CHAPTER 12

Evolution of Viral Proteins

Eugene V. Koonin • Mart Krupovic

Virus hallmark proteins

RNA-dependent RNA polymerase and reverse transcriptase

Family B DNA polymerases

Rolling circle replication initiation endonuclease

Palm/RRM domain, the core of the virus replication machinery

Helicases and genome packaging NTPases

Virus capsid proteins

Evolutionary roots of the virus hallmark proteins and implications for the origin of viruses

Moderately conserved proteins involved in core virus functions

P-loop enzymes

Proteases

DNA-dependent RNA polymerases and transcription factors

Capping enzymes

Lineage-specific virus proteins involved in core processes

Virus proteins involved in virus-host interactions

Dark matter of virus proteomes

Exaptation and recruitment of host proteins as major routes of virus protein evolution

Concluding remarks: organization of the virus pan-proteome and challenges in its analysis

Virus genomes span about three orders of magnitude in genome size, from <2 kilobases (kb) in the smallest RNA and single-stranded (ss) DNA viruses to more than 2 megabases (Mb) in the giant pandoraviruses. However, from the dwarfs to the giants of the virus world, viruses share a signature feature, the high density of protein-coding genes. Although some viruses encode multiple RNA species, such as tRNAs as well as other noncoding RNAs, at least 90% of the genome sequence of any virus is dedicated to protein coding.[120] Viral proteins are responsible for essential roles in virus reproduction, such as the formation of virions and at least some functions of the virus genome replication. Typically, the proteins that are essential for virus reproduction are shared by large groups of viruses (hereafter, virus hallmark proteins, or VHP).[96,132] The simplest viruses with smallest genomes encode primarily or exclusively VHPs.[136] Viruses with larger genomes encode a great variety of additional proteins that are primarily involved in virus-host interactions, in particular, counteracting host defenses. The genomes of giant viruses encode hundreds of such ancillary proteins that remain poorly characterized.[16,126,154]

The key feature of virus genome evolution is its much higher pace compared to the genomes of cellular life forms. The evolution rates differ widely among viruses, but in many cases,[51,203,221] even a single family of viruses can explore a larger region of the sequence space in its evolution than an entire domain of cellular life forms.[51,203,221] This fast evolution of virus proteins presents major challenges for the analysis of the evolutionary relationships among virus proteins and consequently, among different groups of viruses.[36] Even VHPs often can be identified only by applying the most sensitive sequence comparison approaches and/or methods for protein structure comparison. As for ancillary proteins, virus proteomes remain replete with "dark matter," proteins for which neither structure nor function can be predicted without direct experiment.

Evolution of viruses involves extensive gene exchange with the hosts.[98,123] Therefore, the evolutionary histories of virus proteins are diverse and often intricate. For the VHPs, a long history of evolution within the virosphere is traceable, and origin from specific cellular homologs at the start of that history is apparent for some but not other of these key viral proteins. For the ancillary virus proteins, diverse evolutionary scenarios can be reconstructed. Apart from the dark matter, these proteins span a wide range of sequence and structure similarity to cellular homologs, suggestive of both different modes of evolution and different timing of gene capture by viruses. On many occasions, adaptation of a captured host protein by a virus represents exaptation,[80,81] a distinct mode of evolution whereby a protein acquired by a virus changes its function (eg, an enzyme is inactivated and repurposed for a structural role), resulting in major changes, at least at the amino acid sequence level. In other cases, the functional and structural modification is less dramatic, for example, when a component of a cellular molecular machinery is exploited by a virus as a dominant negative inhibitor of the respective host function, such as programmed cell death.

In this chapter, we present an overview of the currently available data and concepts on the origins and evolution of different classes of virus proteins. Our description of the evolutionary trends among virus proteins is structured in accordance with the recently developed

comprehensive hierarchical taxonomy of viruses.[95,127] This taxonomy organizes the virosphere throughout the multiple taxonomic levels, down from the top rank of realms (Table 12.1; Fig. 12.1).

TABLE 12.1 The top levels of virus taxonomy

Realm	Families	Hosts	Genome Type	Defining Properties
Adnaviria	4	Archaea	dsDNA	Filamentous virions with linear A-form dsDNA genomes
Duplodnaviria	50	Archaea, bacteria, eukaryotes	dsDNA	Viruses with icosahedral capsids made of HK97-fold MCPs
Monodnaviria	20	Archaea, bacteria, eukaryotes	ssDNA and some dsDNA	Viruses with ssDNA genomes replicated using rolling-circle mechanism and encoding HUH superfamily encoducleases
Riboviria	117	Bacteria and eukaryotes	RNA, RT-RNA, RT-DNA	RNA and reverse-transcribing viruses encoding palm-domain RdRPs or RTs
Ribozyviria	1	Eukaryotes	(–)RNA	Viruses with circular (–)RNA genomes with ribozyme features and lacking RdRP gene
Varidnaviria	18	Archaea, bacteria, eukaryotes	dsDNA and some ssDNA	Viruses with icosahedral virions made of DJR-MCPs and derived viruses

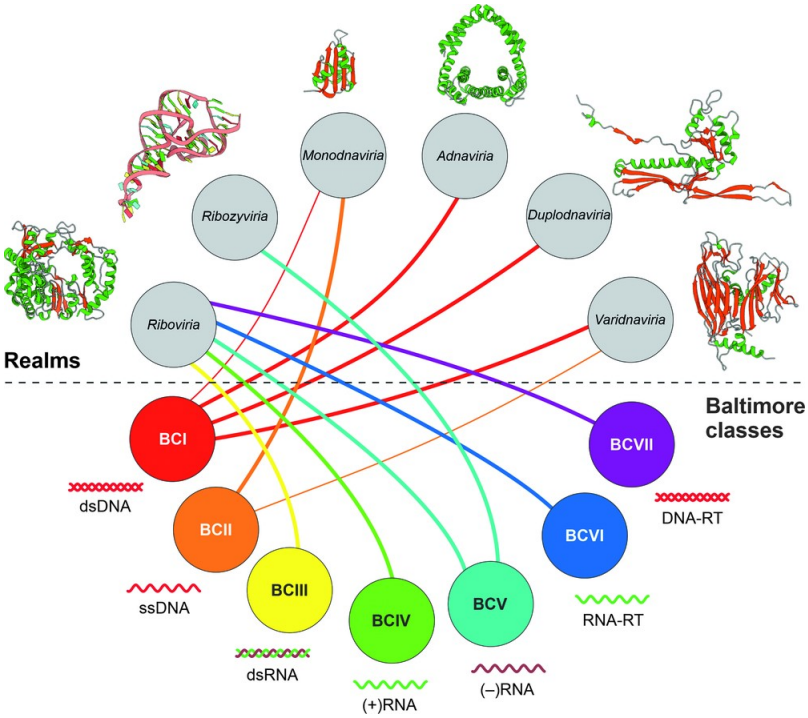

FIGURE 12.1 **The Baltimore classes and monophyletic realms of viruses**. The connections between the Baltimore classes and the virus realms are shown by colored edges. *Thick lines* denote major associations, and *thin lines* denote exceptional cases. For each virus realm, a ribbon diagram of a hallmark structure is shown as follows: *Riboviria*, poliovirus RdRP (PDB id: 1ra7); *Ribozyviria*, HDV ribozyme (PDB id: 4prf); *Monodnaviria*, porcine circovirus 2 rolling circle replication initiation endonuclease domain (PDB id: 5xor); *Adnaviria*, major capsid protein of Sulfolobus islandicus rod-shaped virus 2 (PDB id: 3j9x); *Duplodnaviria*, major capsid protein of bacteriophage HK97 (PDB id: 1ohg); *Varidnaviria*, double jelly roll major capsid protein of bacteriophage PRD1 (PDB id: 1hx6). The protein structures are colored by secondary structure: α-helices, *green*; β-strands, *red*. (Used with permission of American Society for Microbiology from Koonin EV, Krupovic M, Agol VI. The Baltimore Classification of viruses 50 years later: how does it stand in the light of virus evolution? *Microbiol Mol Biol Rev*. 2021;85(3):e0005321; permission conveyed through Copyright Clearance Center, Inc.)

Virus Hallmark Proteins

Proteins that are shared by a broad range of viruses are hallmarks of the virus state.[132] Indeed, these proteins are responsible for the key functions in virus reproduction, namely, virion formation and replication of virus genomes. These two categories of functions differ in that the major components of virions are encoded in any virus genomes, whereas genome replication, at least, in viruses with DNA genomes, is mediated by interacting virus and host proteins, in widely different proportions across various groups of viruses.[68,128,136,212,256]

The VHPs are difficult to define formally, and some degree of arbitrariness in this definition is hard to avoid. Nevertheless, the number of VHPs, obviously, is small, no more than 20, depending on the criteria applied (Table 12.2). Several of these proteins are “super-VHPs,” which connect different Baltimore classes of viruses, that is, viruses that encapsidate different forms of nucleic acids (single-stranded or double-stranded RNA or DNA) and accordingly employ distinct routes of genome expression (Fig. 12.1).[19,129] Other VHPs bring together multiple, diverse groups of viruses within a single Baltimore class. Furthermore, deeper connections among the VHPs exist at the level of domain folds. In the description that follows, we group the VHPs by such deep commonalities that imply ancient common origin. In the currently adopted high level taxonomy of

viruses, the VHPs serve as signatures defining six virus realms (Fig. 12.1), the highest level of the taxonomic hierarchy, and to a large extent, the kingdoms, the next level taxa.[127,128,143]

