or laboratory signs distinguish MERS from other respiratory disease so that laboratory-based diagnosis is critical.[20] Health care workers generally develop mild disease in large part because most do not have underlying conditions. As was the case with SARS patients, MERS patients usually seek medical attention for nonspecific signs including fever, cough, difficult breathing, and diarrhea. As in SARS patients,[331] peak virus loads occur in the 2nd week of illness.[317] Renal damage is common in MERS patients.[19,63] Kidney damage may result from direct infection, possibly because levels of renal DPP4 are high: coronavirus-like particles were observed on autopsy of a patient with MERS.[12] Patients develop laboratory abnormalities similar to those described for SARS.[489] MERS is relatively uncommon in pediatric patients, and those that become infected generally develop mild disease.[6]

DIAGNOSIS

Most human coronavirus infections, other than SARS and MERS, are not diagnosed because they cause mild, self-limited upper respiratory disease, and no specific therapy is available. Diagnosis is laboratory-based because coronavirus infections cannot be distinguished clinically from other causes of URT infections, such as rhinoviruses. However, in some clinical settings, such as in hospitalized patients with pneumonia and in epidemiological studies, specific diagnosis is important. Coronavirus infections in animals and humans were initially diagnosed by isolation of infectious virus, by electron microscopy and using serologic assays, with the caveat that some coronaviruses, especially those in the stool, are not easily cultured. HCoV-229E, HCoV-OC43, and HCoV-NL63 can now be grown in tissue culture cells, but HCoV-HKU1 has been grown only in primary human airway epithelial cells.[351] As is now true for many virus infections, reverse transcription (RT)-PCR–based methods and immunofluorescence assays (IFAs) for virus antigen are the gold standards for diagnosis of respiratory coronavirus infections. PCR primers can be designed to be broadly reactive or strain specific, based on primer location and design. Use of these primers in multiplex assays provides a convenient and rapid method of diagnosis.[145,440] With a sensitive system to detect the PCR amplicon (e.g., a real-time assay), less than five RNA copies in the reaction mixture can be consistently detected.[134] While EM examination of clinical material contributed to the identification and characterization of many coronaviruses, including SARS-CoV,[127,222,284,333] its use at present is confined to the identification of coronaviruses in patients with enteritis,[206] recognizing that such findings are suggestive but not diagnostic.

A variety of serologic assays have been used to detect URT-associated coronavirus infections, including complement fixation, hemagglutination inhibition (HI) for viruses with an HE protein (i.e., some betacoronaviruses), neutralization and immunofluorescence (IFA) assays, and ELISAs (enzyme-linked immunosorbent assays). These assays use virus lysates, inactivated whole virus, cloned expressed proteins, synthesized peptides, and pseudoviruses (e.g., references[39,439]).

SARS and MERS present a different diagnostic situation. A specific diagnosis is critical to guide clinical management, and the diagnosis of MERS or SARS has public health implications. However, testing should only be considered when, based on the likelihood of an exposure and clinical

features of the illness, infection is plausible. SARS-CoV was initially isolated in tissue culture cells, but during the 2002–2003 epidemic, a combination of serologic and RT-PCR assays, not virus culture, was used to detect and confirm SARS-CoV infection.[332] With very sensitive PCR assays (e.g., a nested or real-time PCR assay) and RNA extraction procedures that increased the amount of specimen available for the assay, the positivity rate in respiratory specimens obtained during the 2nd and 3rd days of illness increased from less than 40% to more than 80% as the epidemic progressed.[346] SARS-CoV N protein ELISAs were positive in 50% to 80% of serum specimens collected during the 1st week of illness and in more than 50% of respiratory and stool specimens collected during the 2nd and 3rd weeks of illness.[239] SARS-CoV–specific antibodies were usually detected by 14 days into the illness, but sometimes not until 4 weeks after infection.[177,181] Whereas RT-PCR provided the best way to make an early diagnosis, serologic assays were important in confirming or ruling out SARS-CoV as the cause of infection. Because serum specimens from persons not infected with SARS during the 2002–2003 outbreak have rarely tested positive for SARS-CoV antibodies,[247] a single serum specimen positive for SARS-CoV antibodies was usually considered diagnostic; a negative test on a serum specimen collected late in the illness (28 days or later after onset of illness) was used to rule out SARS-CoV infection. SARS-CoV–specific antibodies were relatively transient, because they could not be detected 6 years after the epidemic ended.[410]

MERS, like SARS, must be diagnosed rapidly and accurately because its clinical features are indistinguishable from those of other acute respiratory infections.[65] Guidelines for MERS testing and diagnosis have been published.[60,207,448] Only patients with a high suspicion for MERS should be tested, to avoid false-positive results. During the acute phase of the illness, a two-step quantitative RT-PCR assay is used for diagnosis, with confirmation by sequencing of PCR products if only a single RT-PCR assay is positive. Isolation of infectious MERS-CoV requires a BSL3 laboratory, so virus isolation is not generally attempted. Measurements of MERS-CoV–specific antibodies are not used for diagnosis during the acute phase since they are generally not detected until 2 to 3 weeks after infection onset.[128] Antibody measurements are useful for studies of disease prevalence, but MERS-CoV–specific antibodies are not detected or are transient in some patients with mild

or subclinical disease,[13,217] making them insensitive for this purpose. Even in patients with more severe disease, antibody responses appear to rapidly wane. Initially, screening is generally performed by ELISA, with confirmation by IFA and neutralizing antibody measurements. Patients with detectable neutralization titers may be ELISA negative or borderline, indicating that a combination of ELISA and neutralization assays should be considered in high-risk patients.[14] Virus-specific T cells can be detected during the acute phase in patients with severe disease[383] as well as at 6 to 24 months in all survivors of severe MERS and in some with mild disease. Most of the latter were seronegative.[477] Additionally, SARS-CoV–specific T-cell responses were detected for up to 11 years after the epidemic ended,[312] again suggesting that the T-cell response may be a better measure of prior infection. Detection of virus-specific T-cell responses is technically difficult, but their measurement will be useful in some epidemiological studies. Antibody and T-cell measurements must be carefully controlled and standardized to minimize nonspecific responses mediated by cross-reaction with community-acquired coronavirus infections. Serological cross-reactivity has been reported for SARS-CoV, but not for other coronaviruses.[64]

TREATMENT

At present, there are no approved antiviral drugs for human coronavirus infections and therapy is supportive. During the SARS epidemic, most patients were treated with ribavirin and high-dose steroids, based on the belief that the virus would be susceptible to ribavirin and steroids might diminish immune-mediated bystander damage. However, meta-analyses of outcomes showed that neither drug was efficacious and steroid use was associated with worse outcomes.[400] Late in the epidemic, IFN-α, SARS convalescent phase immunoglobulin, and lopinavir plus ritonavir, two proteases licensed for the treatment of HIV, were used to treat patients. Review of all of these therapies concluded that while some showed efficacy in inhibiting SARS-CoV replication in tissue culture cells, none showed a beneficial effect in patients.[400] Similarly, convalescent sera and various combinations of ribavirin, IFN-α, corticosteroids, and lopinavir–ritonavir did not improve outcomes in MERS patients, although corticosteroid use delayed

virus clearance.[21,488] The mechanism of coronavirus replication involves several proteins that are potential targets for antiviral drugs, including the viral RdRp, virus-encoded proteases, host cell receptors used by the virus for entry, and the viral S glycoprotein. Consequently, several antiviral drugs targeting these viral proteins or processes have been developed and evaluated for their ability to inhibit SARS-CoV and MERS-CoV replication *in vitro* and in experimentally infected animals.[65,488] These include protease inhibitors,[18] monoclonal antibodies that inhibit binding to cells, peptides from the heptad repeat regions of the S protein that inhibit receptor binding or fusion, small interfering RNAs, and polymerase and helicase inhibitors.[65,382,488] A second promising category of drug is a set of 3CLpro inhibitors with broad activity against coronaviruses. One drug, GC376, is most active against feline coronaviruses, although it also has activity against other coronaviruses. Remarkably, it was shown to effect recovery of cats with clinical FIPV, a uniformly fatal disease.[211]

PREVENTION

No vaccines are available to prevent human coronavirus infection, but vaccines against domestic animal coronaviruses, such as IBV, PEDV, TGEV, and BCoV, are routinely used to prevent serious disease in young animals. Efforts are ongoing to improve these vaccines and to enhance safety and efficacy while minimizing the likelihood of reversion to a virulent strain and recombination with circulating strains.[367] In addition, several SARS-CoV vaccines have been developed, including inactivated whole virus, live virus vectors expressing single viral proteins, and recombinant proteins and DNA vaccines.[156] Nearly all of these vaccines express the surface glycoprotein and are designed to induce SARS-CoV neutralizing antibodies. For some of these vaccines, efficacy has been demonstrated in animal models. Large stocks of anti–SARS-CoV neutralizing antibody have been prepared and are available for passive immunization of health care workers and other high-risk personnel if SARS recurs.

MERS was identified in 2018 by the WHO and Coalition for Epidemic Preparedness Innovations (CEPI) as a key target for vaccine development, because it may evolve to pose an epidemic threat. Similar to SARS-CoV,

several MERS-CoV–specific vaccines are under development, including subunit, measles, adenovirus, and vaccinia vaccines expressing the S glycoprotein, recombinant proteins, nanoparticles, VLPs, and DNA vaccines.[318] Some of these vaccines are presently in phase I clinical trials. Additionally, several potently neutralizing antibodies have been detected,[65,488] which will be useful for passively immunizing health care workers and other exposed individuals in outbreak settings. Given the small number of MERS patients, it is unlikely that active vaccination will ever be used widely in human populations, unless the virus mutates so that human-to-human transmission is greatly increased. As an alternative strategy, vaccination of camels is considered a more feasible approach. Vaccination with a camel poxvirus expressing the MERS S glycoprotein conferred immunity against both MERS-CoV and camelpox, representing a vaccine candidate with dual efficacy.[163] Use of a poxvirus has the advantage of inducing potent antivirus T-cell as well as antibody responses.

In general, live attenuated vaccines are most effective in inducing protective immune responses against coronaviruses. This has been illustrated elegantly in the case of transmissible gastroenteritis virus (TGEV), an important cause of neonatal diarrhea and death in swine. In the mid-1980s, a naturally occurring, attenuated variant of TGEV, porcine respiratory coronavirus (PRCoV), was identified in pig populations. This virus, which causes mild disease and no enteritis, induces an immune response in pigs that is protective against TGEV and largely eliminated it from infected populations.[241] Live attenuated vaccines induce not only neutralizing antibodies but also antivirus T-cell responses, which are required for virus clearance from infected cells in SARS, MERS, and other coronavirus infections.[71] However, the development of live coronavirus vaccines is challenging.[367] First, in many instances, natural infection does not prevent subsequent infection or disease, so an effective vaccine would need to be superior to immunity induced naturally. Second, the genetic and antigenic variability of coronaviruses and their ability to readily recombine hinder vaccine development. Thus, a vaccine may not provide equal protection to all antigenic variants, and subsequent recombination with vaccine strains could increase the number of different strains circulating in the wild. As an example, recombinants of IBV vaccine and wild-type strains have caused disease outbreaks in chicken flocks.[194] In addition, the finding that

immunization with an S protein–expressing FIPV vaccine led to more severe disease after subsequent natural infection raises the concern that other coronavirus vaccines might also enhance rather than protect from disease.[431] Several strategies to minimize the likelihood of recombination and to attenuate candidate vaccines without compromising efficacy have been recently described. These include engineering viruses with deletions or mutations in nsp1, important for immune evasion[492]; nsp14, critical for RNA genome fidelity; or E protein, important for virus assembly.[156] In other approaches to minimizing recombination of vaccine viruses, the coronavirus genome has been reconstructed, modifying the leader and body TRSs (see *Viral RNA Synthesis*) to eliminate homology with naturally occurring virus sequences.[472]

In the absence of effective vaccines and antiviral drugs, the most important ways to prevent human coronavirus infections are a highly active public health surveillance system and good infection control practices. This was demonstrated unequivocally during the SARS outbreak in 2002–2003, in which sharing of information by national public health agencies and governments and involvement of international agencies such as the World Health Organization resulted in the rapid identification of a coronavirus as the cause of SARS and implementation of measures that minimized spread. At the local level, strict attention to good isolation and infection control practices and identification and management of exposed persons (contacts) minimized human-to-human spread of the virus within a few months of its global spread. The low risk of SARS-CoV transmission before hospitalization and the low rate of asymptomatic infection facilitated the efficacy of these public health measures.[78] The identification of cases of laboratory-acquired SARS-CoV, with subsequent transmission to others after one of these cases,[260,261] reinforces the importance of strict attention to safe laboratory practices. These practices include handling the virus in the appropriate type of facility, using standardized operating procedures and providing appropriate training and medical surveillance programs for staff. Similarly, stringent use of infection control measures and careful screening of patients has diminished nosocomial transmission of MERS-CoV and helped end the Korean outbreak.[183,325]

PERSPECTIVES

Many important problems remain to be resolved in future studies. One critical task will be to develop a detailed understanding of how coronaviruses cross species. Are cross species viral trafficking events rare or common, and what features facilitate or inhibit cross species transmission? While there has been a recent expansion of our knowledge of spike protein interactions with receptors and associated proteases, we cannot yet fully gauge the likelihood of productive adaptation by a spike protein to new receptors and proteases. Such information will be directly relevant to forestalling or coping with the emergence or reemergence of pathogenic HCoVs from ubiquitous bat reservoirs. A second area of crucial importance will be to increase our understanding of the immunopathogenesis of the more severe human and animal coronaviruses and to more precisely define the correlates of immune protection. This will involve delineating the relationship between coronaviruses and their host immune response. Understanding the intricacies in this relationship will inform the effective design and evaluation of vaccines for control of these agents. Third, one of the most exciting areas of future research continues to be addressing the many gaps in our basic knowledge of the intricacies of the coronavirus RTC, the largest and most complicated machinery of RNA synthesis found in any RNA virus. The past few years have seen tremendous advances resulting from structural and biochemical studies, and it is likely that progress will continue apace. A long-term goal is the total *in vitro* reconstitution of coronavirus RNA synthesis, which would definitively identify or confirm the roles of the many viral replicase subunits as well as of putative host factors. It can be expected that studies of this type will reveal fundamental principles common to all RNA-dependent RNA synthesis, in addition to mechanisms unique to the order *Nidovirales*. Knowledge derived from this enterprise will be critical for the design of antiviral drugs to combat diseases caused by existing and emerging coronaviruses.

HISTORY

The known history of filovirus infections spans five decades. Since the first discovery of a filovirus in 1967,[684] 43 natural human filovirus disease (FVD) outbreaks and at least five laboratory-acquired infections (LAIs) have been recorded (Figs. 11.1 and 11.2). Limited clusters of human filovirus infections were likely overlooked in the past.[425] However, improved surveillance and reporting systems together with progress in diagnostic methodologies still support the notion that human filovirus spillover events are extremely rare. Almost all FVD outbreaks have occurred in Equatorial (Western, Middle, and Eastern) Africa,[425] suggesting that filoviruses pathogenic to humans are endemic primarily on the African continent. The majority of FVD outbreaks has been caused by single introductions of a filovirus from an unknown source into the affected human populations with subsequent amplification by direct person-to-person transmission. FVD outbreaks have most commonly occurred in isolated rural areas, rarely involving more than a few hundred people.[425] However, some outbreaks have occurred in urban areas. One outbreak affected almost 29,000 people,[106] demonstrating that filoviruses have the potential for pandemic spread associated with significant socioeconomic impacts.[340]

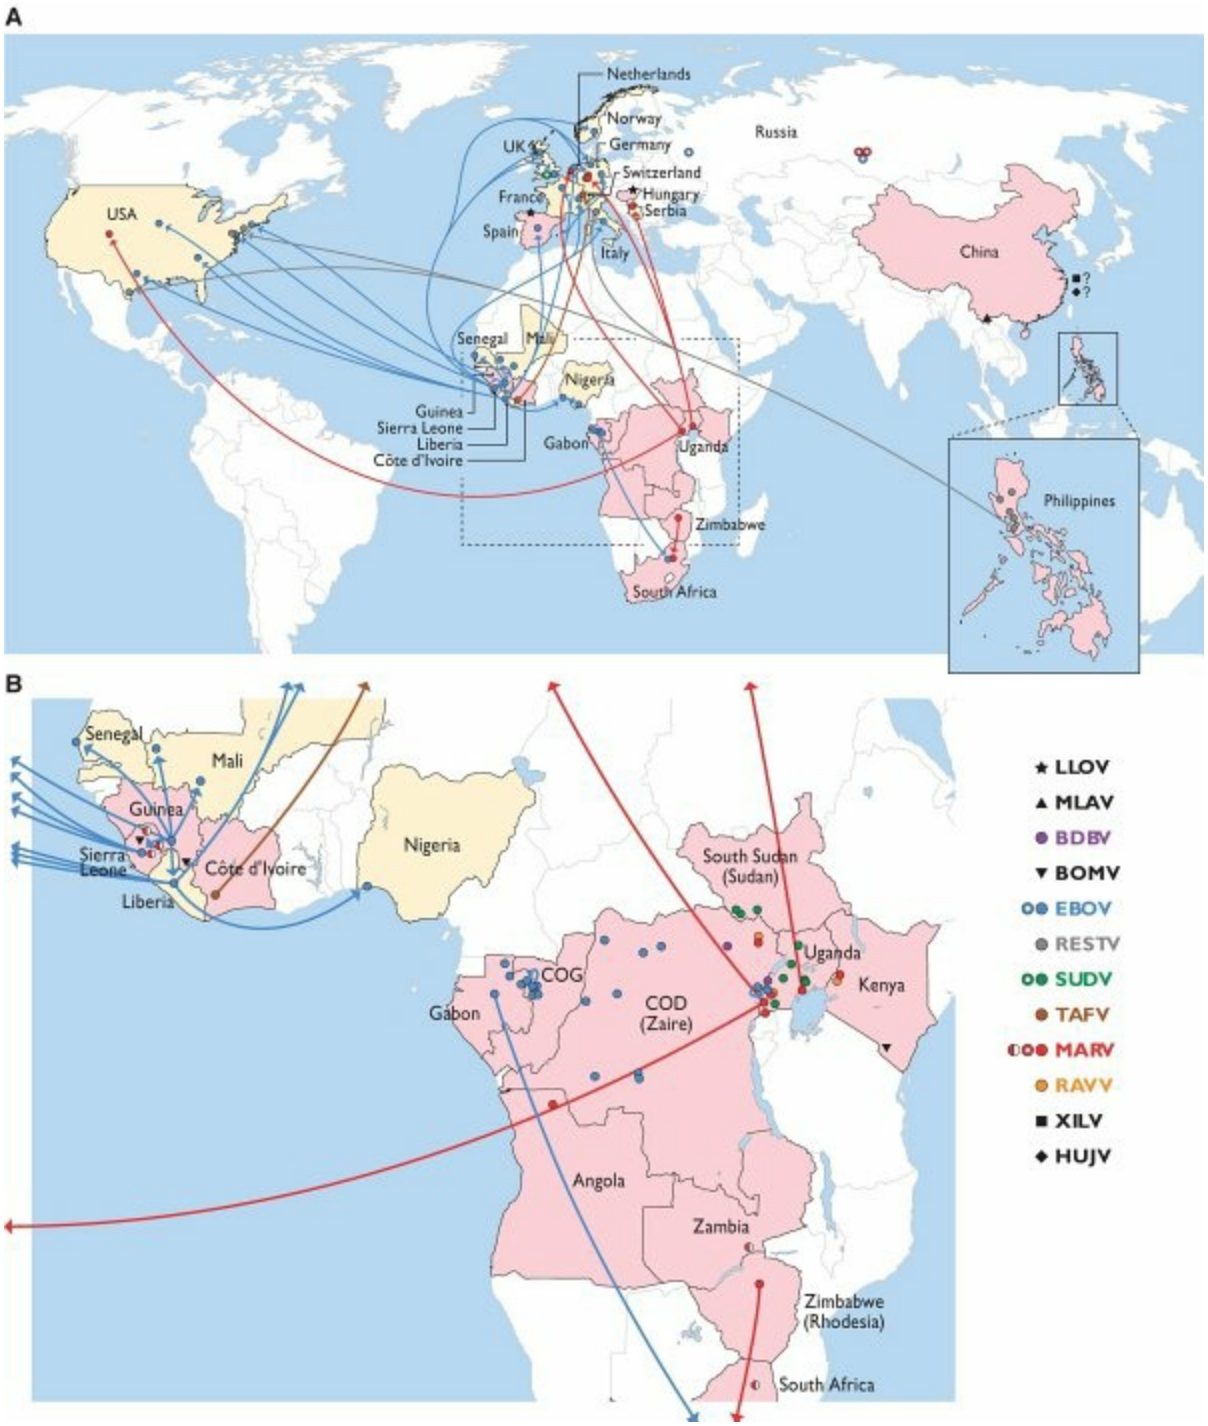

FIGURE 11.1 Global filovirus distribution. A: Human filovirus infections are indicated on a global map by colored dots indicating different filoviruses. Countries where filoviruses are suspected to be endemic are colored pink. Countries affected by imported cases are colored yellow, with arrows indicating origin and destination of

cases. Hollow dots indicate locations of laboratory-acquired infections (LAIs; in this text defined as filovirus infections acquired in nonclinical laboratories during activities known to involve filoviruses). Half-colored dots indicate unambiguous human filovirus detection in nonhuman animals. *Asterisks*, *triangles*, *squares*, and *diamonds* indicate discovery locations of filoviruses, thus far, not associated with human infections. Question marks indicate uncertain origins. Only current country names are shown. **B:** Magnification of *central insert* indicated by *dashed lines* in **(A)**. FIGURE 11.2 Global human filovirus infections. Occurrences are listed by year and etiologic agent. Laboratory-acquired infections are indicated by gray italics; international case exportations are indicated using arrows (*left column*). Case numbers and deaths for each filovirus, all filoviruses of a particular genus, and all filoviruses together are listed for each outbreak in the utmost right columns. Lethality/case-fatality rates for each individual outbreak are indicated by dots plotted in the middle column on a 0% to 100% scale along with 99% confidence intervals (*gray horizontal bars*). Average lethalities over all outbreaks caused by an individual filovirus, filoviruses of a particular genus, or all filoviruses are indicated by vertical lines with 99% confidence intervals shown by dashed lines (*partially overlapping*). Countries are listed according to their official names at the time of filovirus detection. BDBV, Bundibugyo virus; COD, Democratic Republic of the Congo; COG, Republic of the Congo; EBOV, Ebola virus; MARV, Marburg virus; RAVV, Ravn virus; RESTV, Reston virus; SUDV, Sudan virus; TAFV, Taï Forest virus; UK, United Kingdom; USA; United States of America; USSR, Union of Soviet Socialist Republics. *, case numbers as of December 1, 2019.

Marburgviruses

Marburg Virus

The first recorded filovirus, Marburg virus (MARV), was discovered in 1967. Three nearly simultaneous case clusters of severe and frequently lethal human disease occurred among laboratory personnel working in poliomyelitis vaccine–manufacturing institutes in Marburg an der Lahn and

Frankfurt am Main, Hesse, West Germany (today Germany) and Belgrade, Yugoslavia (today Serbia).[294,486,684] The initial West German infections happened during routine tissue harvesting from infected grivets (Primates: Cercopithecidae: *Chlorocebus aethiops* Linnaeus, 1758) imported from Uganda, with subsequent secondary transmission among colleagues and nosocomial transmissions during clinical treatment of patients.[294,486,684] In Yugoslavia, a veterinarian became infected during the necropsy of a grivet that had died from unknown causes. His wife attended to him during his illness and, thereby, became infected herself.[871] These grivets had been imported from the same Ugandan nonhuman primate (NHP) exporter that supplied the West German facilities. Thus, all three case clusters were epidemiologically connected through grivets that likely became infected in Eastern Africa.[320,694] However, the true source of MARV that caused this outbreak, which ultimately affected 31 people and killed 7, was never identified, and this outbreak was the only recorded natural occurrence of MARV infection involving grivets.

Over the subsequent five decades, MARV has caused only a few sporadic infections. In 1975, a student became infected with the virus from an unknown source in Rhodesia (now Zimbabwe). Prior to his death, the student transmitted the virus to his companion and later to a medical professional during treatment in Johannesburg, South Africa.[142,254,256] In 1980, MARV, again acquired from an unknown source and at an unknown location, killed a French citizen in Kenya and led to the infection of one of his doctors.[695]

Further cases of MARV infection occurred in Uganda from 2007 to 2017. In 2007, an outbreak occurred in Ibanda District among three visitors of a Kamwenge District gold mine (Kitaka Cave) inhabited by (cavernicolous and frugivorous) Egyptian rousettes (Chiroptera: Pteropodidae: *Rousettus aegyptiacus* E. Geoffroy, 1810).[2] These bats are now known to be natural hosts of the virus.[21–23,585,737] In 2008, in Bushenyi District, two tourists who had independently visited Python Cave inhabited by Egyptian rousettes became infected and inadvertently exported MARV to Colorado, the United States,[118] and South Holland, the Netherlands,[731] respectively. In 2012, an outbreak in the Ibanda, Kabale, and Kamwenge Districts affected 26 people (15 deaths). Though suspected, none of these infections could be associated

with Egyptian rousette exposure.[402] In 2014, MARV killed a health care worker in Kampala, Uganda.[565] In 2017, the last recorded outbreak occurred in Uganda's Kween District. Four family members became infected, two of them died.[566] Direct exposure to bats did not appear to play a role in these latter outbreaks and the route of MARV introduction into human populations remains unclear.

Thus far, MARV has caused only two large disease outbreaks. From 1998 to 2000, numerous independent introductions of MARV into a population of illegal gold miners caused an outbreak consisting of multiple short transmission chains (at least 153 cases and 128 deaths) in Orientale Province (today Haut-Uele Province), Democratic Republic of the Congo (COD). The outbreak ended after the underground mine was flooded, suggesting that exposures occurred within the mine, likely involving Egyptian rousettes.[52,53,66] In 2004, MARV infected a single individual in northern Angola by unknown means and urban person-to-person transmission ultimately led to a total of 252 infected individuals and 227 deaths.[335,692,738]

In addition to natural outbreaks, MARV has been implicated in at least two additional LAIs. These infections occurred at the same Soviet (today Russian) institute in Novosibirsk Oblast in 1988 and 1990 during research involving the injection of MARV into domesticated guinea pigs (Rodentia: Caviidae: *Cavia porcellus* Linnaeus, 1758).[447,870]

MARV has rarely been detected in the wild in the absence of human infections. Next-generation sequencing (NGS) detected MARV in Egyptian rousette samples collected in 2013–2014 in Limpopo Province, South Africa.[585] Interestingly, the sequenced genome was found to be very closely related to the MARV isolate that caused the 1975 Rhodesia infections.[585] In 2018, MARV was discovered by NGS in Egyptian rousettes sampled in three locations in Sierra Leone (unpublished,[290]) and in Lusaka Province, Zambia.[381]

Ravn Virus

In 1987, a close relative of MARV, Ravn virus (RAVV), was discovered after a 15-year-old Danish boy succumbed to infection in Kenya during a

vacation trip.[372] The source of infection was never identified. Since then, RAVV caused at least two additional human infections. One infection occurred during the 1998–2000 disease outbreak among gold miners caused predominantly by MARV in COD.[53] The other affected an individual who, in 2007, visited the same gold mine (Kitaka Cave) in Uganda that was pinpointed as the origin of three human MARV infections that year.[2] In addition, RAVV was repeatedly detected in or isolated from Egyptian rousettes from Kitaka Cave and from nearby Python Cave from 2007 to 2012.[21,23,737]

Ebolaviruses

Ebola Virus

Ebola virus (EBOV) was discovered in 1976 during a large outbreak that killed 280 of 318 infected people from 55 villages in Équateur Province (today Mongala Province) in Zaire (today COD). In addition to direct person-to-person contact, transmission was associated with the reuse of contaminated needles within health care facilities.[86,373,582,583,821]

Over the past five decades, EBOV has caused at least 17 additional disease outbreaks. One outbreak was a single infection in a 9-year-old girl in Équateur Province (today Sud-Ubangi Province), Zaire in 1977.[327] In 1994–1995, another cluster of at least 52 cases occurred after five independent virus introductions into populations working in three Gabonese gold mining camps in Woleu-Ntem Province.[277] In 1995, an outbreak involved at least 317 urban infections, many of them nosocomial, in and around Kikwit, Bandundu Province (today Kwilu Province), Zaire.[393] Seven smaller outbreaks occurred in the Ogooué-Ivindo and Ogooué-Lolo Provinces of Gabon and/or the Cuvette-Ouest Department of the Republic of the Congo (COG) from 1996 to 2005. Among these, a 1996 outbreak was noteworthy because it began with 18 infected children, whereas a 1996–1997 outbreak occurred among adults in a logging camp. The remainder of the outbreaks were all traced back to hunters who had been in contact with various NHPs or other animals destined for consumption.[85,239,241,275_277,450,510,556,557,602]

After these outbreaks, with one notable exception, EBOV infections were only recorded in COD. These outbreaks occurred in 2007 and 2008–2009 in Kasaï Occidental Province (today Kasaï Province),[289] in 2014 and 2018 in Équateur Province,[471,500] in 2017 in Bas-Uele Province,[564] and from 2018 to time of writing (December 2019) in the Ituri and Nord-Kivu Provinces.[351,499] The exception is the largest FVD outbreak ever recorded. This outbreak likely began in 2013 in Guinea with the typical single index case,[32] followed by substantial direct person-to-person transmission that ultimately involved 28,652 infections and 11,325 deaths distributed over 15 countries (predominantly Guinea, Liberia, and Sierra Leone).[106,115,188,280,735] True to historical precedent, the source of initial human infection in Guinea remains unclear. Indeed, EBOV has yet to be unambiguously detected and/or isolated from a wild animal.

EBOV has also caused at least two lethal LAIs in Russia. The first infection occurred in 1996 within a classified research program at a military institute in Moscow Oblast.[447,867] The second infection occurred in 2004 at the same institute in Novosibirsk Oblast that experienced previous laboratory-acquired MARV infections.[865]

Sudan Virus

Sudan virus (SUDV) was discovered almost simultaneously with EBOV in 1976. While EBOV spread through the population in Zaire, SUDV affected neighboring Sudan (today South Sudan). The three index cases worked in a cotton factory in Nzara, Western Equatoria State (today Gbudwe State). After their admission to Maridi City Hospital, SUDV spread within the hospital and then, via person-to-person transmission, into Maridi and neighboring towns. In total, 151 of 284 people died.[33,86,173,197,244,387,582,822] SUDV reemerged in 1979 in an employee from the same cotton factory implicated in the 1976 outbreak. As before, nosocomial transmission of SUDV contributed to the outbreaks, which ultimately claimed 22 lives.[40]

SUDV was not reencountered until the end of August 2000, when the virus emerged by unknown means in Gulu District, Uganda. Nosocomial transmission amplified the outbreak into Masindi and Mbarara Districts,

ultimately affecting 425 people and killing 224.[73,117,572] After the Gulu outbreak, SUDV caused at least four more outbreaks. In 2004, the virus infection killed 7 of 17 people in South Sudan in the same area that experienced outbreaks in 1976 and 1979.[575,728] In 2011, SUDV infection killed a 12-year-old girl in Luweero District, Uganda.[681] Then, SUDV reappeared twice in Uganda in 2012, in Kibaale District (24 cases, 17 deaths) and Luweero District (7 cases, 4 deaths).[9]

Thus far, a single, nonlethal, laboratory-acquired SUDV infection is on record. In 1976, shortly after the discovery of SUDV in Sudan, a British investigator stuck himself with a contaminated needle at a military laboratory in South West England, United Kingdom, and became ill several days later.[87,205]

Reston Virus

Reston virus (RESTV) infection was identified in 1989 and 1990 in severely ill crab-eating macaques (Primates: Cercopithecidae: *Macaca fascicularis* Raffles, 1821) in U.S. NHP facilities located in Pennsylvania, Texas, and Virginia shortly after arrival from a NHP export facility in Laguna, Luzon, Philippines. The macaques presented with clinical signs typical of simian hemorrhagic fever (SHF); indeed, further studies revealed coinfection of some of the macaques with SHF-causing simarteriviruses (*Arteriviridae*: *Simarterivirinae*).[268,315,357,513] Despite increased surveillance and quarantine measures, RESTV was again exported in crab-eating macaques from the same Filipino primate supplier to Tuscany, Italy, in 1992 and to Texas, United States, in 1996. Simarterivirus coinfections were found only in the macaques euthanized in Texas.[134,512_514,636]

In 2008–2009, RESTV cocirculated together with porcine reproductive and respiratory syndrome virus 2 (PRRSV-2; *Arteriviridae*: *Variarterivirinae*) and porcine circovirus 2 (PCV-2; *Circoviridae*: *Circovirus*) in severely sick domestic pigs (Artiodactyla: Suidae: *Sus scrofa domesticus* Erxleben, 1777) bred in two piggeries on Luzon, Philippines.[42] The contribution of RESTV to the observed disease is unclear. In 2015, RESTV once again emerged in the Philippines, this time again in crab-eating macaques, some coinfected with measles virus, in a NHP facility close to

Manila.[166] Finally, short RESTV gene-like fragments were detected in molossid, pteropodid, and vespertilionid bats trapped in the Philippines[364] and in samples from PRRSV-2–coinfected domestic pigs in China,[580] suggesting widespread RESTV distribution in Asia.

Thus far, a single asymptomatic human infection with RESTV has been proven unambiguously,[12] but seroconversions have been reported several times in individuals in contact with RESTV-infected animals.[42,116,513,824]

Taï Forest Virus

Taï Forest virus (TAFV) was discovered in 1994 during an investigation into the cause of unusual deaths in a troop of western chimpanzees (Primates: Hominidae: *Pan troglodytes verus* Schwartz, 1934) in Taï National Park, western Côte d'Ivoire. A Swiss ethologist, who had performed a field necropsy on one of the apes, fell sick with a dengue fever–like disease. She fully recovered after medical evacuation from Abidjan to Switzerland.[238,442] Histopathological examination of the tissues from the necropsied western chimpanzee suggested that the troop indeed had been infected with, and decimated by, TAFV.[833]

Bundibugyo Virus

Bundibugyo virus (BDBV) was first discovered in Bundibugyo District, Uganda, during a human disease outbreak that lasted from 2007 to 2008, resulting in at least 149 cases and 37 deaths.[470,740,779] BDBV has since been encountered during a smaller outbreak in 2012 in Orientale Province, COD (62 cases, 34 deaths). As in all previous disease outbreaks caused by ebolaviruses, these two outbreaks began with single BDBV introductions into the human population from unknown sources.[9,414] Thus far, BDBV infections have not been associated with human exposure to a particular animal or geographic or ecologic feature or associated with a certain socioeconomic background.

Bombali Virus

Bombali virus (BOMV), which has yet to be isolated, was discovered by NGS in oral and rectal swabs taken from apparently healthy insectivorous little free-tailed bats (Chiroptera: Molossidae: *Chaerephon pumilus* Cretzschmar, 1826) and Angolan free-tailed bats (Chiroptera: Molossidae: *Mops condylurus* A. Smith, 1933) sampled in Sierra Leone in 2016. Although the sampled bats have roosted inside occupied homes, no human BOMV infections have been recorded,[285] and BOMV's pathogenic potential remains to be determined. BOMV RNA has also been found in various organs of Angolan free-tailed bats sampled in Taita-Taveta County, Kenya, in 2018 and Nzérékoré Region, Guinea, in 2018–2019.[237,386]

Cuevaviruses

Lloviu virus (LLOV) was discovered in dead Schreiber's long-fingered bats (Chiroptera: Vespertilionidae: *Miniopterus schreibersii* Kuhl, 1817) by NGS performed on samples collected in Cueva del Lloviu, Asturias Principality, Spain, in 2002.[550] LLOV was also detected by NGS in dead Schreiber's long-fingered bats found in caves in North Hungarian Mountains, Hungary, in 2016.[391] Thus far, LLOV has not been isolated. Whether LLOV caused the deaths of the bats it was sequenced from remains as unclear as is the potential of LLOV to cause human disease.

Striaviruses

Xīlaˇng virus (XILV) was discovered by NGS in a striated frogfish (Lophiiformes: Antennariidae: *Antennarius striatus* Shaw, 1794) captured by a fishing trawler in the East China Sea in 2011.[679] XILV has not yet been isolated.

Thamnoviruses

Huángjiāo virus (HUJV) was discovered by NGS in a greenfin horse-faced filefish (Tetraodontiformes: Monacanthidae: *Thamnaconus septentrionalis* Günther, 1874) captured by a fishing trawler in the East China Sea in 2011.[679] HUJV has not yet been isolated.

Dianloviruses

Měnglaˇ virus (MLAV), first described in 2019, was discovered by NGS in a liver sample collected from an apparently healthy *Rousettus* sp. sampled in 2015 in Yúnnán Province, China. Thus far, MLAV has not been isolated and its pathogenic potential is currently unclear.[841,842]

Other Filoviruses

The recent discovery of BOMV, HUJV, LLOV, MLAV, and XILV in highly diverse animals (e.g., actinopterygid fish, frugivorous and insectivorous bats) in geographically separated areas (e.g., Africa, Asia, Europe) suggests that filovirus diversity and distribution are much broader than previously appreciated. Indeed, filovirus gene-like sequences were discovered in 2009 and 2015 by NGS in samples taken from apparently healthy frugivorous lesser dawn bats (Chiroptera: Pteropodidae: *Eonycteris spelaea* Dobson, 1871) and unspecified rousettes in Yúnnán Province, China. Additional sequences were detected by NGS in frugivorous Leschenault's rousettes (*Rousettus leschenaultii* Desmarest, 1820) sampled in 2013 in the same area.[316,842] In addition, endogenous filovirus-like sequences were found in the genomes of various afrosoricids, bats, eulipotyphla, and rodents, as well as in marsupials, indicating that filoviruses have a long evolutionary history.[62,195,388,721,722]

CLASSIFICATION

Filoviruses are the members of the family *Filoviridae*, which is one of the 11 families in the haploviricotine order *Mononegavirales*.[20] Filoviruses are most closely related to viruses of the mononegaviral families *Paramyxoviridae*, *Pneumoviridae*, and *Sunviridae* and are assigned to six official genera (Table 11.1). Filovirus genus assignment is based on nine determinants: (a) pairwise genome sequence similarities,[39,428] (b) phylogenetic distance of coding-complete genomes, (c) large protein gene (*L*) sequences (Fig. 11.3), (d) RNA-directed RNA polymerase (RdRp) core domain amino acid sequences,[428,814] (e) number and location of open reading frames (ORFs) in genomes, (f) the

presence or absence of cotranscriptional editing sites, (g) geographic distribution, (h) host tropism, and (i) pathogenic potential.[428]

Only the genera *Ebolavirus* and *Marburgvirus* contain viruses known to infect humans. The World Health Organization (WHO) consequently recognizes two major FVD subcategories, Ebola disease (EBOD; caused by BDBV, EBOV, SUDV, or TAFV) and Marburg disease (MARD; caused by MARV and RAVV) along with several secondary subcategories.[427,827]

Due to the extraordinarily high case-fatality rates of most human filovirus infections (Fig. 11.2), the ability of certain filoviruses to spread from one individual to another by direct contact, and the absence of efficacious licensed medical countermeasures (MCMs), filovirus research is prioritized within public health preparedness and biodefense efforts.[121,549] WHO considers all filoviruses that are known to infect humans to be Risk Group 4

(RG-4) pathogens.[823] In the United States, any research involving viable forms or ebolaviruses and marburgviruses requires biosafety level 4 (BSL-4) or animal biosafety level 4 (ABSL-4) containment and adherence to associated standard operating procedures to protect laboratory workers and the public.[750] In addition, most filoviruses are classified as Select Agents under U.S. Federal Law for regulation and oversight of filovirus research activities and/or possession[749] (Table 11.2). Similar classification systems used by other countries also list filoviruses at the top of their risk, safety, or priority categories.

TABLE 11.2 Major filovirus biosafety and biosecurity risk classifications

Filovirus (Abbreviation)	Biocontainment Requirement[750]	CDC Bioterrorism Agent/Disease[121]	NIAID Priority Pathogen[549]	HHS Select Agent[749]	Australia Group Human Pathogen for Export Control[725]

(A)BSL, US (animal) biosafety level; CDC, U.S. Centers for Disease Control and Prevention; HHS, U.S. Department of Health and Human Services; NIAID, U.S. National Institute of Allergy and Infectious Diseases.

[a]Reference[750] lists "Ebola (including Reston)" and "Marburg" as requiring (A)BSL-4 biocontainment. Here, it is assumed that these terms include all ebolaviruses/marburgviruses with significant genomic similarities.

[b]Reference[121] assigns "Viral hemorrhagic fevers, including … [f]iloviruses (Ebola, Marburg)" to Category A. Because the terms "Ebola" and "Marburg" are ambiguous, all human disease-causing ebolaviruses and marburgviruses (rather than just Ebola virus and Marburg virus) are listed here in Category A.

[c]Interpreted here to be included in the ambiguous list phrases "Ebola" or "Marburg."

[d]Interpreted here to be included in the ambiguous list phrases "Ebola virus" or "Marburg virus."

VIRION STRUCTURE

Filovirion morphology data are only available for ebolaviruses and marburgviruses because cuevaviruses, dianloviruses, striaviruses, and thamnoviruses have not yet been isolated. The hallmark of ebolavirus and marburgvirus particles is their predominantly filamentous appearance that is easily identifiable in electron micrographs (Fig. 11.4). Depending on culture conditions and cell or tissue types, particles also can assume branched, toroid, U-shaped, or 6-shaped ("shepherd's crook") forms. Filamentous and other particles are typically less than 1 μm long, but in cell culture, these particles can reach lengths of greater than 20 μm. Their diameters are more uniform, ranging from ≈91 to 98 nm.[63,68,69,202,203,269,644] An initial study using recombinantly expressed proteins suggests that cuevavirions may also form predominantly filamentous particles.[490]

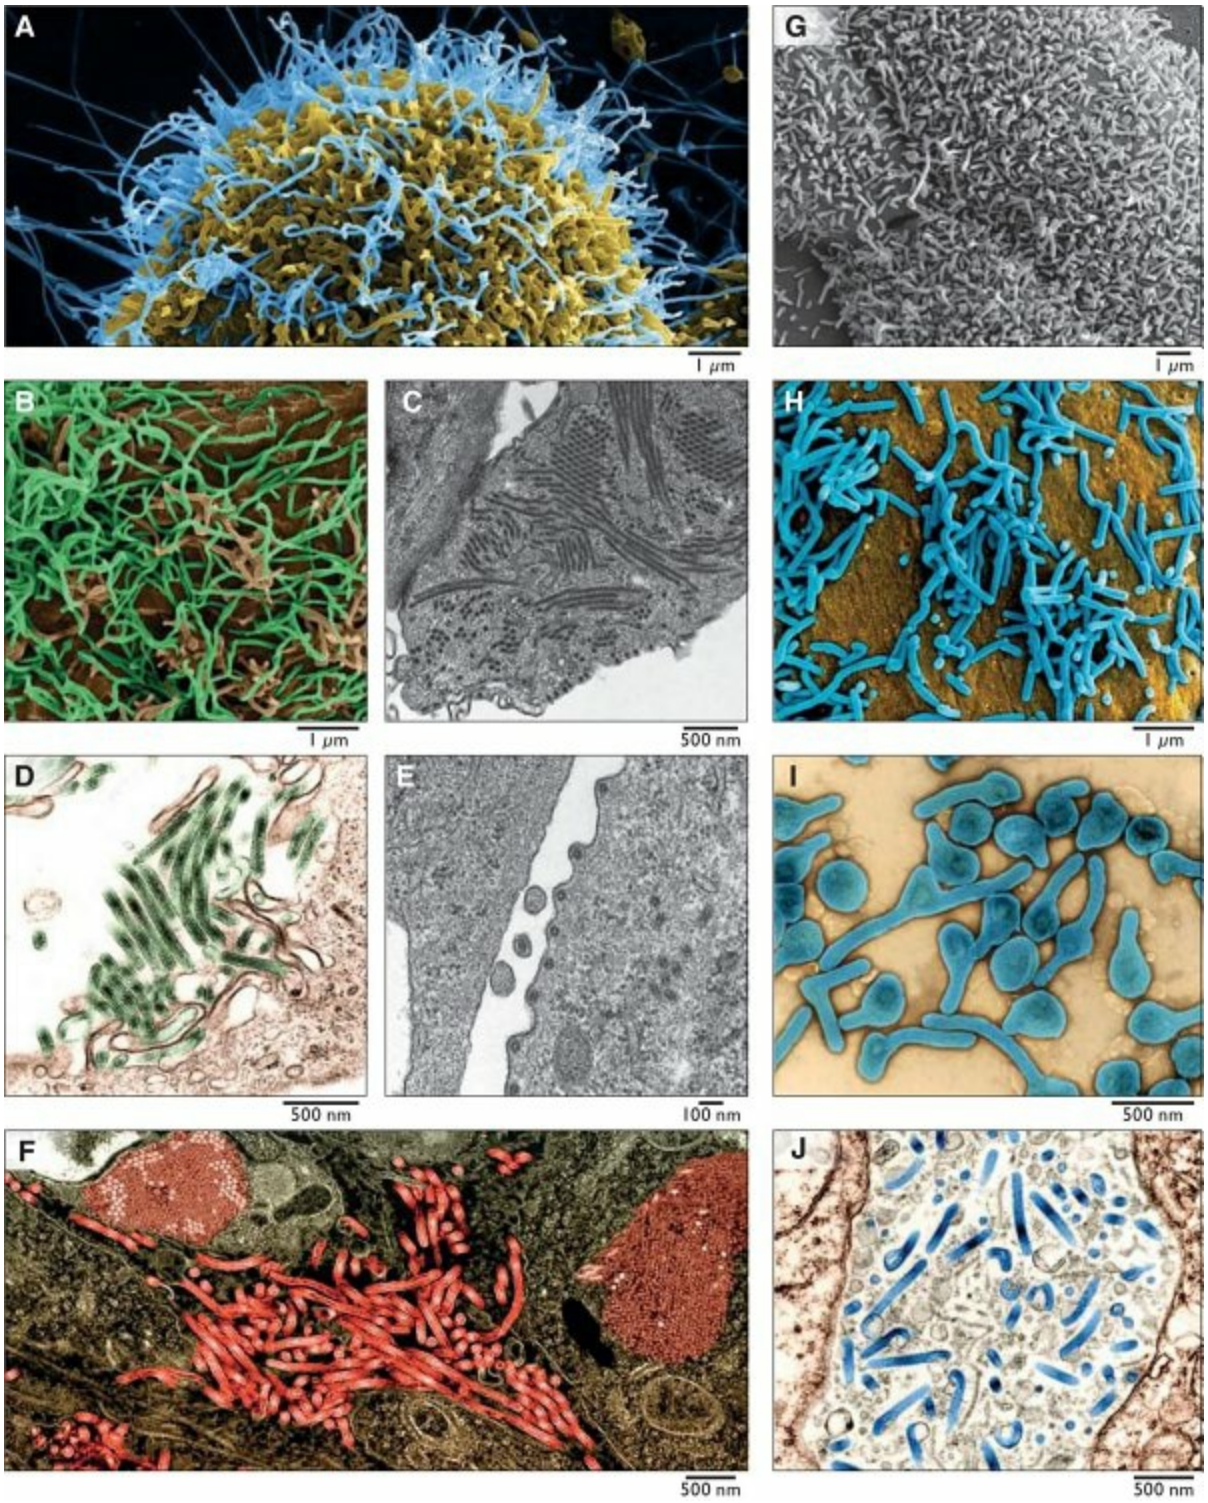

FIGURE 11.4 Mammalian filovirion structure.