TABLE 12.2 Virus hallmark proteins

Protein	Function	Distribution
RNA-dependent RNA polymerase	Replicase of RNA viruses	*Orthornavirae*
Reverse transcriptase	Replicase of all RT viruses	*Pararnavirae*
Rolling circle replication endonuclease	Initiator of rolling circle replication	*Monodnaviria*, some *Duplodnaviria*, *Varidnaviria*, and *Adnaviria*
Family B DNA polymerase	Replication of dsDNA genomes	Many *Duplodnaviria*, *Varidnaviria*, *Naldaviricetes*, several families of archaeal viruses
Superfamily 3 helicase	Unwinding or RNA and DNA genomes during replication	Many *Riboviria*, *Duplodnaviria*, *Varidnaviria*, *Monodnaviria*
Archaeo-eukaryotic primase	Priming of DNA synthesis	Many *Duplodnaviria*, *Varidnaviria*, *Naldaviricetes*
Single jelly roll capsid protein	Major and minor capsid proteins	Many *Monodnaviria*, *Orthornavirae*, *Helvetiavirae*
Double jelly roll capsid protein	Major capsid protein	Majority of *Bamfordvirae*
HK97-like capsid protein	Major capsid protein	*Duplodnaviria*
FtsK-like ATPase	Genome packaging ATPase	Most *Varidnaviria*, *Loebvirae* (filamentous phages)
Terminase, large subunit	Genome packaging ATPase and nuclease	*Duplodnaviria*
Portal protein	Structural protein essential for genome packaging	*Duplodnaviria*

RNA-Dependent RNA Polymerase and Reverse Transcriptase

With few exceptions, RNA replication does not occur in cells, and accordingly, the replication of viruses with RNA genomes that constitute the virus realm *Riboviria* is catalyzed by virus-encoded enzymes (Fig. 12.1). Within the kingdom *Orthornavirae*, which includes viruses with positive-sense (+) RNA, negative-sense (−) RNA, and dsRNA genomes that have no DNA stage in their replication cycle, the enzyme responsible for the genome replication (and transcription, in viruses that produce subgenomic mRNAs) is the RNA-dependent RNA polymerase (RdRP).[196,239,240] The RdRP is the signature of *Orthornavirae*, the only VHP that is universally conserved in the viruses of this kingdom. The second kingdom under *Riboviria* is *Pararnavirae*, which consists of viruses with (+)RNA or dsDNA genomes that include a reverse transcription step in their replication cycles. The signature VHP of *Pararnavirae*, and again, the only protein shared by all viruses in this kingdom is reverse transcriptase (RT) although most members also share the structural module.[139,146]

The RdRPs and the RTs are two homologous families of enzymes that are sufficiently closely related to each other, especially at the structure comparison level (Fig. 12.2),[100,130,183,261] that they are justifiably considered a single “super-VHP.” RdRP-RT brings together five Baltimore classes of viruses, three within *Orthornavirae* and two within *Pararnavirae*, and given its ubiquity in each of these classes, is the most prominent among all the VHPs.

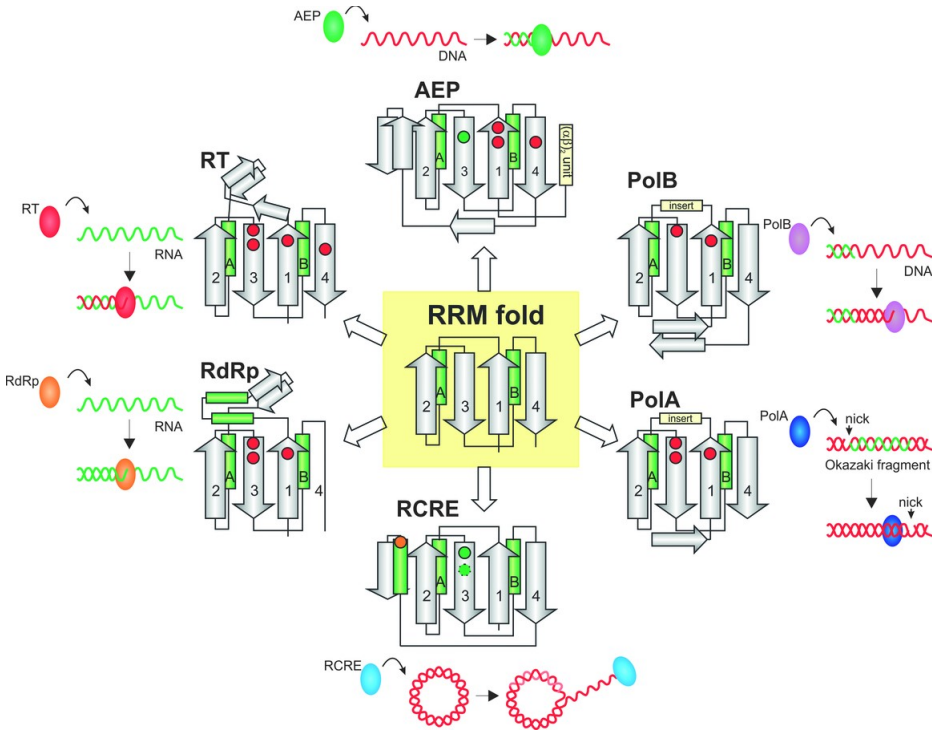

FIGURE 12.2 **Virus hallmark proteins involved in genome replication connect the majority of the virosphere**. Schematic structures of the core domains of the replicative proteins in the four major realms of viruses are shown. The RNA recognition motif (RRM) is one of the most common RNA-binding domains and occurs in all forms of cellular life. Structurally related domains are widespread in many viruses and mobile genetic elements. Replication enzymes containing this module include reverse transcriptase (RT); RNA-dependent RNA polymerase (RdRP); rolling circle replication initiation endonuclease (RCRE); DNA-dependent DNA polymerases of families A (PolA) and B (PolB); and archaeo-eukaryotic primase (AEP). The schematic of the catalyzed reaction is shown for each enzyme, with *red and green wavy lines* representing DNA and RNA strands, respectively. Topologies of the proteins are shown with *arrows* for β-strands and *green rectangles* for α-helices, whereas larger insertions are depicted with *yellow rectangles*. *Red, green, and orange circles* represent catalytic Asp, His, and Tyr residues, respectively. In bacteria, PolA participates in the replication of the lagging DNA strand by connecting Okazaki fragments and in various repair processes, whereas in certain viruses, it functions as the replicative DNA polymerase that was also recruited from a bacteriophage for mitochondrial genome replication in eukaryotes.

RdRP and RT belong to the much broader class of proteins that contain the so-called Palm,[100,130,183] Thumb, and Fingers subdomains and include various polymerases as well as nucleotide cyclases and nucleases (hereafter Palm domain proteins, for brevity). Two families of Palm domain proteins are among the VHPs.

Family B DNA Polymerases

A broad variety of dsDNA viruses in the realms *Varidnaviria* and *Duplodnaviria* encode a DNA-dependent DNA polymerase (DdDP) that is responsible for the virus genome replication. The overwhelming majority of these DdDPs belong to family B (hereafter PolB for brevity), a distinct group of Palm domain proteins (Fig. 12.2) that, apart from the viral polymerases includes the replicative DdDPs of eukaryotes and some groups of archaea.[111,130,209,236] Because, unlike in the case of *Riboviria*, dsDNA viruses have the opportunity to engage the host replication machinery, PolB is not universally present in dsDNA viruses. More specifically, the majority of viruses of the realm *Varidnaviria*, especially those with larger genomes and infecting eukaryotes, encode PolB, but in the realm *Duplodnaviria*, a substantial fraction of viruses lack it.[136,256] Generally, the larger the genome the more replication proteins the virus encodes. All viruses with genomes larger than 140 kb encode DNA polymerases.[112] A distinct subfamily of PolB, the protein-primed DdDPs, is found in several groups of viruses with genomes smaller than 50 kb in the realms *Varidnaviria* (tectiviruses, autolykiviruses, polintoviruses, adenoviruses) and *Duplodnaviria* (phi29-like phages of the family *Salasmaviridae*) as well as in several groups of archaeal viruses (thaspiviruses, halspiviruses, ampullaviruses, ovaliviruses, wyrdviruses) and viruslike DNA plasmids and other Mobile Genetic Elements (MGEs) (eg, casposons, the only group of prokaryotic self-synthesizing transposons currently known).[114,137,140,252]

The small dsDNA viruses that belong to the realm *Monodnaviria* (papillomaviruses and polyomaviruses) as well as the viruses of the realm *Adnaviria* and most of the other dsDNA viruses of hyperthermophilic Thermoproteota (formerly Crenarchaeota) do not encode PolB or any other DdDP (with the exception of ampullaviruses and ovaliviruses). Again, because of the abundance of functionally exchangeable homologs in cellular life forms, the evolutionary history of PolB is far more complex than that of the RdRP-RT. On multiple occasions, viral PolBs apparently were replaced by cellular homologs although protein-primed PolB remains a genuine virus hallmark.[111]

Rolling Circle Replication Initiation Endonuclease

The third VHP with the Palm domain is the endonuclease of the so-called HUH superfamily (after the signature amino acid motif of these nucleases, where U is a hydrophobic amino acid), which is involved in the initiation of DNA replication via the rolling circle mechanism (RCRE, rolling circle replication endonuclease).[34,94,122] The RCRE is universal among the ssDNA viruses in the *Monodnaviria* and is the signature of this virus realm.[127] Some dsDNA viruses in the realms *Adnaviria*, *Duplodnaviria*, and *Varidnaviria* encode RCRE as well.[113] In small dsDNA

viruses of the families *Papillomaviridae* and *Polyomaviridae*, the large protein involved in virus replication (known as T [for tumor] antigen in polyomaviruses) contains a DNA-binding domain that is an inactivated derivative of the RCRE.[58,173]

Palm/RRM Domain, the Core of the Virus Replication Machinery

Apart from the three VHPs discussed above, the Palm domain is represented in another replication VHP, archaeo-eukaryotic primase (AEP; Fig. 12.2) that is encoded by many dsDNA viruses in the realms *Varidnaviria* and *Duplodnaviria*.[94,112] Additionally, some DNA viruses in the realm *Duplodnaviria* and one group of viruses in *Varidnaviria*, the Sputnik-like lavidaviruses (virophages), encode DdDPs of family A (PolA; Fig. 12.2), another group of Palm domain enzymes, that either function in replication or were recruited for a role in transcription.[99,112,119]

The Palm domain is a distinct variety of the RNA Recognition Motif (RRM; Fig. 12.2), one of the most common RNA and DNA binding domains present in a wide variety of proteins in all life forms.[37] Thus, the Palm/RRM domain is the most prominent protein structural unit that connects the replication machineries of all four major realms of viruses as well as all Baltimore classes.[141] Later in this chapter, we discuss the deep implications of this unity for the origin and evolution of viruses.

Helicases and Genome Packaging NTPases

Superfamily 3 Helicases

The most common protein fold in nature is the P-loop domain, the scaffold that harbors the catalytic sites of an enormous diversity of ATPases and GTPases.[157,170,251] Viruses also encode a broad variety of P-loop NTPases, which function in various DNA or RNA transactions during genome replication and/or packaging into capsids, but only three of these qualify as VHPs. By far the most widespread group of P-loop NTPases in viruses is the protein family known as Superfamily 3 helicases (S3H; Fig. 12.3).[78] Notably, S3H is encoded by viruses in different realms and Baltimore classes that widely differ with respect to the genome size and replication mechanisms.[132,141] These include many RNA viruses in the kingdom *Orthornavirae* (primarily, in phylum *Pisuviricota*), the eukaryotic ssDNA viruses in the kingdom *Shotokuvirae* (realm *Monodnaviria*), large DNA viruses that constitute the phylum *Nucleocytoviricota*, and many viruses in the realm *Duplodnaviria*. In all these viruses, the S3H helicases appear to be directly involved in RNA or DNA unwinding during the genome replication. However, in some viruses, for example, parvoviruses, besides its role in genome replication, S3H also functions as a motor that drives the packaging of the viral DNA into preformed empty capsids.[116] Other viruses employ different helicases that are only distantly related to S3H, in the same capacity, as discussed below.

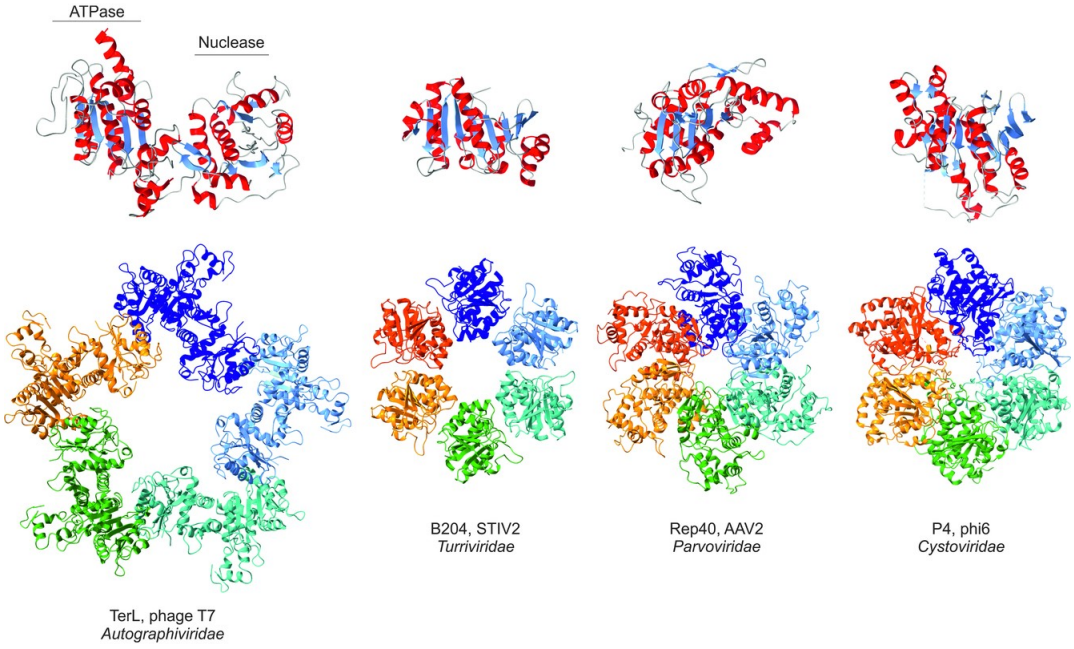

FIGURE 12.3 **Viral helicases and genome packaging ATPases**. The structures of individual proteins and the functional protein oligomers are shown by ribbon diagrams. The structures in the *upper panel* are colored by secondary structure: α-helices, *red*; β-strands, *blue*, whereas in the *bottom panel*, each chain in the corresponding multimeric assemblies is colored differently. PDB ids: T7 TerL, 4bij; STIV2 B204, 4kfu; AAV2 Rep40 monomer, 1s9h; AAV2 Rep68 hexamer, 7jsi; phi6 P4, 5muv. The ATPase and nuclease domains of the TerL are indicated.

Large Terminase Subunit

All dsDNA viruses of the realm *Duplodnaviria* encode another P-loop enzyme, distantly related to SF2 helicases, that contains an N-terminal ATPase and a C-terminal RNase H-like nuclease domain, and is known as the large subunit of the terminase complex (TerL) (Fig. 12.3). The C-terminal nuclease domain of TerL is responsible for the cleavage of virus DNA concatemers formed during replication into genome-sized units, whereas the ATPase domain packages these units into the virus capsid utilizing the energy of ATP hydrolysis.[22,211,262]

FtsK-like Genome Packaging ATPase

Numerous, although not all, dsDNA viruses in the realm *Varidnaviria* encode an ATPase distinct from the large terminase subunit that, however, performs a similar function in DNA packaging into virus capsids (Fig. 12.3). This ATPase belongs to the FtsK family that includes ATPases involved in DNA pumping into daughter cells during bacterial cell division.[101,233] Filamentous ssDNA bacteriophages of the kingdom *Loebvirae* (realm *Monodnaviria*) also encode FtsK-like ATPases which, however, instead of packaging the viral dsDNA into icosahedral capsids, pump the viral ssDNA through the cytoplasmic membrane of the host during virion extrusion.[169,219,232]

RNA viruses typically do not encode genome packaging enzymes, with nucleic acids being coassembled with major structural proteins to form virions.[244] The only currently known exception to this trend are the dsRNA bacteriophages of the family *Cystoviridae* (ream *Riboviria*) that encode packaging enzymes related to the superfamily 4 helicases.[28,56,109,174,175] All packaging enzymes mentioned above form pentameric or hexameric ring-shaped assemblies with a central channel for the translocation of the viral RNA or DNA genome (Fig. 12.3).

Virus Capsid Proteins

Virus capsids show remarkable structural diversity. Compared to proteins involved in genome replication, the sequences of capsid proteins (CPs) evolve much faster, so that the principal approach for the identification of distant relationships among CPs is structure comparison. Altogether, about 20 major CPs with distinct structures have been identified.[138] Importantly, however, the abundances of different capsid shapes and distinct capsid proteins differ widely, so that there are a few common forms and a long tail of rare, odd ones. The majority of viral capsids have icosahedral symmetry, whereas a substantial minority are filamentous or rod-shaped, with helical symmetry. Both icosahedra and helices are thermodynamically favorable forms of protein aggregation, so that both capsid architectures can be built from multiple, unrelated proteins. In particular, at least 10 unrelated protein folds were detected among the major CPs of icosahedral capsids.[138] Among these, only three families consisting of protein components of icosahedral capsids are common enough to qualify as VHPs.

Single Jelly Roll Capsid Protein

The single jelly roll (SJR) CP is the most common of the virus capsid proteins, being the major component of the icosahedral capsids of diverse positive-sense RNA viruses in the kingdom *Orthornavirae* as well as ssDNA and dsDNA viruses in the realm *Monodnaviria* (Fig. 12.4A).[138] Distinct varieties of SJR CP are present also in the dsDNA viruses in the kingdom *Helvetiavirae* (realm *Varidnaviria*),[42,216,222] and as minor capsid proteins, in most other members of the *Varidnaviria*.[60,249]

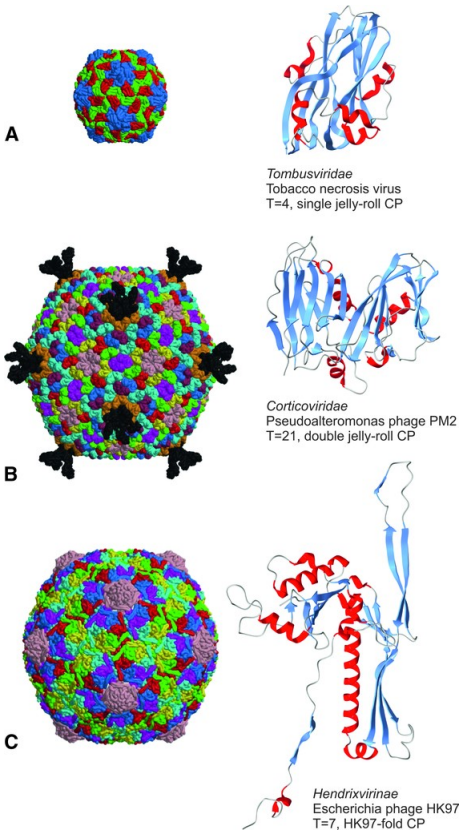

FIGURE 12.4 **Major types of capsid proteins found in icosahedral viruses**. The capsid architectures and ribbon diagrams of the individual capsid proteins are shown. **A**. SJR fold is represented by the CP of tobacco necrosis virus (*Tombusviridae*), PDB id: 1tnv. **B**. DJR fold is represented by the CP of Pseudoalteromonas phage PM2 (*Corticoviridae*), PDB id: 2vvf. **C**. HK97 fold is represented by the CP of *Escherichia* phage HK97, PDB id: 1ohg. The capsid proteins are colored by secondary structure: α-helices, *red*; β-strands, *blue*. (The figures/data were obtained from VIPERdb. (http://viperdb.scripps.edu). VIPERdb v3.0: a structure-based data analytics platform for viral capsids. Montiel-Garcia D, Santoyo-Rivera N, Ho P, Carrillo-Tripp M, Johnson JE, Reddy VS. *Nucleic Acids Research* (2020); doi: 10.1093/nar/gkn1096.)

SJR is a widespread domain in a broad variety of cellular proteins, many of which function by binding carbohydrates, in some cases as multidomain proteins containing SJR fused to a carbohydrate-active enzyme.[138] At least some of the cellular SJR proteins, in particular those of

the tumor necrosis factor (TNF) superfamily, form aggregates resembling virus capsids and thus appear to represent facile material for recruitment as virus CPs.[165] Typically, such recruitment involved acquisition of additional positive charge regions at the protein termini that interact with the viral nucleic acid, promoting its encapsidation.[215] The SJR CPs of eukaryotic RNA and ssDNA viruses, on the one hand, and those of bacterial microviruses (*Monodnaviria*) and halopaniviruses (*Varidnaviria*), on the other hand, show affinity to different groups of cellular SJR proteins.[138] Thus, SJR CPs apparently have been recruited by viruses from cellular ancestral proteins on at least two and likely more independent occasions.