J: TEM image of mature filamentous MARV particles (*colored blue*) from the liver of a rhesus monkey. (Figure courtesy of John G. Bernbaum and Jiro Wada, IRF-Frederick, Fort Detrick, MD, USA.)

Ebolavirions and marburgvirions possess a central core, the helically-arranged ribonucleoprotein (RNP) complex. This RNP is ≈30 to 41 nm in diameter with a pitch of ≈7 to 7.5 nm. The RNP is embedded in a matrix layer surrounded by a lipid envelope obtained during particle budding from host cell membranes. The lipid envelope is decorated with globular peplomers (≈7 nm in diameter and ≈13 nm in length) at intervals of ≈15 ± 4 nm (1 peplomer per 250 nm^2).[63,68,69,202,203,269,644,802] These peplomers largely determine the antigenicity of filovirions.

Filovirions are sensitive to desiccation, heat, pressure, UV light, γ-irradiation, detergents (e.g., diethyl ether, phenolic compounds, sodium deoxycholate), formaldehyde, and commercial oxidizing agents (e.g., sodium hypochlorite/bleach), but inactivation/disinfection efficiency is dependent on disinfectant type, concentration, and contact time and varies based on the volume, titer, and type of contaminated material.[17,88,126,224,229,301,433,522,604,696,805,869]

GENOME STRUCTURE AND ORGANIZATION

Filovirus Genomic Organization

Filovirus genomes are components of filovirion RNPs and are organized like those of most mononegaviruses,[576] consisting of linear, nonsegmented, negative-sense RNAs with the general gene order 3′-*N-P-M-G-L*-5′ (filovirus terminology: 3′-*NP-VP35-VP40-GP-L*-5′). Filovirus-specific genes are inserted at various locations throughout the genome depending on genus affiliation. For instance, dianlovirus, ebolavirus, and marburgvirus genomes have the gene order 3′-*NP-VP35-VP40-GP-VP30-VP24-L*-5′ (Fig. 11.5). However, cuevaviruses appear to synthesize *VP24* and *L* expression products from a single gene using a bicistronic transcript. Striavirus genomes appear to contain at least 10 genes with only 9 (*NP*, *VP35*, *VP40*, *GP*, *VP30*, and *L*) that are obvious homologs to those of ebolaviruses and marburgviruses.[343,679] Finally, thamnoviruses are classified as filoviruses primarily because of their *NP*, *GP*, and *L* genes, whereas their four other genes do not have obvious filovirus homologs.[343,679] In addition to gene content, filovirus genomes differ in length (≈15 kb [thamnoviruses] to ≈19 kb [cuevaviruses, ebolaviruses, and marburgviruses]), number and location of gene overlaps (0–9), and absence (dianloviruses, marburgviruses, striaviruses, thamnoviruses) or presence (cuevaviruses, ebolaviruses) of overlapping reading frames in the *GP* gene that can be accessed via cotranscriptional editing[222,349,550,649,652,679,765,841] (Fig. 11.5).

(Adapted and expanded from Kuhn JH, Amarasinghe GK, Basler CF, et al. ICTV virus taxonomy profile: *Filoviridae*. *J Gen Virol* 2019;100:911–912. Figure courtesy of Jiro Wada, IRF-Frederick, Fort Detrick, MD, USA.)

Complete genome information has only been obtained for five ebolaviruses (BDBV, BOMV, EBOV, RESTV, and SUDV) and one

marburgvirus (MARV). The 3′ ends of these genomes are not polyadenylated, and the 5′ ends are neither capped nor covalently linked to any protein. The 3′ leader and 5′ trailer sequences of the genomes are conserved (particularly within genera) and, in part, complementary. They contain *cis*-acting signals for mRNA transcription and genome replication, including promoters.[79,148,222,396,624,768]

Mammalian filovirus (cuevavirus, dianlovirus, ebolavirus, and marburgvirus) genes are identifiable through their genus-/species-specific conserved gene start and end/polyadenylation signals within relatively long noncoding regions.[104,222,349,649,651,740] These regions may be separated from each other by intergenic regions or overlaps, which influence transcription reinitiation and/or virus growth in manners that need to be better defined.[93]

Filovirus Genome Expression Products

Filovirus genomes encode 6 to 10 proteins, some of which are further processed by proteolytic cleavage. Most of the main proteins are expressed from single genes, although cotranscriptional editing (cuevaviruses, ebolaviruses) and possibly bicistronic transcripts (cuevaviruses) are also used to access ORFs.[550,652,765] The mammalian filovirus *NP*, *VP35*, *VP40*, *VP30*, *VP24*, and *L* genes encode nucleoprotein (NP), polymerase cofactor (VP35), matrix protein (VP40), transcriptional activator (VP30), RNA complex–associated protein (VP24), and large protein (L), respectively. Dianlovirus and marburgvirus *GP* genes encode only the glycoprotein ($GP_{1,2}$) and a cleavage product thereof (shed glycoprotein [$GP_{1,2\Delta}$]), whereas cuevaviruses and ebolaviruses express six products from these genes: secreted glycoprotein (sGP), Δ-peptide, $GP_{1,2}$, $GP_{1,2\Delta}$, sGP–GP_2, and secondary secreted glycoprotein (ssGP).[198,199,222,395,649] NP, VP35, VP40, $GP_{1,2}$, and L are the functional analogs (and NP and L are also functional homologs[41,814]) (Fig. 11.5) of core proteins encoded by all mononegaviruses (typically designated N, P, M, G, and L, respectively).[41,605,814] The expression products of piscine filoviruses (striaviruses and thamnoviruses) have yet to be characterized. However, these viruses encode some obvious homologs to proteins expressed by other filoviruses (striaviruses, NP, VP40, VP30, L; thamnoviruses, NP and L) (Fig. 11.5; Table 11.3).

TABLE 11.3 Characterized mammalian filovirus proteins

Protein Designation (Abbreviation)	Characteristics	Function
Nucleoprotein (NP)	• RNP complex and cellular inclusion body component. Homo-oligomerizes to form helical polymers • Binds to ssRNA, VP35, VP40, VP30, and VP24 • Phosphorylated and, in ebolaviruses, also *O*-glycosylated and possibly sialylated • Marburgviruses: contain a late-budding (PSAP) motif	• RNP formation through encapsidation of filovirus genomic or antigenomic RNA • Genome replication and transcription • Marburgviruses: RNP transport and budding • Determinant in filovirus rodent adaptation
Polymerase cofactor (VP35)	• RNP complex and cellular inclusion body component • Homo-oligomerizes and binds to dsRNA, NP, and L; phosphorylated • Absent from striaviruses and thamnoviruses • Interacts with DYNLL1 • EBOV: ubiquitinylated by TRIM6	• Polymerase cofactor in the filovirus polymerase holoenzyme (L+VP35) • Cuevaviruses: inhibits IRF3 phosphorylation, IFNA1/B1 production, and protein kinase R phosphorylation • Ebolaviruses: inhibits innate immune response by interfering with IRF3, IRF7, IFIH1, DDX58, and RNAi pathways; inhibits stress granule formation • Marburgviruses: inhibits innate immune response by interfering with IRF3, IRF7, and DDX58 pathways and inhibits EIF2AK2 activity • Ebolaviruses: RNA silencing suppressor; prevents stress granule formation
Matrix protein (VP40)	• Consists of two distinct functional domains that drive homo-oligomerization to form dimers, linear hexamers, and circular octamers. Dimers bind to cellular membranes; hexamers polymerize to matrix filaments; octamers bind ssRNA. Binds NP • Dianloviruses and marburgviruses: contains PPXY late-budding motif that interacts with NEDD4 and TSG101 • Cuevaviruses and ebolaviruses: contains PPXY and P(T/S) AP late-budding motifs that interact with NEDD4 and TSG101; binds to α-tubulin and are ubiquitinylated • Absent from thamnoviruses	• Matrix component • Negative regulator of genome transcription and replication • Regulator of virion morphogenesis and egress • Ebolaviruses: RNAi silencing suppressor • Marburgviruses: inhibits JAK1/TYK2 STAT pathway
Glycoprotein ($GP_{1,2}$)	• Trimeric type I transmembrane and class I fusion protein consisting of disulfide-linked GP_1–GP_2 heterodimers; heavily *N*- and *O*-glycosylated, phosphorylated, acylated. Sialylation extent different depending on the virus • Absent from striaviruses and thamnoviruses	• Virion adsorption to filovirus-susceptible cells via cellular attachment factors; induction of virus–cell membrane fusion subsequent to endolysosomal binding to NPC1 • Determines filovirus cell and tissue tropism • Inhibits intrinsic immune response by interfering with BST2
Shed glycoprotein ($GP_{1,2A}$)	• Secreted $GP_{1,2}$ trimer produced by ADAM17-mediated cleavage of membrane-bound $GP_{1,2}$ • Absent from striaviruses and thamnoviruses	Hypothesized to be an anti-$GP_{1,2}$ antibody decoy
Secreted glycoprotein (sGP)	• Secreted disulfide-linked parallel homodimeric nonstructural protein that is C-mannosylated and *N*-glycosylated • Not encoded by marburgviruses, dianloviruses, striaviruses, and thamnoviruses	Hypothesized to be an anti-$GP_{1,2}$ antibody decoy and an anti-inflammatory agent
Secondary secreted glycoprotein (ssGP)	• Secreted disulfide-linked homodimeric nonstructural protein that is *N*-glycosylated • Not encoded by marburgviruses, dianloviruses, striaviruses, and thamnoviruses	Unknown
Δ-peptide	• Secreted nonstructural protein that is *O*-glycosylated and sialylated. Assembles as a pentameric chloride-selective viroporin • Not encoded by marburgviruses, dianloviruses, striaviruses, and thamnoviruses	Hypothesized to suppress filovirus superinfection of infected host cells

Protein Designation (Abbreviation)	Characteristics	Function
Transcriptional activator (VP30)	• RNP complex and cellular inclusion body component • Homo-oligomerizes; Cys_3-His zinc finger; binds ssRNA, NP, and L; phosphorylated • Absent from thamnoviruses	• Transcription initiation, reinitiaition, enhancement, and antitermination • Cuevaviruses and ebolaviruses: *GP* gene editing regulator • Ebolaviruses: RNAi silencing suppressor
RNP complex–associated protein (VP24)	• RNP complex and cellular inclusion body component • Associates with membranes • Absent from striaviruses and thamnoviruses	• Negative regulator of genome transcription and replication; regulator of virion morphogenesis and egress; determinant in filovirus rodent adaptation • Cuevaviruses: inhibits tyrosine phosphorylated STAT1 binding to KPNA5, STAT1 nuclear accumulation, and IFN-induced gene expression • Ebolaviruses: inhibits phosphorylation of MAPK14 and prevent karyopherin shuttling from the cytoplasm into the nucleus; inhibits host cell signaling downstream of IFNA1/B1/G • Marburgviruses: targets KEAP1 to activate NFE2L2-induced cytoprotective responses
Large protein (L)	• RNP complex and cellular inclusion body component and catalytic center of the filovirus polymerase holoenzyme (VP35+L) • Binds to filovirus genomic and antigenomic RNA and recognizes specific promoters and gene start and end signals • Binds directly to VP35 and VP30	• Genome replication via antigenomic intermediates • mRNA synthesis, capping, methylation, and polyadenylation • Determinant in filovirus rodent adaptation • Cuevaviruses and ebolaviruses; cotranscriptional editing of *GP* mRNAs

ADAM metallopeptidase domain 17 (ADAM17, formerly TACE); DDX58, DExD/H-box helicase 58 (formerly RIG-I); IFIH1, interferon induced with helicase C domain 1 (formerly MDA5); IFN, interferon; IRF, interferon regulatory factor; KEAP1, Kelch-like ECH-associated protein 1; MAPK, mitogen-activated protein kinase; NPC1, NPC intracellular cholesterol transporter 1; RNAi, RNA interference; RNP, ribonucleoprotein; STAT1, signal transducer and activator of transcription 1.

Filovirus Ribonucleoprotein Complex Components

NP, VP35, VP30, VP24, L, and the viral genome form the mammalian filovirus RNP complex, which is embedded in the virion matrix composed of VP40 surrounded by the envelope containing $GP_{1,2}$ peplomers[38,60,63,401,534,709,802] (Fig. 11.6). Mammalian filovirions may be polyploid, containing up to 22 individual RNPs. Extremely long particles, typically seen in tissue culture, are likely highly polyploid.[63] The RNPs of piscine filoviruses remain to be defined.

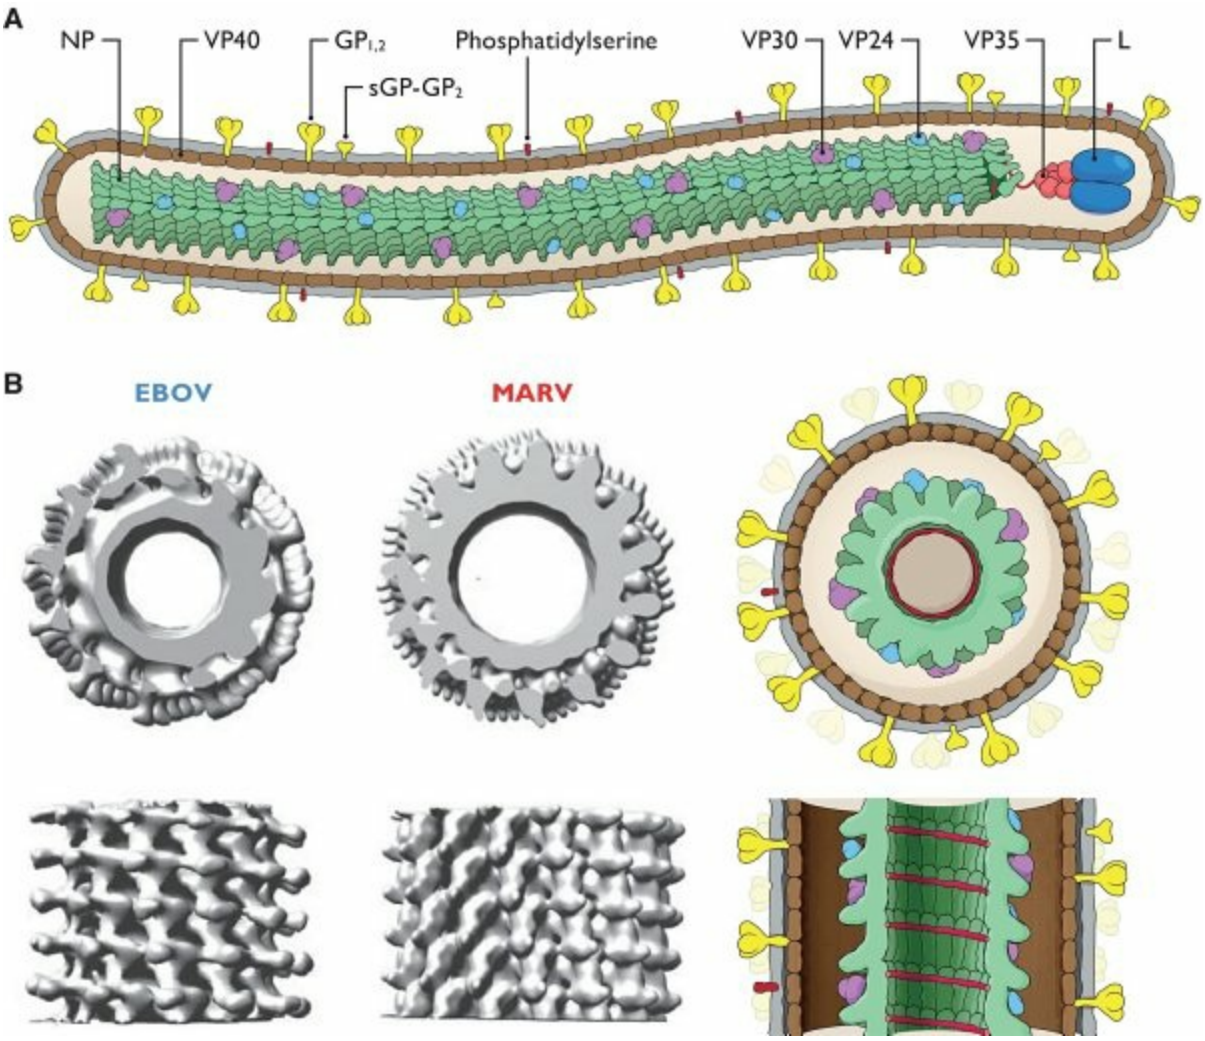

FIGURE 11.6 Mammalian filovirion structure. A: Artist rendering of an idealized filamentous EBOV particle. A ribonucleoprotein (RNP) complex, consists of the filovirus genome bound to helically polymerized nucleoprotein (NP) monomers in association with VP35, VP30, VP24, and L. The complex is embedded in the virion matrix composed of VP40 polymers surrounded by a cellular membrane–derived envelope containing $GP_{1,2}$ peplomers, sGP–GP_2, and, among other components, phosphatidylserine. **B:** Reconstruction of the EBOV RNP (*left*, *top*, viewed along the helical axis; *bottom*, side view) and MARV (*middle*, *top*, viewed along the helical axis; *bottom*, side view) from cryoelectron tomography and subtomogram averaging.[69] Right:

(Cartoon inspired by Hoenen T, Brandt J, Caì Y, et al. Reverse genetics of filoviruses. *Curr Top Microbiol Immunol* 2017;411:421–445, Ref.[329])

Nucleoprotein

Ebolavirus and marburgvirus NPs are phosphorylated or dephosphorylated by cellular kinases and phosphatases at C-terminal threonine and serine residues at various stages of the filovirus life cycle.[58,198,465] Partially phosphorylated NP monomers associate via their two-lobed N-terminal domains (NTDs) to form long, left-handed helical polymers that encapsidate filovirus genomes or antigenomes[58,63,68,69,400,498,558,560,706] (Fig. 11.7). These complexes serve as the templates for transcription and replication performed by L and VP35 and also for underlying structures of an array of morphologically distinct inclusion bodies. These inclusion bodies take the shape of lamellae, threads, or sponges (likely representing different RNP maturation forms) in the cytoplasm of filovirus-infected cells.[269,339,408,787,872] NP, via its NTD, binds directly to viral single-stranded (ss) RNA, VP35, and VP30,[58,60,292] all of which also interact directly with L and are recruited into inclusion bodies.[74,292,526] The EBOV NP NTD recruits PP2A-B56 phosphatase through an LxxIxE motif. This interaction dephosphorylates VP30, thereby triggering its transcriptional activation function.[419] The NP NTD also binds directly to VP24[38] and to VP40, which forms a matrix around RNPs.[562] Marburgvirus, but not ebolavirus, NP C-terminal domain (CTD) contains a late-budding (PSAP) motif that likely regulates RNP transport and particle budding. In ebolaviruses, such a motif (PTAP) is located in VP40.[178] The function of the ebolavirus NP CTD, which is tethered to the NTD through an unstructured sequence, is currently unclear.

Polymerase Cofactor (VP35)

VP35 consists of two distinct domains. The VP35 N-terminal oligomerization

domain mediates VP35 homo-oligomerization and, thereby, filoviral replication and RNP complex formation. Binding of this domain via an SQTQT motif to host dynein light chain LC8-type 1 (DYNLL1) stabilizes the domain and increases viral RNA synthesis. The VP35 C-terminal interferon inhibitory domain (IID) binds double-stranded (ds) RNA at a distinct central basic patch. The region between the N-terminal and the C-terminal regions is likely unstructured in the absence of binding partners. VP35 IID's N-terminal NP-binding peptide (NPBP) binds to the NP NTD, and phosphorylation of IID may regulate this interaction[49,111,311,421,451,453,454,467,528,860] (Fig. 11.8). Interleukin enhancer-binding factor 3 (ILF3) binds to VP35 IID and, thereby, inhibits filovirus VP35–NP interaction and transcription/replication.[675] Ubiquitinylation of IID, promoted by host cell TRIM6, promotes EBOV replication.[67] A recent study has revealed that EBOV VP35 can hydrolyze all types of NTPs and unwind RNA helices in $5' \rightarrow 3'$ direction in an ATP-dependent manner.[682] In addition, filovirus VP35 is an immunomodulator that antagonizes infected host cell antiviral responses via its IID.[49,50,111,124,194,218,226,342,606,669]

A: EBOV polymerase cofactor (VP35) contains an N-terminal oligomerization domain (*blue*, *top*; PDB 6GBO) and a C-terminal interferon inhibitory domain (IID; PDB 3FKE; *blue*, *bottom left*), which binds to dsRNA (*gray*, *bottom right*; PDB 4GHL).[860] **B:** EBOV transcriptional activator (VP30) has a C-terminal domain (*purple*, *left*; PDB 2I8B) that binds to NP's PPXPXY motif (*right*; PDB 5VAO).[836] **C:** EBOV RNP complex–associated protein (VP24) adopts a pyramid-like structure (*orange*) that is important for binding to a subset of importin molecules that transport STAT1 into the nucleus (PDB 4U2X).[856] **D:** Prediction structural model of EBOV large protein (L). Monomers resemble right hands with fingers (*chartreuse*), palms (*green*), and thumbs (*rust*) structural domains. (**D** from Jácome R, Becerra A, Ponce de León S, et al. Structural analysis of monomeric RNA-dependent polymerases: evolutionary and therapeutic implications. PLoS One 2015;10(9):e0139001.)

Transcriptional Activator (VP30)

Ebolavirus VP30 is a Cys_3–His zinc finger that acts as a transcriptional activator and regulator of ebolavirus RNA synthesis. VP30 facilitates L to read through an RNA hairpin in the 5′-untranslated region (UTR).[369,797,836] In addition, ebolavirus VP30 is speculated to promote L transcription reinitiation during the sequential transcription of all ebolavirus genes[482] and to regulate cotranscriptional *GP* gene editing.[507] VP30's activity is regulated via phosphorylation (resulting in transcriptional repression) and dephosphorylation (transcriptional activation) by cellular kinases and phosphatases[72,419,525,526,730] and by Zn^{2+}.[369,524] VP30 oligomerization is required for activation of ebolavirus transcription but not for NP binding.[307,308] In addition, ebolavirus VP30 antagonizes the cellular RNA interference (RNAi)

pathway.[214] The VP30 CTD binds a PPXPXY motif located in the NP CTD (Fig. 11.8B). The cellular ubiquitin ligase RB binding protein 6 (RBBP6) mimics ebolavirus NP and binds to ebolavirus VP30 using a similar motif, thereby down-regulating ebolavirus transcription and replication.[51]

The role of marburgvirus (and likely dianlovirus) VP30 is not as clear as that of ebolavirus VP30. Although marburgvirus VP30 is structurally very similar to ebolavirus VP30, Marburgvirus VP30 enhances transcription only minimally but is essential for the marburgvirus life cycle. Akin to ebolavirus VP30, marburgvirus VP30 phosphorylation regulates its activity.[10,207,399,531,730,803]

RNP Complex–Associated Protein (VP24)

VP24, which adopts single-domain *α*/*β*-structure with the overall shape resembling a pyramid[855,856] (Fig. 11.8C), is a RNP assembly factor. VP24 acts through a direct interaction with NP, thereby condensing RNP complexes. This interaction inhibits transcription and replication and facilitates RNP transport to budding sites and packaging into virions.[38,330,561,719,790,791] In addition, cuevavirus and ebolavirus VP24s counter the innate host cell antiviral response by binding to nuclear transporter karyopherins (KPNA1, 5, and 6) that transport STAT proteins to the nucleus to activate interferon-stimulated gene expression.[193,374,495,578,626,627,671,834]

Large Protein (L)

Filovirus L is the catalytic part of the filovirus polymerase holoenzymes (VP35+L).[79,532,534,723,768] Filovirus Ls contain six highly conserved regions (CRs) mediating nucleotide triphosphate binding (CRI), RNA template recognition (CRII), RNA polymerization (CRIII), polyadenylation (CRIII), mRNA capping/polyribonucleotidyl transfer (CRIV and CRV), and methylation (CRVI). These regions are organized in four distinct domains: (a) RdRp and polyribonucleotidyltransferase (PRNTase), (b) a connector domain, (c) methyltransferase (MTase), and (d) a CTD. Structurally, all mononegavirus RdRps resemble right hands with clearly discernible finger, palm, and thumb structural domains. Since efforts to obtain structural information on filovirus L have not been successful thus far, structural

considerations currently rely on computational modeling[227,360,457,458,479,532,658,745] (Fig. 11.8D). Analogous to other mononegaviruses, filoviral genomes and antigenomes likely possess a single L entry site (promoter) at the 3′ ends of the encapsidated genomes and antigenomes, respectively. After binding to the promoter region, L either replicates the genome or antigenomes over their entire lengths (replication) or scans the genome (but not the antigenome) for gene start and gene end signals to transcribe the individual genes (transcription). Transcription includes viral mRNA G capping, N^7 methylation of the G cap and 2′-*O*-methylation (capI structure), cap-independent methylation, and polyadenylation. Cuevavirus and ebolavirus polymerases additionally mediate cotranscriptional mRNA editing.[479,652,765] Adaptation of MARV to domesticated guinea pigs results in mutations in the L sequence, thereby up-regulating L's activity.[404]

Matrix Protein (VP40)

Mammalian filovirus VP40 is a multifunctional protein that can assume multiple structural states.[81,618,789] The basis for these structural states is the VP40 protomer, which consists of a distinct NTD and a distinct CTD[168] (Fig. 11.9A). Within the protomer, the position of NTD and CTD relative to each other[81,168,286,672] drives at least three types of VP40 polymerization. One type is a symmetric NTD–NTD VP40 dimer in which the CTDs are tightly bound to the NTDs, resulting in a structure resembling a butterfly[81,168,732] (Fig. 11.9B). Butterfly dimers traffic through the cell and ultimately localize at cell membranes. Through VP40's ability to directly bind to NP and VP35, VP40 recruits RNPs to cell membranes.[3,68,69,78,81,198,328,333,370,546,559,561,581,734] The second type of VP40 polymerization originates in CTD interaction with membrane phosphatidylserine, resulting in VP40 hexamerization with hexamers consisting of three linearly arranged VP40 dimers that are structurally distinct from butterfly dimers[3–5,81,672,699] (Fig. 11.9C). CTD–CTD interactions at ends of hexamers then polymerize the hexamers, resulting in virion matrix filaments that cylindrically engulf RNPs[3,5,81,584] (Fig. 11.9D) and facilitate budding.[4,5,168,312,363,581,641,672,700] Finally, VP40 can form octameric rings via NTD–NTD interactions used for hexamerization and

additional, distinct NTD–NTD interfaces not available in either butterfly or hexamer dimers[81,286,641,732] (Fig. 11.9E). The VP40 octamer is a nonstructural protein that does not localize to cell membranes but instead binds RNA in its lumen, thereby likely negatively regulating filovirus transcription.[81,286,328,330,333,581,734]

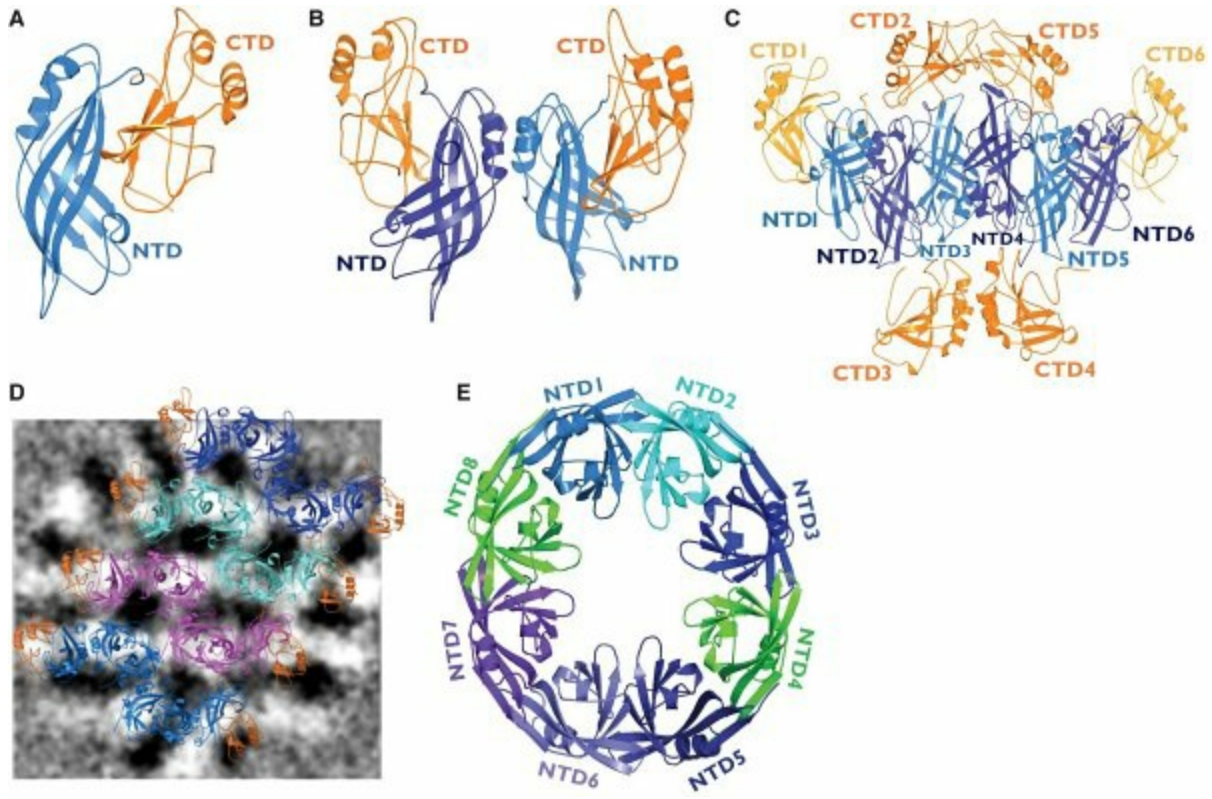

FIGURE 11.9 Structure of EBOV matrix protein (VP40). A: VP40 protomer showing the characteristic N-terminal domain (NTD, *blue*) and C-terminal domain (CTD, *orange*). **B:** Butterfly dimer consisting of two VP40 monomers that interact via their NTDs with sprung CTDs.

C: Hexamer. **D:** Octamer. **E:** Model of the cylindrical VP40 matrix showing four VP40 hexamers side by side superimposed on 2D averages of virion tomograms. (From Pavadai E, Gerstman BS, Chapagain PP. Pavadai E, Gerstman BS, Chapagain PP. A cylindrical assembly model and dynamics of the Ebola virus VP40 structural matrix. *Sci Rep* 2018;8(1):9776. Figure arrangement courtesy of Jiro Wada, IRF-Frederick, Fort Detrick, MD, USA.)

The N-terminus of VP40 contains late-budding motifs that are important for budding. Filoviruses differ in type and number of these motifs. For instance, ebolavirus VP40s have overlapping P(T/S)AP and PPXY motifs, whereas marburgvirus VP40s only contain PPXY motifs.[313,459,704] Finally, marburgvirus and likely dianlovirus, but not ebolavirus VP40 counter the cellular innate antiviral response.[568,757,758]

Filovirus *GP* Gene Expression Products

The cuevavirus and ebolavirus *GP* genes contain three ORFs located in the three possible reading frames (Fig. 11.10). The 0 frame is preceded by a Kozak sequence and contains a stretch of seven consecutive uridine residues (7U editing site) within a predicted hairpin loop. Transcription of this ORF by the filovirus polymerase (L+VP35) and subsequent translation yield a nonstructural protein precursor (pre-sGP). The two other ORFs begin in the −1 and +1 reading frames at the 7U editing site, respectively. Cotranscriptional polymerase stuttering (editing) at the 7U site results in mRNA transcripts that contain more or less than the expected seven cognate adenosine residues, thereby transcribing the −1 and +1 ORFs.[550,652,674,765,771]

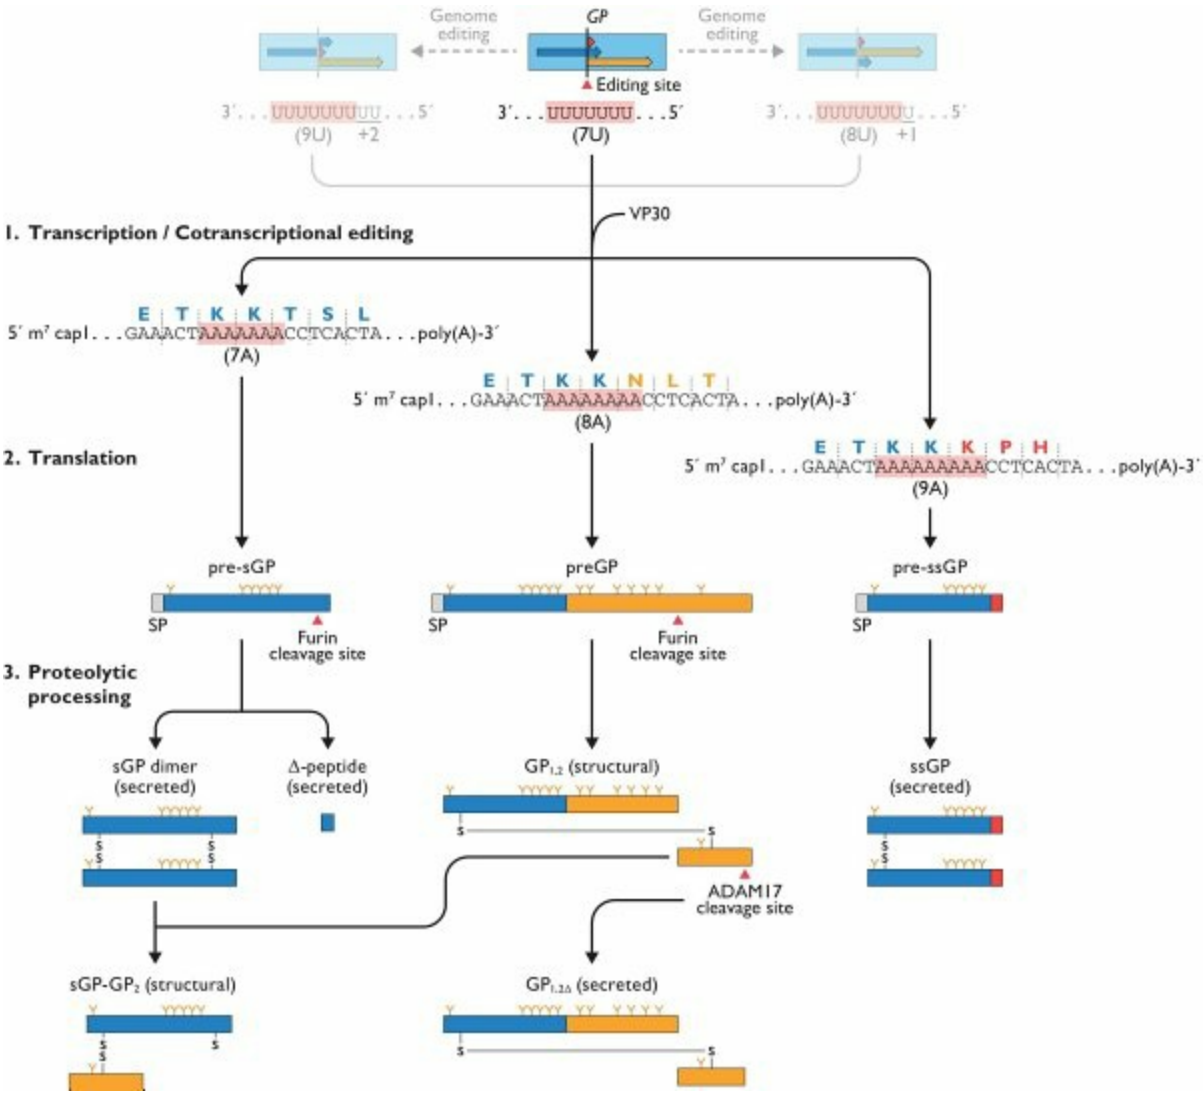

FIGURE 11.10 EBOV *GP* gene expression. The *GP* of most wild-type ("7U") EBOV isolates contains a single open reading frame (ORF) preceded by a proper Kozak sequence (*blue arrow*, emphasized middle *GP* gene, top) and a 7U editing site (*vertical black bar*). Transcription of this ORF, regulated by VP30, results in a capped and polyadenylated 7A mRNA, which is translated into pre-sGP (*left pathway*). Pre-sGP's signal peptide (SP) is removed by a signalase, and the protein is further proteolytically processed by furin into secreted sGP and Δ-peptide. At top middle of figure: cotranscriptional mRNA editing by the EBOV polymerase holoenzyme (L+VP35) under VP30 regulation leads to frameshifts,

thereby accessing novel ORFs (*orange* and *red arrows*, emphasized middle *GP* gene, *top*). Addition of a single nontemplated A results in mRNAs that are translated into preGP, which is further processed by a signalase (SP removal) and furin to the EBOV $GP_{1,2}$ peplomer, which can be shed from membranes after ADAM metallopeptidase domain 17 (ADAM17, formerly TACE) cleavage (*middle pathway*). Disulfide bond switching between the sGP homodimer and the $GP_{1,2}$ heterodimer can connect sGP monomers to GP_2 monomers to form virion-structural sGP–GP_2 heterodimers. Addition of two nontemplated As results in mRNAs that are translated into pre-ssGP, which is further processed by a signalase and matures to secreted ssGP (*right pathway*). Genome editing can result in alternative *GP* editing sites (*top*, deemphasized *left and right* GP genes). Cotranscriptional mRNA editing results in the same expression products but with altered expression frequencies. (Figure courtesy of Jiro Wada, IRF-Frederick, Fort Detrick, MD, USA.)

Expression of these mRNAs, therefore, yields two distinct proteins, the major glycoprotein ($GP_{1,2}$) precursor (preGP; −1 frame editing) and the secondary secreted glycoprotein precursor (pre-ssGP; +1 frame editing). The N-termini of the three *GP* gene-encoded proteins are identical (i.e., the amino acid residues encoded in the 0 reading frame up to the editing site; EBOV: 295 N-terminal amino acid residues), but the proteins differ in their C-termini.[652,765] Because multiple adenosine residues can be inserted or skipped during cotranscriptional editing, all three proteins are expressed in various isoforms. For instance, insertion of three adenosine residues into the nascent mRNA still yields pre-sGP because the 0 frame is maintained, but this sGP now contains one additional amino acid residue compared to unedited mRNA.[14,674] Cotranscriptional editing is regulated by *cis*-acting sequences located nine nucleotides upstream and downstream of the editing site in synergy with VP30 as a *trans*acting factor.[507] The expression ratio of pre-

sGP:preGP:pre-ssGP is roughly 61% to 72%:19% to 28%:1% to 5% depending on cell type and virus in the 7U context.[11,506,674]

Cell culture passaging or animal inoculation of ebolaviruses can result in uridine additions or deletions in the *GP* editing site within the genome, thereby shifting the pre-sGP:preGP:pre-ssGP expression ratio at the genomic level.[766] For instance, passaging of 7U EBOV or 7U SUDV in Vero E6 cells results in the selection of 8U viruses. However, injection of a domesticated guinea pig–adapted 8U EBOV into domesticated guinea pigs or crab-eating macaques results in evolution of predominantly 7U EBOV. Likewise, injection of 9U SUDV into crab-eating macaques results in partial reversion to 7U SUDV. On the other hand, injected 7U SUDV does not convert to 8U SUDV.[14,423,770] The significance of these selections remains to be clarified. Differences in disease progression were not observed in domesticated guinea pigs or crab-eating macaques injected with either 7U or 8U EBOV[743,766] or in crab-eating macaques injected with either 7U or 8U SUDV at high inoculation doses.[14] However, at extremely low inoculation doses (0.01 plaque-forming units [PFU]), both 8U EBOV and 8U SUDV can be less lethal to crab-eating macaques than 7U control viruses.[15]

Dianlovirus and marburgvirus GP genes contain single ORFs without editing sites. The only deduced or known expression product from these genes is preGP.[807,841]

Secreted Glycoprotein

Cuevavirus and ebolavirus pre-sGP is synthetized into the endoplasmic reticulum (ER). Proteolytic cleavage of pre-sGP by furin-like endoproteases at a conserved C-terminal R-X-R-R↓ motif and further maturation in the ER yield mature sGP and Δ-peptide. sGP is a nonstructural protein that is C-mannosylated at a conserved W-X-X-W motif, *N*-glycosylated, and is secreted through the Golgi apparatus in high amounts by infected cells as a disulfide-linked parallel homodimer.[43,44,216,579,772,773] In EBOD patients, this secretion leads to high sGP concentrations in the blood. Because sGP, $GP_{1,2}$, and ssGP have identical N-terminal amino acid sequences (including one of the two cysteine residues responsible for sGP homodimerization), each sGP

monomer contains the residues that correspond to the GP_1 head, glycan cap, and base (see below). Therefore, this monomer is partially cross-reactive with several anti-GP_1 antibodies.[336,520,538,579,741,857] The observed serologic cross-reactivity with anti-$GP_{1,2}$ antibodies suggests an antibody decoy function for circulating sGP in infected animals.[354,527] However, the function of sGP is still unknown. *In vitro*, sGP restores the endothelial barrier destroyed by exposure to Ebola virion–like particles and tumor necrosis factor (TNF), suggesting an anti-inflammatory role of sGP.[774] However, recombinant domesticated guinea pig–adapted EBOV engineered not to produce sGP is not attenuated in infected domesticated guinea pigs compared to wild-type EBOV,[331] and marburgviruses are as virulent as ebolaviruses without producing sGP.

Δ-peptide

Δ-peptide, the C-terminal cleavage product of cuevavirus and ebolavirus pre-sGP, is an *O*-glycosylated and sialylated peptide of ≈40 amino acid residues that is secreted from infected cells.[773] Exogenous BDBV, EBOV, SUDV, and TAFV (but not LLOV or RESTV) Δ-peptides inhibit EBOV and MARV replication in cell culture, suggesting that these peptides may control filovirus superinfection of host cells.[617] Recent studies indicate that Δ-peptide is a chloride-selective viroporin that forms pentameric pores in host cell plasma membranes.[317,601] The actual function of the peptide during *in vivo* infection remains to be determined.