Double Jelly Roll Capsid Proteins

The CPs of the diverse dsDNA viruses in the kingdom *Bamfordvirae* of the realm *Varidnaviria* consist of two fused jelly roll domains and are known as double jell roll (DJR) CPs (Fig. 12.4B).[4,135] The second kingdom currently included in *Varidnaviria*, *Helvetiavirae*, consists of three families of bacterial and archaeal viruses, *Sphaerolipoviridae*, *Simuloviridae*, and *Matshushitaviridae*, that possess two SJR CPs encoded in separate genes.[42,216,222] The SJR CPs of *Helvetiavirae* form homo- and heterodimers, which further aggregate into pseudohexagonal, heterohexameric capsomers that structurally resemble the homotrimeric capsomers of DJR-CPs of the *Bamfordvirae*. Given this structural similarity, it has been hypothesized that DJR-CPs evolved via fusion of the two SJR-CPs following a gene duplication.[213] However, subsequent focused search for cellular homologs of the DJR-CP identified several families of such proteins, in some of which the DJR domain is fused to various carbohydrate-active enzymes.[144] The jelly roll domains of the DJR CPs of *Bamfordvirae* show closer structural similarity to some of these cellular proteins than to the SJR-CPs of *Helvetiavirae*, suggesting that the capsid proteins in the two kingdoms of *Varidnaviria* were acquired independently from different cellular ancestors.[144]

HK97 Capsid Proteins

The third capsid protein VHP is the CP of the tailed icosahedral viruses of the realm *Duplodnaviria*,[4,49,234] which has a characteristic HK97-like fold, after the phage for which the capsid structure was solved first.[258] No cellular homologs of the HK97 CP with the same domain architecture have been identified (except for nanocompartments known as encapsulins that apparently were derived from the HK97 CP), but a more complex relationship with two families of cellular proteins has been discovered. Apparently, the HK97 CP evolved from bacterial proteins known as dodecins, via insertion of an uncharacterized domain (Fig. 12.4C).[92,142] Dodecins are involved in flavin storage in bacteria and form dodecameric spherical structures that can be considered (mini)capsidlike.[82]

Evolutionary Roots of the Virus Hallmark Proteins and Implications for the Origin of Viruses

The observations on the origins of the two functional classes of VHPs, those involved in virus genome replication and those forming virus structure or facilitating its formation like packaging ATPases (replication and structural VHPs, for brevity), suggest different routes of evolution and translate into a parsimonious scenario for the origin of viruses. The replication VHPs, particularly RdRP and RT but also protein-primed DNAP, RCRE, and S3H, have only distant homologs among cellular proteins, suggestive of an early origin, likely antedating the Last Universal Cellular Ancestor (LUCA). Evolutionary reconstructions suggest that the LUCA was a population of organisms comparable in complexity with the extant prokaryotes.[69,118,142,180,191,199] In particular, multiple polymerases and helicases were apparently already represented in the LUCA.[66,130,156] Furthermore, RdRP and RT are the types of replicative enzymes that can be expected to exist at the time of the transition from the hypothetical primordial RNA-protein world to the DNA-RNA-protein life of the modern variety.[65,90] Looking even deeper into the earliest stages of evolution, it seems likely that the currently ubiquitous RRM was one of the first protein domains to become a component of the replication system in the hypothetical RNA world,[141] conceivably, as a cofactor to ribozyme polymerases. The subsequent diversification of the RRM including the emergence of catalytic sites gave rise both to the replication VHPs and to cellular polymerases.

The origins of the structural VHPs appear to be quite different. For each of these, in particular, each of the three widespread CPs that form icosahedral capsids, as well as the packaging ATPases, specific cellular ancestors could be identified.[138] The respective families of cellular proteins are present and highly diversified in all three domains of life, suggesting that they have already emerged by the time of the LUCA. Thus, the structural VHPs, most likely, evolved from cellular ancestors early in the evolution of life, but already after the advent of modern-like protocells.[141] For other structural components of virions, later origin from cellular ancestors was inferred.

Taken together, the findings on the origins of the replicative and structural VHPs suggest a mixed scenario for the origin of viruses (Fig. 12.5).[141] The replication machineries of viruses appear to originate from the primordial pool of replicators in which different forms of RNA and DNA genomes that subsequently gave rise to different Baltimore classes of viruses have already evolved. The replication machineries of viruses, particularly those with DNA genomes, were substantially reshaped by recruitment of components from the hosts, in some cases with replacement of ancestral genes. Nevertheless, the cores of virus replication systems seem to antedate modern cells. In terms of the traditionally discussed hypotheses on the origin of viruses, this part of the scenario corresponds to the “virus early” hypothesis. In contrast, the structural VHPs clearly derive from cellular ancestors and were recruited for functions in the virions at different stages of evolution, which corresponds to the “escaped genes” hypothesis of virus origin. This mixed, “chimeric” scenario appears to be the most parsimonious explanation of the origin of viruses, and remarkably, it is recapitulated at later stages of the evolution of many viruses. In particular, various groups of ssDNA viruses in the realm *Monodnaviria* appear to have evolved independently when a small RCR plasmid merged with the gene encoding the SJR CP of a positive-sense RNA virus.[113,134]

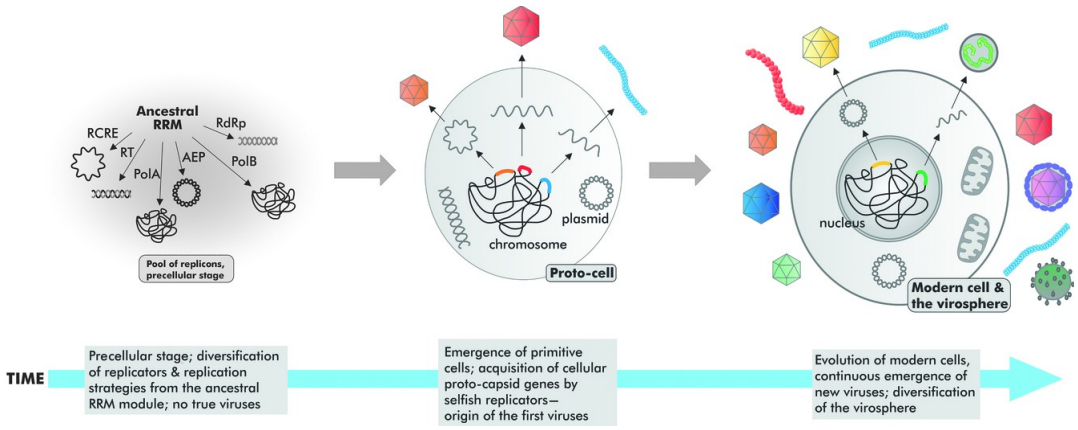

FIGURE 12.5 **The chimeric scenario for the origin of viruses**. (Modified with permission from Krupovic M, Koonin EV. Multiple origins of viral capsid proteins from cellular ancestors. *Proc Natl Acad Sci U S A*. 2017;114(12):E2401-E2410.)

The first virus genomes to emerge, most likely, encoded only a replication VHP coming from a primordial replicator and a structural VHP captured from a host cell. One of such prototypical combinations would have been RdRP-SJR-CP, an arrangement that is found in some of the simplest extant RNA viruses, such as totiviruses. Subsequent evolution of most virus lineages involved accretion of proteins through recruitment of host genes as outlined in the next sections.

Moderately Conserved Proteins Involved in Core Virus Functions

Beneath the VHPs in the hierarchy of virus proteins by evolutionary conservation is a larger collection of proteins that are conserved in a substantial but limited diversity of viruses within a kingdom (more typically, within a phylum) and participate in core functions, such as genome replication and expression. Most viruses encode such additional core proteins, with the exception of those with the smallest genomes and simplest genome organization, such as several groups of RNA viruses in the kingdom *Orthornavirae*, for example, toti-like and tombus-like viruses, and many ssDNA viruses in the realm *Monodnaviria*, for example, circoviruses and parvoviruses, in which the protein repertoire is limited to VHPs. For most of these moderately conserved proteins, origin via recruitment of a host gene is readily traceable.

Viruses vary enormously in the extent to which core functions, such as genome replication and expression, rely on virus-encoded proteins or are relegated to directly recruited host proteins. The "logic" of the labor separation between virus and host proteins appears traceable in some cases but not others. In particular, among RNA viruses, the polymerases responsible for genome replication are typically encoded in the virus genome because RNA replication does not normally occur in uninfected cells. Otherwise, however, these viruses substantially differ in the extent of their replicative autonomy from the host, with those with the smallest genomes encoding no additional proteins for core functions, but those with larger genomes accruing several such proteins. The small genomes of the viruses in the realm *Monodnaviria* accommodate a single replicative protein, otherwise relying on the cellular machinery. The dsDNA viruses with larger genomes, in the realms *Varidnaviria*, *Duplodnaviria*, and *Adnaviria*, demonstrate striking diversity. In particular, most of the large and giant viruses within *Nucleocytovirecetes* encode (nearly) complete replication and expression systems, which can be construed as an essential adaptation for the autonomous replication of these viruses within "virus factories" in the cytoplasm of infected cells.[126] However, some members of *Nucleocytovirecetes* underwent different degrees of reductive evolution that accompanied relocation of the virus replication and expression site to the cell nucleus,[248] and involved the loss of many or even most of the viral genes involved in these core processes. Some of the smaller viruses within *Varidnaviria* that reproduce in prokaryotic cells or in the eukaryotic nuclei encode DNA polymerases but otherwise primarily rely on host proteins for the genome replication and expression. Among the dsDNA viruses in the realm *Duplodnaviria*, the variation is even greater as some of these viruses encode virtually autonomous replication and transcription systems,[112,206] whereas others have virtually no proteins involved in these processes.[256] More specifically, most of the dsDNA viruses of hyperthermophilic Thermoproteota, in particular, those in the realm *Adnaviria*, apparently rely on the host replication and expression apparatus (almost) completely.[147]

There are several recurrent structural and functional themes among the moderately conserved core virus proteins. It is unrealistic to cover in this chapter all or even most of these proteins, but we discuss the most common and characteristic ones.