Glycoprotein ($GP_{1,2}$)

Mammalian filovirus preGP contains a signal peptide at the N-terminus that targets the protein into the ER and a C-terminal type I transmembrane domain that tethers the protein to the ER membrane. In the ER, the protein acquires oligomannosidic *N*-glycans. After translocation to the Golgi, hybrid and complex *N*-glycan modifications are finalized, and the protein becomes *O*-glycosylated. Ebolavirus preGPs are typically also highly sialylated, whereas sialylation is weaker or absent in marburgvirus preGPs, dependent on cell type. The overall glycan content constitutes at least one-third of the molecular mass of the preGP. The majority of glycosylations occurs in a highly

variable, so-called mucin-like subdomain at the center of preGP.[59,139,223,225,278,629,767,769] Glycosylated preGP dimerizes via a disulfide bond and is then cleaved in the *trans*-Golgi apparatus by furin-like endoproteases at a conserved R-X-R-R↓ motif into GP_1 and GP_2 subunits. The role of this highly conserved cleavage event is unclear, as recombinant EBOV engineered to forgo preGP cleavage is fully functional and equally virulent in rhesus monkeys (Primates: Cercopithecidae: *Macaca mulatta* Zimmermann, 1780) as wild-type control virus.[553] These subunits remain attached to each other through a disulfide bond ($GP_{1,2}$ heterodimer). Prior to transport to the cell membrane, which is independent from any other filovirus proteins, these heterodimers trimerize to form the mature $GP_{1,2}$ peplomer that is incorporated into virions.[546,653,767,769,820]

GP_1 is the virion surface-exposed $GP_{1,2}$ moiety that mediates cell-surface attachment via a distinct filovirus receptor-binding site.[34,171,365,431,445,476,477] GP_1 is structured into base, head, glycan cap, and mucin-like subdomains (Fig. 11.11A). The receptor-binding site is situated in the head of each GP_1 monomer in the trimer, but the sites are masked by the glycan caps consisting of *N*-glycans. The mucin-like subdomains are located upward and outward from these caps and shield $GP_{1,2}$ from host antibodies.[63,314,742] Marburgvirus GP_1 is phosphorylated, but the role of this posttranslational modification is unclear.[654]

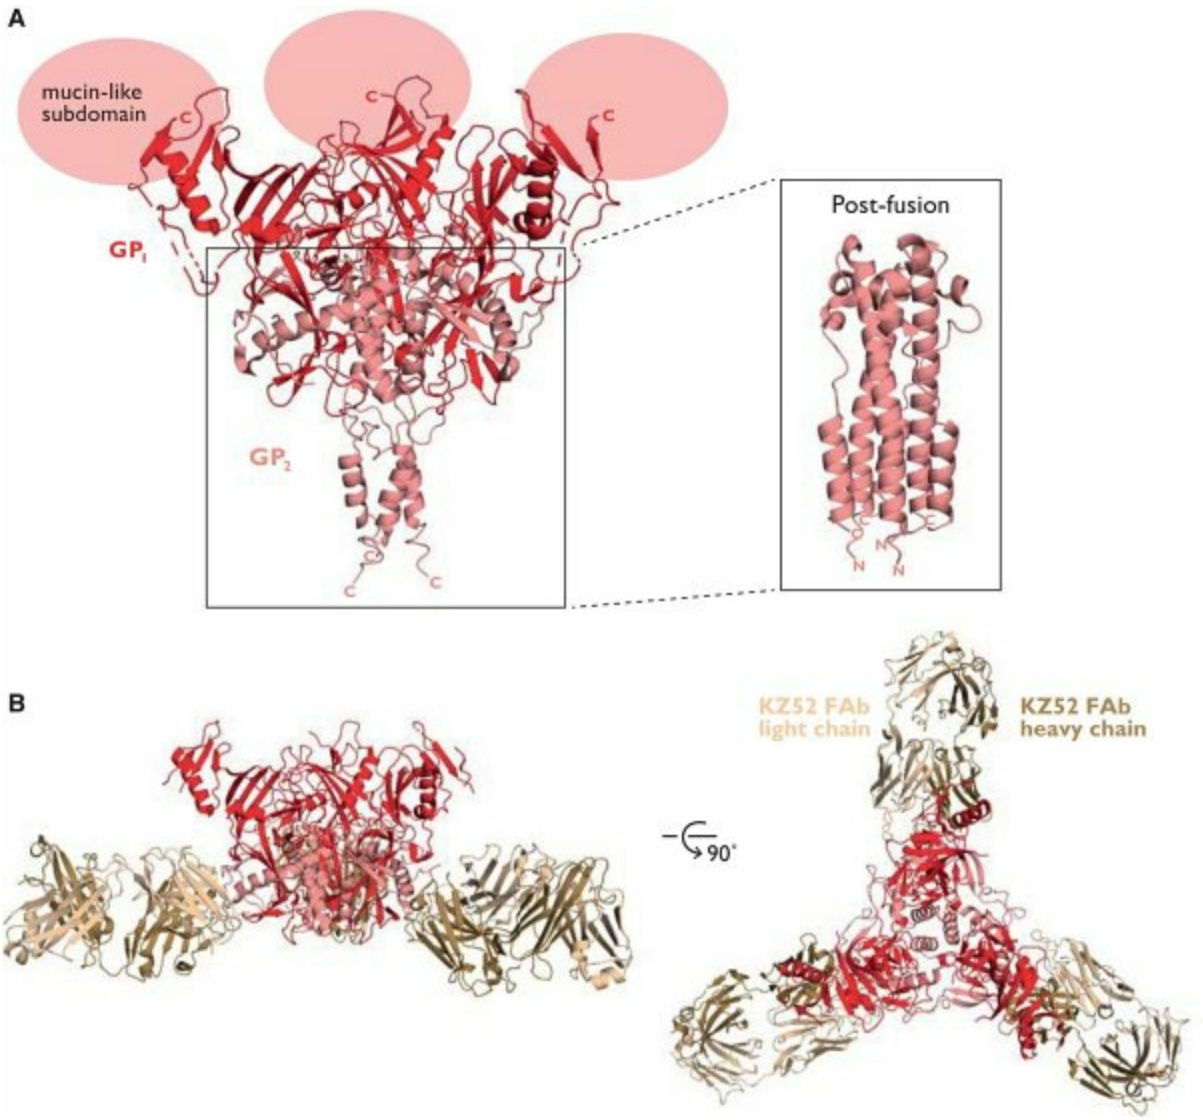

FIGURE 11.11 Glycoprotein ($GP_{1,2}$) structure.

A: Side view of the mature prefusion EBOV $GP_{1,2}$ peplomer consisting of three GP_1 (*red*)-GP_2 (*pink*) heterodimers ("chalice"-like structure with the three GP_2s pointing toward the envelope and the three mucin-like subdomains decorating the bowl; PDB 5JQ3). Low pH and cathepsin cleavage lead to glycan cap and mucin-like subdomain removal, insertion of the fusion peptide into the cellular target membrane, membrane–envelope fusion, and a characteristic "six-helix bundle" $GP_{1,2}$ postfusion structure (*inset box*; PDB 2EBO).

B: Prefusion EBOV $GP_{1,2}$ in complex with EBOV-neutralizing mAb KZ52's antigen-binding fragment (Fab light chain, *light brown*; heavy chain, *dark*

brown), which binds at the GP_1–GP_2 interface (PDB 1CSY).

GP_2 is a typical class I fusion protein containing helical heptad-repeat regions that flank a CX_6CC motif, a conserved fusion loop defined by a disulfide bridge between two cysteine residues and the transmembrane domain that tethers $GP_{1,2}$ to the virion membrane.[103,250,251,445] Similar to retrovirus transmembrane proteins, filovirus GP_2 also contains a short immunosuppressive motif.[103,838] In addition, GP_2s are acylated at their cytoplasmic domains.[247] GP_2 drives fusion of the viral envelope with host cell membranes through $GP_{1,2}$ conformational changes induced by GP_1 receptor binding.

Virion $GP_{1,2}$ trimers assume the shape of a chalice, with the three GP_1 subunits angling outward but bound together at their bases where they connect to the stalk-like GP_2 trimer (Fig. 11.11A). The GP_2 fusion loops wrap around the outside of the GP_2 trimer into the neighboring GP_1s.[34,171,445]

Filovirion antigenicity is primarily determined by $GP_{1,2}$. Cuevavirions, ebolavirions, and marburgvirions are antigenically distinct, and individual species members can be differentiated with certain anti-$GP_{1,2}$ antibodies. Monoclonal antibodies that neutralize filovirus infection *in vitro* do not necessarily protect experimentally infected animals *in vivo*. Vice versa, nonneutralizing antibodies have been described that play important parts in disease protection.[91,171,234,235,246,314,398,445,490,493,516,655,656,794,804] Filovirus-neutralizing monoclonal antibodies, such as EBOV-specific KZ52, EBOV-specific 2G4, EBOV-specific 4G7, and EBOV-specific mAb114 and SUDV-specific 16F6, often bind to a GP_1–GP_2 epitope at the base of the $GP_{1,2}$ trimer, thereby mechanically preventing the $GP_{1,2}$ conformational changes required for fusion[171,445,520,538,579,741] (Fig. 11.11B). Other antibodies target the fusion loop or the GP_2 stalk[82,236,248,389] or the mucin-like subdomain.[446,809]

Shed Glycoprotein ($GP_{1,2\Delta}$)

Luminal proteolytic cleavage of EBOV and MARV $GP_{1,2}$ near the GP_2's transmembrane anchor by ADAM metallopeptidase domain 17 (ADAM17, formerly TACE) produces a soluble, trimeric $GP_{1,2}$ variant ($GP_{1,2\Delta}$).[181] ADAM17 expression is up-regulated at days 4 to 6 postexposure in EBOV-infected crab-eating macaques, and $GP_{1,2\Delta}$ can be detected at high concentrations at that time.[639] *In vitro*, $GP_{1,2\Delta}$ activates noninfected dendritic cells and macrophages to secrete pro- and anti-inflammatory cytokines (TNF, CXCL8, interleukin [IL] 1B, IL1R1, IL6, IL10, IL12B) that increase endothelial cell permeability.[210] Because the structure of $GP_{1,2\Delta}$ is highly similar to that of $GP_{1,2}$, $GP_{1,2\Delta}$ could also serve as an antibody decoy in the circulation.

sGP–GP_2

Under yet-to-be-defined conditions, sGP monomers can connect to GP_2 monomers via a disulfide bridge between cysteine residues most often used for sGP dimerization and the GP_1–GP_2 connection. The resulting sGP–GP_2 heterodimer is anchored to the ER and, later, to the plasma membrane via the GP_2 transmembrane domain and may become incorporated into the envelope of budding virions. Due to the significant sequence similarity between sGP and GP_1, sGP–GP_2 could function as an anti-$GP_{1,2}$ antibody decoy directly on the virion, thereby protecting $GP_{1,2}$ peplomers from host recognition.[160,355]

Secondary Secreted Glycoprotein

Pre-ssGP is produced at low frequency by cuevaviruses and ebolaviruses via cotranscriptional editing from the *GP* gene.[11,506,674] During maturation in the ER, pre-ssGP becomes *N*-glycosylated and is subsequently secreted from infected cells as a disulfide-linked homodimer (mature sGP). The function of the protein is unclear, but similarly to sGP and sGP–GP_2, ssGP could be an antibody decoy.[506,772]

STAGES OF REPLICATION

The filovirus life cycle can be divided into virion attachment/entry, replication/transcription/translation, and assembly/budding (Fig. 11.12).

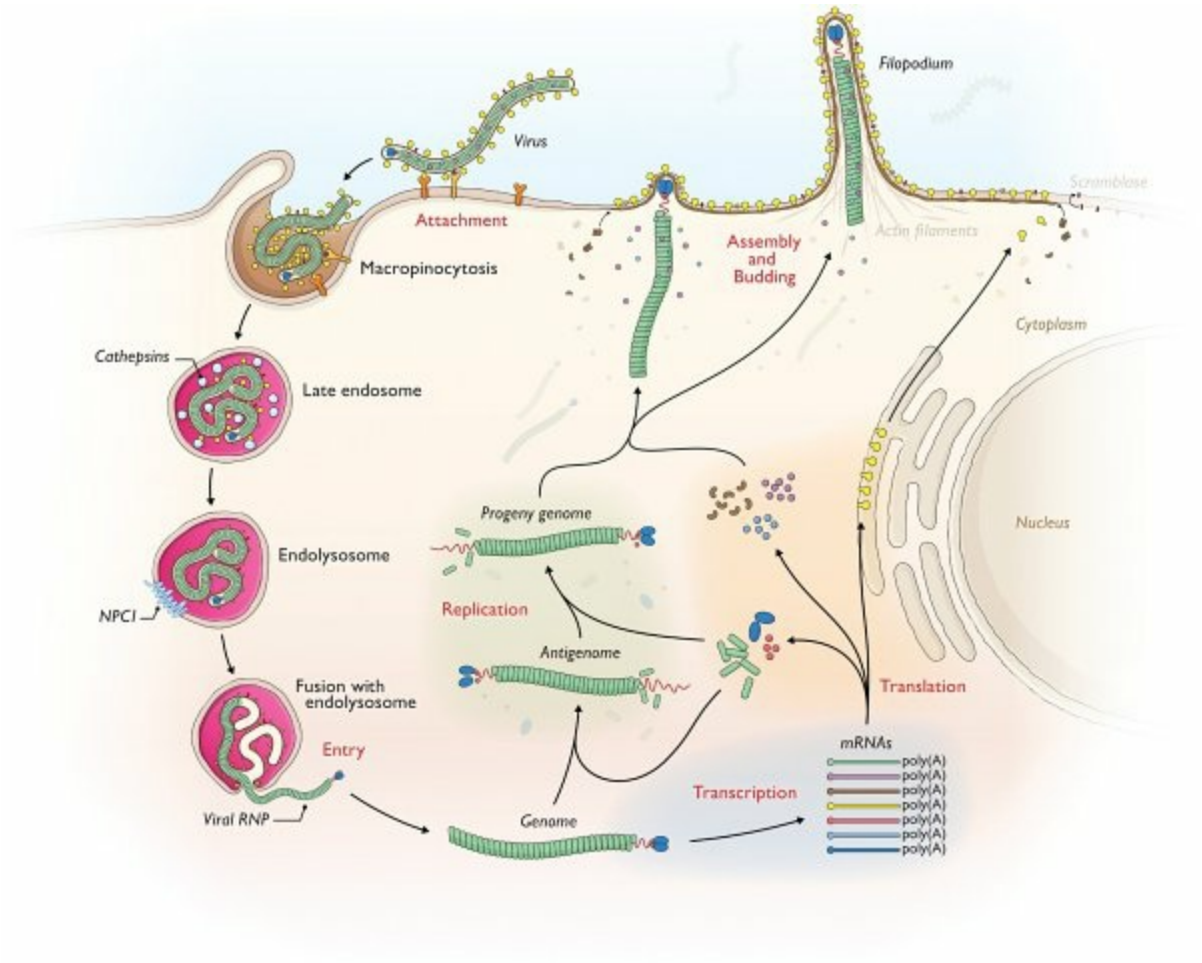

FIGURE 11.12 Mammalian filovirus life cycle. Filovirion $GP_{1,2}$ peplomers and/or phosphatidylserine in the filovirion envelope mediates binding to host cell-surface attachment factor (*orange*), resulting in virion endocytosis (predominantly macropinocytosis). Low pH and cathepsin-mediated cleavage of $GP_{1,2}$ in the late endosome lead to engagement of the filovirus receptor, NPC intracellular cholesterol transporter 1 (NPC1; *light blue*) and, thereby, fusion of the virion envelope with the endolysosomal membrane. The virion ribonucleoprotein (RNP) core is released into the cytosol, where filovirus gene transcription and genome

replication take place. Replication occurs by synthesis of encapsidated antigenomes that serve as templates for progeny genome synthesis. Following translation, mature progeny RNPs are transported to the $GP_{1,2}$-containing plasma membrane of filopodia for matrix embedding and envelopment. Budding occurs at the plasma membrane via a VP40-mediated process. (Figure courtesy of Jiro Wada, IRF-Frederick, Fort Detrick, MD, USA.)

Filovirion Cell-Surface Attachment and Host Cell Entry

Mammalian filoviruses infect a wide variety of vertebrate cell types from a broad range of species.[425,644,848] The cell types and host tropisms of all mammalian filoviruses are almost identical *in vitro*. However, some filovirus genus- or species-specific tropism differences have been uncovered.[220,555] Filovirus *in vitro* species and cell-type specificity are not necessarily predictive of *in vivo* tropism, as, thus far, only mammals of a few species have been infected successfully with mammalian filoviruses (Table 11.4).

TABLE 11.4 Overview of animal models of mammalian filovirus infections

Experimental Animal (Species)	Exposure Filovirus	Outcomes
Artiodactyla		
Domestic pigs/wild boars (*Sus scrofa domesticus* Erxleben, 1777)	EBOV, RESTV	Viremia in the absence of overt clinical signs[403,478,554,798]
Carnivora		
Domestic ferrets (*Mustela putorius furo* Linnaeus, 1758)	BDBV, EBOV, RESTV, SUDV	Uniformly lethal disease[149,398,404,819]; partially lethal transmission model[159]
	MARV, RAVV	Absence of viremia and clinical signs[150,818]
Chiroptera		
Egyptian rousettes (*Rousettus aegyptiacus* E. Geoffroy, 1810)	BDBV, EBOV, RESTV, SUDV, TAFV	Absence of viremia and clinical signs[377,587]
	MARV, RAVV	Viremia in the absence of overt clinical signs[22,376,377,586]
Lagomorpha		
European rabbits (*Oryctolagus cuniculus* Linnaeus, 1758)	Domesticated guinea pig–adapted EBOV	Variably lethal disease[643]
Primates		
Common marmosets (*Callithrix jacchus* Linnaeus, 1758)	EBOV, MARV	Uniformly lethal disease[113,697,698]
Common squirrel monkeys (*Saimiri sciureus* Linnaeus, 1758)	MARV	Uniformly lethal disease[687,688]
Crab-eating macaques (*Macaca fascicularis* Raffles, 1821)	EBOV, MARV, RAVV	Uniformly lethal disease[16,19,153,245,266,272,273,321]
	BDBV, RESTV, SUDV, TAFV	Variably lethal disease[215,230,263,322,361,517,864]
Grivets (*Chlorocebus aethiops* Linnaeus, 1758)	EBOV, RESTV, SUDV, MARV	Variably lethal disease[47,155,230,296,623,642,687,688,864,866]
Hamadryas baboons (*Papio hamadryas* Linnaeus, 1758)	EBOV, MARV	Uniformly lethal disease[642,644,868]
Rhesus monkeys (*Macaca mulatta* Zimmermann, 1780)	EBOV, SUDV, MARV, RAVV	Uniformly lethal disease[47,154,200,232,259,356,358,371,439,623,687,688,864]
Rodentia		
Domesticated guinea pigs (*Cavia porcellus* Linnaeus, 1758)	Domesticated guinea pig–adapted EBOV, SUDV, MARV, and RAVV	Uniformly lethal disease[57,140,149,265,410,462,645,707,714,748,816]; partially lethal transmission model[817]
	RESTV	Viremia in absence of overt clinical signs[162]
Golden hamsters (*Mesocricetus auratus* Waterhouse, 1839)	Laboratory mouse–adapted EBOV, domesticated guinea pig- and golden hamster-adapted MARV	Uniformly lethal disease[191,686,775,862]
	RESTV	Viremia in the absence of overt clinical signs[162]
Laboratory mice (immunocompetent)	Laboratory mouse–adapted EBOV, MARV, RAVV	Uniformly lethal disease[96,98,296,611,620,785,795,863]
	RESTV	Viremia in the absence of overt clinical signs[162]
Laboratory mice (immunodeficient)	BDBV	Nonlethal disease[92]
	EBOV, RESTV, SUDV	Partially to uniformly lethal disease[92,98,162,455,621,863]
	TAFV	Viremia in the absence of overt clinical signs[92,621]
	MARV, RAVV	Uniformly lethal disease[95,455,621,783]

Filovirion attachment to host cells is mediated, likely at neutral pH, by the $GP_{1,2}$ peplomer[476,477,717,819] or by filovirion outer leaflet envelope components such as phosphatidylserine. The glycans on $GP_{1,2}$ bind directly

to a broad range of C-type lectins (CLECs), such as asialoglycoprotein receptor 1 (ASGR1), CD209 (formerly DC-SIGN), C-type lectin domain family 4 member M (CLEC4M, formerly DC-SIGNR), C-type lectin domain containing 10A (CLEC10A, formerly MGL), C-type lectin domain family 4 member G (CLEC4G, formerly LSECTin), and mannose-binding lectin 2 (MBL2).[18,61,288,367,490,492,685,716,754] Filovirion attachment can also be mediated by hepatitis A virus cellular receptor 1 (HAVCR1, formerly TIM-1) and T-cell immunoglobulin and mucin domain containing 4 (TIMD4, formerly TIM-4), which bind phosphatidylserine at the outer leaflet of the filovirion envelope.[186,409,434,628,849] In addition, other cell-surface factors, such TAM family receptor tyrosine kinases (i.e., AXL, MERTK, TYRO3), facilitate filovirion attachment in an unknown manner.[99,680]

Importantly, filovirion attachment factors are not bona fide virion receptors, because individual factors are not necessary or sufficient for filovirion entry. Instead, they appear to function in a complementary manner to adsorb virions at the target cell surface—if a particular factor is absent, another will take over this function.[496,853] For instance, deletion of the $GP_{1,2}$ mucin-like subdomain, and thereby deletion of most $GP_{1,2}$ glycans, does not diminish but rather increases EBOV $GP_{1,2}$–mediated particle entry *in vitro*,[365] indicating that factors such as HAVCR1 could substitute for lectins. Likewise, absence of HAVCR1 (for instance, on primary filovirus targets such as macrophages) does not abrogate filovirion entry—possibly TIMD4 or other, yet-to-be-identified, attachment factors could take over. In addition, within-species HAVCR1 polymorphism influences host cell susceptibility to filovirus infection,[435] suggesting that the temporal progression of filovirus infection from initial to late target cells may be influenced by multiple factors at the cell-attachment step.

Subsequent to attachment, filoviruses enter host cells by endocytosis, generally, but likely not exclusively, by macropinocytosis.[13,70,345,536,543,646,648] In the low pH environment of the endolysosome, the GP_1 subunit is cleaved by cathepsins B and L,[123,284,287,483,490,519,656,663] thereby releasing the mucin-like subdomains and glycan caps to expose the receptor-binding site.[82,187,334,383,782] β1 integrins are thought to regulate these cathepsins, explaining why β1

integrin–deficient cells are refractory to filovirus infection.[664,718] Once exposed, the GP_1 receptor-binding site engages the second luminal domain C of the universal mammalian filovirus receptor, the lysosomal NPC intracellular cholesterol transporter 1 (NPC1),[112,144,285,324,417,555,782,841] which also interacts directly with HAVCR1.[434] The GP_1–NPC1 interaction results in extensive conformational changes in the metastable prefusion $GP_{1,2}$ molecule. These changes involve unwinding GP_2 from GP_1 (and possibly release of GP_1) and unwinding of GP_2's fusion loop containing a fusion peptide from the GP_2 trimer and penetrating the fusion loop into the endolysosomal membrane. While assuming a so-called six-helix bundle structure (Fig. 11.11A), GP_2 pulls the endolysosomal membrane into proximity of the filovirion envelope, thereby triggering membrane–membrane fusion and release of the filovirion RNP into the cytosol of the host cell.[405,445,473,799,800] These last steps are controlled by host two pore segment channels 1 and 2 (TPCN1 and TPCN2), but their exact mechanism of action remains to be determined.[647]

Filovirus Genome Replication and Transcription

Filovirus replication occurs exclusively in the cytosol and begins with mRNA transcription from incoming genomic RNPs. The filovirus replication promoter is bipartite, consisting of a first promoter element (PEI) located in the 3′ genomic leader region and a second promoter element (PEII) located in the UTR of the *NP* gene, downstream of the *NP* gene start signal (Fig. 11.13A). The antigenomic promoter, likely also bipartite, is located at the 3′ end of the antigenome. Ebolavirus and marburgvirus promoters are similarly organized but differ in length and secondary structure.[206,796] Importantly, in contrast to most other mononegavirus genomes that have complementary 3′ and 5′ terminal nucleotides, filovirus genome termini are heterogenous, and the terminal nucleotides are not completely complementary.[164] The 3′ ends of ebolavirus genomes and antigenomes have a single nucleotide overhang compared to the complementary sequence at the 5′ ends. Ebolavirus genome replication begins with the polymerase initiating RNA opposite of a highly conserved 3′-CCUGU motif with the first C residue located at position 2 of

the genome. In contrast, MARV genomes lack a 3′ overhang, and the conserved motif has the sequence 3′-UCUGU. The polymerase commences the synthesis of full-length antigenomes that are encapsidated by NP as the antigenome chain elongates. Using the antigenomic promoter, these antigenomic RNPs then serve as templates for the synthesis of progeny genomic RNPs.[164,531,534] Synthesized genomic and antigenomic RNPs accumulate in cytoplasmic perinuclear inclusion bodies, which are readily visible in filovirus-infected cells.[180,332,339,546]

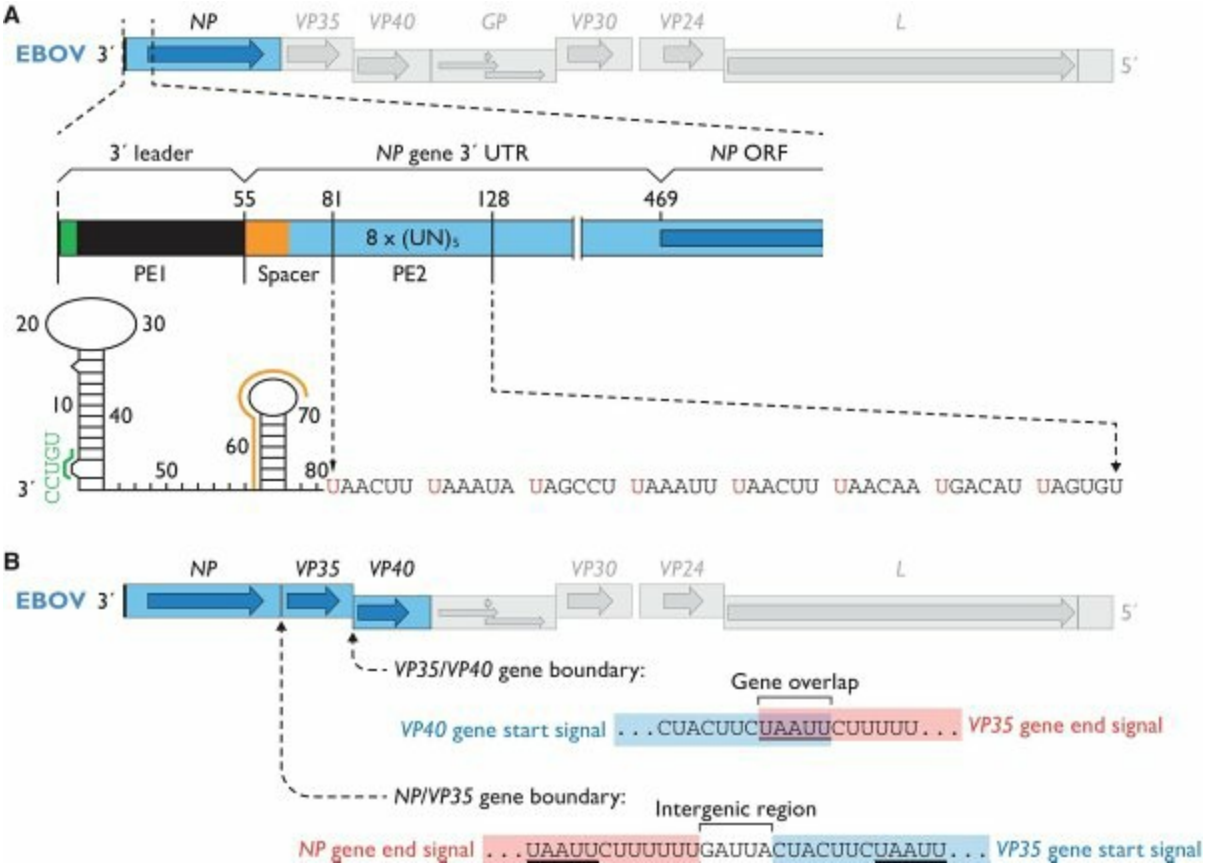

FIGURE 11.13 Mammalian filovirus genomic regulatory signals. A: Organization of the bipartite EBOV promoter, which consists of two promoter elements (PE1 and PE2) separated by a spacer containing the *NP* gene start signal (*orange*). PEII consists of an EBOV-characteristic 8x$(UN)_5$ sequence. The EBOV polymerase initiates RNA synthesis opposite of a highly conserved

3′-CCUGU motif (*green*) at position 2 of the genome. This motif is located within a putative hairpin structure. **B:** Examples for EBOV gene overlaps and intergenic regions. ORF, open reading frame; UTR, untranslated region. (Figure inspired by Mühlberger E. Filovirus replication and transcription. *Future Virol* 2007;2(2):205–215, Ref.[530] and courtesy of Jiro Wada, IRF-Frederick, Fort Detrick, MD, USA.)

The mechanism regulating the switch from transcription to replication is still unclear, but analagous to other mononegaviruses, the concentration of NP might play a role. Ebolavirus VP30 serves as a transcriptional activator and replication inhibitor in a phosphorylation-dependent manner. The transcription-activating function of VP30 depends on an RNA hairpin structure that is formed at the gene start signal of the first gene, the *NP* gene.[72,419,525,526,730] Marburgvirus VP30 functions like ebolavirus VP30 but is a much less potent transcriptional activator.[72,307,308,419,482,524_526,730] Binding of a small stem–loop structure in the genomic trailer by heat shock protein family A (Hsp70) member 8 (HSPA8) is essential for replication.[715] In addition, VP40 and VP24 are both involved in regulation of transcription and replication in ways that remain to be defined,[330] but in the case of VP24, it most likely involves nucleocapsid condensation.[38]

The typically monocistronic, cotranscriptionally capped and polyadenylated mRNAs are synthesized by the viral polymerase from the viral genome (Fig. 11.5) with polar attenuation. mRNAs produced from the utmost 3′ gene (typically *NP*) are synthesized in high abundance, whereas mRNAs produced from the utmost 5′ gene (*L*) are synthesized in the lowest concentrations. Each filovirus gene is flanked by filovirus species/genus-conserved gene start (≈12–14 nt) and gene end (≈11–12 nt) signals (frequently containing the sequence pentamer 3′-UAAUU-5′; Fig. 11.13B). The gene-specific mRNA concentration gradient likely results because the polymerase complex enters the genome at the 3′ end and then moves along the template until it recognizes a gene end signal, which contains a short stretch of uridines. Here, the polymerase stutters, leading to the addition of a

poly(A) tail to the nascent mRNA strand. Concomitantly, the polymerase occasionally falls off the template. Since only a single polymerase entry site is at the 3′ end of the genome, the more 5′-located genes are less likely to be transcribed by the polymerase.[79,293,531,533,534]

Filovirion Assembly and Budding

Mammalian filovirion morphogenesis is regulated by NP, VP35, VP40, and VP24, which initiate and regulate RNP transport, RNP envelopment, and virion budding. Mature genomic progeny RNPs move from their perinuclear location to the plasma membrane or, in particular cell types, to the membranes of endosomal multivesicular bodies (MVBs) in an actin-dependent manner.[69,180,406,407,546,665,719] RNP transport is mediated at least in part by late-budding motifs contained in VP40 of ebolaviruses or in NP and VP40 of marburgviruses. These motifs interact with cellular proteins that contain WW domains, such as components of the endosomal sorting complexes required for transport (ESCRT) and MVB trafficking pathways (e.g., programmed cell death 6 interacting protein [PDCD6IP; formerly Alix], itchy E3 ubiquitin protein ligase [ITCH], NEDD4 E3 ubiquitin protein ligase [NEDD4], tumor susceptibility 101 [TSG101], WW domain containing E3 ubiquitin protein ligase 1 [WWP1]),[178,179,304_306,459,489,552,733,751,752,843] and are dependent on numerous other proteins, such as vacuolar protein sorting 4 homolog A (VPS4A), RAB9A, and RAB11A.[541,545]

ESCRT-dependent filovirion budding at the plasma membrane occurs at VP40 layer–associated lipid rafts and/or filopodia, which also accumulate $GP_{1,2}$ trimers in a tubulin-dependent manner.[55,523,581,665] Consequently, budding filovirions not only contain part of the plasma membrane (including phosphatidylserine) but also the membrane-incorporated $GP_{1,2}$ as progeny peplomers.[4,165,406,700,802] Phosphatidylserine, the substrate for filovirion attachment factors such as HAVCR1, is flipped from the inner leaflet of the plasma membrane to the outer leaflet of the filovirion envelope by cellular scramblases (e.g., XK-related family [XKR], anoctamin 6 [ANO6]).[544,847]

PATHOGENESIS AND PATHOLOGY

The understanding of FVD pathogenesis has been limited by the very low number of autopsies that have been performed in affected individuals.[174,201,256,257,267,384,539,683,694,695,850,852] This low number is explained by opposition to these procedures among particular FVD-affected populations, by a lack of appropriate facilities and staff that could perform these procedures in outbreak areas, and by biosafety risk assessments (exposure to even a very low filovirion numbers can result in lethal FVD).

As a result, the current understanding of FVD pathogenesis (Fig. 11.14) is an amalgam gathered from experimental exposures of mammals belonging to different species using different filoviruses, filovirus variants, and variable exposure doses and inoculation routes (Table 11.4). In the past, animal models that achieved face validity (phenotypic similarity of the disease induced in an animal compared to that observed with human infections) were favored. Face validity was relatively easily achieved because little was known about FVD pathogenesis in humans. Consequently, any "gold-standard" animal model only needs to mimic a few salient characteristics of human FVD to be considered valid. Ethical, financial, logistical, and regulatory (e.g., Food and Drug Administration [FDA] Animal Efficacy Rule) arguments further influence the debate on which of these animal models ought to be used for a particular experiment.[411]

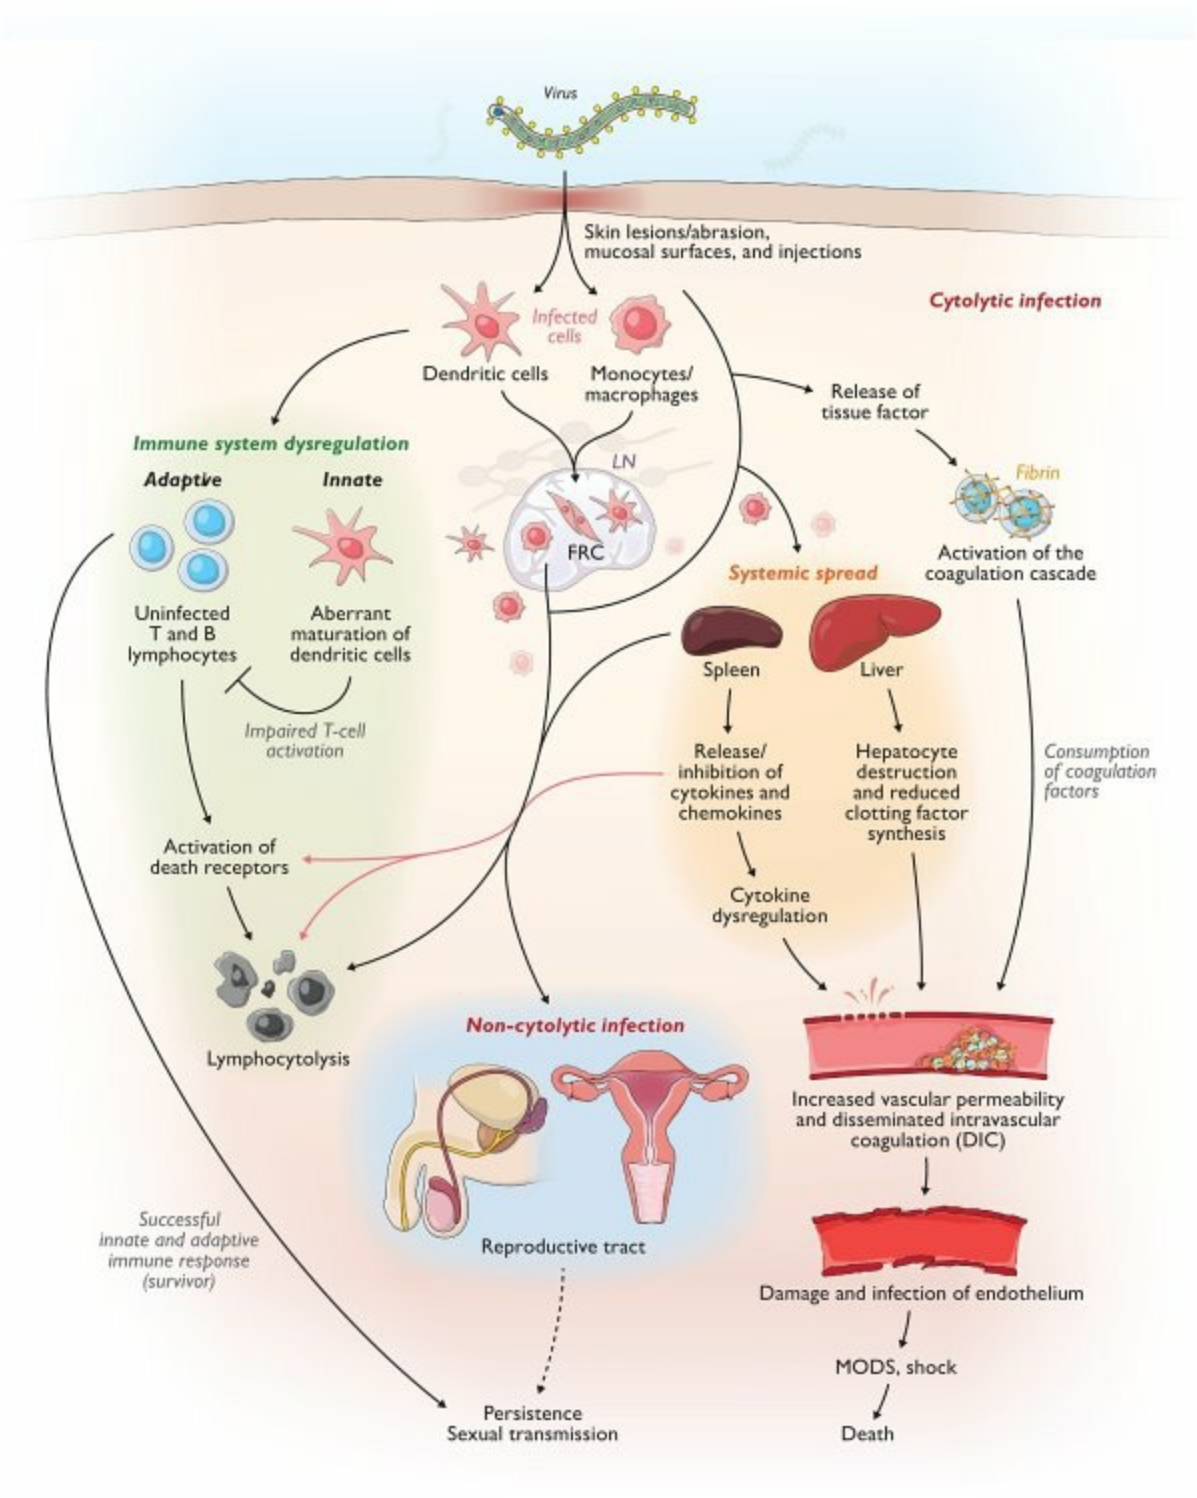

FIGURE 11.14 Overview of pathogenesis of filovirus disease (FVD). Following exposure to virions through skin lesions, contact with mucosal surfaces, or injection, filoviruses infect dermal

dendritic cells and/or monocytes/macrophages and begin replicating. The infected cells transport virus via the lymphatics to regional lymph nodes (LNs). In the LN, the virus spreads to follicular dendritic cells, to monocyte/macrophage populations, and to resident fibroblastic reticular cells (FRCs) that create the three-dimensional network in LNs on which leukocytes compartmentalize and migrate. Filovirus VP35 inhibition of DDX58 inhibits dendritic cell maturation, impairing antigen presentation to T cells and B cells. Infected mononuclear phagocytic cells release a variety of cytokines CXCL8, IL1B, IL6, TNF and express coagulation factor III, increasing vascular permeability and inducing a proinflammatory and procoagulable state. A dysregulated immune response leads to largely unimpeded viral replication. From lymph nodes near the exposure site, the virus spreads systemically, infecting resident macrophages throughout the body, including those in the lungs, spleen, and liver. Lymphocytolysis occurs by unknown mechanisms thought to be associated with cytokine dysregulation and paracrine signaling from infected fibroblastic reticular cells (FRCs), resulting in severe lymphopenia. Hepatocyte infection leads to widespread hepatocellular degeneration and necrosis with a concomitant decrease in the production hepatocyte-synthesized clotting factors and albumin. A consumptive coagulopathy or disseminated intravascular coagulation results in thrombosis, shock, and multiple organ dysfunction syndrome (MODS). Alternatively, in individuals that mount a successful immune response and survive infection, rare cases of sexual transmission have been reported. (Inspired by Schmidt KM, Mühlberger E. Marburg virus reverse genetics systems. *Viruses* 2016;8(6):178, Ref.[659] and figure courtesy of Jiro Wada, IRF-Frederick, Fort Detrick, MD, USA.)

Rodent models of FVD have the advantage of being less expensive than primates, but clinically evident infection in immunocompetent laboratory mice requires exposure to relatively high doses of species-adapted filoviruses. However, infection of rodents with serially passaged or adapted virus in most immunocompetent rodent FVD models still fails to reproduce hallmark features of FVD including cutaneous rashes, coagulopathies, and lymphocyte death.[96,140,191,686,783,785] Nonetheless, because of the genetic homogeneity of rodent strains and small size, sufficiently powered, highly standardized experiments can be performed using rodents with reduced sampling error attributable to population variance. Similar studies would be difficult to replicate using a genetically diverse study population due to the sample sizes required. In addition, some strains of laboratory mice are very well characterized immunologically, making them advantageous for studies of the host immune response against filoviruses. The increasing ability to create novel laboratory mice (e.g., creation of knockout mice, collaborative cross mice, or humanized mice susceptible to wild-type filoviruses) expands the spectrum of possible pathogenesis studies.[98,441,620,701]

The domestic ferret (*Mustela putorius furo* Linnaeus, 1758) is a recently characterized and promising model of EBOD (but not MARD). Intramuscular or intranasal exposure of domestic ferrets to wild-type ebolaviruses results in a rapid onset of uniformly lethal clinical disease with the development of a cutaneous rash, lymphopenia, a consumptive coagulopathy, and necrotizing lesions in both the liver and spleen.[150,151,159,412,418,818,839] These are all features seen in NHP FVD models. Whereas NHPs are sometimes considered to be the best available or “gold-standard” FVD models,[271] studies using NHPs can typically be performed with only small numbers of animals at high financial cost. These restrictions make the verification of research findings or validation through reproducibility difficult. These issues are compounded by the challenges associated with working in maximum containment and ethical considerations, as NHP experimentation is controversial.

Experimental infection of NHPs is typically achieved via parenteral injection or small particle aerosol exposure (i.e., exposure routes that do not mimic the direct person-to-person transmission route in naturally acquired infection).[411] Injection or inhalation of large doses of virus leads to rapid, fulminating disease that is typically uniformly fatal 6 to 9 days later. The

hallmark features of human FVD including cutaneous rashes, coagulopathies, and lymphocyte death[96,140,191,686,783,785] are consistently observed in NHP models following intramuscular exposure to even low doses of wild-type virus.[15,515] Whereas humans with FVD commonly develop massive gastrointestinal fluid losses,[413] gastrointestinal signs are typically absent in the NHP models. Uniform mortality, or a lack of heterogeneity in disease severity, in the high-dose NHP FVD models is appropriate for stringent studies of vaccine protection or MCMs. However, with a uniform mortality model, questions of the natural correlates of protection leading to survival, subclinical infection, viral persistence and sexual transmission, or clinical sequelae seen in convalescent human survivors (including disease relapse) cannot be answered. Although perfect animal disease models do not exist, refinement of existing models based on the most current data may result in models with construct validity in the near future (i.e., animal models in which pathogenic processes are homologous to those in humans with FVD).

The pathologic characterization of filoviruses in their natural reservoir hosts or accidental hosts other than humans has barely started and is thus far restricted to individual studies of EBOV and RESTV in subclinically infected domestic pigs,[403,478,554,798] a histopathological examination of TAFV in a western chimpanzee,[833] and the characterization of MARV and RAVV in subclinically infected Egyptian rousettes.[22,376,377,586]

Pathogenesis Following Filovirus Host Entry

Human-to-human filovirus transmission occurs through direct contact via microabrasions, cuts, or scratches in the skin or mucous membranes. Fomite-to-human transmission can occur through contact with contaminated biological or nonbiological materials, accidental needlesticks, or contact with deceased FVD victims during preparation of bodies for burial.[185,353,393,577,821,822,852]

The filovirion $GP_{1,2}$ peplomer, the host cell–specific expression of $GP_{1,2}$ attachment factors, and NPC1 are the major factors that determine filovirus *in vivo* cell and tissue tropism and the sequence in which susceptible cells and tissues become infected. At the exposure site, filoviruses target resident tissue (typically dermal or submucosal) dendritic cells and macrophages and begin

replicating. These infected mononuclear cells migrate to the lymphatics and enter regional lymph nodes. Virus replication continues in dendritic cells, monocytes, and fibroblastic reticular cells within the regional lymph nodes. Then, both mature virions and infected monocytes spread the virus systemically.[155,747] Filoviruses exhibit a wide tissue tropism, infecting resident tissue macrophages throughout the body; mesenchymal connective tissue cells, including those in lymphoid organs and the reproductive tract; and epithelial cells. The liver is a major target organ of infection[48,97,143,221,266,270,588,644,852] (Fig. 11.15).

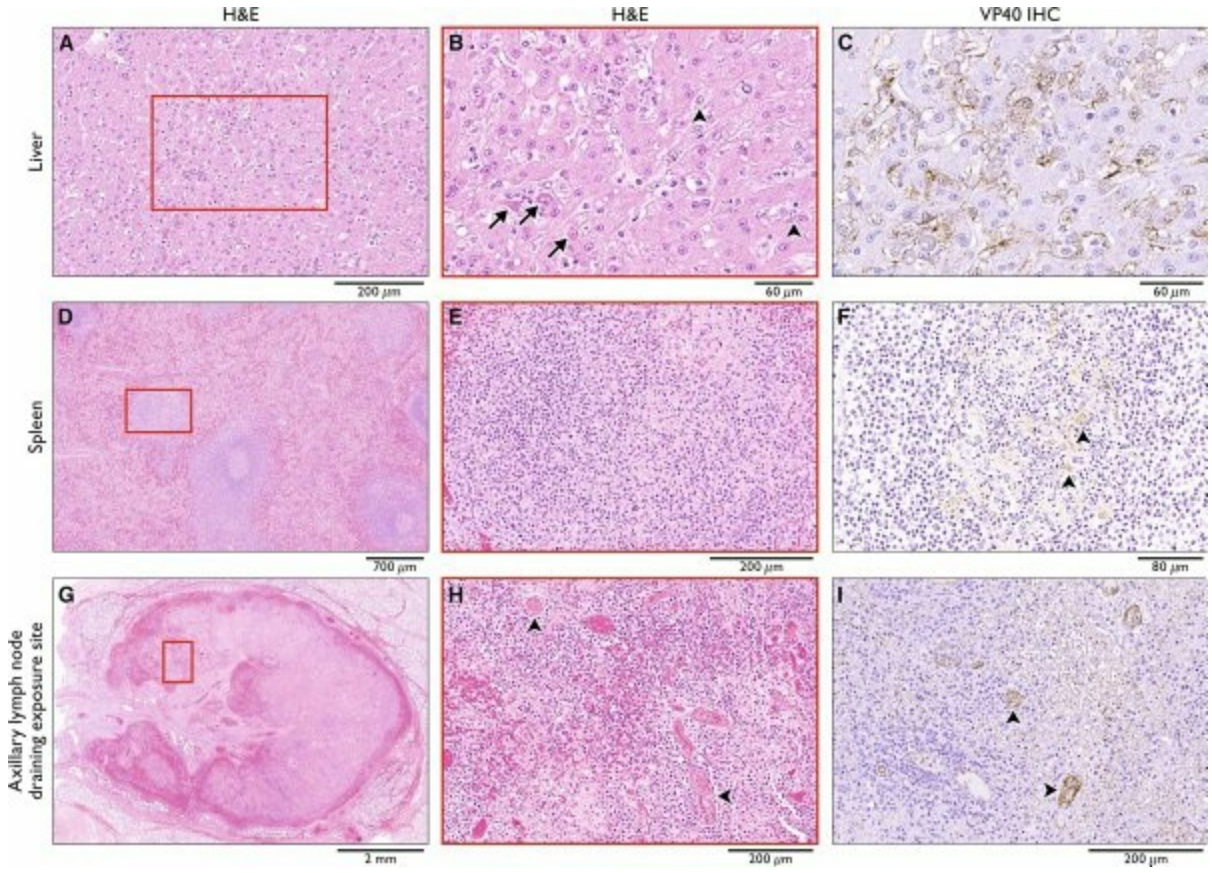

FIGURE 11.15 Histopathology of experimental filovirus infection in rhesus monkeys.

A: Hepatocellular degeneration and necrosis in the liver 8 days after EBOV exposure (magnification bar 200 μm).

B:*Insert* of **(A)**. Hepatocellular swelling is diffuse, apart from individual and small clusters of hepatocytes that are hypereosinophilic and irregularly

shrunken (necrotic hepatocytes, *black arrows*). Kupffer cells are enlarged with vacuolated cytoplasm (*black arrow head*) (magnification bar 60 μm).

C: EBOV VP40 staining (DAB, *brown*) identifies individual hepatocytes and Kupffer cells within the sinusoids in addition to positive serum staining (magnification bar 60 μm).

D: Severe fibrinoid necrosis and lymphoid depletion in the spleen 7 days after MARV exposure (magnification bar 700 μm). Fibrin deposits expand and replace the pre-existing sinusoidal splenic architecture.

E:*Insert* of **(D)**. A splenic lymphoid follicle with severe lymphoid depletion and lymphocytolysis (magnification bar 200 μm).

F: EBOV VP40 staining (DAB, *brown*, IHC) reveals infection in the few degenerate follicular dendritic cells remaining (*black arrowheads*), whereas the surrounding lymphocytes are uninfected (magnification bar 80 μm).

G: Axillary lymph node draining an intramuscular EBOV exposure site 8 days after EBOV exposure (magnification bar 2 mm).

H:*Insert* of **(G)**. Diffuse necrosis effaces the normal architecture of the lymph node with hemorrhage extending into the perinodal connective tissues. Diffuse congestion and hemorrhage with multifocal vascular thrombosis (*black arrowheads*) are present within the subcapsular sinuses and extend into the underlying cortex. The normal cortical lymphoid tissue has been replaced by fibrin admixed with hemorrhage and cellular debris (magnification bar 200 μm).

I: EBOV VP40 staining (DAB, brown, IHC) reveals infection of the few intact macrophages, fibroblastic reticular cells, and virions in the serum (*black arrow heads*; magnification bar 200 μm). DAB, 3,3′-diaminobenzidine; H&E, hematoxylin and eosin stain; IHC, immunohistochemical stain. (Figure courtesy of Reed F. Johnson, NIH/NIAID/DIR/EVPS, and Matthias J. Schnell, Thomas Jefferson University.)

Most infected cells produce copious amounts of progeny virions, resulting in tissue and blood titers reaching 10^6 to 10^8 PFU/mL in humans and up to 10^9 PFU/mL in certain animal models.[158,273,321,420,738,852] The relationship

between inoculum/exposure dose and route has been impossible to characterize in humans, but limited data from animal models suggest a very low median lethal dose in EBOV-infected laboratory mice (LD_{50}≈1 PFU).[96] In crab-eating macaques infected with EBOV or SUDV, a target dose of 0.01 PFU of EBOV or SUDV still suffices to cause fatalities.[15] Extrapolating from animal data, human-to-human filovirus transmission via microabrasions is, not surprisingly, highly efficient.

Filovirus Intrahost Distribution and Pathologic Consequences

Viremia has been detected in the NHP model as soon as 2 days following intramuscular EBOV exposure, often coinciding with the onset of fever,[189] but the temporal development of infection varies with the dose and route of exposure.[16] Whereas few studies with a limited number of animals have evaluated coagulation abnormalities, detectable derangements in hemostasis, such as increases in coagulation factor III (F3, tissue factor) expression and fibrinogen concentrations, have been seen as early as 2 days postexposure. Increases in laboratory-measured clotting times, activated partial thromboplastin time, and prothrombin time occur as early as 3 to 4 days postexposure, and elevations in fibrin degradation products are detected at 5 days postexposure.[189,273,321,488] A similar consumptive coagulopathy has been reported in humans with EVD shortly after the onset of clinical signs.[810] A maculopapular rash of varying severity can be seen as early as day 2 postexposure[266] but typically manifests later, by 5 days postexposure[189] (Fig. 11.16).

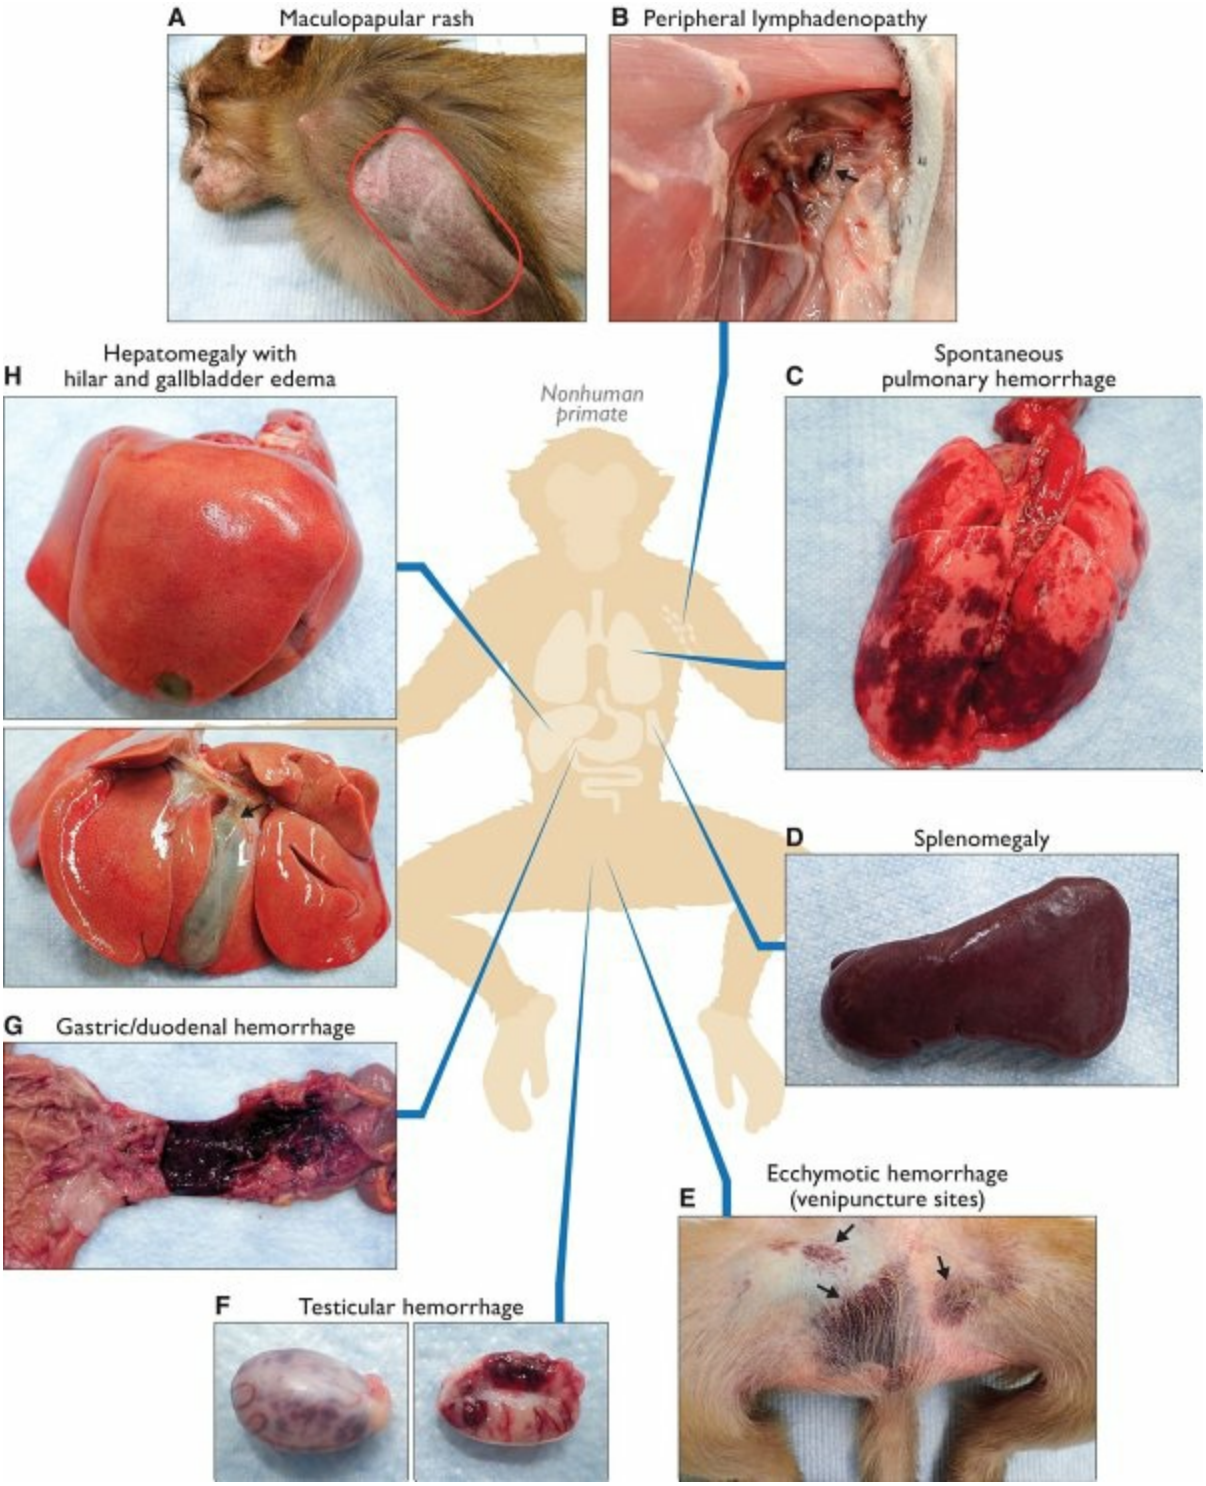

FIGURE 11.16 Gross pathology of experimental filovirus infection in rhesus monkeys.

A: The left lateral face, thorax, and arm of a macaque 8 days after exposure to Marburg virus (MARV) showing a locally extensive, maculopapular rash.

B: The left axilla with exposed axillary lymph nodes *in situ* showing diffuse axillary lymphadenopathy with moderate edema in the surrounding connective tissues from a macaque 7 days after exposure to Ebola virus (EBOV).

C: The dorsal surface of the lungs with multifocal to locally extensive, acute pulmonary hemorrhage in a macaque 9 days after MARV exposure.

D: Severe diffuse splenomegaly in a macaque 9 days after MARV exposure.

E: Inguinal skin with multifocal ecchymotic hemorrhages at venipuncture sites in a macaque 6 days after MARV exposure.

F: Testicles (the testis on the right is cross-sectioned) with multifocal, acute-to-subacute testicular hemorrhage in a macaque 7 days after EBOV exposure.

G: The stomach and proximal duodenum with acute-to-subacute, locally extensive, proximal duodenal hemorrhage in a macaque 8 days after EBOV exposure.

H: Diaphragmatic (top image) and visceral (bottom image) surfaces of the liver. Severe, diffuse hepatomegaly and pallor with edema of the hilar connective tissue and gallbladder wall in a macaque 9 days after MARV exposure. (Figure courtesy of Reed F. Johnson, NIH/NIAID/DIR/EVPS, and Matthias J. Schnell, Thomas Jefferson University.)

Hematologic findings include changes in total leukocyte, monocyte, and platelet numbers. A neutrophilic leukocytosis typically increases the white blood cell count with a concomitant lymphopenia and a decrease in platelet numbers, while monocyte numbers vary. Lymphopenia and decreased platelet numbers are consistent clinicopathologic findings by 4 days postexposure in most NHPs infected with 1,000 PFU of EBOV by the intramuscular exposure route. Platelet numbers typically continue to decrease with disease progression. A terminal thrombocytopenia is one of the clinicopathologic hallmarks of FVD, and thrombocytopenia and clinically significant increases in laboratory measurements of clotting time and fibrin degradation products are diagnostic for disseminated intravascular coagulation (DIC).[189,266,488] Normal megakaryocyte numbers in the bone marrow have been reported in the few human patients examined with FVD.[481] However, a systematic assessment of the presence or absence of

megakaryocyte infection by filoviruses and study of the effect of FVD on megakaryopoiesis or megakaryocyte and platelet function have not been undertaken in any animal model of FVD.

Systemic filovirus spread results in the infection of hepatocytes and Kupffer cells causing acute degeneration with marked (>10 times the upper limit of normal range) increases in alanine transaminase (ALT) and aspartate transaminase (AST) activities. As the disease progresses, hepatocellular necrosis occurs (Fig. 11.15A-C), further increasing both ALT and AST activities. ALT, a cytosolic enzyme, is the most specific marker of hepatocyte damage commonly measured in FVD, though lower activity of this enzyme is present in the kidneys, myocardium, skeletal muscle, pancreas, spleen, lungs, and red blood cells. AST, a cytosolic and mitochondrial enzyme, is present in the cardiac muscle, skeletal muscle, the kidneys, pancreas, spleen, lungs, and red blood cells, in addition to the liver. Terminally, increases in AST activity could be associated with ischemic damage and/or hemorrhage in any of these organs, but the abrupt, marked increases in AST activity seen typically by 4 days postexposure are thought to be derived from hepatocytes. Whereas cholestasis is not a feature in the NHP FVD model, marked increases in gamma-glutamyltransferase (GGT) activity are also typical. Although GGT is present in cells of several organs, including intestine, kidneys, pancreas, and prostate gland, the enzyme is interpreted to be a specific marker for hepatocellular and biliary epithelial cell damage. Increases in alkaline phosphatase (ALP) activity are also observed, but the multiple isoforms of this enzyme in different tissue types have typically not been measured individually. ALP is therefore not as specific as other markers of hepatic damage commonly measured in FVD models. As the disease progresses, ongoing hepatocellular damage is thought to decrease the production of albumin and hepatocellular-synthesized coagulation factors, potentiating the coagulopathy.[189] Similar changes have been documented in human disease, albeit in small numbers of patients.

Fibrin accumulation in the spleen is a consistent histopathologic feature in NHPs, regardless of exposure route, as is severe lymphoid depletion and destruction in both the splenic white pulp and lymph nodes[16,747] (Fig. 11.15D–I). Currently no evidence is available that lymphocytes are infected with filoviruses in vivo. However, in vitro, abortive infection of lymphocytes by EBOV appears to occur. The lymphopenia observed in FVD had

previously been thought to be a result of paracrine signaling, possibly stemming from infected fibroblastic reticular cells in lymphoid tissues. However, the molecular mechanisms underlying FVD-associated lymphocyte death are not clear.[155,702,848]

Prerenal azotemia (secondary to dehydration) occurs later in the disease course, typically from days 5 to 8 postexposure. The kidneys are likely not initial targets in FVD, though terminal DIC often results in thrombosis of vasa recta and, occasionally, the glomeruli in affected animals. Multifocal acute tubular necrosis, thought to be secondary to reduced perfusion or ischemia associated with multiple organ dysfunction syndrome (MODS), is sometimes seen in macaque models histopathologically.[266,321,481]

Adrenal cortical cells are also often infected.[642] This observation has led to widespread speculation that filovirus infection decreases both mineralocorticoid and glucocorticoid production leading to reductions in blood volume and vascular tone. However, concentrations of these hormones in animal models of FVD and in humans with FVD have not been reported. A progressive hypoproteinemia, perhaps secondary to both reduced hepatic production of albumin and protein loss resulting from increased vascular permeability, reduces oncotic pressure. This hypoproteinemia is occasionally severe enough to result in third spacing or edema. Quantitative assessments of protein loss via renal and gastrointestinal routes have not been reported. The coagulopathy associated with FVD can lead to spontaneous hemorrhage, but more frequently, DIC with thrombosis occurs in the NHP model. Thrombosis can be seen in almost any organ, but in the NHP model, thrombosis is predominantly seen in lymph nodes near the exposure site (Fig. 11.15G, H), renal vasa recta, the submucosal vessels supplying the proximal duodenum (Fig. 11.16G), lungs, ciliary pars plicata, renal glomeruli, testes, hepatic sinusoids, and choroid plexus of the brain. Death occurs as a result of MODS.[19,47,48,97,98,155,189,230_232,256,259,266,267,270_273,321,353,356,540,635,642_645,660,717,851,861]

Immune Response to Filovirus Infection

Filoviruses have evolved to overcome elements of the intrinsic, innate (Fig. 11.17), and adaptive arms of the host immune system. The result is almost unrestricted replication and ultimately cytolysis in the absence of a significant

influx of inflammatory cells in infected tissues.[481,521] Key filoviral proteins facilitating evasion of the host immune response include VP35, VP40, VP24, and $GP_{1,2}$.

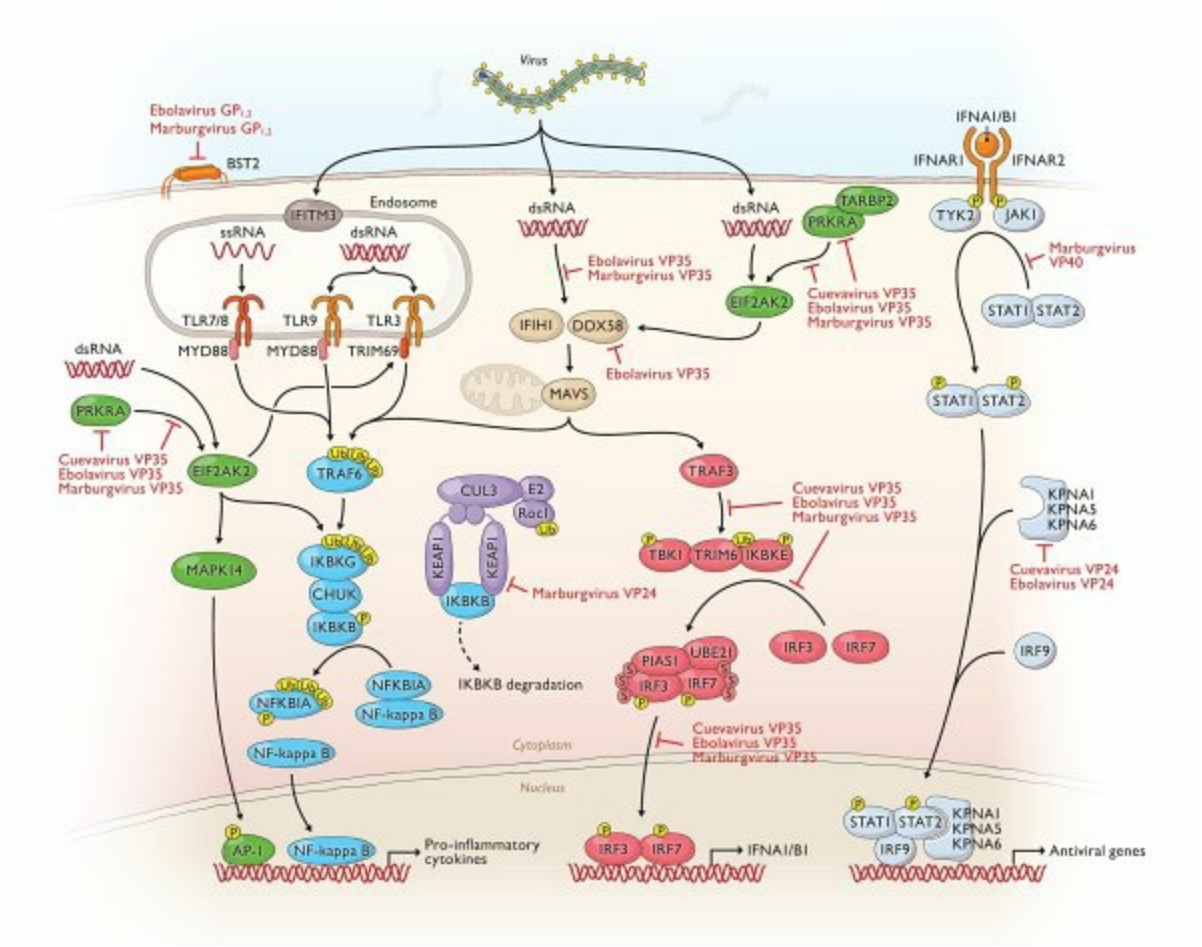

FIGURE 11.17 Mammalian filovirus escape from host intrinsic and innate immune responses. Simplified cartoon showing major intrinsic and innate immune pathways and sites of putative inhibition by filovirus proteins. BST2, bone marrow stromal cell antigen 2 (formerly also tetherin); DDX58, DExD/H-box helicase 58 (formerly RIG-I); EIF2AK2, eukaryotic translation initiation factor 2 alpha kinase 2 (formerly PKR); IKBKB, inhibitor of nuclear factor kappa B kinase subunit beta (formerly IKK-β); IKBKE, inhibitor of nuclear factor kappa B kinase subunit epsilon

(formerly IKKε); PRKRA, protein activator of interferon-induced protein kinase EIF2AK2 (formerly PACT). For meaning of other protein abbreviations, see https://www.genenames.org/.

Filovirus VP35 IID cloaks dsRNA intermediates, thereby preventing dsRNA detection by host pathogen-associated molecular pattern (PAMP) receptors such as interferon induced with helicase C domain 1 (IFIH1, formerly MDA5) and DExD/H-box helicase 58 (DDX58, formerly RIG-I).[35,36,397,454] For instance, EBOV VP35 binds protein activator of interferon-induced protein kinase EIF2AK2 (PRKRA, formerly PACT), thereby blocking PRKRA-induced DDX58 signaling and preventing DDX58-triggered IFNA1/B1 production. VP35 also prevents IFNA1/B1 production in two ways by (a) binding kinases that otherwise would activate interferon regulatory factors 3 and 7 (IRF3/IRF7), inhibitor of nuclear factor kappa B kinase subunit epsilon (IKBKE, formerly IKK*ε*), and TANK-binding kinase 1 (TBK1) via phosphorylation[49,50,111,194,218,309,311,453,468,475,606,619] and (b) forming a complex with IRF7 and protein inhibitor of activated STAT 1 (PIAS1, a small ubiquitin modifier [SUMO] E3 ligase), promoting sumoylation and therefore inactivation of IRF7.[124] VP35 also associates noncovalently with polyubiquitin chains and thereby inhibits TRIM6-mediated type I IFN induction.[67] In addition, filovirus VP35 inhibits the cellular response to IFNA1 expression and induction of apoptosis by inhibiting EIF2AK2 (formerly PKR).[218,226,342,669] Ebolavirus VP35 also acts as a host cell RNAi silencing suppressor (RSS) by interaction with PRKRA and TARBP2 subunit of RISC-loading complex, two components of the RNA-induced silencing complex (RISC), independent of the presence of small interfering RNA (siRNA).[214,299] In addition, PRKRA interaction with ebolavirus VP35 impairs the association between VP35 and L and downstream viral RNA synthesis.[468]

Through EBOV VP35 inhibition of DDX58 signaling, virus-induced maturation of dendritic cells is blocked.[350,368,452,466,844,845] Exposure of cells to mutant EBOV encoding altered VP35 resulted in a strong IFN immune

response.[310] *In vivo* administration of mutant EBOV that impairs VP35 suppression of DDX58 signaling to laboratory mice and guinea pigs resulted in severely attenuated EBOV infection.[607]

Marburgvirus and likely dianlovirus, but not cuevavirus and ebolavirus, VP40 synergistically supports VP35 by inhibiting Janus kinase1 (JAK1)-dependent tyrosine phosphorylation of signal transducer and activator of transcription (STAT) proteins, thereby disrupting JAK-STAT signaling in response to type I and II IFN.[568,757,758]

Cuevavirus and ebolavirus, but not marburgvirus, VP24 synergistically supports VP35 and inhibits IFN signaling by binding to karyopherin subunit alpha 1, 5, and 6 (KPNA1, KPNA5, KPNA6) proteins in the cytoplasm, preventing karyopherin-directed shuttling of tyrosine-phosphorylated STAT1 from the cytoplasm into the nucleus.[218,495,626,627,671,834] Although structurally similar to ebolavirus VP24, marburgvirus VP24 does not bind karyopherin directly. Instead, dimerized cytosolic marburgvirus VP24 binds to cellular oxidative stress pathway–related ubiquitin E3 ligase Kelch-like ECH-associated protein 1 (KEAP1), a repressor of antioxidant transcriptional signaling. KEAP1 up-regulates transcription factor nuclear factor (erythroid-derived 2)-like 2 (NFE2L2) for ubiquitinylation and degradation, which leads to an oxidative stress response.[193,374,578] In absence of the marburgviruses, KEAP1 interacts with inhibitor of nuclear factor kappa B kinase subunit beta (IKBKB), and IKBKB subsequently degrades and prevents the response of nuclear factor-kappa beta (NF-κB) to activating stimuli. Upon binding to KEAP1, marburgvirus VP24 disrupts the interaction of IKBKB with KEAP1, and IKBKB is free to respond to NF-κB-activating stimuli with subsequent gene expression.[192]

Finally, filovirus $GP_{1,2}$ antagonizes the cellular viral restriction factor bone marrow stromal cell antigen 2 (BST2, formerly also tetherin), which is a type I interferon-inducible factor that restricts release of virions from infected cells.[100,378,382,424,464,616] Host cell IFN-inducible transmembrane proteins 1 to 3 (IFITM-1–IFITM3) restrict mammalian filovirus infection at an unknown step during virion cell entry,[338,830] but not sufficiently to prevent entry.

The effects of the various filoviral immunomodulating factors are likely

dependent on the host. For instance, adaptation of EBOV to laboratory mice by serial passaging results in selection of mutations in the EBOV *NP* and *VP24* genes, and these mutations increase the ability of adapted EBOV to evade the IFN response.[190] Adaptation of MARV to laboratory mice or domesticated guinea pigs consistently leads to accumulation of mutations in the VP40 ORF.[795] MARV and RAVV VP40 from the parental viruses do not inhibit IFN signaling in murine cells, but laboratory mouse-adapted VP40s acquire the capacity to function in murine cells. These results suggest that inhibition of IFN signaling may be important for virulence.[219,757] Interestingly, laboratory mouse-adapted RAVV VP40 has impaired capacity to bud from human cells in the absence of $GP_{1,2}$.[217]

Productively infected macrophages are activated and release proinflammatory cytokines (CXCL8, IL1B, IL6, TNF) that recruit further infection-susceptible macrophages to the area. These cytokines alter cell adhesion protein expression and remodel intercellular adherens junction composition that increase vascular endothelial permeability. Increased F3 expression promotes a procoagulative state. EBOV $GP_{1,2}$ plays a crucial role in macrophage activation. EBOV $GP_{1,2}$ and $GP_{1,2\Delta}$ activate toll-like receptor 4 (TLR4) on macrophages, which leads to the induction of the observed proinflammatory response. However, the extent of macrophage activation is species-specific, with EBOV and RESTV inducing profound and weak inflammatory responses, respectively.[94,97,221,272,371,481,573,639,642,660_662,705,774] Interestingly, *in vitro* macrophage activation with subsequent expression of proinflammatory and proapoptotic mediators occurs at the $GP_{1,2}$-cell binding stage, that is, prior to filovirus gene expression.[776]

General measurements of cytokine and reactive oxygen species (ROS) and nitric oxide responses as filovirus disease progresses suggest extensive immune dysregulation that is directly associated with MODS.[30,31,189,266,272,273,295,321,323,346,347,650,764,792] In infected dendritic cells, major histocompatibility complex (MHC) class II expression is suppressed by VP35, inhibiting antigen-presenting cell activity and the development of an adaptive immune response.[350] However, expression of F3 and TNF superfamily member 10 (TNFSF10, formerly TRAIL) increases. The latter factor may contribute to massive death of uninfected (in particular, T cell and

natural killer [NK]) lymphocytes and to general immunosuppression and consequent secondary infections. Bystander lymphocyte death is thought to be provoked by numerous pathways. For instance, VP40-containing exosomes cause apoptosis in recipient T cells. VP40 in parental cells or in exosomes delivered to naïve cells result in the down-regulation of RNAi machinery components argonaute, DICER1, and DROSHA, which therefore may play a role in the induction of cell death in recipient immune cells.[598]

Histopathologically, severe lymphoid depletion occurs in all lymphatic organs and is measurable clinically in the peripheral blood as lymphopenia.[19,31,83,84,189,231,232,245,257,264,266,267,272,273,321,323,356,472,540,622,650,792,861] B cells and NK cells are thought to remain functional, whereas T-cell function is likely disrupted. In addition, filovirus infection ultimately greatly influences the numbers of all three cell types (concomitant with diminished T-cell–derived IL2 and IL4 in blood) and, hence, the ability to mount an effective host humoral and cytotoxic immune response. Retrospective analysis of limited numbers of human patients suggests that the presence or absence of a robust cell-mediated ($CD8^+$ and $CD4^+$) and humoral immune response may determine survival in patients with FVD,[7,90,133,474,501,640] though true mechanistic correlates of protection from infection, disease, or death remain to be identified.

In EVD survivors, cytokines peak only briefly and return to normal concentrations during convalescence. In lethal cases, cytokine concentrations remain uncontrolled, leading to systemic inflammation resembling sepsis.[30,318,792] Survivors typically develop high titers of IgM and IgG antibodies, whereas nonsurvivors do not mount IgG responses and have very low IgM titers.[31,712]

Virulence

From the currently available data detailing FVD case numbers and associated deaths, one cannot determine the most virulent filovirus, although the absolute case numbers and case-fatality rates suggest that marburgviruses may be more lethal than ebolaviruses (Fig. 11.2). However, all case numbers need to be regarded with caution. Case definitions and diagnostic criteria changed considerably since 1967 and were applied differently during

different outbreaks. In addition, lethality differences among different outbreak areas are likely influenced by overall population health status, host genetics, and the specific availability and quality of clinical health care. Experimentally, true side-by-side comparisons of similarly grown and characterized filoviruses in the same animal model are extremely challenging to perform, and statistically significant comparisons can rarely be determined.[430] However, some studies indicate that particular isolates of individual filoviruses may be more virulent than others.[76]

Persistence

Clinical observation of human FVD survivors reveals that mammalian filoviruses may persist for extended periods of time in fluids from immune-privileged compartments (e.g., semen and aqueous humor) in the absence of viremia. This persistence leads to rare but documented recrudescent organ-specific inflammatory disease relapses (meningoencephalitis, uveitis) and sexual (or other undefined) transmission events.[71,75,167,170,177,337,359,390,394,432,485,494,632,760,870] These events have not yet been studied systematically, as current animal models of FVD do not result in significant numbers of survivors. However, widespread, noncytolytic infection of the supporting mesenchymal connective tissues, including the endothelium, throughout the male and female reproductive tract occurs in the NHP model as early as 6 days postexposure (Figs. 11.18–11.20).[588] Retrospective analyses of tissues from a few NHPs that did survive experimental EBOV or MARV infection (and treatment with candidate MCMs) have demonstrated filovirus persistence in tissues such as the eyes, testes, and brain.[137,854] Despite localization of the virus in immune-privileged sites in macaque models, the molecular mechanisms underlying persistence and sexual transmission in the host remain unclear. Experiments with laboratory mice indicate that filovirus persistence can be established through depletion of B cells, suggesting that persistence in humans may be due to certain types of acquired or inherited immunodeficiencies.[297]

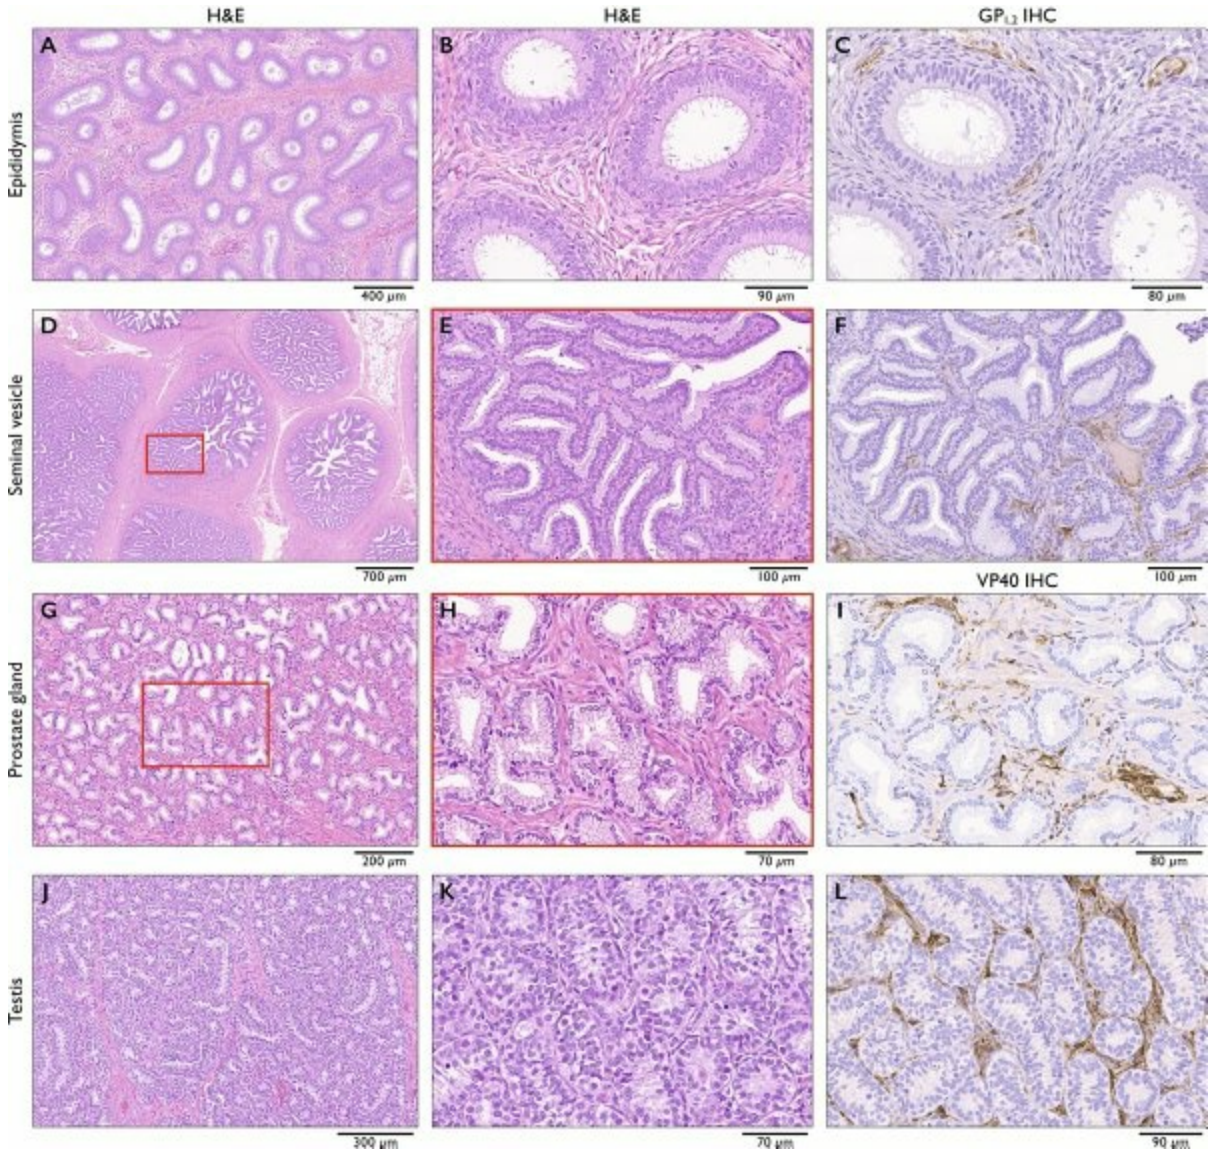

FIGURE 11.18 Histopathology of experimental filovirus infections in crab-eating macaques 6 days after EBOV exposure.

A–C: Slight interstitial edema is present multifocally between epididymal tubules 6 days postexposure (magnification bars **(A)** 400 µm and **(B)** 90 µm). **C:** EBOV $GP_{1,2}$ staining (DAB, *brown*, IHC) is multifocally positive within the stroma despite a lack of significant histopathologic lesions at the light microscopic level (magnification bar 80 µm).

D and E:(*insert* of **D**) No significant lesions are present of the seminal vesicle at the light microscopic level (magnification bars **(D)** 700 µm and **(E)**

100 μm).

F: EBOV $GP_{1,2}$ staining (DAB, *brown*, IHC) shows multifocal positivity within the stroma and rare epithelial cells (magnification bar 100 μm). **(G and H)** (*insert* of **G**) No significant lesions are present within the prostate gland of a macaque at the light microscopic level (magnification bars **(G)** 200 μm and **(H)** 70 μm).

I: EBOV VP40 staining (DAB, *brown*, IHC) shows multifocal positivity within the stromal connective tissue supporting the prostatic acini (magnification bar 80 μm).

J and K: No significant lesions are present within the testis at the light microscopic level (magnification bar **(J)** 300 μm and **(K)** 70 μm).

L: EBOV VP40 staining (DAB, *brown*, IHC) shows positive staining within the interstitial stromal cells supporting the seminiferous tubules (magnification bar 90 μm). DAB, 3,3′-diaminobenzidine; H&E, hematoxylin and eosin stain; IHC, immunohistochemical stain. (Figure courtesy of Reed F. Johnson, NIH/NIAID/DIR/EVPS, and Matthias J. Schnell, Thomas Jefferson University.)

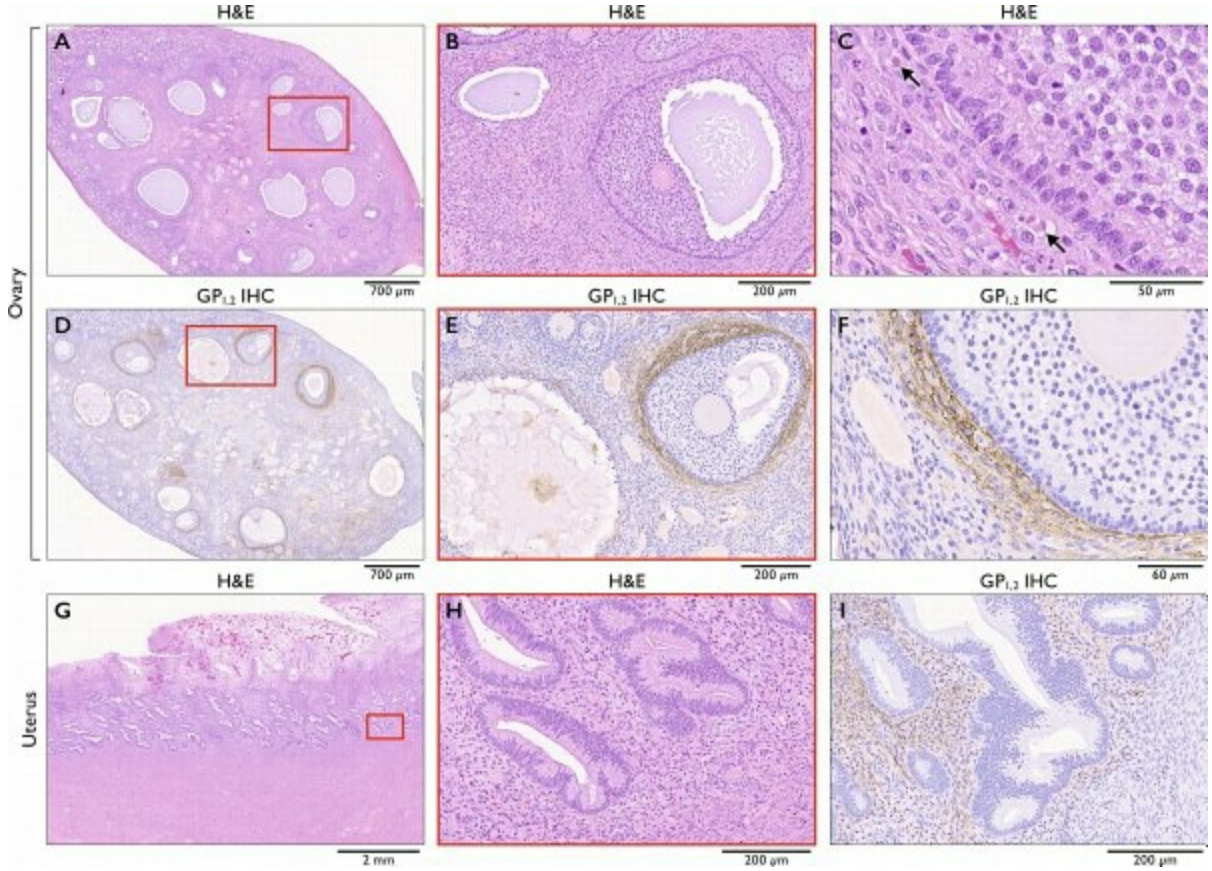

FIGURE 11.19 Histopathology of experimental EBOV infections.

A–C:(**B**, *insert* of **A**) Ovary from a crab-macaque 7 days after EBOV exposure. At the light microscopic level, no significant lesions can be seen within the ovary except for mild, multifocal degeneration and eosinophilic intracytoplasmic inclusion bodies (**C**, *black arrow*) within the thecal cells surrounding maturing ovarian follicles (magnification bars **(A)** 700 µm, **(B)** 200 µm, **(C)** 50 µm).

D and E:(*insert* of **D, F**) (*insert* of **E**) EBOV $GP_{1,2}$ staining (DAB, *brown*, IHC) shows positive staining within the theca cell layers of maturing ovarian follicles and multifocally within ovarian stromal cells (magnification bars **(D)** 700 µm, **(E)** 200 µm, **(F)** 60 µm).

G and H:(*insert* of **G, I**) The uterus from a menstruating crab-eating macaque 7 days postexposure. **(G and H)** At the light microscopic level, no significant lesions can be seen (magnification bars **(G)** 2 mm and **(H)** 200 µm).

I: EBOV $GP_{1,2}$ staining (DAB, *brown*, IHC) shows multifocal positive staining within the endometrial stroma and underlying myometrium (magnification bar 200 μm). DAB, 3,3′-diaminobenzidine; H&E, hematoxylin and eosin stain; IHC, immunohistochemical stain. (Figure courtesy of Reed F. Johnson, NIH/NIAID/DIR/EVPS, and Matthias J. Schnell, Thomas Jefferson University.)