P-loop Enzymes

The P-loop fold is the most common one among all protein domains.[170] The small set of VHPs discussed above includes three P-loop enzymes, SF3 helicases, and two packaging ATPases. In addition, many viruses encode a considerable diversity of P-loop enzymes with a more narrow spread. The most prominent of these are several groups of helicases, some of which are signatures of virus phyla or classes. Apart from the super-VHP, the SF3 helicase, SF1 helicases are represented in a broad variety of positive-sense RNA viruses in the phylum *Kitrinoviricota* and in the order *Nidovirales* of the phylum *Pisuviricota*, whereas SF2 helicases are encoded by two large virus families (*Flaviviridae* and *Potyviridae*) among the *Pisuviricota*, in which most viruses possess S3H.[260] Among the positive-sense RNA viruses, the presence of a helicase strongly correlates with the genome size: all viruses with genomes in excess of about 6 kb encode a helicase, whereas those with smaller genomes do not. This pattern implies that, among the positive-sense RNA viruses, helicases are required for efficient replication of long genomic RNA and were independently acquired on at least four separate occasions, by recruitment of host enzymes or, in some cases, by intervirus recombination. This is a striking case of convergent acquisition by viruses of genes with similar functions (but not necessarily closely related or homologous at all) driven by common selective forces, which may be considered one of the key principles of virus evolution.

SF2 helicases are also encoded by most of the large DNA viruses of the class *Nucleocytovirecetes* in the realm *Varidnaviria* as well as by herpesviruses and numerous tailed bacteriophages in the realm *Duplodnaviria*.[112] Members of *Nucleocytovirecetes* encode up to four distinct SF2 helicases (eg, in poxviruses) that appear to have been independently captured from the hosts and function in virus genome expression and other, still not fully understood roles. Bacterial viruses in the realm *Duplodnaviria* encode the DnaB-like SF4 helicase homologous to the

bacterial replicative helicases that in many viruses is fused to a bacterial DnaG-like primase domain. This architecture of the virus primase-helicase mimics the fusion of S3H and AEP that is a signature of *Nucleocytovirecetes* and is also found in some viruses in *Duplodnaviria* as well as plasmids. Actually, nearly all possible combinations of SF1-SF4 helicases with AEP and DnaG-like primases can be found among dsDNA viruses.[112] In some cases, the fusion proteins even contain family A or family B DNA polymerases. Once again, in different viruses, selection for efficient replication apparently drove the evolution of the composite replicative proteins from distinct but functionally analogous domains. Many bacterial and archaeal viruses within *Duplodnaviria* also encode a DNA-dependent ATPase or helicase of the AAA+ superfamily that is involved in the initiation of virus DNA replication.[168,256] It should be noticed, however, that replicative helicases and ATPases are missing in many groups of DNA viruses, among both *Varidnaviria* and *Duplodnaviria*, conceivably, because host proteins with the corresponding activities are directly recruited to participate in virus genome replication.

Apart from the helicases, a class of P-loop enzymes common among dsDNA viruses with large DNA genomes, in both *Varidnaviria* and *Duplodnaviria*, are nucleotide and nucleoside kinases, in particular, thymidine and thymidylate kinases. These kinases are common but not ubiquitous among *Nucleocytovirecetes* as well as among *Herpesvirales* and *Caudoviricetes*.[72,168,179,266] This is another case of convergent capture of enzymes with the same functionality by multiple lineages of viruses under evolutionary pressure to complement the host nucleotide metabolism that, however, manifests only in certain hosts and cell types.

Proteases

In a broad variety of viruses, all or some of the mature virus proteins are produced by proteolytic processing of precursors. In many families of positive-sense RNA viruses in the phyla *Kitrinoviricota* and *Pisuviricota*, either the entire genomic RNA or its large portion encoding nonstructural proteins are expressed as a polyprotein that contains one or more protease domains.[260] These viruses encode proteases of two expansive families with unrelated folds, papainlike and chymotrypsinlike (MEROPS clans PA and CA, respectively),[75,77] and some viruses encompass both types of proteases (Fig. 12.6). A unique feature of RNA virus chymotrypsinlike proteases is the replacement of the catalytic serine by a cysteine in most of them, such as the well-studied proteases of picornaviruses.[75] Another remarkable twist is the recruitment of a chymotrypsinlike protease as the capsid protein replacing the ancestral SJR CP in alphaviruses within *Togaviridae*, an expansive family of animal positive-sense RNA viruses in the phylum *Kitrinoviricota*. Most likely, alphaviruses acquired the protease from another RNA virus family, *Flaviviridae*,[138] in which this protein is not a virion component but, rather, performs a function typical of proteases, namely, polyprotein processing.[115] Convergently with the case of the SJR CPs, recruitment of the protease as the alphavirus CP involved acquisition of a positively charged, nonstructured N-terminal region.[178] The reverse-transcribing RNA viruses of the kingdom *Pararnavirae* also produce polyproteins that are cleaved by a virus-encoded aspartate protease (Fig. 12.6).[228]

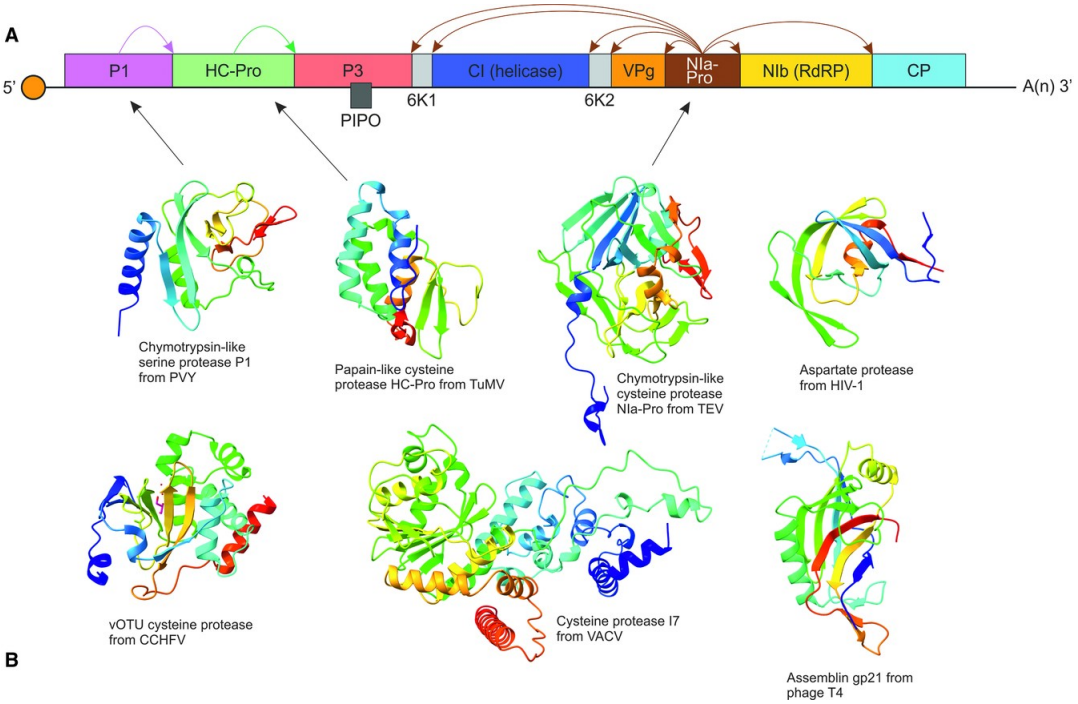

FIGURE 12.6 Proteases encoded by RNA and DNA viruses. **A**. Proteolytic processing of the polyprotein encoded by potato virus Y (family *Potyviridae*). Cleavage sites of the three virus-encoded proteases are indicated by *bent arrows* colored using the same colors as the genes encoding the corresponding proteases. **B**. Ribbon diagrams of the structures of serine, cysteine, and aspartate proteases encoded by RNA and DNA viruses, including the three proteases of potyviruses: P1 (AlphaFold2 model), HC-Pro (PDB id: 3rnv), and NIa-Pro (PDB id: 1lvm); aspartate protease of retroviruses (PDB id: 2i4d); vOTU deubiquitinase of nairoviruses (PDB id: 3phu); virion maturation protease I7 of poxviruses (RoseTTAFold model); capsid maturation protease of duplodnaviruses (PDB id: 5jbl). The structures are colored using the rainbow scheme from blue N-terminus to red C-terminus. Abbreviations: HC-Pro, helper component-protease; CI, cylindrical inclusion protein; VPg, viral protein genome-linked; NIa-Pro, nuclear inclusion a-protease; CP, capsid protein; PIPO, pretty interesting *Potyviridae* ORF; PVY, potato virus Y; TuMV, turnip mosaic virus; TEV, tobacco etch virus; HIV-1, human immunodeficiency virus 1; CCHFV, Crimean-Congo hemorrhagic fever virus; VACV, vaccinia virus.