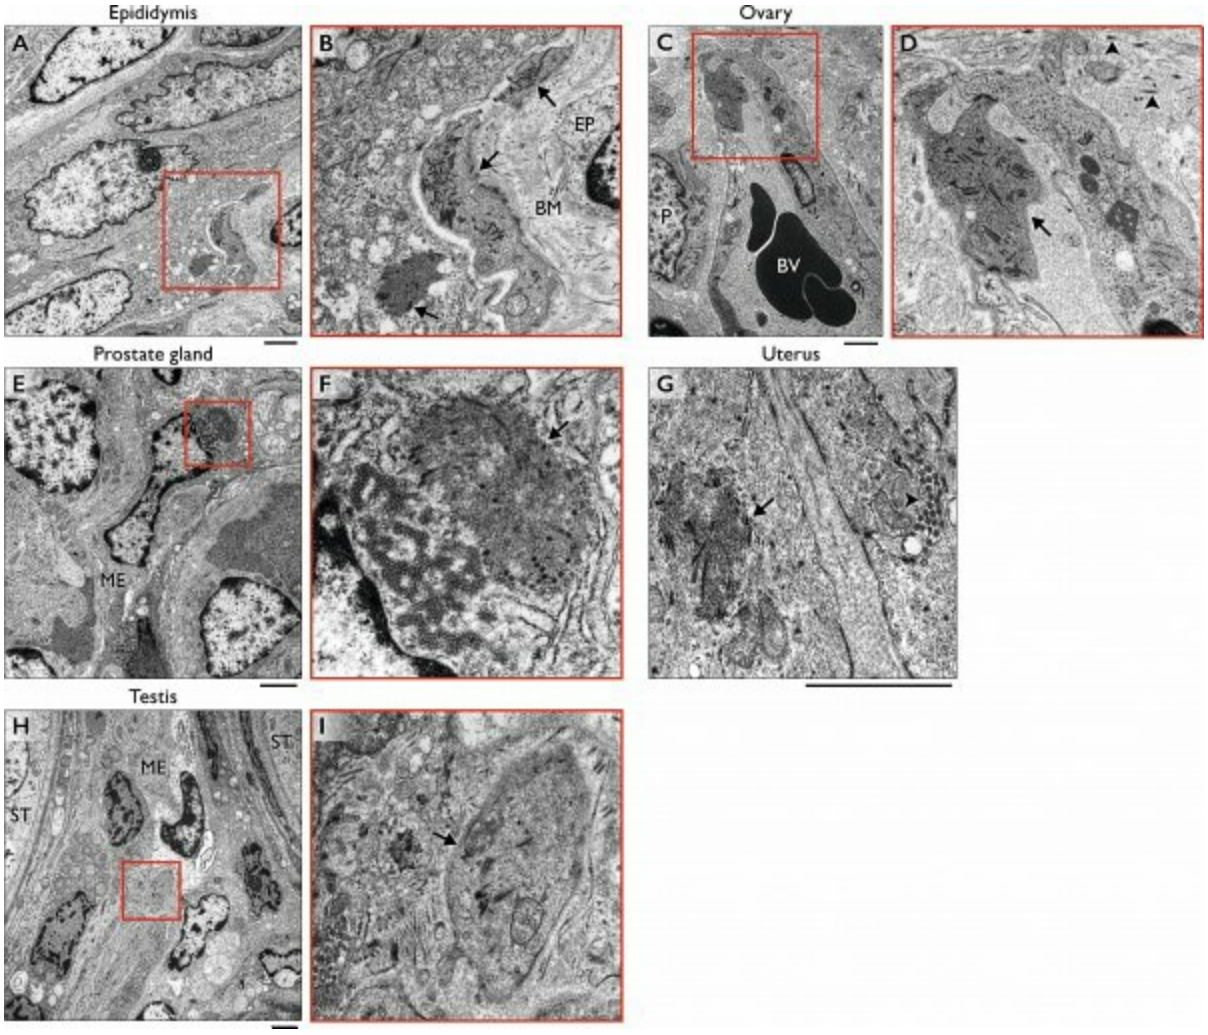

FIGURE 11.20 Transmission electron micrographs from reproductive organs following experimental EBOV infections.

A and B:(*insert* of **A**) Epididymis (crab-eating macaque 6 days after EBOV exposure): three intracytoplasmic inclusion bodies are present within the mesenchymal cells (*red-boxed area*) adjacent to the basement membrane (*BM*) of the epididymal epithelium (*Ep*). Higher magnification shows

filamentous nucleocapsid structures forming within the inclusion bodies (*black arrows*).

C and D:(*insert* of **C**) Ovary (crab-eating macaque 7 days after EBOV exposure): intracytoplasmic inclusion bodies (*red boxed area*) are present in the endothelium lining a blood vessel (*BV*) and in an adjacent pericyte (*P*, *left*). Higher magnification shows a large intracytoplasmic inclusion body (*black arrow*) containing nucleocapsid proteins forming filamentous nucleocapsid structures within the endothelial cell. Adjacent to the vessel, a few mature EBOV particles are free within the interstitium (*black arrowheads*).

E and F:(*insert* of **E**) Prostate gland: an intracytoplasmic EBOV inclusion body (*red boxed area*) is present within a mesenchymal cell (*Me*) of the prostate gland. Higher magnification shows filamentous EBOV nucleocapsid structures forming within the inclusion body (*black arrow*).

G: Uterus (crab-eating macaque 7 days after EBOV exposure): an intracytoplasmic inclusion body (*black arrow*) is present in a smooth muscle cell of the myometrium. Adjacent to the smooth muscle cells, mature filamentous EBOV particles are free within the interstitial spaces (*black arrow head*).

H and I:(*insert* of **H**) Testis: two intracytoplasmic EBOV inclusion bodies (*red boxed area*) are present within mesenchymal cells (Me) of the testis adjacent to the seminiferous tubules (ST). Higher magnification shows filamentous EBOV nucleocapsid structures forming within one of these inclusion bodies (*black arrow*). (Figure courtesy of Reed F. Johnson, NIH/NIAID/DIR/EVPS, and Matthias J. Schnell, Thomas Jefferson University.)

EPIDEMIOLOGY

Filoviruses associated with human disease have been encountered in Western Africa (EBOV, MARV, TAFV), Middle Africa (BDBV, EBOV, MARV), Eastern Africa (BDBV, SUDV, MARV, RAVV), and Southern Africa (MARV) (Figs. 11.1 and 11.2). The definite distribution of pathogenic filoviruses is further substantiated by the proven infection of western

chimpanzees with TAFV (Western Africa)[833] and of Egyptian rousettes with MARV and RAVV (Western, Eastern, and Southern Africa).[21-23,290,381,585,737] Classical epidemiological investigations, but also environmental niche modeling, indicate that ebolaviruses are endemic in humid rain forests and that marburgviruses occur in caves located in arid woodlands. Ebolavirus emergence appears to be correlated with unusually heavy rainfall subsequent to extended dry periods. These predictions suggest that some filovirus reservoir hosts might react to climate anomalies in ways that further their interaction with humans.[440,589,590,592–596,746] Finally, serological surveys indicate that humans are exposed to filoviruses in numerous countries that, thus far, have not reported disease outbreaks (e.g., certain African countries, Belarus, Ukraine). However, the results of most of these surveys are considered controversial because of the applied methodologies and the likelihood of serological cross-reactions.[89,425,668]

The discovery of Egyptian rousettes as marburgvirus hosts[21–23,585,737] and the presence of BOMV and MLAV in insectivorous and frugivorous bats, respectively,[237,285,841,842] tempt one to hypothesize a chiropteran connection for all mammalian filoviruses. Indeed, numerous studies have either detected anti-ebolavirus antibodies in bats of various species or found short viral genomic fragments. However, the definitive reservoir host(s) of pathogenic ebolaviruses remain(s) unknown, and the means of human transmission of marburgviruses from Egyptian rousettes are unclear. As a result, the origins of all FVD outbreaks remain murky.[24,107,777]

Indeed, the majority of the few recorded FVD outbreaks began with single human infections through contact with unknown reservoir hosts. These rare events indicate that host–human transmissions are likely not as simplistic as exposure of a human to an infected bat or its excreta or secreta. For instance, MARV and RAVV transmission occurs at low levels among Egyptian rousettes throughout the year with peaks of infection occurring only in older (male and female) juveniles. Such juveniles shed marburgviruses orally and rectally.[21,22,377,737] In experimental settings, this shedding is sufficient for bat-to-bat transmission,[666] but infected bats clear the virus and develop long-term protective immunity against reinfection.[667] These results suggest that contact with particular subpopulations of bats, such as juveniles,

at certain times of the year may increase the risk for bat-to-human marburgvirus transmission.

Numerous outbreaks have occurred that were not even anecdotally associated with bat exposure but instead associated with exposure of the index cases to various mammals, including NHPs.[379,425] Past EVD outbreaks were temporally associated with significant declines of central chimpanzee (*Pan troglodytes troglodytes* Blumenbach, 1775), western lowland gorilla (*Gorilla gorilla gorilla* Savage, 1847), and arteriodactyl duiker (*Cephalophus* spp.) populations in Gabon and COG, and EBOV antigen and short genomic fragments were detected in a few of these animals.[65,341,449,638,778,812] These data indicate that apes, and likely other primates, and duikers are occasionally exposed to filoviruses and that human infection could begin through human contact with such accidental hosts.

Once a host–human transmission has occurred, filoviruses spread by direct, human-to-human contact (in particular, within the family unit and among patients and health care workers) or contact with contaminated bodily fluids (e.g., amniotic fluid, blood/plasma/serum, breast milk, feces, saliva, semen, skin swabs, tears, urine) or fomites contaminated with infectious material derived from patients or cadavers. Importantly, asymptomatic individuals only rarely transmit virus to another human. Airborne transmission does not contribute to FVD outbreaks except in hospital or laboratory environments, where centrifugation of samples, intubation of patients, or suction during surgical procedures can potentially lead to aerosolization of large numbers of virions.[25,54,185,249,379,380,529,563,633,678] Nosocomial spread by means of contaminated and reused equipment, in particular needles and syringes, was a major contributor to past FVD outbreaks.[185,274,380,633,678,821,822]

In regard to host susceptibility to infection or severe outcome, filovirus infections do not have a sex or ethnicity predilection, and individuals of all ages can become infected. Differences in sex, ethnicity, and age distribution between outbreaks can be largely explained by local demographics. For instance, in countries where women traditionally care for the sick, women become infected in higher numbers compared to men. Fewer children are typically affected by FVD than adults during an outbreak, but this finding may be due to children having less direct contact to potentially infected

people than adults. However, children less than 5 years old with EVD typically have a shorter incubation period, shorter disease duration, and increased lethality.[8,27,127,184,282,385,693] Infected pregnant women often miscarry or deliver stillbirths due to transplacental filovirus transmission. Neonates of infected mothers rarely survive, and maternal lethality is very high.[28,56,300,537,551,569_571,670] Only two studies have evaluated the influence of host genetics on FVD outcome. Expression of killer immunoglobulin-like receptor proteins KIR2DS1 and KIR2DS3 was associated with fatal EVD outcome in a Gabonese population.[793] HLA-B alleles B*67 and B*15 were associated with fatal outcomes, and alleles B*07 and B*14 were associated with nonfatal SVD outcomes in a Ugandan population.[635]

The evolution of filoviruses during human-to-human transmission has only been analyzed during the 2013–2016 Western African EVD outbreak. Interestingly, genomic mutations leading to at least three amino acid mutations rose to high frequency early in the outbreak and became fixed over time: mutation R111C in the homo-oligomerization domain of NP, A82V in GP_1's receptor-binding site, and D759G in the active center of L. *In vitro*, GP_1 A82V increased $GP_{1,2}$-mediated cell entry into primate cells but decreased cell entry into bat cells, whereas NP R111C and L D759G decreased and increased viral replication and transcription depending on cell type.[172,176,491,753,781] The selective pressure leading to these mutations is unclear, as are their effects on EBOV transmissibility and virulence. Initial experiments in immunocompromised laboratory mice and rhesus monkeys did not reveal phenotypic disease associated with these mutations, but the viruses used differed by additional nucleotide changes beyond these three mutations, thereby preventing direct comparison.[491] Results from a second study indicated that L D759G may increase survival of EBOV-infected laboratory mice and delay death in infected domestic ferrets.[815]

CLINICAL FEATURES

Since the discovery of the first filovirus, MARV, in West Germany and Yugoslavia in 1967[684] until the large disease outbreak caused by EBOV in

Western Africa in 2013–2016,[32,106,115,188,280,735,826] filoviruses have caused only 36 known FVD outbreaks (2,882 infections/1,968 deaths) (Fig. 11.2). The majority of these outbreaks has occurred in resource-limited and often remote African settings without efficient epidemiological surveillance programs, modern health care facilities, and well-trained and capacitated health care workers. Consequently, the clinical presentation and evolution of FVD in humans have not been well characterized by systematic study. Instead, clinical descriptions have been based on an accumulation of case or case cluster observations summarized by different individuals or expert groups in different locations, often focusing on different clinical parameters.[53,108,353,387,470,572,597,630] These descriptions were further complemented by more detailed clinical observations made from a few patients cared for in modern health care settings in 1967, 1975, and 1994[196,240,256,484,703] and from three individuals with filovirus LAIs.[205,865,870]

A lack of systematic data collection and country- and region-specific differences in overall patient health status has led clinicians to conclude that FVD caused by distinct filoviruses follow a common path. FVD infections were correctly described to begin with a nonspecific influenza-like phase followed by either recovery or progression to critical illness leading to MODS, shock, and death. However, experimental laboratory infections of mammals (Table 11.4) and the increased molecular–biological characterization of distinct filoviruses indicated that pathogenic ebolaviruses (BDBV, EBOV, SUDV, TAFV) and marburgviruses (MARV, RAVV) may cause infections with distinct clinical phenotypes. Infections by distinct ebolaviruses likely are more similar to each other than to those of marburgviruses and vice versa. This hypothesis is now reflected in WHO's International Classification of Diseases revision 11, which divides FVD into diseases caused by ebolaviruses (EBOD) and marburgviruses (MARD). These subcategories are further subdivided according to the specific filoviruses: Bundibugyo virus disease (BDV), Ebola virus disease (EVD), Sudan virus disease (SVD), and Marburg virus disease (MVD), respectively (Table 11.5).[427,827]

TABLE 11.5 Human filovirus disease classification as of

2018

BDBV, Bundibugyo virus; CNS, central nervous system; EBOV, Ebola virus; ICD-11, International [Statistical] Classification of Diseases [and Related Health Problems] (ICD) version 11; MARV, Marburg virus; RAVV, Ravn virus; SUDV, Sudan virus.

The 2013–2016 Western African EVD outbreak (28,652 cases and 11,325 deaths)[32,106,115,280,735] was the first opportunity to systematically characterize a FVD using increased patient cohorts that achieved statistical significance. In August of 2014, WHO formally declared the outbreak a Public Health Emergency of International Concern (PHEIC). This declaration further supported an already steadily growing international response, which resulted in the establishment of local, sometimes modern, Ebola [virus disease] Treatment Units (ETUs) staffed with national health care workers and international health care providers, occasionally including specialist infectious disease and critical care physicians.[1,110,242,281,362,436,461,463,788] The international concern about the outbreak, combined with growing local and international support capacities for identification, isolation, treatment, and longitudinal follow-up of patients, resulted in a much more sophisticated definition of EVD than was used prior to 2013. This definition was further defined by data collected during subsequent outbreaks.[547]

Though presentation is variable from patient to patient, EVD can generally be characterized after an incubation period into typical clinical phases: a nonspecific prodrome, a gastrointestinal phase progressing to peak illness, and subsequent death or slow recovery (Fig. 11.21). Classically bounded from 2 to 21 days and only mildly influenced by EBOV exposure route and dose,[761] the incubation period is 6 to 10 days, after which patients develop an influenza-like illness that usually includes fever, anorexia, severe fatigue/asthenia, myalgia/arthralgia, and headache. Around day 5 of illness, patients often develop gastrointestinal symptoms (diarrhea, nausea/vomiting, abdominal pain) that may result in dramatic gastrointestinal fluid losses (stool volumes of 5–10 L/day) with concomitant hypotension, third-spacing due to increased vascular permeability with edema (often apparent in the face), and rhabdomyolysis. Patients with milder initial prodrome or gastrointestinal

symptoms may begin to improve. Other less common signs include conjunctival injection or hemorrhage, hiccups, dyspnea, and cough. Infrequently, patients may develop hemorrhagic manifestations (ecchymoses, epistaxis, hematemesis, melena, oozing from injection sites, and petechial rashes) likely due to clotting factor deficiency, thrombocytopenia, or DIC. As illness progresses, severely ill patients develop signs of hypovolemic or septic shock (often with metabolic acidosis and severe electrolyte abnormalities) progressing to MODS, including acute kidney and liver injury, respiratory failure, and encephalopathy or seizures. Often presenting with altered mental status or seizures, the etiology of CNS manifestations may include meningoencephalitis (associated with EBOV detection in cerebrospinal fluid), metabolic causes (hypoglycemia, hyponatremia), and CNS hypoperfusion associated with hypovolemia or septic shock.[45,128,129,146,156,175,243,413,469,505,610,810,813,835]

Refs.[46,599] and figure courtesy of Jiro Wada, IRF-Frederick, Fort Detrick, MD, USA.)

Although the underlying mechanistic correlates have yet to be defined, accumulated clinical experience has identified a number of host and illness-specific predictors of fatal FVD outcomes. The most consistent factor across multiple outbreaks and filoviruses is the admission or peak viral load (or nadir cycle threshold value in RT-qPCR). The most ominous clinical factors include signs of organ dysfunction, most significantly acute kidney injury (AKI; signaled by elevated creatinine levels), CNS manifestations (altered mental status, coma, seizures), and severe liver injury (indicated by AST and ALT activity increases).[156,420,502,505,563,835] Only recently, retrospective analyses of EVD and SVD outbreak data have identified biomarkers that predict human disease outcome. Of interest, these biomarkers may be different in adult and pediatric disease. For instance, in adults with EVD, hemorrhage and death have been associated with increased serum thrombomodulin and ferritin concentrations. In addition, increased serum concentrations of soluble vascular cell adhesion molecule 1 (VCAM-1) and von Willebrand factor (VWF) have been associated with hemorrhage, and elevated concentrations of F3 and tissue plasminogen correlate with viremia. Increased concentrations of sCD40LG have been associated with survival. Increased serum concentrations of soluble intracellular adhesion molecule and VWF are also characteristic in fatal pediatric cases, but increased serum C–C motif chemokine ligand 5 (CCL5, formerly RANTES) and decreased serpin family E member 1 (SERPINE1, formerly plasminogen activator inhibitor 1) and VCAM-1 concentrations correlate with survival.[502–504] In both EVD and SVD, viral load is inversely associated with patient survival.[152,233,650,739]

The impact of co- or secondary infections that complicate and/or confuse

the clinical presentation (e.g., gram-negative sepsis due to bacterial translocation from the gastrointestinal tract, HIV-1, plasmodium infections)[114,138,415,416,591,637,763] on prognosis remains an important question that requires systematic investigation. The observation of disseminated *Pseudomonas aeruginosa* superinfection in a child with RAVV infection[372] and the development of mucormycosis in an acute EVD patient[384] indicate that secondary infections may be common complications of FVD.

Prolonged sequelae (2 years and longer) in some FVD survivors and occasional filovirus persistence associated with disease relapse or sexual transmission were observed prior to the 2013–2016 EVD outbreak[29,37,108,394,432,485,632,870] and also during a BVD outbreak.[135] However, longitudinal follow-up of EVD survivors of the 2013–2016 EVD outbreak clarified that sequelae such as abdominal pain, symmetric polyarticular arthralgia, fatigue, headaches, myalgia, and insomnia are common complaints (Fig. 11.22). Alopecia, confusion, hearing loss or tinnitus, seizures, and uveitis and other ocular sequelae (e.g., blurry vision, cataracts, light sensitivity) have been relatively frequent events that could be confirmed clinically.[208,212,497,548,612,673,676,677,727,729]

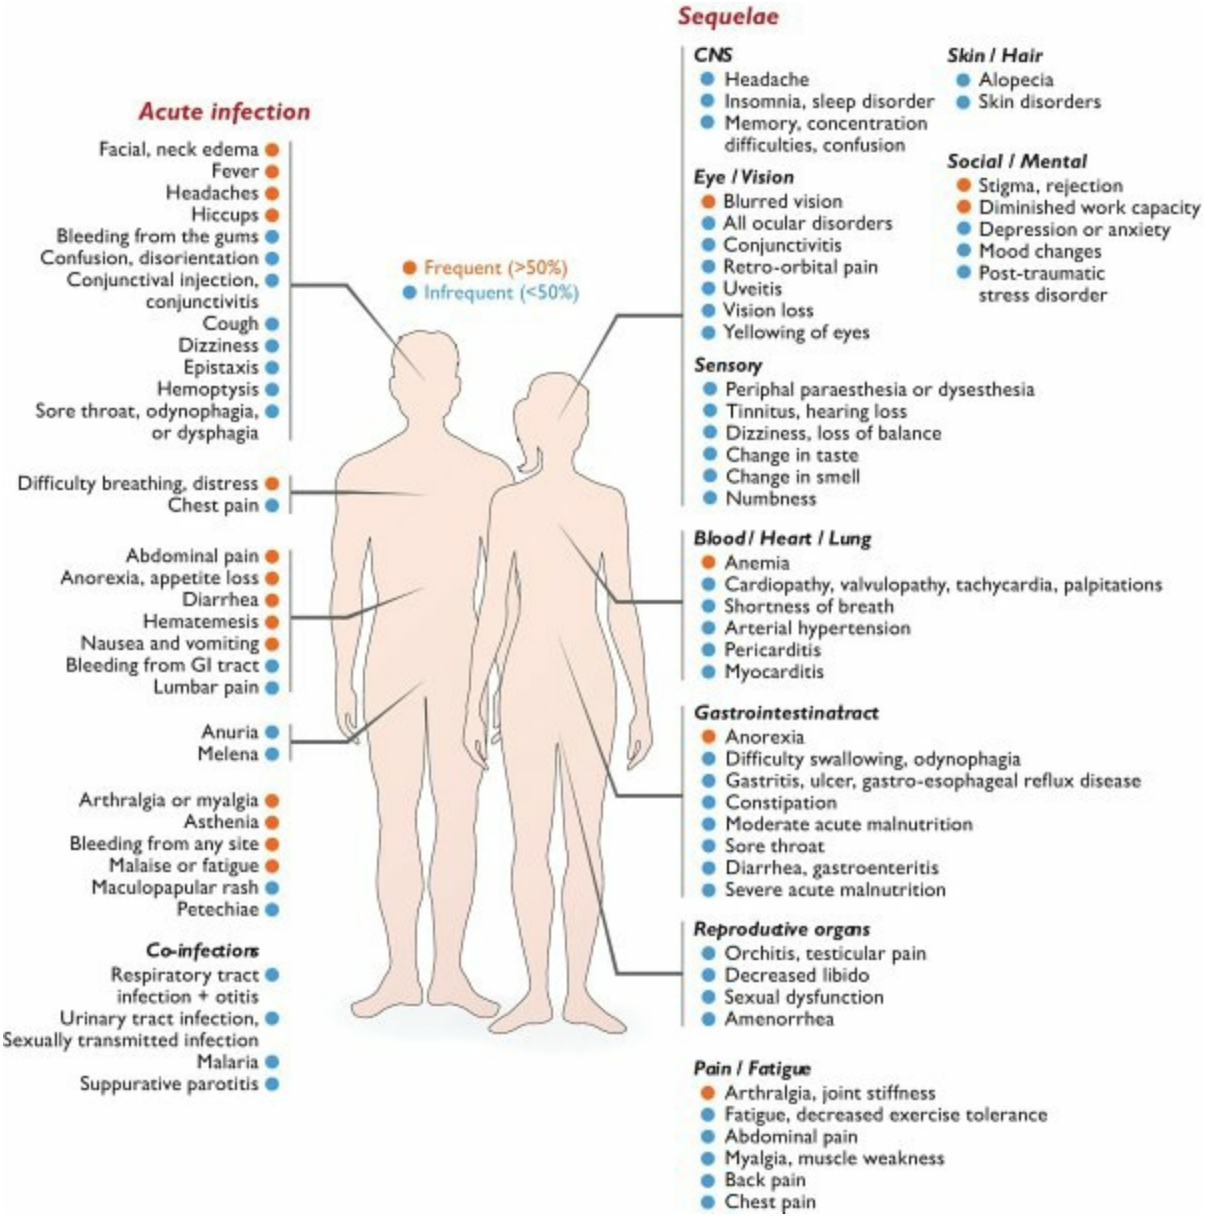

FIGURE 11.22 Clinical presentation of acute filovirus disease (FVD). Listed are typical symptoms and clinical signs of adults in acute infections and reported or observed sequelae among survivors.[53,64,108,470] (Figure courtesy of Jiro Wada, IRF-Frederick, Fort Detrick, MD, USA.)

Thus far, substantiation of whether EBOV causes these symptoms or clinical signs has been difficult. Currently, no animal EVD survivor models

are available in which causal relationships between infection and sequelae can be established. However, individual case reports indicate that some of the reported sequelae could be due directly to persistent (nonlatent) EBOV infection. For instance, EBOV was detected in the cerebrospinal fluid of two nonviremic EVD survivors with encephalopathy[337,359] and in the aqueous humor of a nonviremic survivor with uveitis.[760] Additionally, EBOV RNA could be detected in breast milk and vaginal swabs and up to 2 years or longer in the seminal fluid of numerous EVD survivors.[54,163,229,460,690,755] Both genomic and antigenomic EBOV RNAs, indicating ongoing replication, could be detected in the aqueous humor, semen, and urine of EVD survivors.[806] In at least some instances, EBOV persistence led to sexual or undefined EBOV transmission from survivors to naïve contacts, thereby causing new EVD cases and transmission chains.[167,170,177,228,494]

DIAGNOSIS

Differential Diagnosis

No pathognomonic features exist to establish an unequivocal diagnosis of FVD at the bedside. Instead, FVD needs to be considered a possibility in any patient (febrile or not) with a recent travel history to or in Africa, particularly if the patient traveled to areas with known prior or ongoing outbreaks and/or had contact with wildlife (bats, duikers, or primates) or visited rain forests or caves/mines. The differential diagnosis includes numerous other infectious and noninfectious diseases that present similarly with a much higher prevalence and incidence than FVD[80,567] (Table 11.6). Any suspicion of FVD should be reported to the responsible public health authorities, and special operating procedures should be implemented to ensure safety of hospital staff and prevention of further filovirus transmission.

TABLE 11.6 Filovirus disease (FVD) differential diagnosis

Bacterial Disease	Etiological Bacterium
Cholera	*Vibrio cholerae*
Enterohemorrhagic *Escherichia coli* infection	Enterohemorrhagic *Escherichia coli* (EHEC)
Gram-negative bacterial septicemia	Gram-negative bacterium
Intestinal infections due to *Shigella*	*Shigella* spp.
Leptospirosis	*Leptospira* spp.
Rickettsioses	*Rickettsia prowazekii, Rickettsia typhi*
Typhoid fever	*Salmonella* Typhi
Fungal Disease	**Etiological Fungus**
Histoplasmosis	*Histoplasma capsulatum*
Protozoan Disease	**Etiological Protozoan**
Malaria due to *Plasmodium falciparum*	*Plasmodium falciparum*
Viral Disease	**Etiological Virus**
Acute or subacute hepatic failure due to hepatitis virus (fulminant hepatitis)	Hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), hepatitis D virus (HDV)
Crimean-Congo hemorrhagic fever (CCHF)	Crimean-Congo hemorrhagic fever virus (CCHFV)
Lassa fever (LF)	Lassa virus (LASV)
Measles	Measles virus (MeV)
Rift Valley fever (RFV)	Rift Valley fever virus (RVFV)
Rubella	Rubella virus (RuV)
Yellow fever (YF)	Yellow fever virus (YFV)
Other	**Cause**
Acute promyelocytic leukemia	White blood cell cancer
Dermatoses resulting from anticoagulant therapy	Warfarin
Factor VII, IX, and X deficiencies	
Hemolytic uremic syndrome	Genetic disorder
Hereditary hemorrhagic telangiectasia	Genetic disorder
Mucocutaneous lymph node syndrome	Idiopathic
Snake envenomation	Snake bites
Thrombotic thrombocytopenic purpura	Idiopathic

Laboratory Diagnosis

Today, filoviruses can be detected safely and in a straightforward fashion in mobile, field, and international reference laboratories using a variety of complementary methods and samples (Table 11.7). Several methods, in particular commercial PCR-based assays and handheld lateral flow immunoassays, are recommended for field use (Table 11.8). The choice of assay may depend on the filovirus and filovirus variant, stage of illness,

available sample type, laboratory capacity, and training of the diagnostician. For the first time, in COD in 2018 to time of writing, a single diagnostic field-deployable platform (Cepheid GeneXpert) and a single set of protocols are used across all laboratory sites, making systematic comparison of viral titers at the time of diagnosis and during disease progression possible. Even in this setting, diagnostic challenges include test interpretation in the setting of large-scale preventive vaccination of close contacts as vaccinated individuals may test positive as a result of vaccination. Also, infected asymptomatic or paucisymptomatic people (including acutely infected as well as survivors with ongoing filovirus replication in immune-privileged compartments) pose a challenge because of the absence of viremia and the time lag between infection and development of detectable IgM and IgG antibodies.[54,132,169,209,283,448,563,689,690]

TABLE 11.7 Advantages and disadvantages of common filovirus laboratory detection methods

Test	Target	Source Material	Advantages	Disadvantages
Primary methods				
Antigen enzyme-linked immunosorbent assay (ELISA)	Filovirus antigen/ proteins	Blood, serum, tissues	Rapid (faster than RT-qPCR) and highly sensitive; can be performed on inactivated samples	Requires special equipment, but capable of high-throughput; less specific than RT-qPCR; low sensitivity in early infection
IgG or IgM enzyme-linked immunosorbent assay (ELISA)	Antifiloviral antibodies	Serum	Rapid (faster than RT-qPCR) and highly sensitive; useful for seroprevalence studies in nonviremic populations; can be performed on inactivated samples	Requires special equipment, but capable of high-throughput; less specific than RT-qPCR; relatively high rate of false positives or within-genus cross-reactions; need to consider time point of appearance of IgG and IgM antibodies in response to infection (of limited use early in infection); some patients do not seroconvert
Reverse transcription quantitative polymerase chain reaction (RT-qPCR)	Filovirus genomic or antigenomic nucleic acids	Blood, serum, tissues	Most sensitive detection method; rapid and easy to adapt to any known or new filovirus; relatively simple to perform (in particular when commercialized); can be multiplexed; can be performed on inactivated samples	Requires expensive equipment sensitive to environmental factors and dependent on electricity; reagents may be temperature-sensitive; cannot be used for detection after viral clearance; number and types of fluorescent dyes limit multiplexing; release of RT-PCR inhibitors from tissue can lead to false-negative results
Reverse transcription polymerase chain reaction (RT-PCR)	Filovirus genomic or antigenomic nucleic acids	Blood, serum, tissues	Most straightforward nucleic acid detection method; minimal training requires (in particular when commercialized); more rapid than RT-qPCR; can be performed on inactivated samples	Requires expensive equipment sensitive to environmental factors and dependent on electricity; reagents may be temperature sensitive; cannot be used for detection after viral clearance; less sensitive than RT-qPCR; release of RT-PCR inhibitors from tissue can lead to false-negative results
Confirmatory methods				
Electron microscopy (EM)	Filoviral particles or cellular inclusion bodies	Blood, serum, tissues	Unique morphology enables family-specific diagnosis; immunostaining is possible for confirmation and species-specific differentiation	Insensitive; requires expensive equipment
Indirect fluorescent assay (IFA)	Antifiloviral antibodies	Serum	Rapid and simple; useful for seroprevalence studies in nonviremic populations	Subjective interpretation; high rate of false positives; low sensitivity; some patients do not seroconvert
Immunohistochemistry (IHC)	Filovirus antigen/ proteins	Tissues	Detection of filovirus antigen in the absence of viremia	Slow; for use outside of BSL-4 containment, material needs to be inactivated but works well in fixed tissues
In situ hybridization (ISH)	Filovirus genomic or antigenomic nucleic acids	Tissues	Highly sensitive if used with amplification (e.g., RNAscope); useful for detection of persistent infection in the absence of viremia	Slow; material needs to be inactivated but works well in fixed tissues
Fluorescence assay (FA)	Filovirus antigen/ proteins	Tissues	Rapid and simple	Subjective interpretation; high rate of false positives; low sensitivity
Next-generation sequencing (NGS)	Filovirus genomic or antigenomic nucleic acids	Blood, serum, tissues	Unequivocal identification of filovirus; discovery of novel filoviruses; enables monitoring of genetic drift and MCM escape; can be performed on inactivated material	Expensive; slow; requires special equipment and highly trained staff for *in silico* interpretation of data

Test	Target	Source Material	Advantages	Disadvantages
Virus isolation	Filovirus	Blood, bodily fluids, tissues	Definite diagnosis; availability of virus isolates for experiments, including validation of novel detection methods	Requires transport of potentially infectious material to facilities with BSL-4 containment laboratories; need for filovirus-susceptible cells and secondary filovirus detection methods to confirm isolation; increased risk to laboratory workers due to work with live virus; cannot be applied for batch testing
Western blot	Antifiloviral antibodies	Serum	Specific	Interpretation sometimes difficult; dependent on availability of filovirus-specific antibodies

MCM, medical countermeasure.

PREVENTION AND CONTROL

Prevention

Prevention of initial filovirus introductions into human populations is currently impossible due to the lack of understanding of filovirus reservoir hosts, host-to-human transmission dynamics, and the likely existence of inapparent human infections outside of the context of an ongoing FVD

outbreak. However, the risk of filovirus infection can be mitigated through behavioral education. Avoidance of direct contact with wildlife (in particular, apes, bats, and duikers), caution during preparation of freshly hunted bushmeat, rejection of undercooked or uncooked meat, sexual abstinence or sexual intercourse using appropriate protection, and elimination of direct person-to-person contact with apparently sick individuals will decrease the risk of filovirus transmission. During ongoing FVD outbreaks, such behavioral education should be emphasized via local media and community outreach. Locals and anthropologists should be consulted to help modify cultural practices that are associated with increased filovirus transmission risk (e.g., embalming of bodies, handshaking) in community-acceptable ways. Health care personnel should always wear appropriate personal protective equipment, apply strict barrier nursing procedures, avoid reuse of any medical equipment in the absence of appropriate disinfection, and wear powered air-purifying respirators (PAPRs) or fit-tested N95 respirators during procedures that may generate virus-contaminated aerosols.[54,119,122,352,366,380,613,614,631,634] Patient isolation until resolution of clinical signs for greater than 3 days and/or negative RT-qPCR testing, ideally in local ETUs staffed with experienced infectious disease experts, greatly diminishes further filovirus transmission.[422,825] Cadavers of FVD patients ought to be buried as soon as possible because they may contain viable filoviruses for up to 7 days after death.[604] Any potentially contaminated, disposable material in the surrounding area of a patient or body should be autoclaved, irradiated, or burned as filoviruses can stay viable in drying blood for up to 5 days.[229] For dried blood, 5% peracetic acid can be used to inactivate filovirions.[696]

FDA has recently approved single vaccine for EVD prevention. Numerous candidate vaccines have been developed and shown promise in animal models of FVD. These candidates include adenovirus,[131,258,322,603,710,711,713] alphavirus,[325,326,608,609,808] lyssavirus,[77,78] orthopoxvirus,[279] paramyxovirus,[102,105,509,840,846] and vesiculovirus[154,252,260_262,517] platforms that encode filovirus proteins, naked DNA vaccines that encode filovirus proteins,[322,480,508,759,837] and filovirion-like particles created by coexpression of recombinant filovirus NP, VP40, and

$GP_{1,2}$.[487,714,784,786] A few promising candidate vaccines for the prevention of EVD are in various phases of clinical trials (Table 11.9). A few promising candidate vaccines for the prevention of EVD are in various phases of clinical trials (Table 11.9) with one of them, rVSVΔG-ZEBOV-GP, now FDA-approved.[319] The same candidate vaccine has been administered to more than 255,000 people at risk of EBOV infection during the currently still ongoing EVD outbreak in the Ituri and Nord-Kivu Provinces of COD. Preliminary evaluation indicates that the vaccine may be efficacious.[801,828] and the vaccine has recently been granted conditional marketing authorization by the European Medicines Agency. A second candidate vaccine, hAd26-ZEBOV-GP/MVA-BN-Filo, is currently administered in COD.

TABLE 11.9 Examples for candidate vaccines for prevention of Ebola virus disease evaluated in clinical trials

Candidate Vaccine	Vaccine Type	Clinical Trial Stage	Advantages and Disadvantages	References
• rVSVΔG-ZEBOV-GP • rVSVN4CT1-EBOVGP1	Replication-competent recombinant vesicular stomatitis Indiana viruses (rVSIVs) expressing EBOV $GP_{1,2}$ instead of VSIV glycoprotein (G)	I–III in numerous studies performed in at least 10 countries with and without homotypic boosts; rVSVΔG-ZEBOV-GP received conditional marketing authorization by the European Medicines Agency and FDA approval in the USA in December 2019	• Antibody titers resulting from single injection last ≥2 years • rVSVΔG-ZEBOV-GP submitted for WHO EUAL • rVSVΔG-ZEBOV-GP used to vaccinate >255,000 people during the 2018–present EVD outbreak in COD • Mild adverse effects such as arthralgia, fever, headaches, myalgia pain at injection site, vector viremia	6,204,252,302,319,348,392,518,600,625,828
• GamEvac-Combi • GamEvac-Lyo	Replication-competent recombinant vesicular stomatitis Indiana virus (rVSIV) and human adenovirus 5 (hAd5) vectors expressing EBOV $GP_{1,2}$	I–II	Pain at injection site	182
• hAd5-ZEBOV-GP • hAd26 ZEBOV-GP • hAd35 ZEBOV-GP • ChAd3-EBO Z GP	Replication-defective chimpanzee or human adenovirus vectors expressing EBOV $GP_{1,2}$	I–III with and without homotypic boosts and with modified vaccinia virus Ankara (MVA) expressing EBOV $GP_{1,2}$ (MVA-BN-Filo or MVA-EBO-Z) boosts; hAd26-ZEBOV-GP/MVA-BN-Filo currently in use in COD.	• Pain at injection site (human vectors); fatigue, headaches, malaise, pain at injection site (chimpanzee vector) • Preexisting immunity to used human adenovirus vector is a common issue	161,213,392,443,444,456,511,720,762,811,832,858,859

Treatment

Currently, no FDA-approved filovirus-specific antivirals are available for the

treatment of FVD. Regardless, FVD patients should receive aggressive supportive care to mitigate homeostatic imbalances. Pillars of supportive care include the standardized assessment, triage, and monitoring of vital signs, recognition and appropriate administration of oral or intravenous fluids to prevent and treat hypovolemic or septic shock, supplemental oxygen, laboratory monitoring and appropriate treatment of hypoglycemia and common electrolyte imbalance, the prevention and treatment of co- or secondary infections (with antimalarials and broad-spectrum antibiotics), and the relief of symptoms (acetaminophen for fever and pain, antiemetics, sedation as needed).[130,145,344,437,469,657,756,825] Though not always the case, the will and capacity to routinely provide optimized supportive or standard of care (oSOC) are increasingly emphasized in African outbreak settings.

Care of FVD patients who progress to MODS is extremely challenging in outbreak areas. Thus far, the utmost critical care (e.g., renal replacement therapy, mechanical ventilation) has been delivered routinely only in well-resourced US or European settings, though such care has been administered in extraordinary circumstances in Western Africa.[26,141,243,303,375,438,542,708,736,756,813,829] Likewise, management of high-risk obstetric cases and children less than 5 years old with EVD remains a significant challenge, but population-specific care is being similarly emphasized and optimized to improve patient outcomes.[109,120,183,744]

Numerous promising filovirus-specific candidate therapeutics have been evaluated *in vitro* and in animal models *in vivo*.[831] Some of them have been administered to EVD patients under compassionate care protocols, but their safety and efficacy could not be established in these anecdotal settings. During the Western African outbreak, a number of clinical trials of varying design were initiated. Unfortunately, the only one that was designed to truly determine safety and efficacy (PREVAIL II randomized controlled trial [RCT]) failed to enroll the target number of patients to provide a definitive result. This trial did however, suggest that the monoclonal antibody cocktail ZMapp was superior to standard-of-care alone. Accordingly, ZMapp was chosen as the control arm for the PALM study, an RCT comparing the nucleotide analogue remdesivir, the single monoclonal antibody mAb114, and the monoclonal antibody cocktail REGN-EB3 to ZMapp. This study was prematurely stopped when the mAb114 and REGN-EB3 arms were shown to

be superior to ZMapp.[535] These two investigational products are now the treatments of choice for patients with EVD. Only a handful of candidate therapeutics have been or currently are evaluated in clinical trials, thus far, with unclear results (Table 11.10). Of note, an ongoing randomized clinical trial of four candidate therapeutics is enrolling patients in the EVD outbreak that at the time of writing was still ongoing in COD.

TABLE 11.10 Candidate therapeutics in clinical trials for treatment of Ebola virus disease

Investigational Agent	Drug Class	Efficacy	Advantages	Disadvantages
mAb114	Monoclonal antibody against EBOV $GP_{1,2}$	• Phase II randomized study comparing drug with remdesivir, REGN-EB3, and ZMapp prematurely terminated. mAb114 and REGN-EB3 are now the treatments of choice for EVD.[535]	• Antibody isolated by from a COD survivor[253] • Single rapid infusion (30 minutes) • Currently, no dose-limiting toxicity[147]	• Associated with myalgia, headache, chills, nausea, arthralgia, fever, shaking, nausea, vomiting, pain, dizziness, dyspnea, hypo- or hypertension, pruritus, rash, facial edema, diarrhea, tachycardia, or chest pain
REGN3470, REGN3471, REGN3479 (REGN-EB3)	Monoclonal antibody cocktail against EBOV $GP_{1,2}$	• Phase II-III randomized study comparing drug with remdesivir, mAb114, and ZMapp prematurely terminated. REGN-EB3 and mAb114 are now considered treatments of choice for EVD.[147,535,691] • Available through extension phase of study	• Single intravenous infusion • Antibodies were isolated from humanized mice • Generally well tolerated[147]	• Associated with headache, myalgia, dyspnea, chills, shaking, dizziness, fainting, cough, hypotension, rash, hives, or swelling around the mouth, throat, or eyes
Remdesivir (GS-5734)	Prodrug of adenosine nucleoside analog	• Phase II randomized study comparing drug with REGN-EB3, mAb114, and ZMapp prematurely terminated. REGN-EB3 and mAb114 are now considered treatments of choice for EVD.[535]	Does not require refrigeration[125]	• Requires monitoring of ALT/AST; may not be available in limited resource settings • Associated with transient constipation, heartburn, pruritus, dizziness, loss of appetite, nausea, vomiting, shaking, headache, loose stools, or upset stomach
ZMapp	Monoclonal antibody cocktail (c2G4, c4G7, c13C6) against EBOV $GP_{1,2}$	• Trend in efficacy from phase I trial in Western Africa[726] • Phases II–III randomized study comparing drug with REGN-EB3, mAb114, and remdesivir prematurely terminated. REGN-EB3 and mAb 114 now considered treatments of choice for EVD.[147,535]	Showed the potential for mAb cocktails like REGN-EB3 to be effective against EVD.[211]	• Long IV infusion duration under supervision[147] • Requires cold chain[125] • Antibodies were isolated from immunized mice[253] • Erythema, tachycardia, chills, hypo- or hypertension, pruritus

COD, Democratic Republic of the Congo; mAb, monoclonal antibody.

PERSPECTIVE

Since the discovery of MARV in 1967 until 2012, filoviruses were largely considered exotic tropical pathogens with little overall public health impact.

This view changed dramatically during the 2013–2016 Western African EVD outbreak, which demonstrated that filoviruses can infect tens of thousands of individuals and be inadvertently exported globally. Results from recent studies, performed with international urgency, illuminated many forgotten or novel aspects of filovirus infection (e.g., filovirus persistence in immune-privileged sites, frequent sequelae in survivors, sexual transmission). In addition, these results greatly advanced the repertoire of potential MCMs (e.g., EUA-/EULA-approved diagnostic tests, two candidate vaccines in the field, and two standard-of-care therapeutics). Nevertheless, true control of FVD, let alone complete FVD prevention, remains a remote prospect. The still very fragmented understanding of filovirus ecology, including the lack of identified viral host(s) and potential vectors, makes prediction of hot spots of filovirus–human interfaces difficult. The socioeconomic, logistic, and infrastructural shortcomings in potentially filovirus-endemic or filovirus-epidemic areas continue to pose immense challenges to outbreak responders and to hinder performance of clinical trials. In some FVD outbreaks, ongoing strife within epidemic regions can foster mistrust of existing institutions. As foreign responders align themselves with the host government to contain the outbreak, mistrust of government may morph into mistrust of the offered foreign assistance. Cultural norms, linguistic diversity, and differences in disease concepts held by traditional healers and western medicine create cognitive dissonance in the community that also contributes to resistance of foreign assistance. A combination of scientific advances, investment in infrastructure, and social anthropology will hopefully be brought to bear in future outbreaks.

FOOTNOTE

Country and geographic region nomenclature (including country abbreviations) was standardized throughout according to the United Nations geoscheme (https://unstats.un.org/unsd/methodology/m49/). Gene and protein names were standardized throughout according to the most recent nomenclature of the HUGO Gene Nomenclature Committee (https://www.genenames.org/). Mammal and mammal species names were standardized throughout following recommendations in Wilson and Reeder's *Mammal Species of the World*, third edition

(https://www.departments.bucknell.edu/biology/resources/msw3/).

CHAPTER **12**

Paramyxoviridae: The Viruses and Their Replication

Richard K. Plemper • Robert A. Lamb

Introduction
Classification
The Structure and Replication Strategy of the *Paramyxoviridae*
Virion Structure
The *Paramyxoviridae* Genomes and Their Encoded Proteins
- The Nucleocapsid Protein
- The *P* Gene and Its Encoded Proteins
- The Large Protein
- The Matrix Protein
- Envelope Glycoproteins
- Other Envelope Proteins

Stages of Replication
- General Aspects
- Virus Adsorption and Entry
- Viral RNA Synthesis
- Genome Replication
- Virion Assembly and Release

Paramyxovirus Accessory Genes and Their Interference with the Cellular Antiviral Response
- Antagonists of Interferon Synthesis
- Antagonists of Interferon Signaling Pathways

Engineered Paramyxovirus Minigenomes and Recombinant Viruses: Reverse Genetics

INTRODUCTION

The *Paramyxoviridae* are important and ubiquitous disease-causing viruses of humans and animals, including one of the most infectious viruses known (measles virus [MeV]); some of the most prevalent viruses known (MeV, parainfluenza viruses, and mumps virus [MuV]); a virus that has been targeted by the World Health Organization for eradication (MeV) and the second virus successfully eradicated (rinderpest virus [RPV]); viruses that have a major agricultural impact (Newcastle disease virus [NDV] and Nipah virus [NiV]); and many recently identified viruses (Hendra virus [HeV], NiV, J virus, and Belong virus), some of which cause deadly diseases (HeV and NiV). The *Paramyxoviridae* are enveloped negative-strand RNA viruses that have special relationships with three other families of negative-strand RNA viruses, namely, the *Orthomyxoviridae* (for the biological properties of the envelope glycoproteins) and the *Pneumoviridae* and *Rhabdoviridae* (for the similarity of organization of the nonsegmented genome and its expression). Both the *Paramyxoviridae* and the *Pneumoviridae* are defined by having a fusion (F) protein that causes merger of viral and cell membranes at neutral pH. The genomic RNA of all negative-strand RNA viruses has to serve two functions: (a) as a template for synthesis of mRNAs and (b) as a template for synthesis of the antigenome (+) strand. Negative-strand RNA viruses encode and package their own RNA-dependent RNA polymerase (RdRP), but mRNAs are only synthesized once the virion has been uncoated in the infected cell. Viral replication occurs only after the synthesis of viral mRNAs and proteins has been initiated and requires the continuous synthesis of viral proteins. Newly synthesized antigenome (+) strands serve as the template for further copies of the (−) strand genomic RNA.

CLASSIFICATION

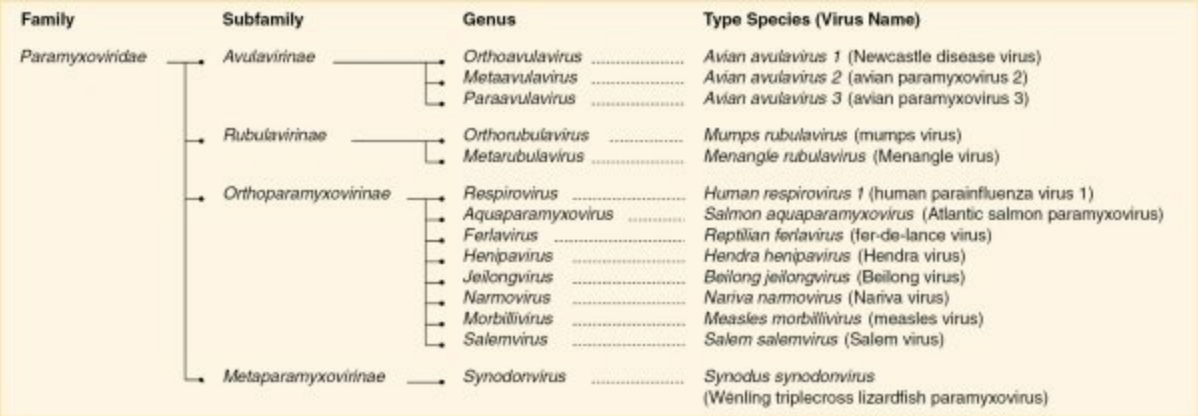
According to the February 2019 classification accepted by the International

Committee on the Taxonomy of Viruses, the family *Paramyxoviridae* is grouped into seven genera: *Morbillivirus*, *Henipavirus*, *Respirovirus*, *Rubulavirus*, *Avulavirus*, *Aquaparamyxovirus*, and *Ferlavirus* (Table 12.1). This organization was originally developed based on historic classification criteria such as morphologic features, genome organization, and biological activities of individual proteins and further refined based on sequence relationships after an increasing number of genome sequences became available. However, the recent discovery of numerous new paramyxoviruses has prompted a proposal for taxonomic reorganization driven by novel, sequence-based demarcation criteria including RdRP sequence motifs and pairwise amino acid sequence comparison to negotiate inconsistencies that arose from the historical classification approach.[487] This initiative organizes the *Paramyxoviridae* into four subfamilies, the *Avulavirinae*, *Rubulavirinae*, *Orthoparamyxovirinae*, and *Metaparamyxovirinae* (Table 12.2), that contain a combined total of 14 different genera with 69 classified and 3 unassigned species. The future discovery of additional new paramyxoviruses is highly likely.[595]

TABLE 12.1 Classification of the *Paramyxoviridae* family, ICTV 2018

Family	Genus	Type Species (Virus Name)
Paramyxoviridae	*Aquaparamyxovirus*	*Salmon aquaparamyxovirus* (Atlantic salmon paramyxovirus)
	Avulavirus	*Avian avulavirus 1* (Newcastle disease virus)
	Ferlavirus	*Reptilian ferlavirus* (fer-de-lance virus)
	Henipavirus	*Hendra henipavirus* (Hendra virus)
	Morbillivirus	*Measles morbillivirus* (measles virus)
	Respirovirus	*Murine respirovirus* (Sendai virus)
	Rubulavirus	*Mumps rubulavirus* (mumps virus)

TABLE 12.2 Proposed reorganization of the *Paramyxoviridae*



The distinguishing morphologic feature among enveloped viruses for the family *Paramyxoviridae* is the size and shape of the nucleocapsids (variable among different family members; approximate length is 1 μm, diameter and pitch range from 18–20 nm and 4.7–8.3 nm, respectively), which have a left-handed helical symmetry. Historic biological organization criteria are (a) antigenic cross-reactivity between members of a genus and (b) the presence or absence of neuraminidase (NA) activity. In addition, the differing coding potentials of the *P* genes were considered—members of the *Avulavirinae*, *Rubulavirinae*, and *Metaparamyxovirinae* and the genus *Ferlavirus* do not encode a C protein—and some *Rubulavirinae* and *Jeilongviruses* contain an extra *SH* gene. Most closely related to the *Paramyxoviridae* are the *Pneumoviridae*, which until recently were jointly classified in a single family. Pneumoviruses (respiratory syncytial viruses [RSVs] and the metapneumoviruses) can be distinguished from the *Paramyxoviridae* based on their narrower nucleocapsids, a greater number of open reading frames (ORFs) in the genomes, and a different structural organization and functional role of their attachment proteins.

THE STRUCTURE AND REPLICATION STRATEGY OF THE *PARAMYXOVIRIDAE*

Paramyxoviruses contain nonsegmented single-stranded RNA genomes of negative polarity and replicate entirely in the cytoplasm. Their genomes are

14,296 to 21,523 bp in length and harbor six (*Avulavirinae*, most *Orthoparamyxovirinae*, *Metarubulavirus* genus) to eight (*Jeilongvirus* genus) tandemly linked genes. By the convention used for paramyxoviruses, the term “gene” refers to the genome sequence encoding a single mRNA, even if that mRNA contains more than one ORF and encodes more than one protein. A lipid envelope containing two surface glycoproteins (F and the attachment glycoprotein variously called hemagglutinin-neuraminidase (HN), hemagglutinin (H), or glycoprotein (G)) surrounds the virions. Inside the envelope lies a helical nucleocapsid core containing the RNA genome and the nucleocapsid (N), phosphoprotein (P), and large (L) proteins, which initiate intracellular transcription and replication. Residing between the envelope and the core is the viral matrix (M) protein that serves as a virion assembly organizer and is released from the core during virus entry. In addition to the genes encoding structural proteins, paramyxoviruses express “accessory” proteins that are encoded in alternative reading frames overlapping with the *P* gene.

Intracellular replication of paramyxoviruses begins with the viral RdRP (minimally, a hetero-oligomeric complex consisting of a P homotetramer and a single L protein) transcribing the N-encapsidated genomic RNA (N–RNA) into 5′-capped and 3′-polyadenylated mRNAs. In transcriptase mode, the viral RdRP initiates RNA synthesis at the 3′ end of the genome and transcribes the genes into mRNAs in a sequential (and polar) manner by terminating and reinitiating at each gene junction. The junctions consist of a gene-end (GE) sequence, at which polyadenylation occurs by the reiterative copying of four to seven uridines (followed by release of the mRNA), a short nontranscribed intergenic (IG) region, and a gene-start sequence that specifies mRNA initiation and, presumably, by analogy with rhabdovirus gene expression, capping. While RdRP generates predominantly monocistronic viral mRNAs, it occasionally misses GE sequences resulting in the synthesis of polycistronic mRNAs, of which only the first gene is translated. In addition, the RdRP sometimes fails to reinitiate transcription at a gene-start sequence and/or detaches from the template N–RNA prematurely, resulting in the creation of an mRNA transcription gradient that is inversely proportional to the distance of the gene from the 3′ end of the genome. After primary transcription and translation, when sufficient amounts of unassembled N protein have accumulated in the infected cell, the RdRP can switch into replicase mode, becoming highly processive and concomitantly N-

encapsidating the nascent RNA chain while ignoring all IG junctions and editing sites. The resulting product is an exact complementary antigenomic [+] RNA chain of the viral genome in a fully assembled nucleocapsid.

VIRION STRUCTURE

The *Paramyxoviridae* contain a lipid bilayer envelope that is derived from the plasma membrane of the host cell in which the virus is grown (reviewed in Ref.[93]). *Paramyxoviridae* are generally spherical, 150 to 350 nm in diameter, but can be pleiomorphic in shape, and filamentous forms exceeding one micron in length have been observed.[266] Inserted into the envelope are glycoprotein spikes that extend approximately 8 to 12 nm from the surface of the membrane and can be readily visualized by electron microscopy (EM). Inside the viral membrane is the ribonucleoprotein (RNP) core that contains the 14,296 to 21,523 (depending on paramyxovirus species) nucleotide single-stranded RNA genome. Figure 12.1 shows a stylized schematic diagram of the virion by example of the *Morbillivirus* genus. The pleiomorphic nature of virion particles is illustrated in the negative-stain electron micrographs and cryoelectron microscopy (cryo-EM)–derived tomograms shown in Figure 12.2, and a comparison of the RNPs of influenza virus, rabies virus, and Sendai virus (SeV) is shown in Figure 12.3.

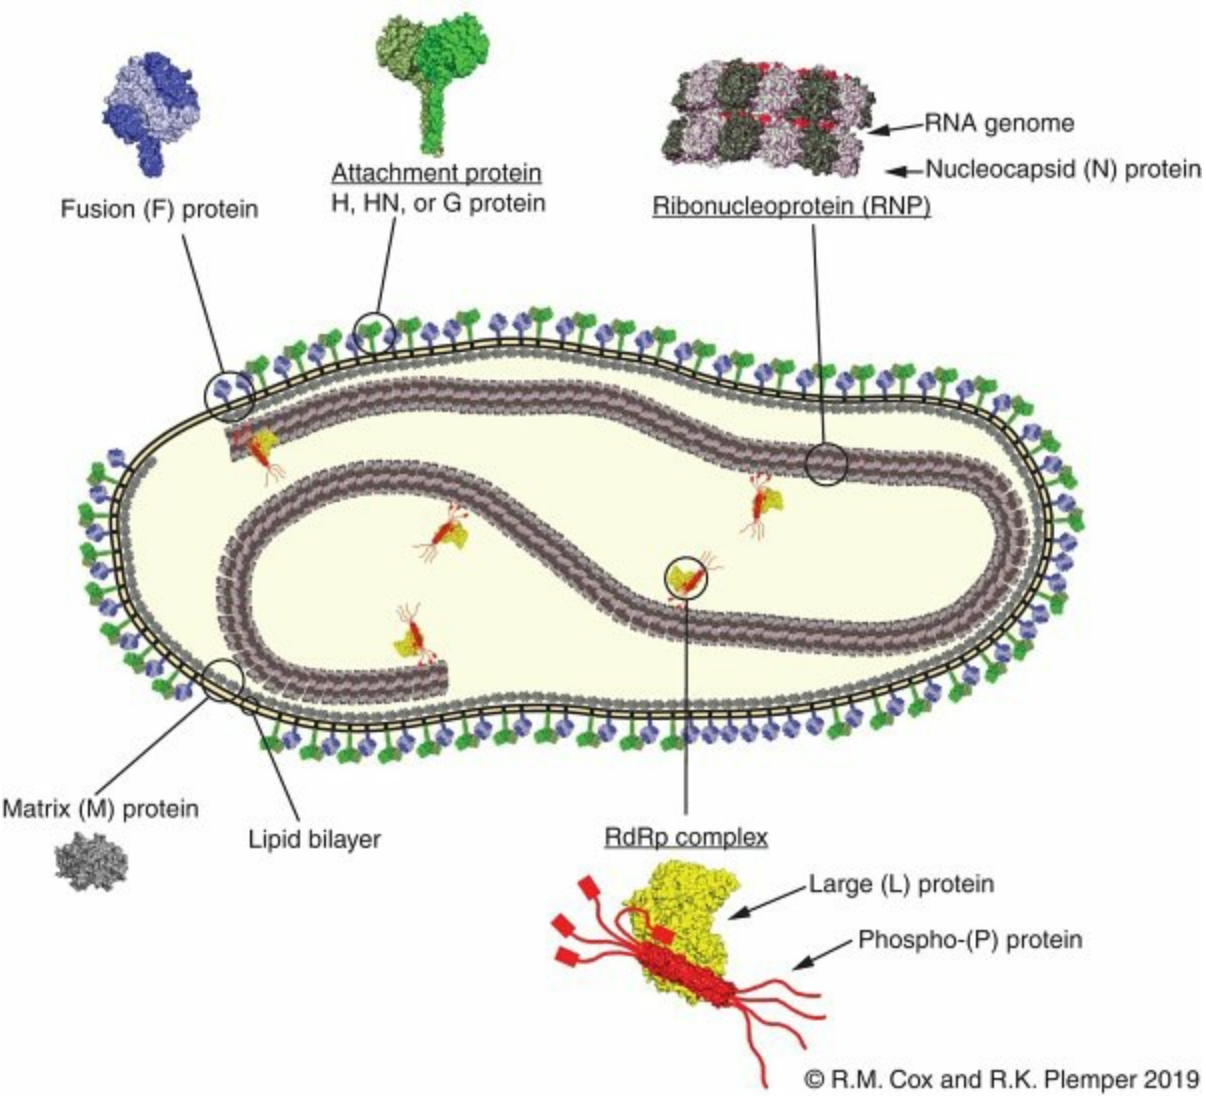


FIGURE 12.1 Schematic diagram of a paramyxovirus (not drawn to scale). Shown are the lipid envelope and the underlying viral M protein array. Inserted into the envelope are the attachment protein (hemagglutinin [H], hemagglutinin-neuraminidase [HN], or glycoprotein [G] depending on virus species) and the F protein. The relative abundance of attachment and F proteins is not accurately illustrated by the diagram. The attachment proteins form tetrameric structures composed of a stalk region and a globular head. The F proteins exist as trimers. The ribonucleoprotein (RNP) complex is composed of the negative-strand viral RNA genome encapsidated by the N protein. Associated with the RNP are RNA-

dependent RNA polymerase (RdRP) complexes, consisting of the L and P proteins.

Promotion of virus assembly and organization by the measles virus matrix protein. *Nat Commun* 2018;9(1): 1736, CC BY 4.0; the original image was cropped, scale bars were relocated, and *arrows* were removed; http://creativecommons.org/licenses/by/4.0/.)

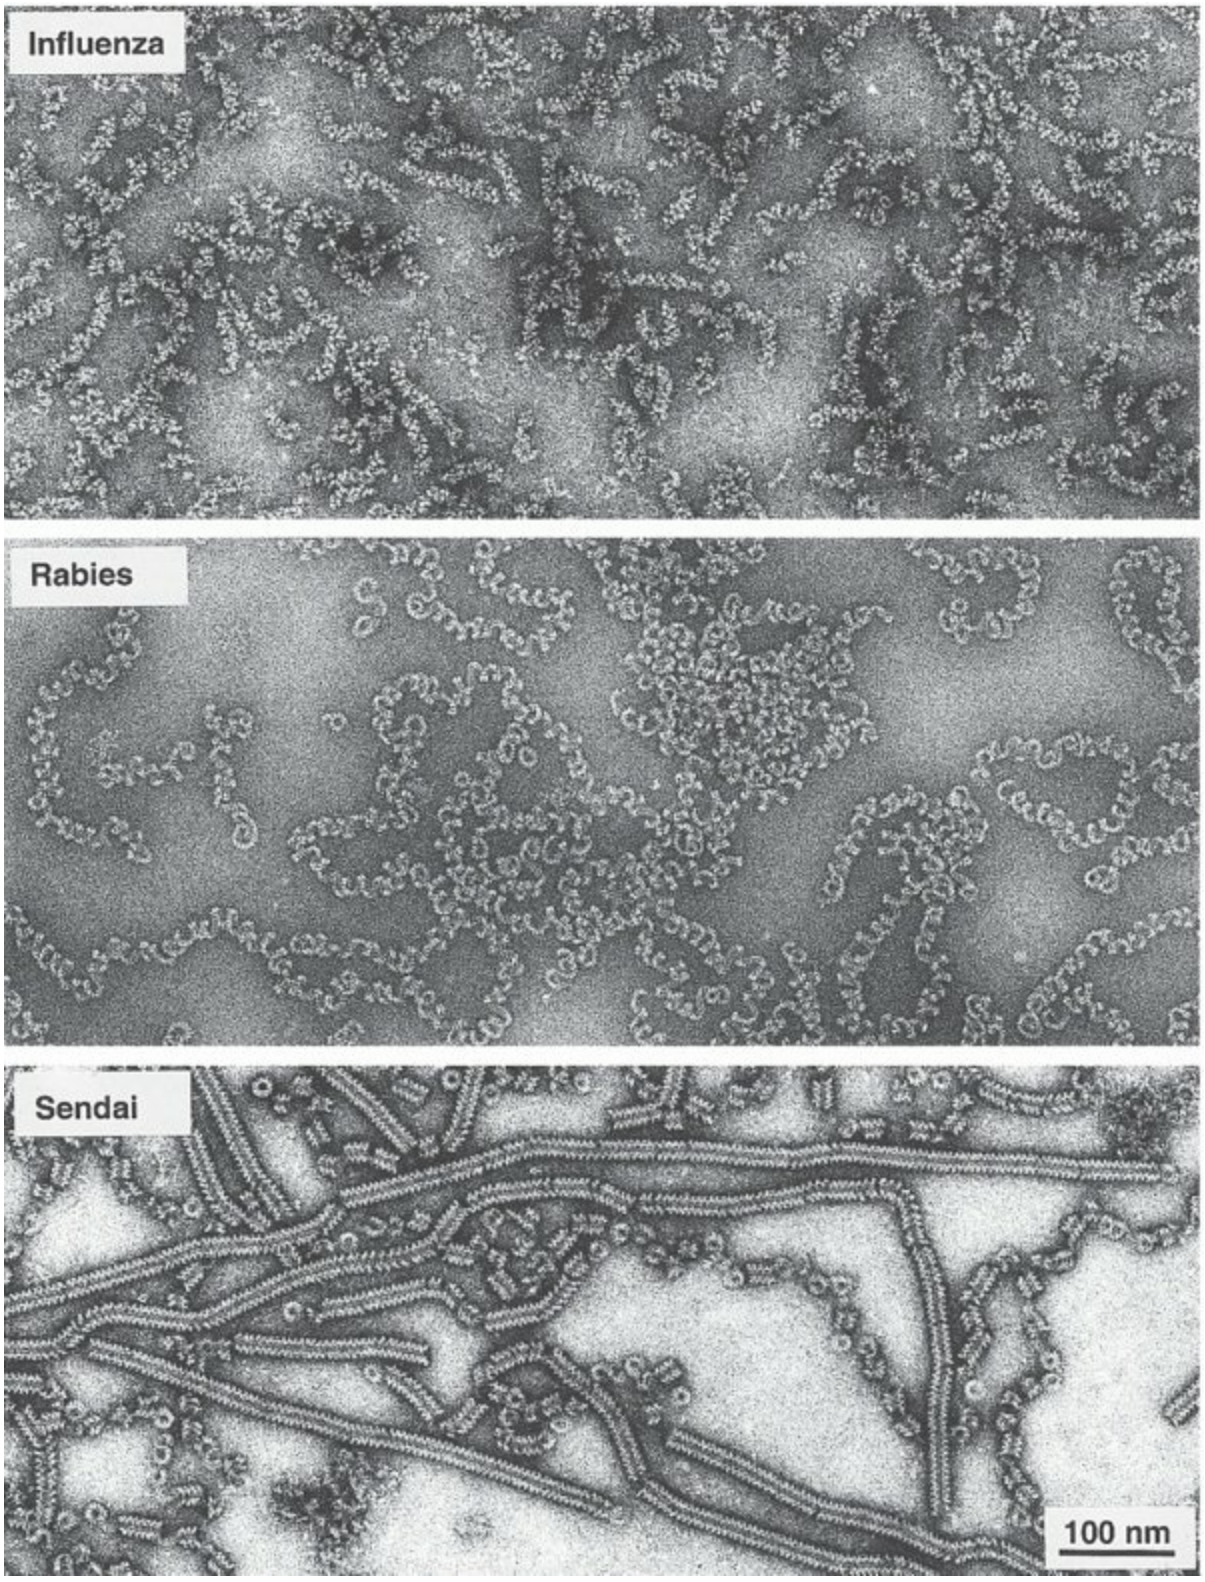

FIGURE 12.3 Nucleocapsids of negative-strand RNA viruses. Negative-stain electron micrographs of the nucleocapsids of three

negative-strand RNA viruses.

Top: Ribonucleoprotein particles of influenza virus (*Orthomyxoviridae*) with a stoichiometry of 24 nucleotides per NP monomer.

Middle: Nucleocapsids of rabies virus (*Rhabdoviridae*) with a stoichiometry of 9 nucleotides per N monomer.

Bottom: Nucleocapsids of SeV (*Paramyxoviridae*) with a stoichiometry of 6 nucleotides per N monomer. All micrographs have the same magnification; scale bar is 100 nm. (Micrographs courtesy of Rob Ruigrok, EMBL, Grenoble, France.)

The helical nucleocapsid, rather than free genome RNA, serves as the template for all RNA synthesis. For SeV, each nucleocapsid is composed of approximately 2,600 N, 300 P, and 50 L proteins.[291] The N protein and genomic RNA together form a core structure, to which the P-L complexes are attached. This nucleocapsid core is remarkably stable because it withstands the high salt and gravity forces of CsCl density gradient centrifugation. In the EM of nucleocapsids and more recent cryoelectron tomography (cryo-ET) reconstructions, the P and L proteins are not observed, and they have only been visualized through immunostaining.[467] Holonucleocapsids (N–RNA plus P-L) have the capacity to transcribe mRNAs *in vitro*, presumably mimicking primary transcription in infected cells, and they are believed to be the minimum unit of infectivity.

SeV nucleocapsids were shown to exist in several distinct morphologic states at normal salt concentration.[150,210] The most prevalent form in negatively stained preparations is the most tightly coiled one, with a helical pitch of 5.3 nm. Two other forms, one with a slightly larger pitch of 6.8 nm and another with a much larger pitch of 37.5 nm, have also been noted. The fact that no structures of intermediate pitch have been found indicates that these are distinct states. It is believed that the template is copied without dissociation of N protein from the nucleocapsid, routing the interlocking N protein chain over the surface of the P-L complex as the polymerase advances. Local uncoiling of the nucleocapsid may be necessary for the polymerase to gain access to the RNA bases. It is possible that the viral polymerase traverses the nucleocapsid template by uncoiling the helix in front of it and recoiling it once the polymerase has passed a given position,

much the same as cellular RNA polymerase generates its template “bubble” in traversing dsDNA.

As expected, the diameter of the nucleocapsid decreases as the pitch increases and the nucleocapsid lengthens. For SeV, the diameter is 3.5 nm less for the 6.8-nm form than for the 5.3-nm pitch form. These latter values are similar to those of *Pneumoviridae* nucleocapsids, which also have a pitch of 7 nm. As discussed previously, these differences in nucleocapsid morphology can be used to distinguish between the *Paramyxoviridae* and *Pneumoviridae*, but they may relate simply to which form predominates in negatively stained preparations.

THE *PARAMYXOVIRIDAE* GENOMES AND THEIR ENCODED PROTEINS

The complete genome sequences for all known members of the *Paramyxoviridae* have been obtained and are available online. The genomic RNAs contain a 3′ extracistronic region of approximately 50 nucleotides known as the leader and a 5′ extracistronic region of 50 to 161 nucleotides known as the trailer (or [−] leader). These control regions are essential for transcription and replication and flank the six to eight genes. The coding capacity of the genomes is extended by the use of overlapping ORFs in the *P* gene. The gene order of representative paramyxoviruses is shown in Figure 12.4. At the beginning and end of each gene are conserved transcriptional control sequences that are copied into mRNA. Between the gene boundaries are IG regions. These are precisely three nucleotides long for the respiroviruses and morbilliviruses but are quite variable in length for the *Rubulavirinae* (1–47 nucleotides) (Table 12.3).

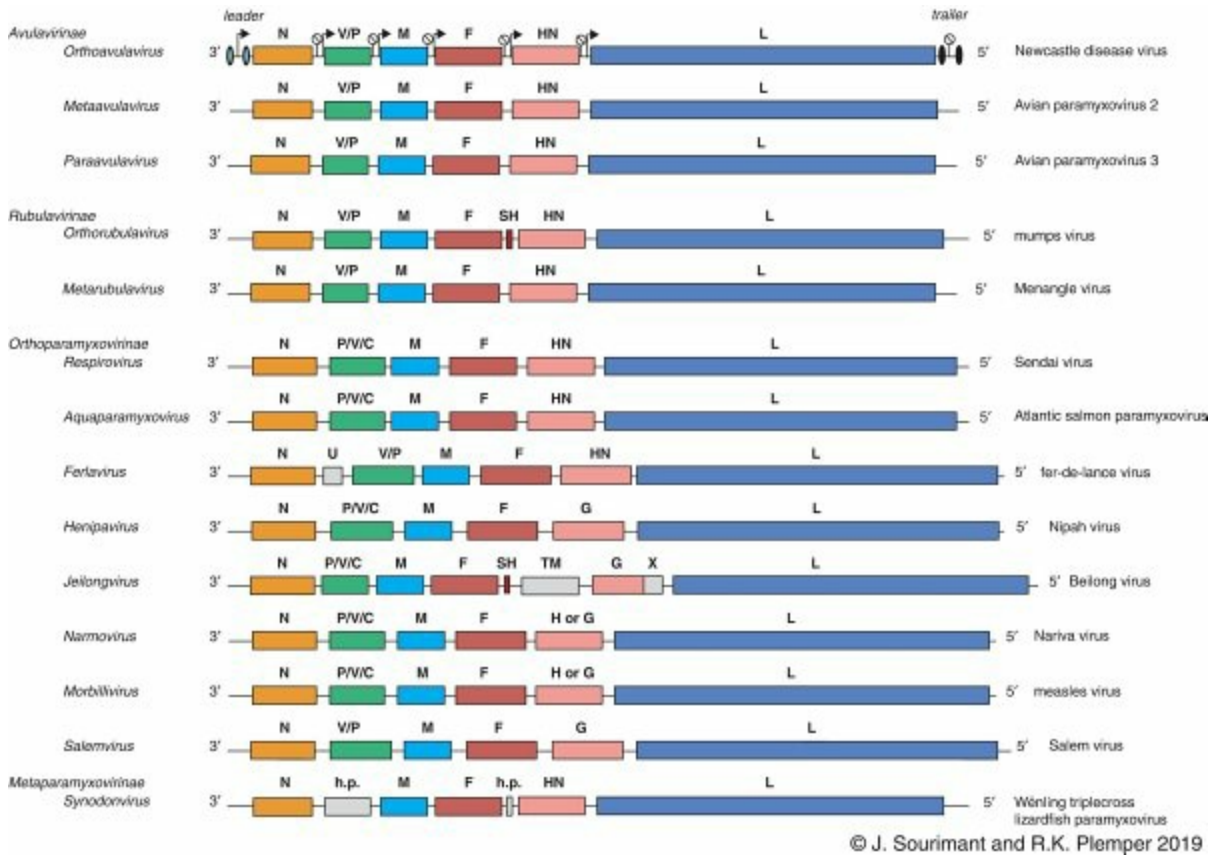

FIGURE 12.4 Schematic diagram of the genomes of selected viruses representing each genus of the *Paramyxoviridae*. Intergenic junctions are shown as single *black lines*; transcribed sections are depicted as *boxes* drawn to approximate gene length scale and color-coded by encoded protein type: N proteins (*orange*), P proteins (*green*), M proteins (*light blue*), F proteins (*red*), attachment proteins (*pink*), and L proteins (*dark blue*). When present, SH proteins are shown in red. Uncharacterized proteins are colored in *gray*. For *Jeilongvirus* genus, X denotes an internal ORF in the G gene of unknown function. Hypothetical proteins (h.p.) predicted based on the complete genome of the newly discovered *Synodonvirus* genus are indicated. Bipartite promoters (*oval circle*) and transcriptional gene end (*crossed circle*) and transcription gene start (*black arrow*) sequence are shown for NDV only.

TABLE 12.3 Gene-end, Gene-start, and intergenic sequences in representative members of the *Paramyxoviridae*

The Nucleocapsid Protein

The nucleocapsid (N) protein is present as the first transcribed gene in the viral genome of all paramyxoviruses and ranges in size from 489 to 553 amino acids (molecular weight ~53–57 kDa). N is an RNA-binding protein that coats full-length viral (−) sense genomic and (+) sense antigenomic RNAs to form the helical nucleocapsid template, which is the only biologically active form of these viral RNAs. EM and three-dimensional image reconstruction for MeV, parainfluenza virus 5 (PIV-5), and SeV nucleocapsids reveals that N binds precisely 6 consecutive nucleotides and 13 N subunits constitute each turn of the nucleocapsid helix.[6,150,193] In general, these parameters also apply to other paramyxovirus nucleocapsids, although there can be slight differences in the number of N subunits per helix turn and in the pitch of the helix.[27] The binding of N to RNA to form a helical structure is believed to serve several functions, including protection from nuclease digestion, alignment of distal RNA segments to create a functional 3′-end promoter, and providing interaction sites for assembly of progeny nucleocapsids into budding virions.

Expression of paramyxovirus N proteins in the absence of other viral components results in the formation of nucleocapsid-like structures, suggesting that N has inherent self-assembly properties and that N–N interactions drive nucleocapsid assembly.[163,386,387,403,529,557] Biochemical and mutational studies have shown that the N protein can be generally divided into two main structural regions: (a) Ncore, an N-terminal domain representing approximately three-fourths of the protein that is conserved in sequence among related viruses, and (b) Ntail, a C-terminal nonconserved acidic domain. The N-terminal approximately 400 residues of the SeV and MeV Ncore are essential for self-assembly and RNA binding.[55,111,271]

A cryo-EM–based reconstruction of purified MeV nucleocapsids after removal of the Ntail domain has revealed an organization of Ncore into two distinct globular domains, the N-terminal NTD (residues 37–265) and C-

terminal CTD (residues 266–372), which are preceded and followed by short NT-arm (residues 1–36) and CT-arm (residues 373–391) extensions, respectively (Fig. 12.5A–C).[193] In the nucleocapsid assembly, the NT-arms interlock with the CTD of the subsequent N protomer, and CT-arms interact with the preceding protomer, creating a stable chain link–like arrangement. Although Ntails were removed prior to reconstruction, the position of the CT-arm suggests that Ntails protrude to the outside of the nucleocapsid between adjacent rungs of the helix. The RNA populates a cleft between NTD and CTD, winding around the outside of the RNP helix (Figs. 12.5D, E and 12.6A).[193] However, paramyxovirus N proteins do not contain conventional RNA-binding motifs that are typically found on cellular RNA-binding proteins. Biophysical properties are furthermore unusual for RNA-binding proteins, since they feature an overall acidic charge (net charge of −7 to −12, with the exception of MuV [+2]). A central region of Ncore that is highly conserved among all members of the family (residues 258–369 for SeV) contains an F-X4-Y-X3-ϕ–S-ϕ-A-M motif (where X is any residue and ϕ is an aromatic amino acid). This region is essential for self-assembly of N with RNA[385] and important for N–RNA interactions.[6,193,349]

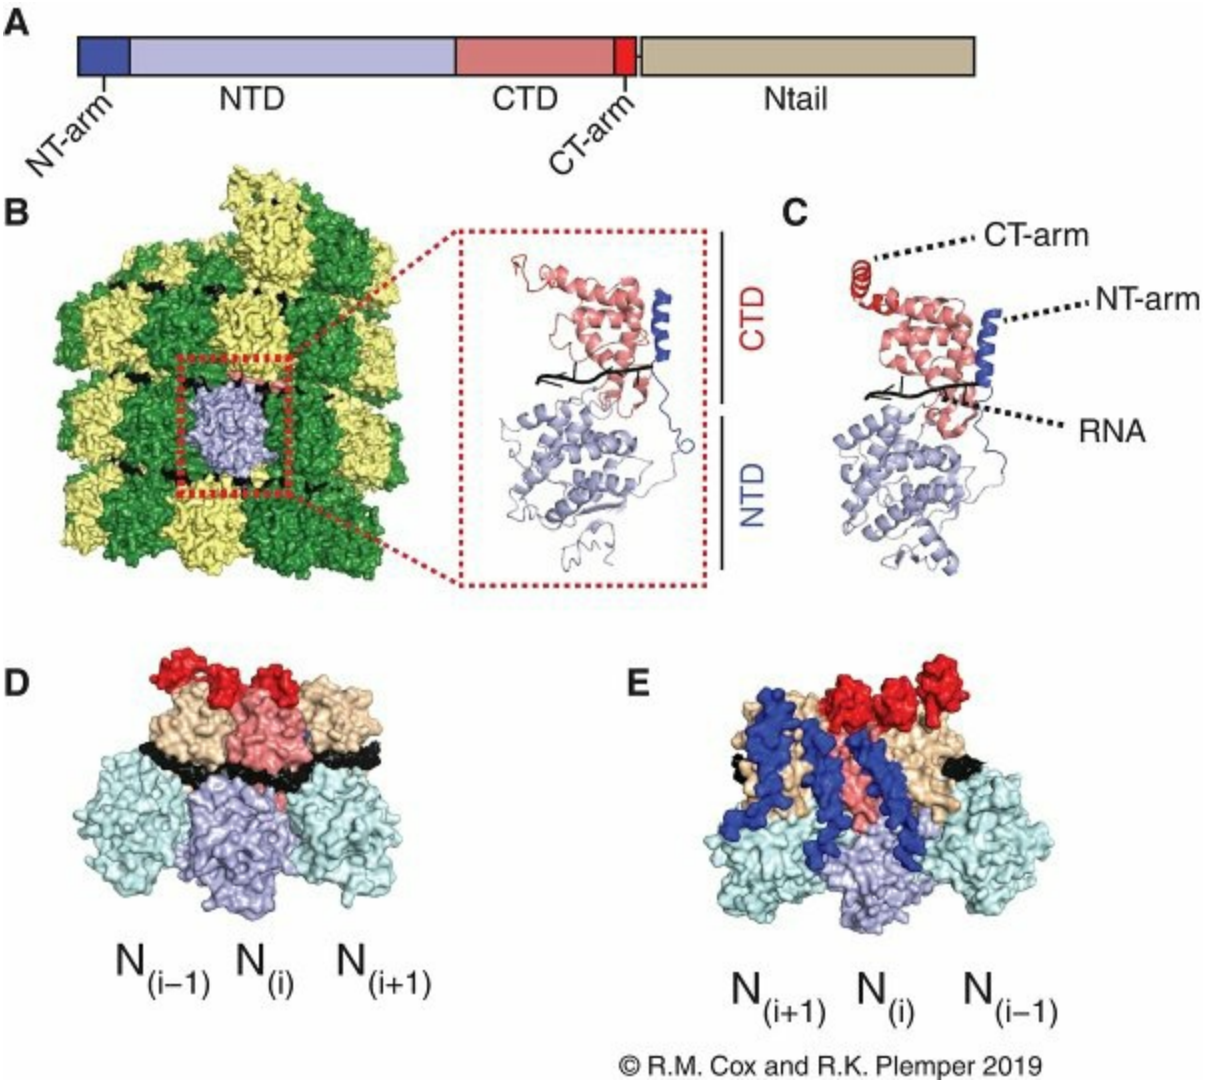

FIGURE 12.5 Structure of the paramyxovirus N protein and RNP assembly.

A: Schematic of the domain organization of the N protein. NT-arm (*blue*) and CT-arm (*red*) are responsible for N–N homo-oligomerization. RNA is encapsidated between NTD (*light blue*) and CTD (*pink*). The C-terminal Ntail domain is flexible and disordered.

B: Cryoelectron microscopy structure of the MeV nucleocapsid (PDB ID: 4UFT).[193] The structure is based on a truncated N protein (residues 1–391) and lacks Ntail. *Insert*: Single N protomer. The NTD (*light blue*) and CTD (*pink*) domains and viral RNA (*black*) are highlighted.

C: Crystal structure of the PIV-5 N protein lacking the Ntail domain. The domain architecture is similar to MeV N, color-coding as in **(B)**.

D and E: Enlarged views of three neighboring protomers, taken from outside (**D**) or inside (**E**) the helical RNP. NT-arm of $N_{(i)}$ interacts with an adjacent $N_{(N+1)}$, while CT-arm interacts with the other neighboring $N_{(N-1)}$ monomer. Color-coding of the arms as in **(C)**. FIGURE 12.6 N–RNA binding and N^0–P interaction. The N-terminus of the P protein is responsible for chaperoning newly synthesized N proteins to the nascent RNA strand during replication. Crystal structures of these N^0–P complexes have been solved.[4,192,641] **A:** Cartoon of an assembled helical nucleocapsid with intact Ntails (not drawn to scale). The Ntail domain is proposed to extend from the helical nucleocapsid into the surrounding environment.[251] *Insert:* Enlargement of a single N protomer; major folding domains, the tail domain, and the RNA are highlighted. **C:** *Left*, surface representation of an MeV N protomer in the RNP assembly with the NT-arm of the neighboring N protomer shown in *blue*; *top*, surface representation of an MeV N^0–P crystal structure (complex [PDB ID: 5E4V][192]). **D:** Cartoon

representation of overlays of MeV N^0–P (NTD, *light blue*; CTD, *pink*; P, *green*) and NC model (*light gray*). The N-terminus of P ($P_{1–48}$) interacts specifically with the first and second helices of the CTD of N (*α*-9 and *α*-10; *arrow*). This interaction blocks NT-arm interactions from neighboring N subunits, preventing premature N–N oligomerization. In addition, binding of $P_{1–48}$ induces a conformational change in the *α*-6 helix of the NTD, blocking RNA encapsidation. (Images copyright © 2019 by Richard K. Plemper and Robert M. Cox.)

The approximately 125–amino acid C-terminal Ntail region is intrinsically structurally disordered[40] and poorly conserved among different paramyxoviruses. It is dispensable for RNA binding and the assembly of N–RNA complexes.[111] While Ncores are resistant to trypsin proteolysis, treatment of purified nucleocapsids with trypsin removes most of Ntail, resulting in bioinactive, rigidified RNP helixes with a shortened pitch of 5 nm compared to the native 6.4-nm form detected in infected cells.[27,28,111,209,377,529] This apparent link between the physical presence of Ntail and flexibility of the native nucleocapsid is consistent with Ntail being routed between adjacent turns of the helix. Supported by the high degree of structural disorder, a role of Ntail in a diverse array of protein–protein interactions was proposed. For instance, three short conserved sequence elements (Boxes 1–3) are embedded in *Morbillivirus* Ntails, spanning residues 400 to 420, 489 to 506, and 517 to 525 (Fig. 12.6A).[130] The second of these elements, termed a molecular recognition element (MoRE), has been shown to interact with a C-terminal X domain of the P protein (P-XD), undergoing an induced conversion into a short alpha helical structure upon contact.[40,197,252,620] A crystal structure of a recombinant MeV P-XD fused to a MoRE-derived peptide was solved, revealing a stable four-helix arrangement.[273] This interaction with P appeared to support a proposed role of Ntail in recruiting P-L to the nucleocapsid, since a C-terminal truncation of residues 495 to 525 had been shown to abolish RdRP activity in MeV minireplicon reporter assays.[659] However, further truncation of the MeV Ntail by up to 40 additional residues has been unexpectedly shown to

progressively restore polymerase activity, indicating that initial loading of the RdRP complex onto the template occurs independent of interaction between Ntail and P-L.[282] Rather, recruitment of the RdRP complex to the RNP is thought to depend on direct interactions between P-L and Ncore.[555] While specific microdomains involved in this interaction are unknown, binding of MuV P to Ncore was demonstrated.[101,271]

Once the polymerase complex is loaded onto the template, iterative cycles of MoRE to P-XD binding and release contribute to preventing premature termination of the advancing RdRP.[57,271,325] These productive interaction cycles are independent of spatial flexibility provided by Ntail-embedded MoRE and cis-acting elements in Ntail, since recombinant MeVs expressing engineered N proteins in which MoRE was relocated from Ntail into Ncore replicated efficiently.[102] However, these engineered MeVs and likewise recombinant canine distemper viruses (CDVs) containing N proteins lacking up to 55 of the structurally disordered central Ntail residues showed altered RdRP transcriptase function, implicating Ntail in regulating proper viral protein expression.[594] A nonessential role of the structurally disordered Ntail section was also confirmed for the related henipaviruses,[594] although the relative positioning of N–P interaction regions within Ntail differs between the henipaviruses and morbilliviruses (Fig. 12.6A).[194]

In the case of MeV, two serine-phosphorylation sites (S479 and S510) located before and after MoREs have been mapped that, when mutated to alanines, affect RdRP bioactivity.[195] Both the second and third conserved elements at the Ntail C-terminus were furthermore proposed to bind the cellular chaperone HSP72 and its cofactor HSP40,[100,659] opening an additional path to regulate RdRP activity by modulating the stability of the Ntail P-XD interaction. Residues in the third conserved element in addition interact with the viral matrix (M) protein, outlining a role of Ntail in virion assembly through creation of a link between RNP and viral envelope.[245,485]

The interactions of paramyxovirus N proteins with RNA are remarkably stable, and nucleocapsid-associated RNA is protected from nucleases even at very high salt concentrations or after proteolytic removal of the Ntail domain.[209,377,529] N binding to RNA is believed to be independent of nucleotide sequence and thought to occur through interactions with the phosphodiester backbone.[242] However, the MeV RNP reconstructions have

revealed that of the six nucleotides interacting with a single N protomer, only the first, fifth, and sixth bases are orientated outward and therefore accessible to viral RdRP, while the second to fourth bases face inward.[64,193,259] Encapsidation therefore imprints a hexamer phase on the viral RNA that is consistent with the earlier finding that SeV RNPs are hyperreactive to chemical treatment of cytidine residues predicted to be located at positions one and six of a hexamer of nucleotides.[242] Correct imprinting is ensured by the bipartite organization of the paramyxovirus promoter, which allows formation of a functional promoter only when nucleotides of the distinct promoter elements are properly juxtaposed next to each other in consecutive turns of the RNP helix.[126,365,587,618]

N protein exists in at least two forms in infected cells, one stably associated with RNA in a nucleocapsid structure and a second unassembled soluble form termed N^0, which has been found associated with P in N^0–P complexes for a number of viruses, including SeV,[222] PIV-5 (SV5),[472] HPIV-2 and HPIV-3,[403,661] and MeV.[231,557] N^0 is believed to be the RNA-free functional form of N that allows accumulation of a large pool of RNA-free N in an infected cell before the viral RdRP switches to replicase mode.[114,223] N-terminal regions of Ncore are important for formation of the N^0–P complex,[220] and these domains are distinct from those involved in binding of P to N in the assembled nucleocapsid. A crystal structure of a MeV Ncore fragment (residues 21–408) fused to the first 48 amino acids of P supports comparison of RNA-bound and RNA-free N proteins.[192] In this structure, the P residues directly interact with the first alpha helix in the CTD of the N protein, partially occupying space claimed by the NT- and CT-arms of Ni−1 and Ni+1 of an Ni protomer in RNP assembly (Fig. 12.6C, D). Conceivably, steric hindrance mediated by P residues 1 to 48 prevents spontaneous N homo-oligomerization when in N^0–P complexes.