The utility of proteases for RNA viruses of eukaryotes is obviously linked to the features of the eukaryotic translation whereby the great majority of mRNAs are monocistronic (that is, contain a unique initiation site near the 5′-terminus from which a single protein is translated). Thus, to

produce individual, mature proteins, RNA viruses employ three strategies, some viruses combining two or even all three: proteolytic processing of precursor polyproteins, transcription of subgenomic mRNAs, and genome segmentation. Under the selective pressure for expressing individual proteins, viruses within *Riboviria* acquired unrelated proteases on at least three independent occasions (the papainlike, chymotrypsinlike, and aspartate proteases). Most likely, however, there have been more of such recruitment events because both the papainlike and chymotrypsinlike proteases in different groups of positive-sense RNA viruses are only distantly related to each other (Fig. 12.6). Furtherrmore, some (−)RNA bunyaviruses, such as members of the *Nairoviridae* and *Phenuiviridae* families, and (+)RNA viruses of the orders *Tymovirales* and *Nidovirales* encode homologs of the ovarian tumor protease, a papainlike cysteine protease, which is involved in deubiquitination of various host proteins, thereby promoting evasion of the innate immune response.[18,44,53,207]

For some of the RNA virus proteases, the origin from specific families of cellular proteases is traceable. The chymotrypsinlike proteases in the order *Picornavirales* were apparently derived from the HtrA family of bacterial proteases.[133] The aspartate protease of the reverse-transcribing viruses seems to originate from the Ddi1 protease, a highly conserved component of the eukaryotic ubiquitin signaling network.[148,230]

Although viruses with DNA genomes typically do not encode polyproteins, most of the viruses of eukaryotes in the realm *Varidnaviria* encode a cysteine protease (MEROPS clan CE), distantly related to papainlike proteases (clan CA) that is required for the maturation cleavage of capsid proteins.[11,24,29,160,255] Notably, this protease is specifically related to the eukaryotic deubiquitinating enzyme (DUB) Ulp1 that probably was recruited by varidnaviruses at an early stage of their evolution in eukaryotes.[137] The majority of the dsDNA viruses in the realm *Duplodnaviria* encode an unrelated serine protease with a unique fold (MEROPS clan SH; Fig. 12.6), known as assemblin in herpesviruses, that also catalyzes the proteolytic maturation of the major capsid protein or cleavage of the scaffolding protein.[35,50,242,272] Remarkably, assemblin protease is structurally related to proteins forming the tubes of phage tails,[64] suggesting that the iconic tails of *Caudoviricetes* evolved from a protease, mirroring the evolution of alphaviral CPs from a polyprotein-processing protease and, more broadly, supporting the exaptation scenario where viral structural proteins have evolved through refunctionalization of preexisting cellular and viral proteins. Notably, in some tailed phages, assemblin is replaced by a different serine protease related to bacterial ClpP.[164]

Sporadically, other proteases, such as metalloproteases of the zincin family, are also encoded in phage genomes.[269] Altogether, the diversity and complex evolutionary history of virus proteases further demonstrate the pervasive trend of convergent capture of unrelated host proteins with similar functions by different virus lineages.

DNA-Dependent RNA Polymerases and Transcription Factors

Most of the dsDNA viruses with large genomes within the classes *Nucleocytovirecetes*, *Caudoviricetes*, and *Naldaviricetes* (ie, Baculo-like viruses) encode their own transcription machinery. The DNA-dependent RNA polymerase (RNAP) subunits and core transcription factors encoded by the members of *Nucleocytovirecetes* and *Naldaviricetes* have readily identifiable homologous counterparts among the corresponding components of the eukaryotic transcription machinery (Fig. 12.7A).[27,83,91,171,200] However, the evolutionary history of the RNAPs appears to be highly complex, with multiple gene exchanges and displacements between the viruses and their eukaryote hosts.[84,266]

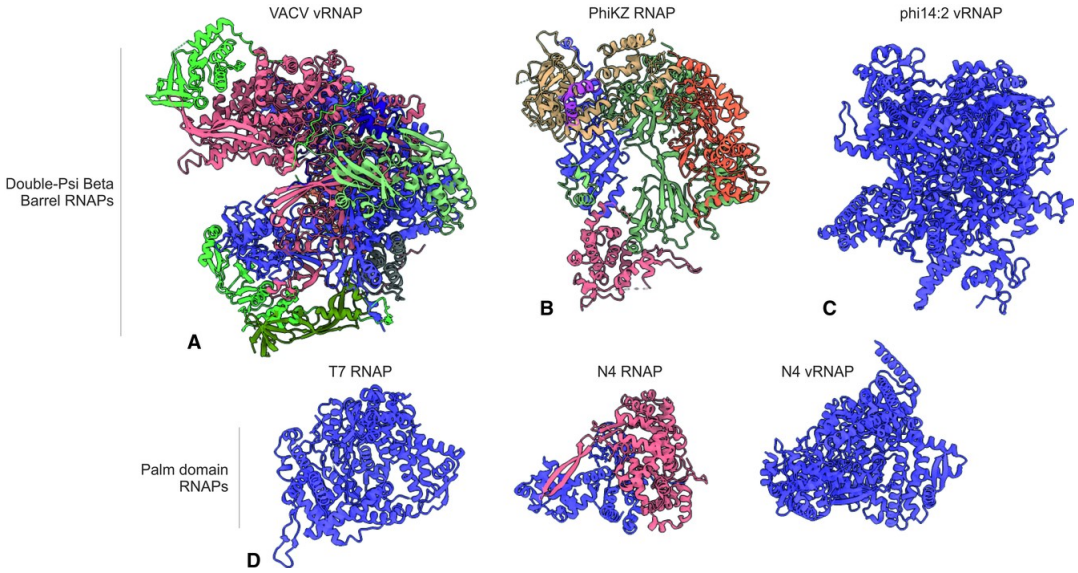

FIGURE 12.7 **Viral DNA-dependent RNA polymerases (RNAPs)**. **A-C**. Double Psi Beta Barrel RNAPs. **A**. Multisubunit RNAP of vaccinia virus (VACV). PDB id: 6ric. **B**. Multisubunit RNAP of *Pseudomonas* bacteriophage PhiKZ. PDB id: 7ogr. **C**. Single-subunit RNAP of *Cellulophaga* bacteriophage phi14:2. PDB id: 6vr4. **D**. Palm domain RNAPs of bacteriophages T7 and N4. Note that RNAP of N4 (*middle*; PDB id: 6dt7) is a heterodimer, whereas T7 RNAP (PDB id: 1h38) and N4 vRNAP (PDB id:2po4) are single-subunit enzymes. Prefix "v" in vRNAP indicates that the RNAP is encapsidated into virions. Each chain is colored differently in the corresponding structures to highlight the difference between single-subunit and multisubunit enzymes.

The diversity of the transcription machinery in tailed bacteriophages is far greater. Different members of *Caudovirecetes* encode two unrelated types of RNAPs. Numerous groups of bacteriophages have homologs of the highly conserved, multisubunit bacterial RNAP in which the Double-Psi Beta Barrel (DPBB) domains from the two large subunits jointly constitute the catalytic site (Fig. 12.7B).[43,231] However, the phage versions are often highly derived, demonstrating extreme divergence as well as subunit fusion and loss of individual subunits.[48] In some phages, the RNAP is reduced to a single protein containing two DPBB domains (Fig. 12.7C). However, several groups within *Caudovirecetes*, in particular, T7-like phages, instead of the DPBB-domain RNAP, encode a single-subunit RNAP containing a Palm domain and derived from the A family

DNAPs (Fig. 12.7D).[103,237] As in the case of DPBB RNAPs, some T7-like RNAPs are partitioned into several subunits.[182] Notably, this RNAP was recruited for mitochondrial genome transcription in eukaryotes, most likely, from a prophage that was integrated into the genome of the pre-mitochondrial endosymbiont.[63,87,227] The driving forces behind the enormous diversification of the RNAPs in tailed phages remain a puzzle. Some of the phage RNAPs, from both the DPBB and the Palm domain varieties, are encapsidated into virions and are injected into the host cell along with the genome to transcribe the phage early genes.[48,188] The structural requirements for such virion RNAPs are likely to be substantially different from those for the RNAP involved in bacterial transcription, resulting in dramatic changes in the phage RNAP sequence, structure, and subunit organization.

Capping Enzymes

Some common components of the virus proteomes can be naturally linked to the key molecular features of the hosts. Nearly all eukaryote mRNAs contain a 5′-terminal cap that is required for translation initiation and protects the mRNA from degradation.[210] Some positive-sense RNA viruses, in particular, those in the orders *Picornavirales* and *Potatovirales* within *Pisuviricota*, circumvent the requirement for the cap by protecting the RNA with a 5′terminal, covalently bound virus protein and initiating translation at distinct RNA domains, known as internal ribosomal entry sites (IRES).[74,104] Alternatively, some RNA viruses, such as hepaciviruses, pestiviruses, and pegiviruses (family *Flaviviridae*), lack both the cap and the terminal protein, and instead only carry an IRES, which enables efficient translation of mRNAs lacking a 5′ cap structure.[229] However, the majority of the viruses infecting eukaryotes make capped mRNAs via one of three strategies. Segmented negative-sense RNA viruses (orders *Bunyavirales* and *Articulavirales* within *Negarnaviricota*) encode a distinct endonuclease that clips off cap-containing 5′-terminal segments of host mRNAs to initiate the synthesis of capped virus mRNAs.[198] Numerous other viruses, primarily, those that (at least, for part of their lifecycle) reproduce inside the nucleus, in particular, all reverse-transcribing viruses in the kingdom *Pararnavirae*, all small DNA viruses in the realm *Monodnaviria*, smaller viruses within *Varidnaviria* (eg, adenoviruses) and herpesviruses, exploit the host capping apparatus.[45] However, viruses reproducing in the host cytoplasm, in particular, the majority of the eukaryote-infecting RNA viruses within *Orthornavirae* and most of the *Nucleocytoviricetes*, encode their own capping enzymes that apparently evolved from the host enzymes on several independent occasions and show complex evolutionary relationships.[125] Some of these enzymes are divergent homologs of the host capping machinery, as in the case of *Nucleocytoviricetes*, which encode the enzymatic domains with RNA 5′-triphosphatase, RNA guanylyltransferase, RNA (guanine-N7)-methyltransferase, and 2′-*O*-methyltransferase activities catalyzing all the steps of cap formation, either as separate proteins or as protein fusions encompassing two or more domains.[150,226] In dsRNA reoviruses, the capping enzyme is part of the virion and contains four enzymatic domains, which sequentially catalyze all four steps of the cap synthesis.[214] Coronaviruses and likely other members of the *Nidovirales* also use the canonical capping pathway and encode the enzymes for all four reactions.[25,45] The RNA guanylyltransferase encoded by these viruses has evaded detection until recently but now has been demonstrated to reside in the NiRAN domain of the RdRP.[155,250]