The *P* Gene and Its Encoded Proteins

The *Paramyxoviridae P* gene is a remarkable example of expanding the coding capacity within a viral gene. The SeV P/V/C gene is the most diverse of the paramyxovirus *P* genes, directing the expression of at least seven polypeptides, including the P, V, W, C′, C, Y1, and Y2 proteins (Fig. 12.7). Although other paramyxoviruses express fewer proteins from the *P*/*V*/*C* gene

than SeV, the *P* gene always produces more than one polypeptide species (Table 12.4). Expression of P/V/C proteins can involve two main mechanisms, with members of a paramyxovirus genus having a characteristic combination of these expression strategies. The first expression mechanism that produces the P, V, and W/I/D proteins has been termed "RNA editing" or pseudotemplated addition of nucleotides.[70,204,438,596,608] This mechanism involves the production of mRNAs whose ORFs are altered by insertion of G residues at a specific position in the mRNA. As described below, the second expression mechanism involves ribosome initiation at alternative translation codons and produces the family of C proteins.

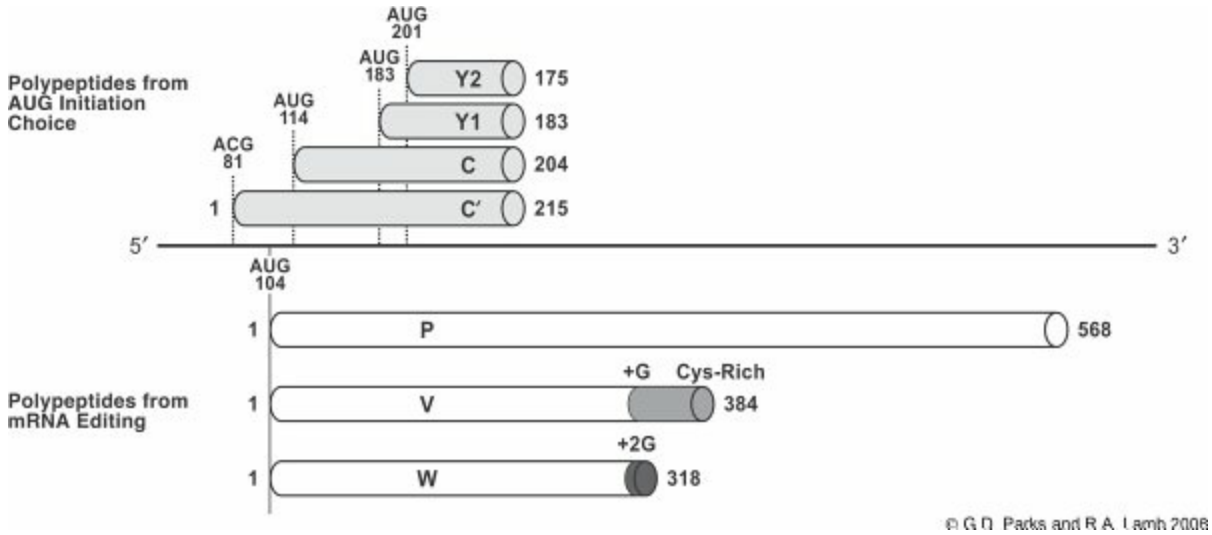

FIGURE 12.7 Representation of the Sendai virus P mRNA to illustrate the mechanisms of producing P, V, and C proteins. The positions of four unique initiation codons for the C′, C, Y1, and Y2 ORFs are shown above the *horizontal black line* representing the *P* gene mRNA. The position of the common initiation codon for the P, V, and W ORFs at base 104 is shown below the mRNA. The *gray cylinder* indicates the V protein Cys-rich C-terminal domain that is fused to the shared P N-terminal domain by addition of a G residue during viral transcription; the *black cylinder* indicates the short W domain, which is accessed by insertion of 2G residues. Numbers denote the amino acids contained within each polypeptide

chain. Note that the initiation codon for C′ is ACG.

TABLE 12.4 Examples of distinct ORFs identified in the paramyxovirus P genes

Paramyxovirus		mRNA Insertion	
		0 +1G +2G	Alternative ORFs
Rubulavirus	PIV-5	V W/I P	
	MuV; HPIV-2		
	HPIV-4		
Avulavirus	NDV	P V I	
Respirovirus	SeV	P V W	C′ C Y1 Y2
	BPIV-3	P V D	C
	HPIV-3	P V D	C
	HPIV-1	P	C′ C
Henipavirus	NiV; HeV	P V W	C
Morbillivirus	MeV; CDV	P V W	C
Unclassified	J virus; TPMV	P V W	C
	MoV		
	MenV; TiV	V W P	
	FDLV	V W P	

The P and V proteins, as well as virus-specific proteins variously called W, I, and D, are produced as a nested set of proteins sharing identical N-terminal sections. These polypeptides are translation products from distinct

mRNAs that differ only by inserted G nucleotides that shift the translational reading frame at the site of insertion, the editing site. As shown in Figure 12.7, the *P* gene of the *Avulavirinae* and members of the *Respirovirus*, *Morbillivirus*, and *Henipavirus* genus codes for a long N-terminal ORF shared by all three proteins and three shorter ORFs starting at approximately base 400 in the mRNA. During transcription of the nucleocapsid template, the viral RdRP is directed to make an accurate copy of the *P* gene template or to insert one or two G residues at the editing site in the nascent mRNA. The result is that the accurate transcription product encodes the full-length P ORF, while the mRNAs with insertions of +1G and +2G have a shift in the translational ORF such that the 5′-end P ORF is fused at the site of insertion in the mRNA coding sequence to a more 3′ ORF encoding V (+1G) or W (+2G). Thus, the P, V, and W/I/D proteins that are produced as a result of RNA editing share a common N-terminal region but differ in their C-terminal regions, starting at the site of G insertion.

All paramyxoviruses except Cedar virus and HPIV-1[350] encode a characteristic editing site in the *P* gene, and the number of inserted G residues, as well as the frequency of inserting G nucleotides, is thought to be determined by both sequences surrounding and within the editing site[204] and the position of the editing site relative to the hexamer phase of the encapsidated genome.[277,300] For example, Sendai and MeV encode the P protein as the translation product from the unedited mRNA (+0G; Fig. 12.8). The V protein is produced from a transcript containing a single G residue at the insertion site (+1G), which fuses the common N-terminal ORF to the V-specific ORF, whereas two inserted G nucleotides code for the W protein (+2G). As depicted in Figure 12.8, *Rubulavirinae* differ from other paramyxoviruses in that V protein is produced by translation of the unedited mRNA (+0G) and P is produced by translation of an mRNA containing a two G insertion (+2G).

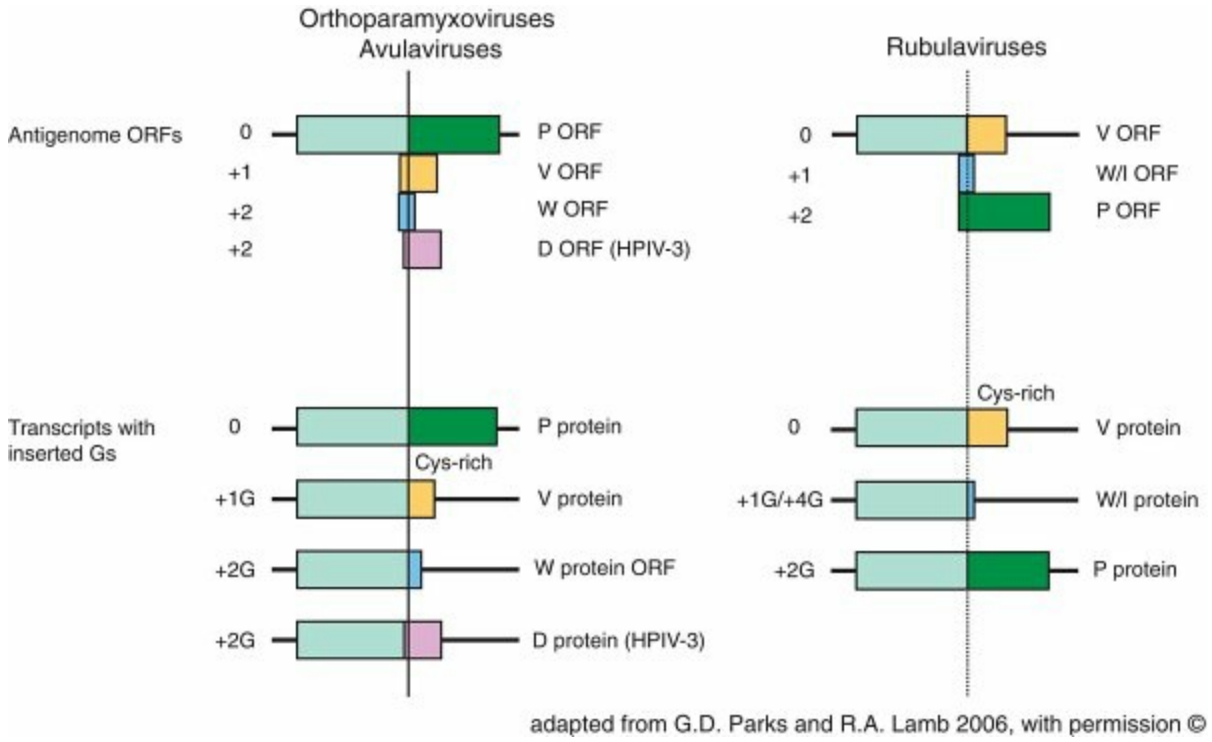

FIGURE 12.8 Schematic diagram of *P* gene ORFs accessed through RNA editing by different paramyxoviruses. The shared N-terminal ORF is shown as a *light green box*. The RNA editing site, at which nontemplated nucleotides are added to the mRNA, is indicated by the *vertical line*. At the bottom, RNA transcripts are shown to contain insertions of up to two additional G residues at the editing site, with *colored boxes* indicating unique C-terminal ORFs fused to the common N-terminal ORF. For the *Orthoparamyxovirinae* and *Avulavirinae*, the mRNA for the P protein is transcribed faithfully (unedited) from the viral genome and is shown as a *light green box* fused to a *dark green box*. Transcriptional RNA editing with the addition of one G nucleotide at the editing site produces an mRNA that encodes the V protein, in which the common N-terminal domain is fused to a different C-terminal frame, represented in *yellow box*. Addition of two G nucleotides at the editing site produces an mRNA that encodes the W (*blue box*) or D (*pink box*) or I proteins (depending on paramyxovirus species). For the *Rubulavirinae*, the unedited

mRNA encodes the V protein, the addition of either one or four G nucleotides produces mRNA encoding the W or I protein, and the addition of two G nucleotides produces the mRNA encoding the P protein.
(Adapted from G.D. Parks and R.A. Lamb, 2006, with permission ©)

Insertion of G residues into *P* gene mRNA transcripts is a cotranscriptional event catalyzed by the viral RdRP[608,609] and is usually limited to insertions of between zero and two nucleotides, depending on the virus. Relative abundance of the different *P* gene mRNA species often rapidly declines with the number of nucleotides inserted,[102,277] but NiV and human and bovine PIV3 are exceptions to these rules, since the different mRNA species were found to be equally abundant and transcripts with multiple G insertion were detected.[168,284]

The Phosphoprotein

The P protein is the only *P*/*V*/*C* gene product that is essential for viral RNA synthesis.[114,115] Paramyxovirus P proteins are generally 400 to 600 amino acids long and heavily phosphorylated at serine and threonine residues, predominantly within the N-terminal region. The major sites of P phosphorylation and the respective kinases have been identified for several viruses.[117,232] The P protein features a modular organization of ordered and intrinsically highly disordered domains,[40,41,257,258] consistent with the requirement for interacting with multiple partners during the viral replication cycle. While lacking inherent enzymatic activity, P is an essential component of both the viral RdRP[196] and the N^0 nascent chain assembly complex that functions to encapsidate RNA during replication.[222] Structural information has been obtained for distinct modular N- and C-terminal domains of P proteins derived from different paramyxoviruses (Fig. 12.9). These domains are instrumental for P activity as an essential polymerase cofactor, mediator of P-L complex loading onto the RNP template, and inhibitor of premature termination of the advancing polymerase complex during transcription and replication.

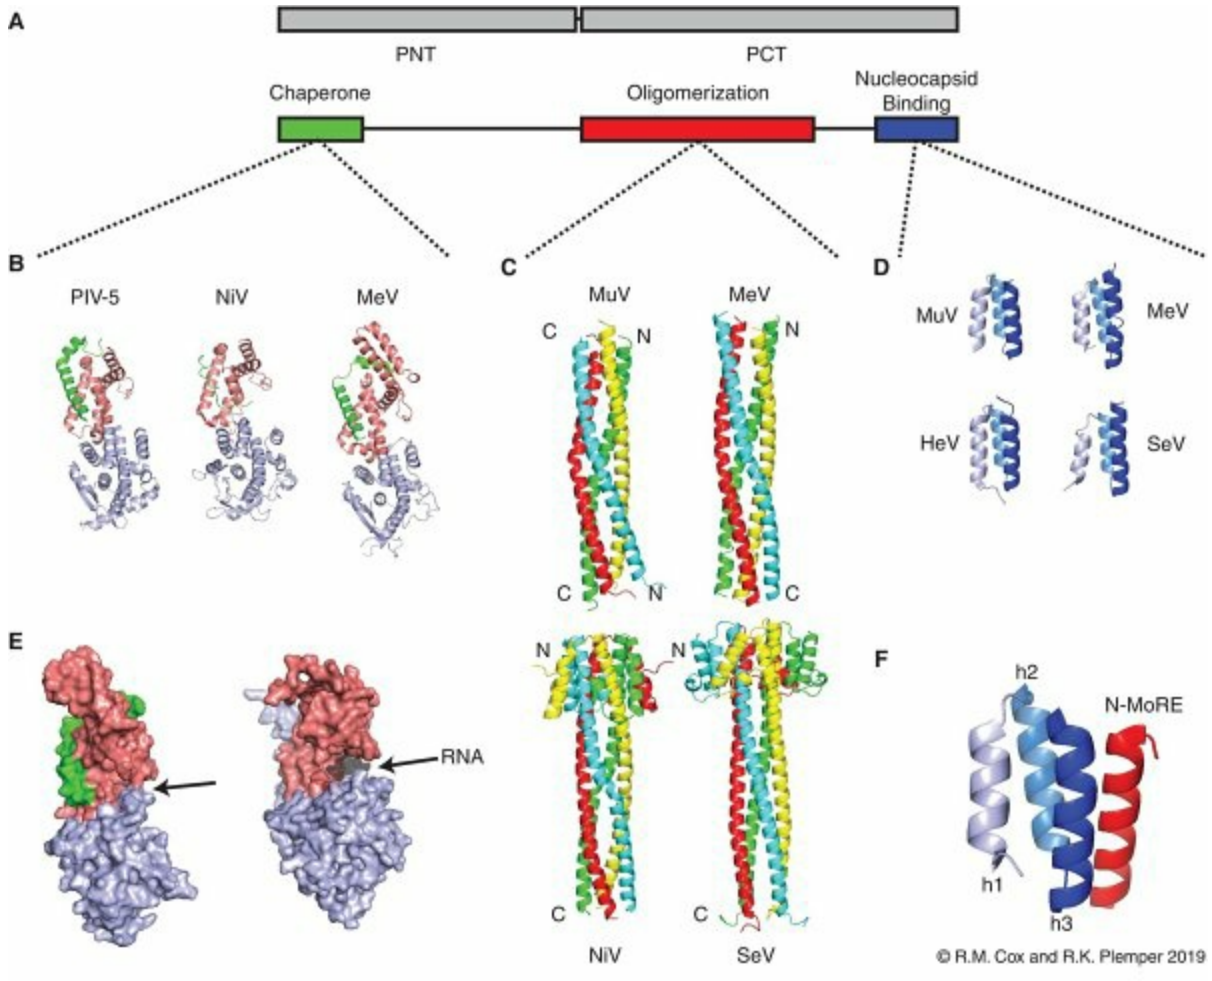

FIGURE 12.9 Structures of paramyxovirus P protein domains. **A:** Schematic of the P protein organization. P proteins are divided into an N-terminal domain (PNT) and a C-terminal domain (PCT). Known functional domains involved in chaperoning, oligomerization, and nucleocapsid binding are highlighted. **B and E:** The chaperone domain prevents premature N multimerization and RNA binding. Three crystal structures have been solved for paramyxovirus N^0–P complexes (PIV-5, PDB ID: 5WKN; NiV, 4CO6; MeV, 5E4V).[4,192,641] **C:** Crystal structures of the P oligomerization domains of MuV (PDB ID: 4EIJ), MeV (PDB ID: 4BHV), NiV (PDB ID: 4N5B), and SeV (PDB ID: 1EZJ).[54,91,101,589] P tetramers form a coiled coil of four parallel

helices, except for MuV, which emerged as a tetramer of parallel and antiparallel helices. **D:** Structures of the nucleocapsid binding X domain (XD) that have been solved for MuV (PDB ID: 3BBZ), MeV (PDB ID: 1OKS), HeV (PDB ID: 4HEO), and SeV (PDB ID: 1R4G).[29,92,252,272] XD structures are highly conserved, all featuring three-helix bundle arrangements. **F:** Crystal structure of MeV P-XD in complex with a C-terminal fragment of MeV N (PDB ID: 1T6O).[273] XD interacts directly with a molecular recognition element (MoRE) located in Box 2 of MeV Ntail. (Images copyright © 2019 by Richard K. Plemper and Robert M. Cox.)

The C-terminal half of the paramyxovirus P protein (termed PCT, residues 304–507 in the case of MeV P) is relatively well conserved in predicted secondary structure across the family. P proteins function as multimers, with an oligomerization domain (P_{OD}) located in the central region of P near the beginning of the PCT. However, P_{OD} sequences and the organization of the assembly may vary considerably between different Ps. While crystal structures of SeV, MeV, and NiV P_{OD}s have been shown to form tetrameric alpha helical coiled coils in parallel arrangements,[54,91,588] a crystal structure of MuV P_{OD} (residues 213–277) suggested a tetramer organization consisting of two parallel pairs of alpha helices, arranged in opposite orientation to each other[101] (Fig. 12.9C).

SeV PCT (residues 325–568) is sufficient for catalyzing viral RNA synthesis because this fragment alone can substitute for intact P protein in all aspects of mRNA transcription.[115] Although the L protein contains all RdRP catalytic activities, L binds to the nucleocapsid template via the P protein.[222] In addition to establishing physical contact between the RNP and L, P proteins are required as cochaperones for proper L protein folding. Transient expression of MeV L protein in the absence of the P protein resulted in low L protein steady-state levels,[225] and MeV P proteins have furthermore been suggested to recruit the host cell chaperone Hsp90 to the L protein.[32] While

the exact nature of the interface between P and L proteins is still unknown, residues located at the C-terminal end of the P_{OD} and in the following domains were consistently found to contribute to facilitating proper interactions in SeV,[45,115] MeV,[91,252] RPV,[78] and human parainfluenza viruses type 2 and 3 (HPIV-2 and HPIV-3)[85,402] P-L complexes. Located at the end of the PCT, the P-XD as discussed above establishes an interaction between P-L and the MoRE residues located in Box 2 of the Ntail.[45,115,506] Structural data obtained for MeV indicate that P-XD induces partial folding of resides in the MoRE, establishing a four-helix bundle arrangement consisting of three XD-derived helices and one formed by the MoRE residues (Fig. 12.9F).[40,197,252,326,620] These interactions with Ntail appear to be predominantly required for preventing premature termination of the polymerase complex at IG junctions,[282] and a correlation between binding strength and transcriptase reinitiation efficiency after IG regions was proposed for MeV RdRP.[31] The ability of P-XD and Ntail to form interactions between intrinsically disordered domains may be important to allow movement of the P-L complex along the RNP template,[29,40,271] although it is unclear at present how separation of P-XD from Ntail, once the induced-fit interface has been established, is initiated and coordinated. So far only for MuV P, the N-terminal PNT has been implicated in RNA de-encapsidation and the local uncoiling of the RNP in front of the approaching RdRP, indicating a direct interaction of MuV PNT with the RNP.[103]

In contrast to viral transcription, genome replication depends on the availability of unassembled N^0 (in N^0–P complexes) facilitating concomitant encapsidation of the nascent strand. The residues located at the N-terminus of the PNT (residues 33–41 for SeV[114,222] and 1–48 for MeV P[192]) have been implicated in preventing premature N aggregation and ensuring productive assembly of the RNP. The remainder of the SeV PNT appears to be dispensable for RNA synthesis and assembly, since a P protein in which residues 78 to 324 have been deleted is still active for minigenome replication in transfected cells.[114] However, phosphorylation of RPV P protein at serine residue 88 prevented the initiation of polymerization,[476] and the phosphorylation status of RPV P appears to modulate transcriptase versus replicase activity,[507] suggesting a major regulatory role of PNT in controlling RdRP activity. Consistent with this theme, the phosphorylation status of MeV

P protein residues S86 and S151 likewise alters RdRP transcriptase activity.[569]

The V Protein

The V protein is an approximately 25- to 30-kDa polypeptide that shares an N-terminal domain with the P protein but has a unique C-terminal domain as a result of RNA editing.[70,203,438,439,596,608] The C-terminal V-specific domain is highly conserved among related paramyxoviruses, with invariantly spaced histidine and cysteine residues forming a novel domain that binds two zinc molecules per V protein[167,307,317,441] (Fig. 12.10). In the case of PIV-5 and MuV, this cysteine-rich domain of V protein directs spontaneous self-assembly into spherical high molecular weight particles that can be visualized by EM.[604] Despite the high level of intracellular synthesis, paramyxovirus particles typically incorporate little V protein into virions,[441] although there can be some variation.[110,626]

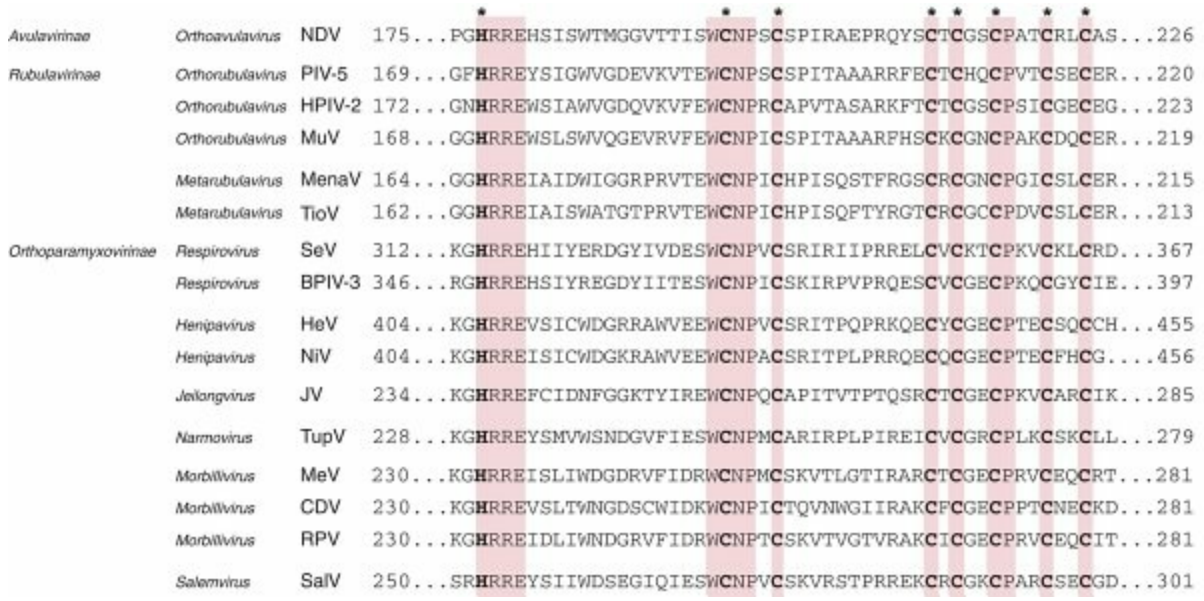

FIGURE 12.10 Amino acid sequence alignment of the conserved cysteine-rich C-terminal region of selected paramyxovirus V proteins. Numbers indicate the amino acid position within the respective proteins. Positions of the conserved histidine and seven conserved cysteine residues that are involved in coordinating Zn

are indicated by *asterisks*. Additional areas of sequence identity are shaded in *red*. New abbreviations: MenaV, Menangle virus; TioV, Tioman virus; BPIV-3, bovine parainfluenza virus 3; JV, J virus; TupV, Tupaia paramyxovirus; CDV, canine distemper virus; SalV, Salem virus.

Paramyxovirus V proteins are the primary viral countermeasure against the host innate antiviral immune response, interfering with type I interferon (IFN) expression and signaling (reviewed in Ref.[433]) and thus ultimately blocking the activation of hundreds of IFN-stimulated genes (ISGs) and the induction of an antiviral state. Accordingly, V proteins are important pathogenesis factors and play a central role in the virus replication cycle, as evidenced by a range of different recombinant paramyxoviruses that have been engineered to disrupt expression of the V protein cysteine-rich domain.[22,120,127,143,207,261,265,527,600,614,650] In many cases, these mutant viruses display an elevated RNA synthesis phenotype, but they generally grow well in many tissue culture cell lines.[121,261,527] However, severely attenuated growth *in vivo* is common, and/or the mutant viruses are cleared more rapidly than the corresponding parental forms from lungs of infected animals.[143,262,446,572,606]

Several paramyxovirus V proteins interact in the cytoplasm with the cellular damage-specific DNA-binding protein 1 (DDB1),[11,316] and a crystal structure of PIV-5 V protein complexed with DDB1 has been solved.[307] This structure reveals a bipartite organization, consisting of a core domain built around a central seven-stranded β sheet, which is in turn sandwiched between one alpha helix and two long loops (Fig. 12.11). The unique C-terminal domain forms the middle two β sheets and part of the central core, and this structure is anchored through the cys-rich zinc-binding region. Thus, despite sharing a 164–amino acid N-terminal domain, the PIV-5 P and V proteins can adopt very different structures due to the unique properties of the C-terminal cys-rich region.

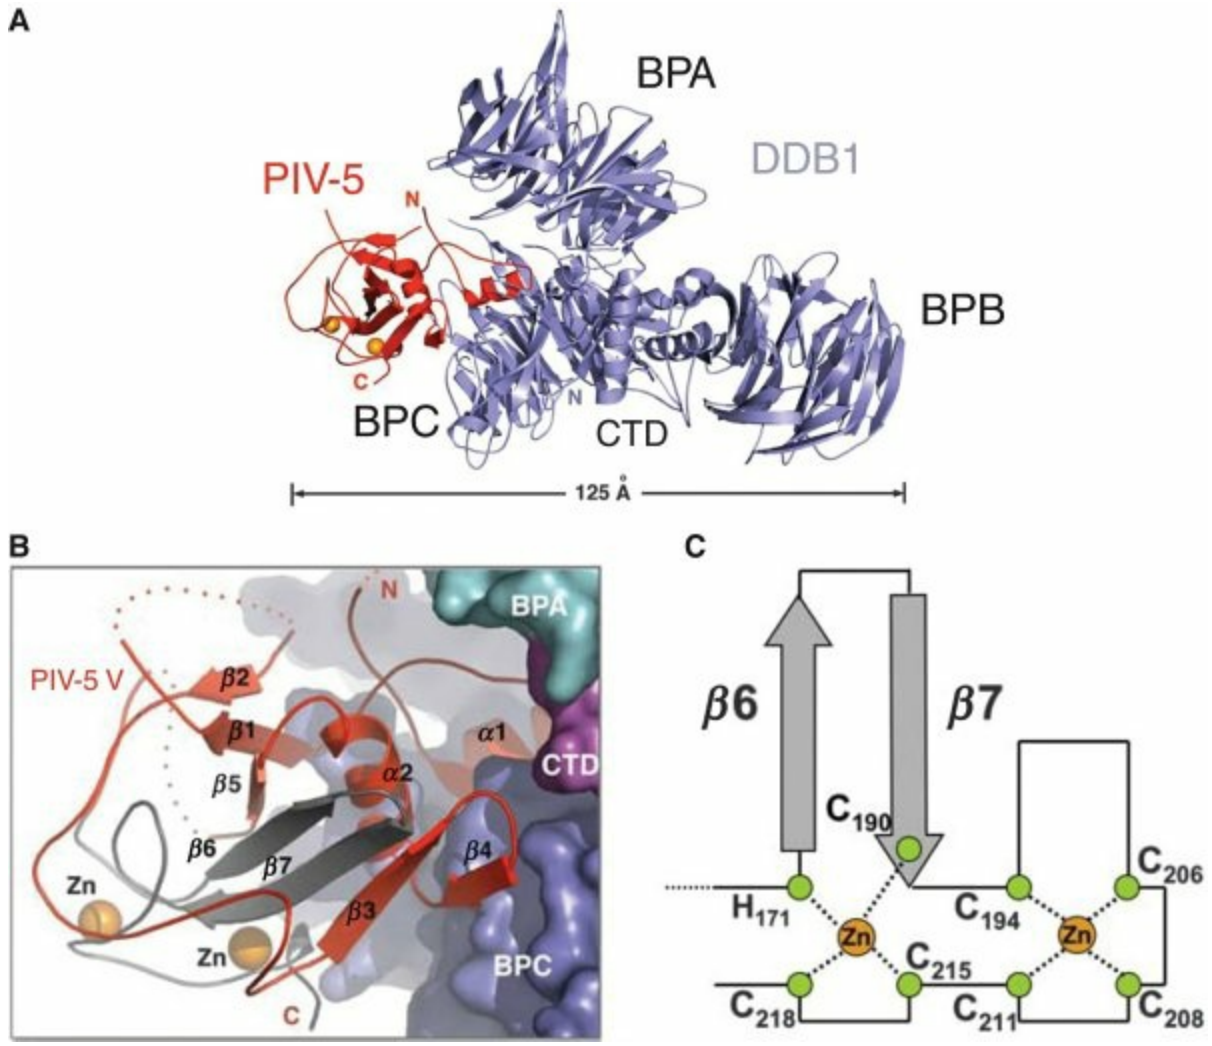

FIGURE 12.11 Atomic structure of the PIV-5 V protein in complex with DDB1. The PIV-5 V protein binds to DDB1, which adopts a four-domain structure consisting of a three-propeller cluster and a helical C-terminal domain. **A:** Overall view of the DDB1-PIV-5-V complex with DDB1 in *blue* and the V protein in *red*. The zinc ions in PIV-5-V are shown as *orange spheres*. The four DDB1 domains are labeled BPA, BPB, BPC, and CTD. The longest dimension of the complex is indicated. **B:** The PIV-5 V protein adopts a bipartite structure upon interacting with the DDB1 BPC domain. DDB1 and PIV-5-V are shown in surface and ribbon representation, respectively. The N-terminal part of the V protein, which is also found in the viral P protein, is colored *red*. The rest of

the V protein, including the zinc-binding sequence, is colored in *gray*. **C:** A novel zinc-finger fold found in the PIV-5-V protein. (Adapted from Li T, Chen X, Garbutt KC, et al. Structure of DDB1 in complex with a paramyxovirus V protein: viral hijack of a propeller cluster in ubiquitin ligase. *Cell* 2006;124(1): 105–117, with permission.)

Through distinct, genus-specific strategies, the paramyxovirus V proteins interfere with type I IFN expression and signaling, antagonizing the innate host cell antiviral response (discussed in the section Paramyxovirus Accessory Genes and their Interference with the Cellular Antiviral Response). In addition to this primary function, V proteins have been shown to regulate viral RNA synthesis in transfection experiments involving model RNA genomes,[114,226,315,645] and recombinant viruses that are engineered with V protein mutations often show increased viral RNA synthesis.[22,120,143,261,265,527,600,625] The shared N-terminal domain of P/V is responsible for the assembly of N^0–P complexes, and V proteins from PIV-5, SeV, and MeV have been found in equivalent N^0–V interactions that, however, are incapable of mediating RNA encapsidation during viral genome replication.[114,226,472,600] A model has been proposed in which V-mediated inhibition of viral RNA synthesis may be a result of V and P competition for soluble N^0.[114,226,645] The cysteine-rich C-terminal domain of MeV and PIV-5 V proteins were likewise implicated in inhibiting viral RNA synthesis.[435,636,645] While mechanistically unclear at present, it is speculated that this inhibitory effect may be mediated through interaction with a host cell factor.[645] Lastly, the V protein is also capable of binding RNA,[316] and in the case of MeV V protein, it has been proposed that this interaction may contribute to inhibiting RNA synthesis.[435]

The W/D/I Proteins

The W and D ORFs of respiroviruses, morbilliviruses, and henipaviruses are expressed from mRNAs with two inserted G residues (Fig. 12.8). Since the W ORF is typically closed by a stop codon shortly after the editing site, the W protein is essentially a truncated P protein containing the N-terminal N^0

assembly module of the P protein and a very short C-terminal extension. The W protein is abundantly expressed during infection[109,321] and, in the case of SeV, has been found to interact with unassembled N^0.[226] Accordingly, W proteins are thought to function as regulators of viral RNA synthesis. In contrast to the predominant presence of P and V in the cytoplasm, however, *Henipavirus* W proteins are transported to the nucleus through specific interaction of an NLS located in the unique C-terminus with cellular importin-α3.[15,537,553] Different subcellular localizations suggested a distinct immunomodulatory strategy for NiV W and V. Consistent with this notion, binding to NiV W is thought to trap STAT1 in the nucleus, blocking IFN signaling through the formation of nonfunctional complexes containing STAT1.

In the case of bovine and human PIV-3, the +2 ORF extends for 131 residues from the editing site, resulting in the synthesis of a unique D protein that is a chimera of the common N-terminal domain of P and this ORF downstream of the editing site.[168] *Rubulavirinae* I protein is generated when the upstream N-terminal P region is fused to a downstream ORF by the insertion of either one or four G residues during RNA editing.[438,596]

The C Proteins

In addition to RNA editing, some paramyxoviruses use a second mechanism to express *P* gene polypeptides that involves the use of alternative translation initiation codons to yield the C proteins (Fig. 12.7). The SeV C′, C, Y1, and Y2 proteins constitute a nested set of carboxy-coterminal polypeptides that range in size from 175 to 215 residues. These proteins are expressed independently from a P/V mRNA through the use of alternative start codons (Fig. 12.7), with the C protein ORF being in the +1 reading frame relative to the P ORF. Consequently, all ORFs of the C protein set terminate at the same stop codon, and the C proteins thus share a common C-terminus. The C′ and C proteins are translated by a leaky scanning mechanism, being initiated at an unconventional ACG triplet at base 81 and AUG at base 114, respectively.[112] In contrast, translation of the Y1 and Y2 proteins occurs through a scanning-independent ribosome-shunting mechanism that is directed by a 5′ noncoding RNA segment, resulting in ribosomes initiating at AUG codons at bases 183 and 201, respectively. The C protein is abundantly expressed in infected cells at levels higher than C′, Y1, and Y2, but virions contain only very low levels

of these polypeptides.[296] morbilliviruses and henipaviruses express only one C protein,[26,198,621,623] whereas respiroviruses such as SeV and HPIV-1 express all four C′, C, Y1, and Y2 polypeptides.[176] *Rubulavirinae* and *Avulavirinae* do not express C proteins (Table 12.4).

C proteins are small basic polypeptides that like the V proteins play important roles in regulating the host IFN response. They are involved in controlling viral RdRP transcription versus replication activity,[19,263,296,335,393,586] enhancing polymerase fidelity,[35,453,577] and facilitating the release of virus from infected cells.[238,431,508,568] The regulatory effect of C proteins on RNA synthesis correlates with their ability to bind to the L subunit of the viral polymerase,[223] and, in the case of SeV, naturally occurring variant C proteins can have differential effects on inhibition of virus RNA synthesis.[19]

Although nonessential for infectivity, SeV mutants engineered to express only a subset of C proteins or lacking expression of all four proteins show defects in virus growth[238,286] and in the absence of all C proteins were entirely unable to suppress the expression of ISGs.[184] Recombinant HPIV-3, SeV, NiV, and MeV with disrupted C protein expression are growth attenuated in mice, hamsters, and nonhuman primates, respectively.[127,143,170,348,650] An additional role for C proteins in the release of some paramyxovirus particles was proposed based on enhanced budding of SeV-like particles (VLPs) when SeV C was coexpressed with the viral M protein.[568] The effect was dependent on the host endosomal sorting complex required for transport (ESCRT) pathway (discussed below), possibly through interactions with the ESCRT factor Alix.[238,508] A similar ESCRT-dependent budding enhancing effect was described for NiV C, in this case through recruiting the ESCRT-I component TSG101.[431]

The Large Protein

The large (L) protein is an essential subunit of the paramyxovirus RdRP. Originally named after its high molecular weight of approximately 220 to 250 kDa, the L protein is invariably encoded as the most promoter-distal gene in the paramyxovirus genome (Fig. 12.4). L proteins are generally present in only very low amounts in infected cells or virions,[291] where they are found

on the nucleocapsid in P-L clusters.[468] L is believed to possess all the enzymatic activities needed for viral RNA synthesis, including phosphodiester bond formation, 5′-end mRNA capping and methylation, and 3′-end mRNA polyadenylation.[90,188,213,416,575] In the presence of amounts of N^0–P complexes sufficient to allow the encapsidation of nascent full-length viral RNAs, the L protein also mediates synthesis of viral genomes and antigenomes.[190,222]

Paramyxovirus L proteins are generally approximately 2,200 amino acids in length. Although the primary L protein amino acid sequences are diverse, the proteins share a similar overall organization and conserved functional motifs. Sequence alignments have identified two short hinge regions of high variability (approximately located at residues 600 and 1,700) in L proteins of SeV, NiV, and morbilliviruses such as RPV and MeV that connect three large regions[53,135,141,354] (Fig. 12.12A). Insertion of green fluorescent protein (GFP) into the downstream hinge region maintained substantial RdRP activity and allowed recovery of viable recombinant viruses encoding these L-GFP hybrid proteins, while insertion into the upstream junction abolished bioactivity.[53,141] It was unclear, however, whether the L regions before and after the downstream hinge region represent fully independent folding domains or assume a native conformation only when synthesized as a single polypeptide, since L proteins of the related rhabdovirus vesicular stomatitis virus (VSV) likewise tolerated large insertions in an interdomain region between subunits,[499] but these subunits were unable to reconstitute a functional polymerase when expressed separately.[478] By contrast, individually expressed NiV and MeV have been found able to restore bioactivity through homotypic transcomplementation when dimerization tags were fused to the fragments, indicating that paramyxovirus L proteins are composed of at least two independent folding domains.[135]

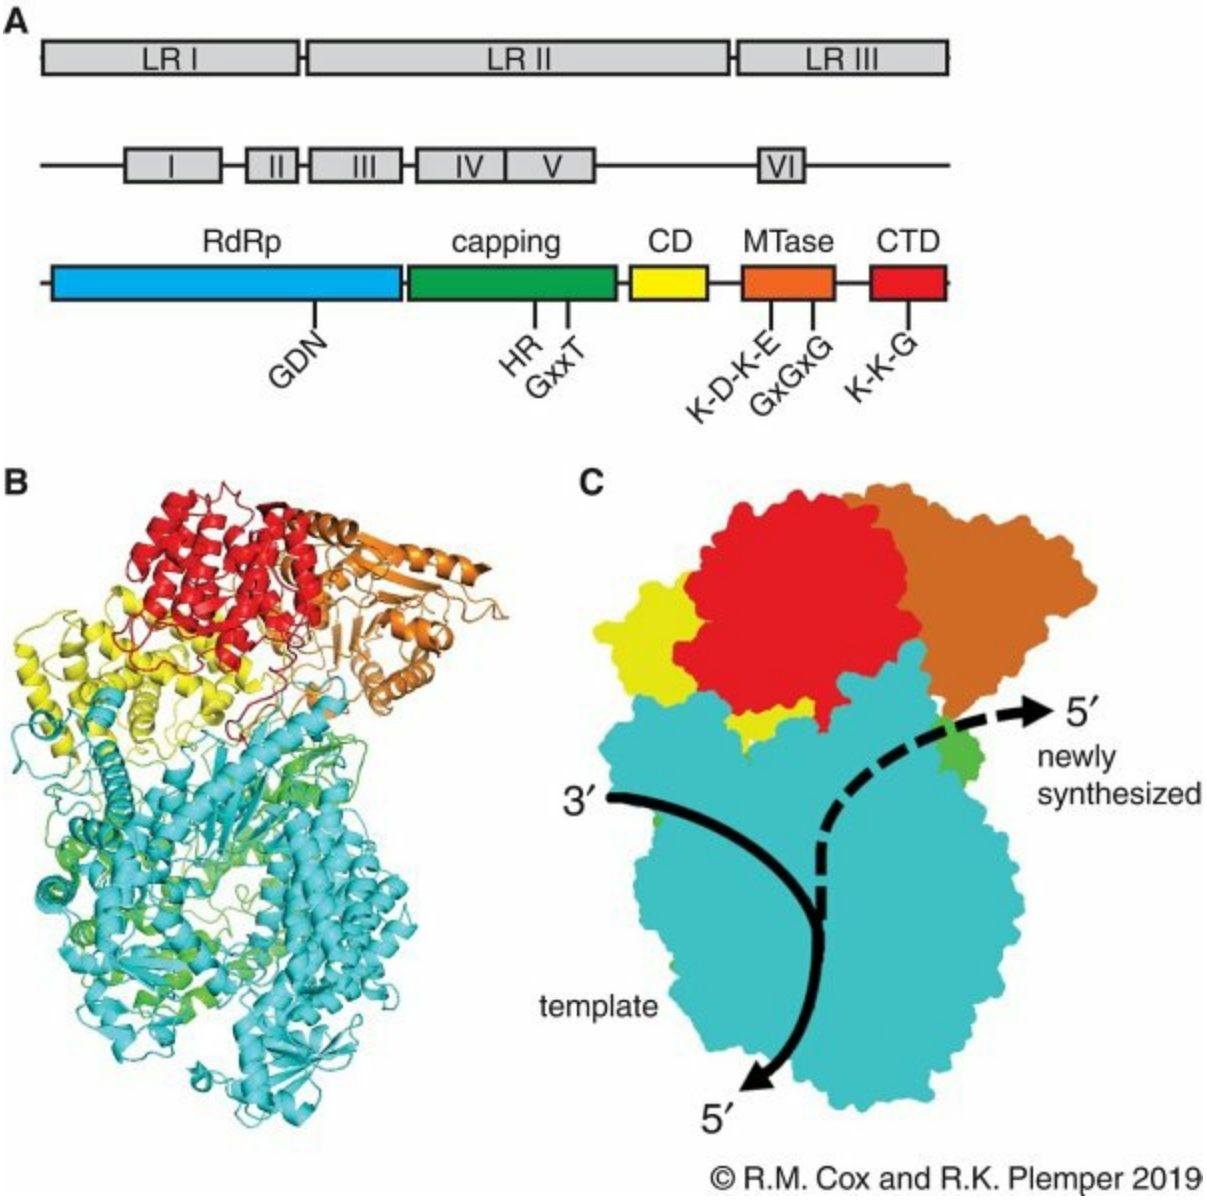

FIGURE 12.12 Structural overview of the L polymerase protein. **A:** Domain organization of the paramyxovirus L protein. **A, top:** The paramyxovirus L proteins can be divided into three large regions (LR I-III), determined by insertion analysis. LR I-II and LR III represent independent folding domains that can form a functional polymerase when expressed separately.[135] **A, middle:** Sequence alignments have revealed six conserved regions (CR I–VI) in the L polymerase proteins. **A, bottom; B:** A cryo-EM–based reconstruction of the VSV L structure shows five main structural

domains: polymerase (*cyan*), capping (*green*), connector domain (*yellow*), methyltransferase (*orange*), and C-terminal domain (*red*).[311] The locations of active site residues are shown for each domain in the cartoon. **C:** Approximate locations of the RNA template and exit channels within the VSV L protein are shown in *black*. Template RNA (*solid line*) is proposed to enter and exit the polymerase complex from the one side, while the newly synthesized strand (*dashed line*) exits on the opposite side. This position of the proposed exit channel places the 5′ end of the nascent mRNA strand in close proximity to the capping and MTase domains. (Images copyright © 2019 by Richard K. Plemper and Robert M. Cox.)

Sequence alignments have identified six conserved regions (CRs I–VI) that were originally proposed to be individually responsible for each of the distinct L functions[461,542,571] (Fig. 12.12A). Residues in regions overlapping with CR I were found to be involved in the essential L interaction with the P protein that is required for the formation of functional P-L complexes.[32,74,79,196,219,222,225,432] CRs II and III contain subdomains common to all L polymerases.[461] Based on a high net positive charge, CR II is considered to be an RNA-binding domain, whereas a GDN tripeptide motif in CR III is extremely conserved and, based on mutational analyses, thought to form part of the catalytic center for nucleotide polymerization.[78,79,246,334] In a cryo-EM structure of the VSV L protein, CRs IV and V mapped to an mRNA capping domain.[462] VSV is a member of the rhabdovirus family that like the paramyxoviruses belongs to the mononegavirales, which are thought to share a comparable overall L organization. CR VI and the L C-terminal domain are required for viral mRNA methylation.

Expression and purification of native L proteins is challenging, reflected by a current lack of high-resolution structural information of the spatial organization of any paramyxovirus L protein. However, recent negative-stain EM images of copurified NiV P-L complexes showed two particle classes, globular 5- to 8-nm particles with even density, and larger 8- to 11-nm ring-

like structures.[253] The latter class resembles previous negative-stain EM images of VSV L proteins that showed a doughnut-like architecture with a globular appendage covering the center of the doughnut and three smaller globular appendages.[478] A cryo-EM reconstruction of VSV L to near-atomic resolution mapped CRs I to III to the polymerase domain, CRs IV and V, the single appendage covering the doughnut, to the capping domain, and the smaller appendages to a connector, CR VI, and C-terminal domain, respectively[462] (Fig. 12.12B, C). A crystal structure of a C-terminal L fragment of human metapneumovirus, a member of the closely related pneumovirus family, revealed that CR VI and the C-terminal domain build a functional MTase.[422] Although small globular attachments comparable to those seen in VSV L were not detectable in the EM images of NiV L, the preserved outline of the CRs and reoccurrence of key features of the low-resolution negative-stain EM images suggest that the molecular organization of the different L proteins may be similar.

mRNA cap formation and cap methylation are crucial processes to form stable mRNA, and viruses have adapted different strategies to form those structures.[119] In mammalian cells, RNA triphosphatase (RTPase) activity first removes the 5′ phosphate of pre-mRNA. Guanylyltransferase (GTase) then transfers a guanylyl monophosphate (GMP) from a guanosine 5′ triphosphate (GTP) molecule on the pre-mRNA, followed by successive methylation of a new cap through guanine-N7-methyltransferase (GN7-MTase) (cap 0 structure) on the cap and 2′O methyltransferase (2′O MTase) (cap-1 structure) activity on the first nucleotide. GN7-MTase activity for cap methylation was attributed to a C-terminal L protein fragment (residues 717–2,183), and sequence alignments revealed K-D-K-E and GxGxG motifs characteristic for 2′O MTases.[161,181,310,416,461,473]

Among mononegaviruses, cap formation strategies are most extensively characterized for rhabdoviruses, which follow an unconventional pathway[411,413,415]: (a) GTP is hydrolyzed to guanosine 5′ diphosphate (GDP) through a nucleotide triphosphatase (NTPase) activity,[411,412] and (b) the nascent 5′ triphosphorylated RNA strand (pppA-RNA) is covalently ligated as a 5′ monophosphate RNA (p-A-RNA) and transferred to GDP to form the capped Gppp-N-RNA through a polyribonucleotidyltransferase [PRNTase] activity.[411,413] The cap is methylated successively at the 2′-O-position of the first nucleotide (Gppp-Am-RNA) and at the cap N^7 position (m^7Gppp-Am-

RNA).[477] Interestingly, PRNTase motifs are conserved across the mononegaviruses suggesting that all viruses in this order could implement an unconventional capping mechanism.[397] Support for this notion comes from the finding that mutation of critical residues in the HR motif of the PRNTase resulted in the loss of the capping activities in HPIV-2[397] and pneumoviruses (RSV[47]). Use of GDP instead of GMP to form the cap structure and NTPase activity has also been described for pneumoviruses.[20,422]

Despite conservation of PRNTase motifs, however, the paramyxovirus mRNA cap formation mechanism is not yet fully understood mechanistically, and PRNTase activity has so far only been confirmed for rhabdovirus L proteins.[411,413,415] Surprisingly, also a C-terminal "K-K-G motif" located downstream of CR VI is well conserved among para-, filo-, and pneumovirus L proteins. This motif appears reminiscent of eukaryotic cell–style GTase activity[397] and is absent from rhabdovirus L proteins but has been shown to be essential for HPIV2 mRNA synthesis.[397] Also, GTase[180] and RTPase[13,546,547] activities have been proposed for RPV L proteins, but a direct structural comparison of the C-terminal domains of HMPV and VSV L reveals that the structural organization of the K-K-G motif in HMPV is distinct from that in eukaryotic GTases, arguing against guanylyltransferase activity as a universal mechanism for paramyxovirus cap formation.

L protein activity in RNA synthesis is highly dependent on protein–protein interactions. Based on biochemical evidence and genetic complementation studies with Sendai and MeV L proteins, the possibility of L-L self-assembly through an N-terminal domain was raised.[74,550,552] The resolution of the NiV L protein EM data is not high enough to extract quaternary structure information, but potential spatial organization and physiological relevance of L-L assembly are not immediately evident from the high-resolution VSV L structure. In contrast, L protein interaction with P is essential for proper folding, and interaction sites were consistently mapped to N-terminal domains of different paramyxovirus L proteins.[74,219,432] A physical interaction of RPV and SeV L proteins with the viral C protein was furthermore demonstrated, in the case of SeV involving the polymerase domain (CRs I–III[223,573]). Paramyxoviruses spontaneously produce some amount of dsRNAs during replication. Infection of cells with engineered SeV, HPIV-1, and MeV lacking functional C proteins, however, resulted in

greatly elevated dsRNA levels, which is consistent with C reducing the formation of defective interfering (DI) genomes by enhancing polymerase fidelity. Other proteins encoded in the SeV *P*/*V*/*C* gene (C′, Y1, and Y2) also interact with L and inhibit defective interfering (DI)-RNA synthesis *in vitro*[189] and *in vivo*.[263]

In addition to interaction with viral proteins, an association of paramyxovirus L proteins with host cell proteins has been proposed. In the case of MeV and SeV, L interactions with tubulin are believed to promote L activity.[378,379] Other cellular proteins have also been suggested to promote viral RNA synthesis (e.g., *β*-catenin for HPIV-3[36]), but the precise role that these proteins play in RdRP function has not been determined.

The Matrix Protein

The paramyxovirus matrix (M) protein is the most abundant protein in the virion. The M proteins contain 341 to 375 residues (Mr ~38,500–41,500), are quite basic in nature (net charge at neutral pH of +14 to +17), and are somewhat hydrophobic. Three major roles have been proposed for the M proteins in the paramyxovirus replication cycle: organization of virions assembly, promotion of particle budding, and sequestering of inhibitory host proteins from the cytoplasm.

Early fractionation studies of infected cells and virions indicated that the M proteins can peripherally associate with membranes, but they are not integral membrane proteins.[155,289,390,513] A temperature-sensitive SeV first suggested a link between changes in M and virus budding efficiency.[651] Purified SeV M proteins have furthermore been shown to self-associate and form two-dimensional paracrystalline arrays (sheets and tubes) in low-salt conditions,[16,211] and M proteins of several paramyxoviruses including SeV and the henipaviruses expressed in isolation are sufficient to drive virus-like particle (VLP) formation.[436,581]

At present, high-resolution structures have only been solved for the NDV and HeV M proteins,[23,318] but the overall organization of M proteins from different mononegavirales is considered to be well conserved.[295] The NDV M crystal structure (Fig. 12.13A–D) showed the protein in a homodimer assembly.[23] Each monomer features two *β*-sheet sandwiches with approximately orthogonal orientation of the opposing *β* strands, which are

connected by a 16-residue linker and surrounded by several short α-helices. A high density of positive charge of the nearly square-shaped face of the dimer oriented toward the membrane supports membrane association of M proteins through electrostatic interactions. Cryo-ET reconstructions of purified NDV particles showed a grid-like arrangement of the matrix layer with approximately square-shaped appearance of the repeating protein units, into which the dimer assembly could be fitted.[23] Electrostatic interactions and hydrogen bonding between pairs of two α-helices in each dimer are proposed to mediate dimer-to-dimer contacts, introducing an approximately 20-degree angle between the symmetry axes of neighboring dimers that results in an overall curvature of the assembled matrix array similar to the membrane curvature in a budding virus (Fig. 12.13E, F).

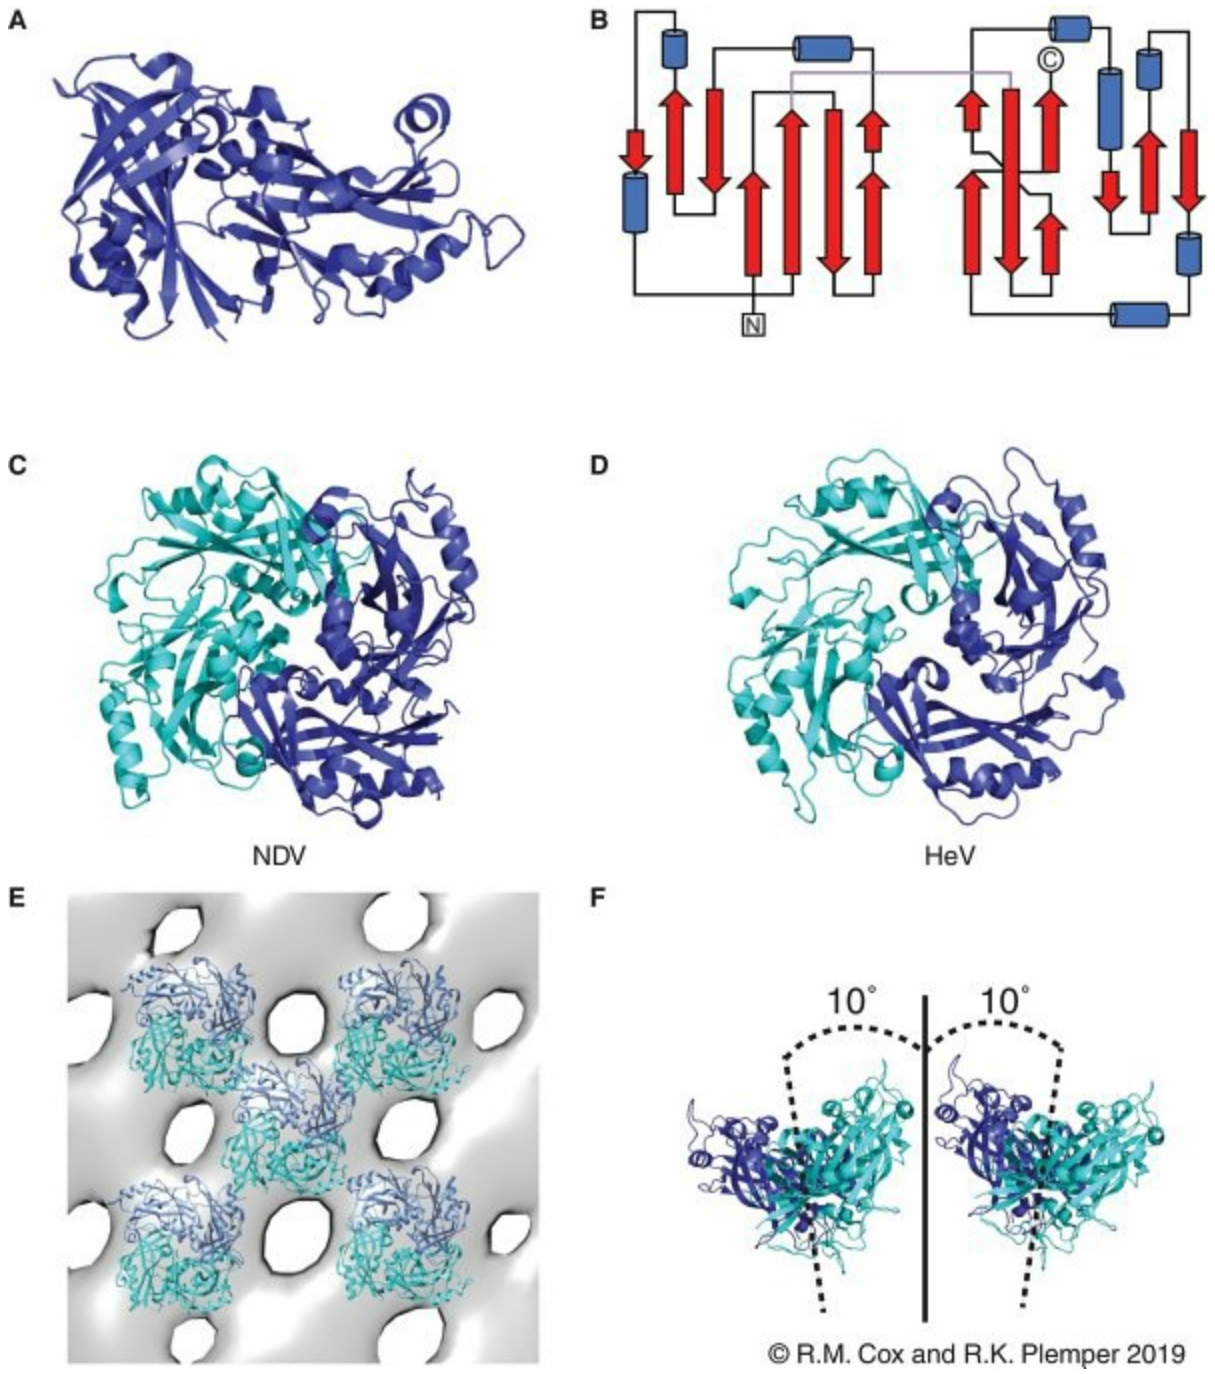

FIGURE 12.13 Structure of the paramyxovirus matrix protein. **A:** Ribbon drawing of the monomeric NDV M crystal structure (PDB ID: 4G1G).[23] **B:** Schematic of the secondary structure of the NDV M monomer. Each NDV M monomer is composed of two *β*-sandwich domains (*red*) that are lined by several *α*-helices (*cyan*). **C and D:** Structures of the NDV and HeV (PDB ID: 6BK6) matrix

proteins,[23,318] showing similar features and folds. **E:** The M protein forms 2D paracrystalline arrays in cells. A subtomographic average of the NDV M protein is shown with the crystal structure docked into place. **F:** Crystal contacts in matrix dimers are similar to those made between adjacent dimers in the virus. The M dimer in the crystal structure forms contacts with adjacent dimers with a 20-degree angle between dimers. Similar contacts are made between adjacent M dimers in NDV virions, but with a smaller 6-degree angle between dimers. This arrangement is thought to allow the M protein to induce membrane curvature to facilitate budding of virions from infected cells. (Images copyright © 2019 by Richard K. Plemper and Robert M. Cox.)

Discussed in detail in the *Virus Particle Formation* section, biochemical data and the reconstruction of cryopreserved paramyxovirus particles have indicated specific interactions between the M protein layer and the cytoplasmic tails of the envelope glycoproteins that are instrumental for efficient particle assembly.[69,266,513,514,521,574] In addition to contacts with the glycoproteins, M specifically associates with the viral RNP, creating a bridge between viral envelope and genome. For instance, SeV M has been shown to associate with nucleocapsids[567]; MuV M, fusion, and N proteins together promote efficient VLP production[309]; and a specific interaction between MeV M and the C-terminal, third conserved element in Ntail was demonstrated in yeast two-hybrid studies and biochemically.[245]

While M lattice-mediated induction of membrane curvature emerged as an important step of the paramyxovirus budding process, several paramyxovirus M proteins appear to engage the actin cytoskeleton,[33,156,177,560] possibly for efficient membrane targeting. Likely, M proteins recruit the cellular vesicle budding machinery for fission of the viral envelope and cellular membranes, although paramyxovirus M proteins lack canonical “late domains” that mediate interaction with components of the host cell ESCRT machinery. Budding of PIV-5, NDV, MuV, and NiV has been shown to depend on vacuolar protein sorting–associated protein 4

(VPS4) ATPase activity.[140,309,431,523] Together with ESCRT-III proteins, VPS4 catalyzes membrane fission. A noncanonical late domain, however, has been suggested for PIV-5, NDV, and MuV protein,[140,309,522,523] while the nonstructural C proteins of SeV and NiV have been implicated in recruiting ESCRT components Alix and TSG101, respectively.[238,431]

Suggesting a possible role of the paramyxovirus M protein distinct from its function in virion assembly and budding, transient nuclear localization of SeV, NDV, and NiV M has been described.[448,622,651] Best characterized for Nipah M, nuclear import was shown to be dependent on the integrity of a putative bipartite nuclear localization signal (NLS) in M that was conserved in SeV and MuV also.[451,622] Following nuclear import, both NDV and NiV M proteins associate with the nucleolar compartment.[139,451] A lysine residue in the NiV M NLS that was found to be subject to monoubiquitination is proposed to regulate subcellular localization of the protein. When ubiquitinated, a likewise conserved nuclear export sequence located in one of the *α*-helix pairs forming the M dimer–dimer interface redirects M to the cytoplasm.[451,622] While the functional importance of transient M localization to the nucleolus is not yet understood, a recent study proposed that *Henipavirus* M specifically targets Treacle protein–enriched regions of the nucleolus, potentially modulating the host DNA damage response–Treacle pathway to optimize the cellular environment for efficient virus replication.[484]

Envelope Glycoproteins

All *Paramyxoviridae* possess two integral membrane proteins, some *Rubulavirinae* encode a third integral membrane protein, and members of *Jeilongvirus* genus feature two additional membrane proteins. One major glycoprotein (HN, H, or G) is involved in cell attachment and the other major glycoprotein (F) in mediating pH-independent fusion of the viral envelope with the plasma membrane of the host cell (Fig. 12.14). The *Rubulavirinae* third integral membrane protein is called SH, and for PIV-5, this 44–amino acid integral membrane protein is believed to block virus-induced apoptosis. *Jeilongvirus* (i.e., J virus, Tioman virus, and Beilong virus) encode a fourth integral membrane protein between SH and G, designated TM.[247] The assignment of specific biological activities of F and HN was originally made

on the basis of purification and reconstitution studies, mainly for SeV and PIV-5 proteins.[517,518] The attachment proteins (HN, H, or G) are all type II integral membrane proteins, and bioinformatics and structural predictions indicate the proteins all exhibit a related propellerlike fold despite having different receptors and the presence or absence of NA activity.

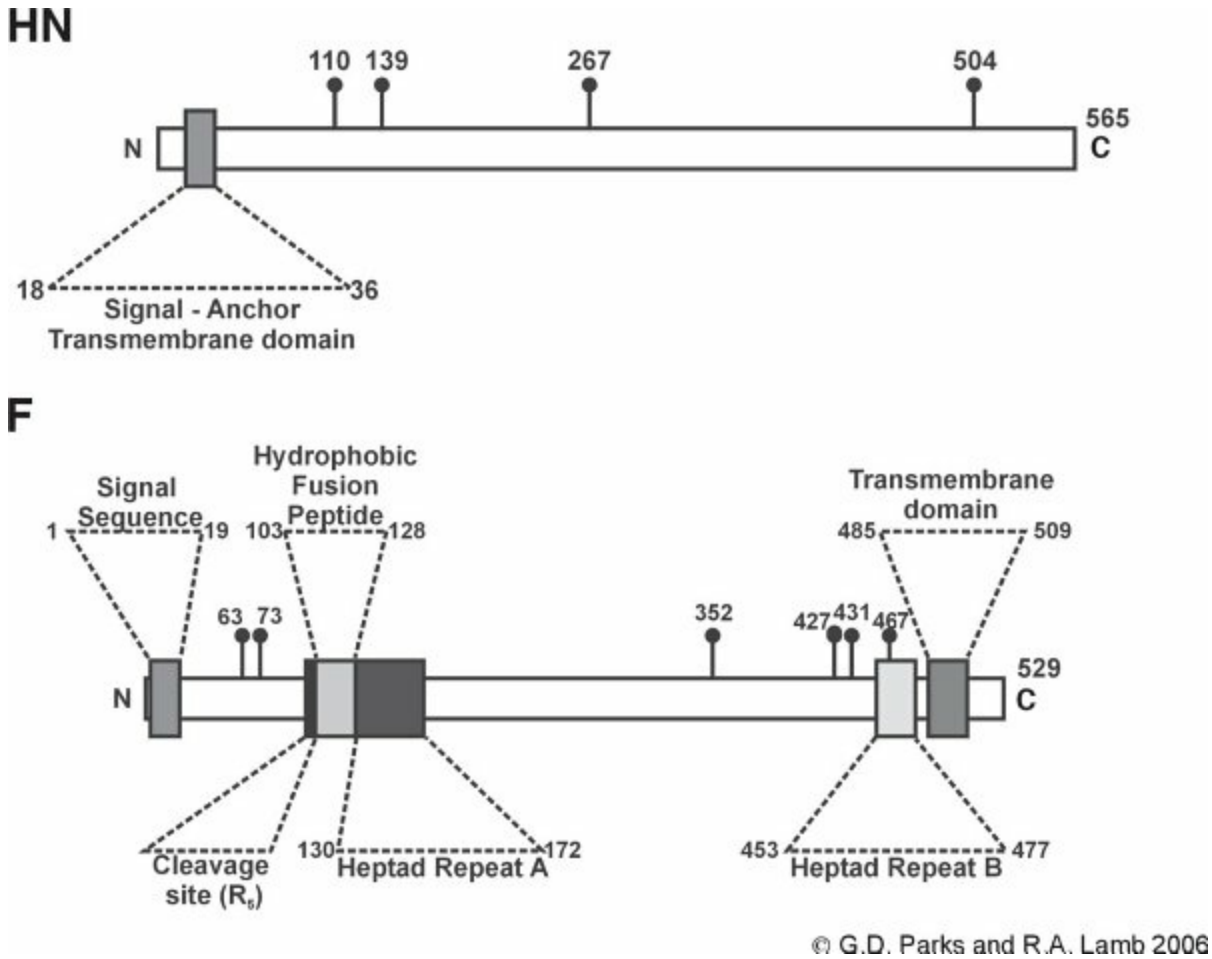

FIGURE 12.14 Schematic diagram showing the orientation and domains of paramyxovirus integral membrane proteins. **Top:** Hemagglutinin-neuraminidase attachment protein (based on the predicted sequence of the PIV-5 HN gene).[214] The signal anchor transmembrane domain and the sites used for addition of N-linked carbohydrate (lollipops)[399] are indicated. **Bottom:** Fusion protein (based on the predicted sequence of the PIV-5 F gene). The

position of the signal sequence, the transmembrane domain, the cleavage site, the hydrophobic fusion peptide, and the heptad repeats A and B are indicated. The sites used for addition of N-linked carbohydrate (lollipops)[17] are indicated. R_5 indicates the five arginine residues site for cleavage activation. (Images copyright © 2006 by G.D. Parks and R.A. Lamb.)

For the respiroviruses and *Rubulavirinae,* the attachment glycoprotein binds to cellular sialic acid–containing receptors, which can be glycoproteins or glycolipids. The binding is probably of fairly low affinity but of sufficiently high avidity that these viruses agglutinate erythrocytes (hemagglutination). The attachment proteins of respiroviruses and *Rubulavirinae* also have NA (receptor-destroying) activity, and the proteins have been designated HN. However, a possible role of a specific protein–protein involvement in infection of host cells has not been ruled out.

The *Morbillivirus* attachment protein (H) can cause agglutination of primate erythrocytes but lacks detectable NA or esterase activity. The restricted host range of MeV for primate cells made it unlikely that sialic acid was the primary receptor for MeV. In 1993, human CD46 was identified as a cellular receptor for Edmonston and Halle strains of MeV.[137,395] Edmonston and Vero cell–adapted strains of MeV are capable of infecting any $CD46^+$ primate cell. However, viruses isolated from B-cell and T-cell lines do not grow in $CD46^+$ cells. To identify the receptor in B cells, a VSV recombinant virus was used that expressed GFP as a marker of infection and MeV H (from a virus isolate propagated on B cells) in place of VSV G. Nonsusceptible 293T cells were transfected with a cDNA library from B95a cells (marmoset B cells) and then infected with VSV-GFP-H. From cells expressing GFP, a cDNA was identified that supported MeV replication in 293T cells. This cDNA encoded the equivalent of human CD150 (also known as signaling lymphocyte activation molecule [SLAM]), a membrane glycoprotein involved in lymphocyte activation.[591,644] All MeV isolates can productively interact with hSLAM, and its predominant expression on activated lymphocytes, dendritic cells, and macrophages is consistent with the strong lymphotropism of the virus.[418] SLAM-dependent infection therefore outlined

a path toward the observed initial virus replication in mediastinal lymph nodes followed by PBMC-associated viremia. However, SLAM tissue distribution was incompatible with basolateral MeV re-entry into the respiratory tract and subsequent dissemination, since the receptor is not expressed on respiratory epithelial cells. The mystery was solved by identifying the adherence junction protein nectin-4 as the missing epithelial cell receptor based on microarray profiling of epithelial cells differentially permissive for CD46 and hSLAM-independent MeV infection.[408] A subsequent report confirmed MeV infection of epithelial cells through nectin-4.[380]

In addition to the morbilliviruses, members of the *Henipavirus* genus also gain cell entry through proteinaceous receptors. Ephrin B2 has been identified as a cognate receptor for both HeV and NiV G glycoprotein. In one approach, direct binding of Nipah G to receptor was obtained, and the identity of the receptor was determined by protein sequencing and bioinformatics.[396] In another approach, microarray analysis was used to identify mRNAs that were expressed in *Henipavirus*-susceptible cells and not in cells refractory to *Henipavirus* infection.[34] Ephrin B2 is a member of a family of cell surface glycoprotein ligands that bind to ephrin (Eph) receptors, a large family of tyrosine kinases. The identification of ephrin B2 as the cellular receptor for both HeV and NiV and the widespread occurrence of ephrin B2 in vertebrates, particularly in arterial endothelial cells and in neurons, provides an explanation for the wide host range of the zoonotic henipaviruses and their ability to cause systemic infections.[147]

Paramyxovirus Attachment Protein Organization

The paramyxovirus attachment glycoproteins are both multifunctional proteins and the major antigenic determinant for the humoral immune response. They are responsible for the adsorption of the virus to target cells, either through contact with sialic acid–containing cell surface molecules (*Respirovirus* and *Rubulavirinae* HN) or specific interaction with proteinaceous receptors (*Morbillivirus* H and *Henipavirus* G). Independent of the chemical nature of the host cell receptor, subsequent to particle binding, the attachment proteins trigger fusion between viral envelope and target cell membranes, mediated through the F glycoprotein (see below). In addition, HN proteins mediate enzymatic cleavage of sialic acid (NA activity) from the

surface of virions and the surface of infected cells. By analogy with the role of influenza virus NA, it seems likely that the role of this NA activity is to prevent self-aggregation of viral particles during budding at the plasma membrane. These dual activities of HN can be modulated by halide ion concentration and pH.[361] Whereas chemical properties of the extracellular environment are optimal for hemagglutination activity, paramyxovirus NAs have acidic pH optima (pH 4.8–5.5), suggesting that NA acts in the acidic trans-Golgi network to remove sialic acid from the HN carbohydrate chains and from the F protein carbohydrate chains.

The attachment protein polypeptide chain ranges from 420 (NiV) to an exceptional 1,052 residues (Tailam virus) but, in most cases, is approximately 600 residues in length. HN proteins of some NDV strains are synthesized as biologically inactive precursors (HN_0) that are activated through proteolytic removal of 90 residues from the C-terminus.[388,389,654] All paramyxovirus attachment proteins are type II integral membrane proteins that span the membrane once and contain an N-terminal cytoplasmic tail, a single N-terminal transmembrane (TM) domain, a membrane-proximal stalk domain, and a large C-terminal globular head domain.[214] The globular head domain harbors the receptor binding and, in the case of HN proteins, enzymatic activity.[434,517,597] The protein is glycosylated and contains from four to six potential sites for the addition of N-linked carbohydrate chains. For PIV-5 and NDV HN and for MeV H, four sites are used.[229,351,400] The attachment proteins are noncovalently associated to form a tetramer, based on biochemical, cross-linking, EM, and structural studies, which, depending on the paramyxovirus, can be composed of two disulfide-linked dimers.[50,106,297,330,352,399,400,457,598,656] The covalent linkage occurs through cysteine residues at the C-terminal end of the stalk domain, adjacent to the beginning of the head domain. The stalk domain is instrumental in tetramerization,[51,656] while the head domains expressed in isolation remain monomeric.[106,297,656]

The structure of the enzymatically active head domain of the attachment protein has been predicted to be similar to that of other NAs or sialidases, such as influenza NA,[152] with the globular head composed of identical subunits arranged with fourfold symmetry. Each NA domain was expected to exhibit the six-blade propeller fold typical of neuraminidase/sialidase

structures from viral, protozoan, or bacterial origin.[58,59,294,592] The predicted structure of the attachment protein head domain was confirmed by the x-ray structures of soluble NDV, HPIV-3, and PIV-5 HN,[106,297,656,658] soluble MeV H,[202,515,660] and soluble NiV G[44,640] globular regions, and it shows the typical sialidase fold consisting of six antiparallel β strands organized as a super barrel with a centrally located active site (Fig. 12.15). The sialidase fold was conserved even in MeV and NiV attachment proteins that bind to proteinaceous receptors and have accumulated mutations eliminating NA catalytic activity. For PIV-5, the HN structure was determined with a bound uncleaved receptor sialyllactose[656] (Fig. 12.16). The seven highly conserved active site residues found in NA and sialidases are found in the paramyxovirus HN structures. Superimposition of the NDV, HPIV-3, and PIV-5 HN monomer structures indicated a high degree of conservation on one face of the molecule with the other face containing more variability and additional protein loops.[656]

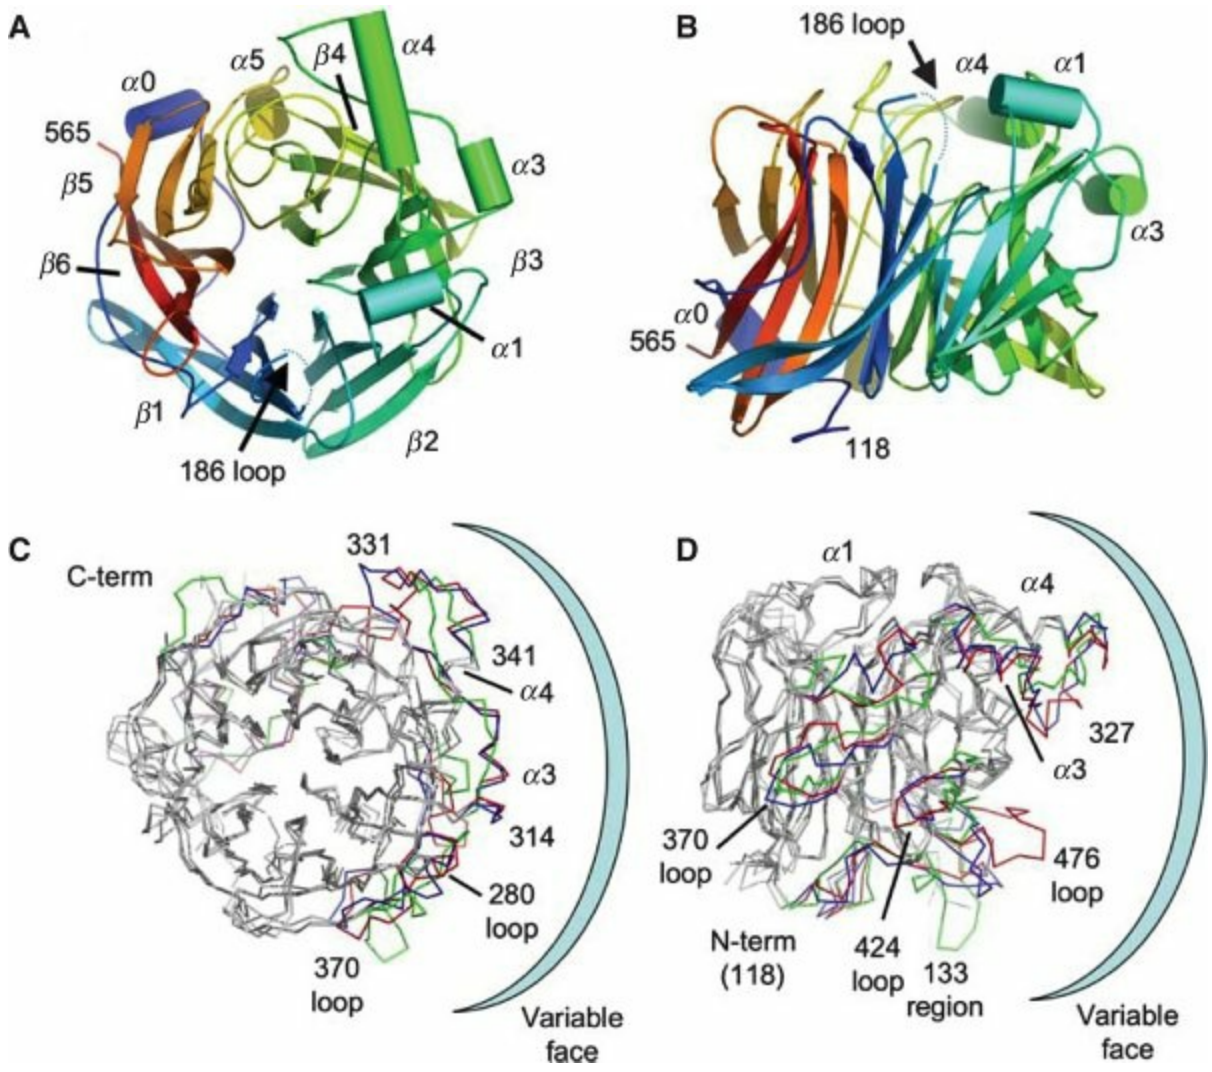

FIGURE 12.15 PIV-5 HN monomer structure and comparison with NDV HN and HPIV-3 HN. **A and B:** Schematic cartoon diagrams showing top and side views of PIV-5 HN. Helices are shown in *cylinders*, and *β* strands are shown in *arrowed belts*. The N-terminus is shown in *blue*, and the C-terminus is shown in *red*. The missing loop from residues 186 to 190 is indicated as a *dashed blue line*. **C and D:** Ribbon diagram of the superposition of PIV-5 HN with NDV and HPIV-3 HN, shown in top and side views. Major differences in the PIV-5, NDV, and HPIV HN structures are colored *red*, *blue*, and *green*, respectively. Areas of major structural differences are labeled, and the highly variable face of the HN monomer is highlighted. (Adapted from Yuan P, Thompson T,

HN tetramer arrangement. **B:** Side view of the PIV-5 HN tetramer arrangement, with a 60-degree packing angle between dimers. (Adapted from Yuan P, Thompson T, Wurzburg BA, et al. Structural studies of the parainfluenza virus 5 hemagglutinin-neuraminidase tetramer in complex with its receptor, sialyllactose. *Structure* 2005;13: 803–815, with permission.)

It has long been debated whether the hemagglutinin and NA activities of the HN-type attachment proteins involve one or two separate sialic acid–binding sites.[106,469,598,658] The disparate theories of one site with dual function or of two distinct sites that are intimately related are both consistent with the observation that sialic acid–derived NA inhibitors interfere with receptor binding.[235,384,518] A single site can provide both hemagglutinin and NA activities by binding sialic acid tightly and hydrolyzing the molecules slowly.[518] For NDV HN, two sialic acid sites have been observed in the x-ray structures: one is the active site and the second site is located at the dimer interface.[658] Strong biological evidence supports the notion of a second sialic acid–binding site in NDV.[43,465] Mutagenesis of a key residue involved in the dimer interface sialic acid–binding site abolishes sialic acid binding to the second site.[43] However, virus containing this key residue mutation is only marginally affected in growth properties.[43] For HPIV-3 and PIV-5 HN, not only was a second sialic acid molecule not observed, but the PIV-5 HN molecule is also unable to form the second sialic acid–binding site between two monomers due to changes in sequence and conformation.[297,656] Thus, the biological importance of the second sialic acid–binding site in NDV HN is unclear.

From the structural studies of NDV HN, it was also suggested that the NA domain could form two distinct dimeric assemblies that were ligand dependent.[106] One of the dimers, observed after cocrystallization with ligand, formed an extensive buried interface, while the second dimer, crystallized in the absence of ligand and at low pH, formed a much smaller interface. Conformational changes were observed in the paramyxovirus attachment protein upon ligand binding, but the dimer of HN that is observed in the HPIV-3 and PIV-5 structures occurs in the absence of ligand binding, and

there is no crystallographic or biochemical evidence that ligand binding influences the oligomeric status of the attachment protein tetramer itself.[52,297,319,656]

The attachment protein tetrameric arrangement[656,658] is unusual because, rather than having fourfold rotational symmetry as might be anticipated, it is arranged with two twofold symmetry axes that are orientated at 60 degrees to each other and in the crystal lattice, allowing neighboring dimers and tetramers to associate in infinitely long oligomers. The calculated buried surface area for each monomer in the PIV-5 HN dimer is 1,818 Å.[595] In contrast to the dimer interaction, the dimer-of-dimers interface is much smaller, involving only 10 residues and burying only 657 Å.[595] The small surface of interaction suggests that the arrangement is not very strong and that the head domain dimers may dissociate.

Upon being transported to the cell surface, the PIV-5 HN protein is rapidly internalized by the clathrin-mediated endocytosis pathway.[305] The signal for internalization is unusual because it is not located in the cytoplasmic tail but rather at the boundary of the TM domain and the ectodomain.[306] The reason for the internalization of PIV-5 HN, a process seemingly in conflict with virus assembly, is not known.

Paramyxovirus Fusion Protein Organization

The paramyxovirus fusion (F) proteins mediate viral penetration by fusion between the viral envelope and the host cell membranes at neutral pH. The consequence of the fusion reaction is that the nucleocapsid is delivered to the cytoplasm. Later in infection, coexpression of the F proteins and the homotypic attachment proteins at the plasma membrane of infected cells can mediate fusion of the infected cell with uninfected neighboring cells to form multinucleated giant cells (syncytia), the hallmark cytopathic effect associated with paramyxovirus infection in cell culture that can lead to tissue necrosis *in vivo* and might be a mechanism of virus spread.

The F proteins are type I integral membrane proteins with a single TM domain and short C-terminal cytosolic tails. The physiological oligomer is a noncovalently associated homotrimer.[80,201,505,637,647,648] First synthesized as inactive precursor proteins (F0), F proteins must be cleaved by a host cell protease at a specific cleavage activation site located in the ectodomain to be

biologically active. This proteolytic maturation step generates a larger, membrane-integral F1 subunit and shorter F2 ectodomain subunit that remains connected to F1 through an intra–monomeric disulfide link.[221,519] A short hydrophobic membrane attack domain, the fusion peptide, is located at the newly liberated N-terminus of the F1 subunit. The paramyxovirus F genes encode 540 to 580 residues. The F0 protein carries at the N-terminus a cleavable signal sequence that targets the nascent polypeptide chain to the membrane of the endoplasmic reticulum (ER) for cotranslational ER import. Located near the C-termini, a hydrophobic stop-transfer TM domain anchors the protein in the membrane leaving a short cytoplasmic tail of approximately 20 to 40 residues. Sequences adjacent to the fusion peptide and the TM anchor domain typically reveal a 4–3 (heptad) pattern of hydrophobic repeats and are designated HRA and HRB, respectively. Approximately 250 residues separate the HRA and HRB domains (Fig. 12.17A).

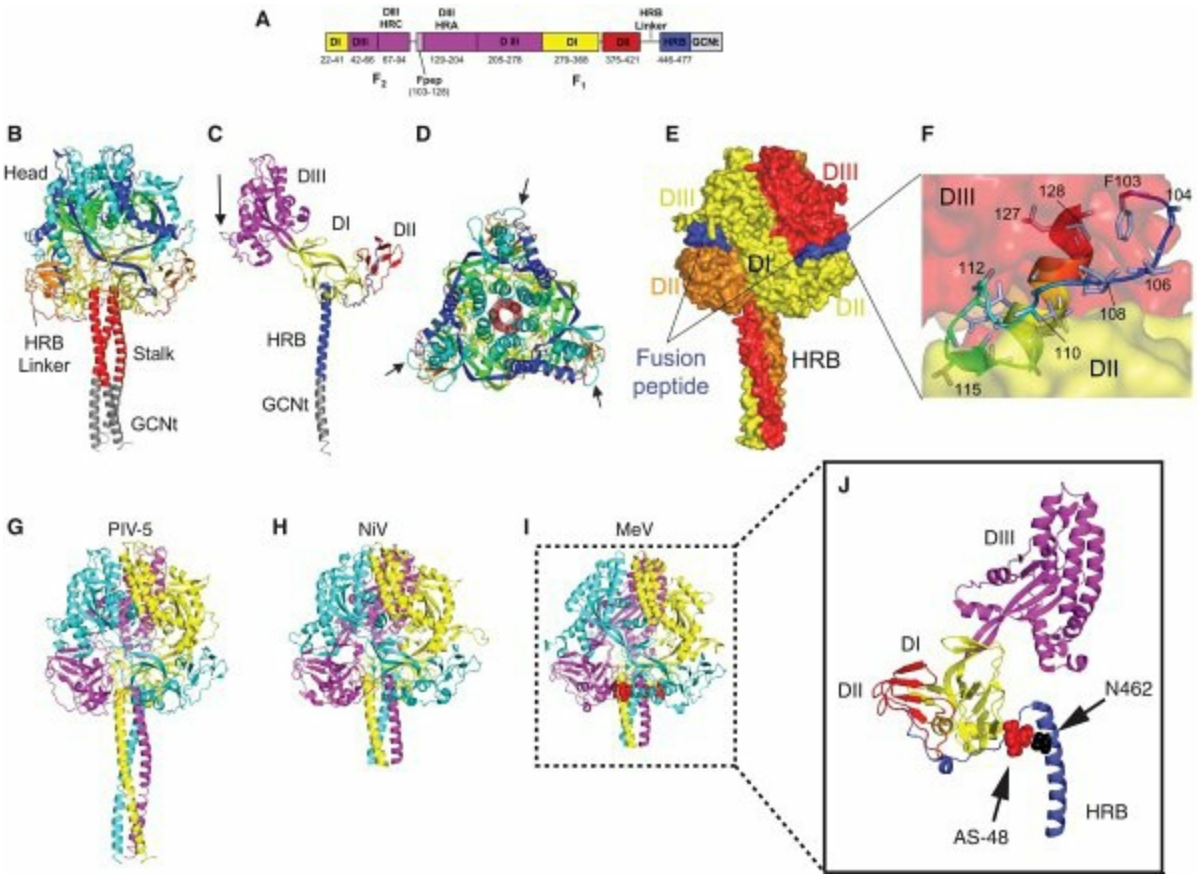

FIGURE 12.17 The F protein prefusion structure.

A: Schematic diagram of the F-GCNt domains. Important domains are colored, and their corresponding residue ranges indicated.

B: Ribbon diagram of the F trimer, with each chain colored by residue number in a gradient from *blue* (N-terminus) to *red* (C-terminus). The head and stalk regions are indicated. HRB linker residues 429 to 432 could not be modeled in one subunit and had high temperature factors in the other two.

C: Ribbon diagram of one subunit of the F trimer colored by domain. The domains are labeled and the colors correspond to those used in **(A)**. The cleavage/activation site is marked by an *arrow*.

D: Top view of the trimer colored as in **(A)**. Cleavage/activation sites are indicated by *arrows*.

E: Surface representation of the F trimer colored by subunit. The fusion peptide exposed surface is shown in *blue*.

F: Close-up view of the fusion peptide (residues 103–128). The peptide is folded back on itself with a small hydrophobic core and contains a mixture of extended chain, 1 β strand, and a C-terminal α-helix. The fusion peptide is sandwiched between two subunits of the trimer, between DII and DIII domains. (Adapted from Yin HS, Wen X, Paterson RG, et al. Structure of the parainfluenza virus 5 F protein in its metastable, prefusion conformation. *Nature* 2006;439: 38–44, with permission.)

G–I: Crystal structures of the prefusion forms of HPIV-5 (PDB ID: 4WSG),[464] NiV (PDB ID: 5EVM),[638] and MeV F (PDB ID: 5YZC)[201] proteins displaying the similar overall structure and domain architecture of paramyxovirus F proteins.

J: Close-up of the MeV F monomer, showing the docking pose of the small-molecule MeV entry inhibitor AS-48 (*red spheres*) that was identified in cocrystals.[201] The compound binds at the intersection of the top of the prefusion F stalk with the head domain. The location of the N462 resistance hot spot to AS-48[138] is shown as *black spheres*.

Like other viral and cellular fusogenic proteins, the paramyxovirus F proteins are believed to be membrane-bending machineries that drive membrane fusion by coupling irreversible protein refolding to the localized introduction of extreme negative curvature into juxtapositioned donor and

target membranes.[82,455] Initially folding into a metastable prefusion form, they undergo a series of discrete/stepwise conformational changes to a lower energy state, the postfusion form, when triggered.[248,288] Cleavage of F0 primes the protein for productive membrane fusion by liberating the internal N-terminus of the fusion peptide, but uncleaved soluble F0 complexes are capable of refolding into a postfusion-like conformation (discussed below).[647] The varying nature of the residues found at the cleavage site, the enzymes involved in cleavage, and the role of cleavage in pathogenesis are discussed later in this chapter.

Comparison of the amino acid sequences of paramyxovirus F proteins (reviewed in Ref.[374]) does not show major regions of sequence identity overall, with the exception of the fusion peptide, which has a conserved sequence (up to 90% identity). However, the overall placement of cysteine, glycine, and proline residues suggests a similar structure for all F proteins and a conserved intramonomeric disulfide bond scaffold of the F ectodomain. The *Respirovirus* and *Rubulavirus* F2 and F1 subunits are glycosylated, and there are a total of three to six potential sites for the addition of N-linked carbohydrate. For PIV-5 F protein, it is known that all four potential sites for addition of N-linked carbohydrate are used.[17] The MeV F protein contains three sites in the F2 subunit for N-linked carbohydrate addition, and all three sites are used; there are no sites in F1 for N-linked carbohydrate addition.[8]

Class I viral fusion proteins