The enzymes responsible for different reactions required for capping can be nonhomologous from one group of viruses to the next. For instance, RNA 5′-triphosphatase, which catalyzes the cleavage of the phosphate bond in 5′-triphosphorylated mRNA, can belong to four different enzyme families,[45] indicative of multiple independent gene acquisitions and/or replacements. Whereas members of the *Nucleocytoviricetes* and reoviruses synthesize their caps using the canonical pathway that also operates in eukaryotes, many RNA viruses evolved unconventional pathways for synthesizing the cap,[45] which, however, has the same structure as that of the hosts (Fig. 12.8). The first of such distinct capping pathways is used by negative-sense RNA viruses of the order *Mononegavirales*.[197] The L protein of mononegaviruses is a multifunctional enzyme responsible for both RNA replication and capping. One of the L subdomains has the GDP polyribonucleotidyl transferase (PRNTase) activity and transfers GDP, rather than GMP, as it occurs in the canonical pathway, to the RNA 5′ end.[197,208] The methyltransferase subdomain of the L protein then methylates both ribose-2′-O position of the first nucleotide, and subsequently, the guanine-N7 position, thereby generating the mature cap structure (Fig. 12.8). Alphaviruses and nodaviruses use a different capping pathway by virtue of a unique bifunctional enzyme with the methyltransferase-guanylyltransferase (MTase-GTase) activity.[6,7] Unlike cellular cap methyltransferases, which methylate GTP only after it is transferred to the 5′ end of the mRNA, the alphaviral MTase-GTase first methylates GTP and only subsequently conjugates it to the 5′ end of the viral mRNA (Fig. 12.8). Furthermore, the first step of the alphavirus/nodavirus capping reaction, namely, dephosphorylation of the triphosphorylated RNA 5′ end, which is performed by a dedicated RNA 5′-triphosphatase in the canonical pathway, is carried out by the viral helicase, using the same NTPase active site that powers the RNA unwinding activity.[7] Remarkably, the MTase-GTase of alphaviruses is located at the neck of membrane-bound replicase complexes, also known as spherules, where it forms a dodecameric, crown-shaped ring, which acts as a gateway between the lumen of virus replication centers and the host cytoplasm.[106,271] The unique MTase-GTase of alphaviruses evolved through relatively minor structural elaborations of the canonical SAM-dependent MTase fold,[106] a testament to the enormous “creativity” of virus evolution, likely stimulated by the prohibitive genome size constraints.

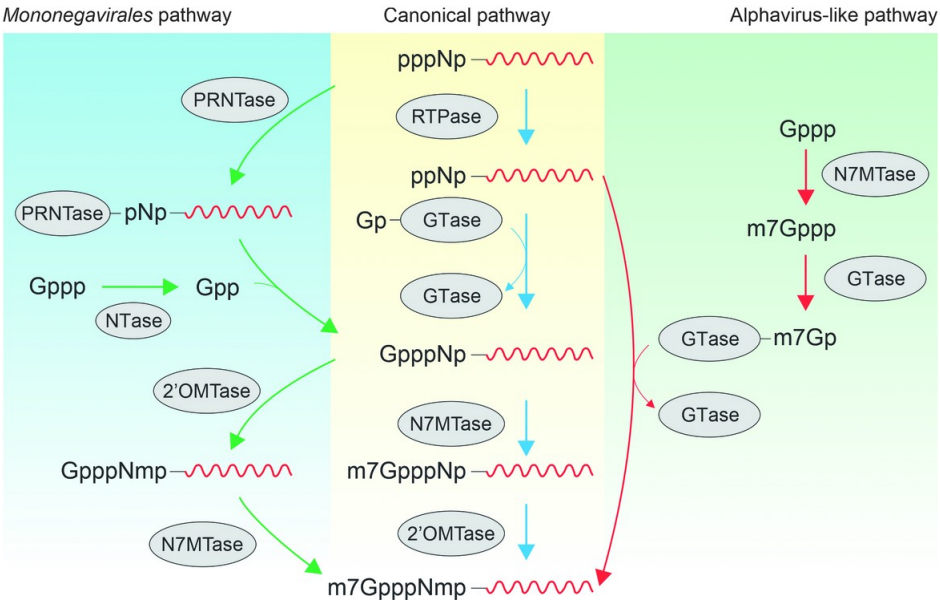

FIGURE 12.8 **Diversity of cap formation pathways encoded by viruses**.

Lineage-Specific Virus Proteins Involved in Core Processes

Apart from the common contributors to the core processes of genome replication and expression as well as morphogenesis, some groups of viruses, including even viruses with larger RNA genomes, encode proteins dedicated to more specific roles in such processes. Notable examples of such specialized proteins contributing to genome replication of RNA viruses are the exonuclease (ExoN) and a pyrimidine-specific endonuclease (NendoU) that are conserved in all viruses of the order *Nidovirales* within *Pisuviricota* but not found in any other viruses.[76,245] Distant homologs of both nucleases were identified in eukaryotes indicating that these genes were recruited from the host at the onset of the evolution of *Nidovirales*. Both enzymes are required for coronavirus RNA replication, where ExoN supplies the proofreading activity which, along with other factors, apparently provides for genome expansion.[61,76] Another group of positive-sense RNA viruses with relatively large genomes, members of the family *Closteroviridae* within *Kitrinoviricota*, encode a molecular chaperone of the HSP70 family that is required for virion assembly.[10,15,47]

Viruses with large dsDNA genomes in the realms *Varidnaviria* and *Duplodnaviria* harbor a vast repertoire of lineage-specific proteins involved in genome replication and expression as well as virion morphogenesis. As an example, it is interesting to mention that viruses from several families within *Nucleocytoviricotes* encode histones.[59,167,218,241,246,264] For instance, members of *Marseilleviridae* encode unique histone doublets, which form nucleosomes remarkably similar to those found in all eukaryotes.[167,246] Certain members of *Phycodnaviridae*, another family within *Nucleocytoviricotes*, instead encode a different chromatin protein of the DVNP family (PFAM: PF19060.3), exemplified by EsV-1-52 from Ectocarpus siliculosus virus 1, that promotes genome compaction and replaced the histones in dinoflagellates, a group of single-celled eukaryotes.[79,97]

Virus Proteins Involved in Virus-Host Interactions

All viruses are entangled in diverse interactions with the host organisms, in particular, coping with the multiple lines of defense, including innate and, in some groups of organisms, adaptive immunity.[5] A key aspect of virus evolution is the perennial arms race with the host whereby the hosts evolve and adapt defense mechanism, whereas viruses escape through the fixation of resistance mutations and evolution of antidefense mechanisms.[67] Thus, both defense and antidefense systems tend to evolve rapidly, in terms of gene gain and loss as well as sequence and structure change. As can be expected, the repertoires of dedicated proteins involved in virus-host interactions are tightly linked to the host biology. In particular, viruses of prokaryotes and eukaryotes have completely different sets of such proteins, and so do viruses of unicellular eukaryotes, plants, and animals.

Viruses with large DNA genomes in the realms *Varidnaviria* and *Duplodnaviria* encode numerous proteins involved in various types of virus-host interactions, mostly, counter-defense. As a rule of thumb, about half of the proteins in large virus genomes (those in excess of about 100 kb) have dedicated functions in virus-host interactions, as observed, for example, in such thoroughly characterized group as chordopoxviruses within *Nucleocytovirecetes*.

Viruses with small genomes in the realms *Riboviria* and *Monodnaviria* encode few proteins that function solely in virus-host interaction. Typical of these viruses is gene sharing whereby virus proteins responsible for core functions moonlight in virus-host interactions. For example, most viruses in the family *Picornaviridae*, in addition to the main chymotrypsinlike protease responsible for most of the polyprotein cleavages (see above) encompass additional proteases, chymotrypsinlike 2A, which is encoded directly downstream of the capsid proteins, or papainlike L(leader), the N-terminal portion of the respective polyproteins. These proteases are essential for virus reproduction because they cleave the polyprotein *in cis*, but their unique function is the cleavage of the host translation initiation factor eIF4G and some other host proteins, inhibiting translation of the host capped mRNAs and suppressing innate immunity, including apoptosis.[5,39,184] Notably, in other picornaviruses, proteins occupying the same positions in the polyprotein but lacking protease activity inhibit host translation via other, nonenzymatic mechanisms. Apart from these "security proteins," the 3A protein of picornaviruses that is responsible for the membrane localization of the virus replication complex has been shown to inhibit apoptosis.[5,102,117]

A heterogeneous set of positive-sense RNA viruses in both *Kitrinoviricota* and *Pisuviricota*, including alphaviruses, rubella virus, hepeviruses,

and some coronaviruses, encode, within their nonstructural polyproteins, the Macro domain (so named after the macro variant of histone H2A that contains this domain).[121] In addition, Macro domains are encoded by some of the *Nucleocytovirecetes* as well some bacteriophages within *Duplodnaviria*. The Macro domains in RNA and DNA viruses are distantly related and apparently were acquired from the host on multiple, independent occasions. Macro domains are phosphohydrolases that are specific for (poly)ADP-ribose.[195] The primary function of the Macro domain is likely to be in antidefense, via the reversal of ADP-ribosylation of virus proteins, given that poly ADP-ribose polymerases are known antivirus factors.[13,55,159] However, direct involvement in virus genome replication cannot be ruled out either, especially, in betacoronaviruses where the nsP3 protein contains two derived Macro domains and binds RNA.[161,162] The macrodomain is a striking case of recruitment of a highly specific enzyme by unrelated viruses infecting diverse hosts, illustrating both the wide spread of some defense mechanisms and the multifunctionality of virus proteins.

However, even some of the viruses with the smallest genomes encode dedicated proteins that contribute to virus-host interaction in a specific manner dictated by the host biology. Viruses of plants, all of which have comparatively small genomes, apparently, because large viruses cannot spread between plant cells, stand out with respect to the prominence of such links between dedicated virus proteins and biological features of the hosts. A prominent case in point are the movement proteins (MP) of plant viruses that enable the movement of viral RNA or DNA among the plant cells through plasmodesmata.[172,238] A great variety of both RNA viruses from *Orthornaviria* and *Pararnaviria*, and ssDNA viruses infecting plants encode homologous MPs of the so-called 30K family that bind virus RNA or DNA and transport it from cell to cell.[177,189] Undoubtedly, the MPs extensively spread horizontally under strong selection because intercellular movement is a condition of virus spread in plants. The origin of the 30K family of MPs remains obscure. Several groups of positive-sense plant RNA viruses within *Kitrinoviricota* lack a 30K family MP but instead encode three unrelated proteins involved in virus movement, one of which is a distinct SF1 helicase, in the so-called triple gene block.[185,190] Other plant viruses employ unrelated proteins as MPs. It appears likely that additional MPs will be discovered in those plant viruses that lack both a 30K MP and the triple gene block. Indeed, carmoviruses (family *Tombusviridae*) encode two small proteins of 7 and 9 kDa, sometimes referred to as double gene block proteins, which are essential for intra- and inter-cellular movement but are unrelated to either 30K or triple gene block MPs,[193] further indicating that the ability to cross plasmodesmata evolved on several occasions. In yet other plant viruses, such as closteroviruses, the functions of the MP are performed by minor virion components including the aforementioned virus-encoded HSP70 family chaperone,[10,15,204] another case of gene sharing.

In addition to the MPs, numerous plant and insect viruses encode proteins, in some cases, more than one per genome, known as silencing suppressors, that inhibit the powerful RNAi systems of their hosts.[40,46,105] Most of the silencing suppressors are small, structurally diverse proteins. Although many show no significant similarity to any known proteins,[163] some RNA and DNA viruses encode silencing suppressors containing the dsRNA binding domain (dsRBD), a small protein motif of ~70 amino acids with an αββββα fold, whose key property is binding dsRNA.[62] It cannot be ruled out that some of the silencing suppressors evolved de novo from spurious open reading frames (ORFs) in viral genomes.

Several small groups of plant positive-sense RNA viruses in the order *Tymovirales* within *Kitrinoviricota* and family *Potyviridae* within *Pisuviricota* encode an RNA demethylase of the AlkB family that repairs oxidative damage in virus RNAs.[12,247] It remains unclear why some but not other plant viruses require this enzyme for their reproduction. One possibility is that the AlkB homolog is present mostly in viruses infecting trees that might exhibit a high level of oxidative stress.

Connections to the host biology are tractable for other viruses as well, especially in well-studied, model host organisms. Thus, most of bacteriophages encode peptidoglycan digesting enzymes (lysins) or other proteins that cause lysis of the cell wall allowing virus egress.[30,31] The lysins belong to several unrelated families of peptidoglycan-cleaving enzymes, indicative of independent capture by different groups of phages.[1] Remarkably, even leviviruses and microviruses, ssRNA and ssDNA phages with extremely compact genomes, respectively, encode distinct lysis proteins which, in these cases, are small membrane proteins encoded in alternative ORFs that cause lysis by inhibiting different stages of the peptidoglycan biosynthesis pathway.[32] Apparently, these are independent cases of de novo emergence of virus proteins whereby spurious ORFs were fixed in evolution under strong selective pressure for the essential lysis activity. Indeed, leviviruses encode several unrelated lysis proteins that were overprinted over different viral genes.[33]

Viruses infecting biologically distinct groups of bacteria display more specific adaptations. Notable examples are the numerous viruses of cyanobacteria (cyanophages), many of which carry genes for the entire photosystem I, photosystem II, or both.[8,70,224,235] The photosystems of cyanophages supplement those of the host cyanobacteria, maintaining the host metabolism at the level sufficient to support the maximum rate of the virus reproduction. Such complementation of the host metabolism that is either overtasked by the virus infection or shut down in response to it is likely to be the driving force behind the capture of a variety of metabolic enzymes by viruses with large DNA genomes. In particular, the widespread nucleoside and nucleotide kinases discussed above and other enzymes of nucleotide metabolism that are common in viruses, for example, ribonucleotide reductases and dihydrofolate reductases, belong in this functional category.[93,168]

A particularly notable example of recruitment of proteins complementing host functions that merits special discussion are protein components of the translation systems that are encoded by many giant viruses, primarily, in the family *Mimiviridae* within *Nucleocytovirecetes*. The most striking case is tupanvirus that encodes all protein components of the translation machinery except for the ribosomal proteins, including the complete set of aminoacyl-tRNA synthetases (aaRS) and translation factors.[3,217] Although the functions on these proteins have not been studied in the native virus-host systems, the activity of some of the aaRS has been demonstrated *in vitro*, and the conservation of the catalytic amino acids indicates that all the viral aaRS are active.[2] Thus, it appears highly likely that virus proteins complement rather than inhibit the host translation system. The presence of multiple translation system components among the mimivirus proteins fueled speculation on the origin of giant viruses from cellular ancestors by reductive evolution.[38,153,192] However, the distribution of the translation system components among the giant viruses is extremely patchy, and phylogenetic analysis indicates that these proteins have been acquired piecemeal during virus evolution.[259,270] Notably, a variety of bacterial and archaeal members of *Caudoviricetes* encode varying sets of ribosomal proteins,[181] numerous tRNAs, and diverse tRNA metabolism genes, occasionally, including aaRS.[89,168]

Analogously to the silencing repressors in viruses of eukaryotes, viruses of bacteria and archaea encode many proteins that target the prokaryote defense machinery, in particular CRISPR adaptive immune systems. Thanks to the CRISPR boom, the anti-CRISPR proteins (ACRs) have been studied in greater detail than other antidefense proteins of prokaryote viruses.[41,124,158,257] The ACRs show enormous structural and functional diversity.[257] The spread of the ACRs among bacterial and archaeal viruses is extremely nonuniform. Some viruses, for example, certain

rudiviruses in the realm *Adnaviria*, encode multiple ACRs that can account for up to 25% of the genome coding capacity, whereas other, related viruses appear to encode many fewer ACRs or none at all.[14,21,88] There is little sequence and even structure conservation among the ACRs from different viruses except for closely related ones, suggestive of rapid sequence evolution and, possibly, de novo emergence of these proteins, again, analogously to the silencing suppressors of plant viruses. Most of the ACRs are small proteins that inhibit a specific variety of CRISPR systems by binding to different parts of the large CRISPR effector complexes (or multidomain effector proteins) and blocking their activity. Some of these proteins are DNA mimics that form unproductive complexes with the CRISPR effectors.[71,166,225] Most of the ACRs lack any enzymatic activity, but there are notable exceptions, such as the viral ring nuclease that is widely spread among bacterial and archaeal viruses, and cleaves cyclic oligoadenylates, abrogating dormancy or cell death induction by type III CRISPR systems that is triggered by these second signal molecules.[14] Notably, this viral ring nuclease adopts a unique protein fold, so far not detected in any other proteins, making its origin enigmatic. Computational methods for ACR prediction from viral genome sequences that have been developed on the basis of salient characteristics of the ACR proteins and genes, such as small size, close gene spacing, and adjacency to genes encoding transcription repressors regulating their expression, indicate that bacterial and archaeal viruses within *Duplodnaviria* and *Adnaviria* encode numerous, still uncharacterized ACRs.[86] Moreover, diverse proteins encoded by prokaryote viruses, some resembling the ACRs in general properties, including the lack of readily identifiable origin, most likely, inhibit other defense systems of bacteria and archaea.[20]

Antidefense systems probably have been studied in greatest detail in chordopoxviruses, in which about 100 of the ~200 encoded proteins have dedicated functions in antidefense.[223] Multiple chordopoxvirus proteins block different innate immunity pathways, in particular, the interferon-mediated resistance, the ubiquitin-proteasome system, and apoptosis, often acting as dominant negative inhibitors.[26,186,187] For example, vaccinia virus (VACV) protein E3 contains a dsRNA-binding domain and functions as a dominant negative inhibitor of the PKR kinase through the formation of unproductive complexes with dsRNA, preventing activation of PKR.[151,176] An unrelated protein, K3, is a structural mimic of the translation initiation factor eIF2a and inhibits via completely different mechanism, directly binding the kinase.[57] Notably, chordopoxviruses encompass four families of defense proteins, each consisting of several paralogs, two of which include proteins containing repetitive structures, namely, Kelch and TPR repeats, as well as Bcl-2 domains inhibiting different stages of apoptosis and so-called PIE (Poxvirus Immune Evasion) domains.[223] The Bcl-2 proteins are a typical case of recruitment of host proteins as dominant negative inhibitors of the respective defense pathways.[149,243] Phylogenetic analysis shows that these protein families evolved by serial gene duplication during poxvirus evolution, following the initial capture by an ancestral chordopoxvirus.[223] The origins of most of these proteins can be generically traced to animal ancestors, but not at the level of specific genes. Moreover, the PIE domain fold appears to be unique, with no similarity to any available protein structures.[194] Taken together, these observations indicate that most of the virus antidefense proteins are substantially altered upon recruitment by viruses, in some cases, even through core fold rearrangements. However, there are some exceptions to this trend, when an apparently recently acquired protein retains high sequence similarity to an obvious ancestor in the host, for example, serpins, inhibitors of caspases that prevent apoptosis.[26]

The repertoire of poxvirus antidefense proteins fully depends on the host biology. Indeed, fish poxviruses, the deepest branch among chordopoxviruses, lack all the characteristic antidefense proteins present in the rest of the group and instead encode a roughly equivalent number of proteins without detectable similarity in the current database.[73] By implication, these proteins can be suspected to function in antidefense, but no specific indications can be gleaned from the analysis of their sequences.

Dark Matter of Virus Proteomes

Fast evolution that often obscures ancestry is arguably one of the key features of virus proteins. Despite the small genome size of most RNA viruses, even these encode many proteins and domains without detectable homologs outside the respective group of viruses. For example, a substantial part of the nidovirus polyproteins remains completely uncharacterized despite conservation in related viruses.[85,220] In the preceding section, we mention silencing suppressors encoded by diverse plant viruses. Most of these are small proteins without detectable homologs among known proteins, and the only information on these proteins comes from direct experiments on a handful of model viruses. The enormous variety of uncharacterized viruses encode their own “ORFans” (a nickname for uncharacterized, poorly conserved ORFs) that can be tentatively implicated in antidefense and perhaps other aspects of virus-host interactions, but their specific functions are currently unpredictable, and their origins remain obscure.[263] The ssDNA viruses in the realm *Monodnaviria* have tiny genomes with few genes, and the encoded proteins consist of known domains except, again, for some uncharacterized small proteins. A distinct family of viruses with small ssDNA genomes, *Anelloviridae*, common commensals of animals including humans, encode several proteins, none of which has detectable homologs outside this virus family.[108,254] Using highly sensitive methods for protein structure prediction, it became possible to determine that the CP of anelloviruses actually is a highly derived SJR protein, but the rest remain dark matter. The viruses with the smallest known genomes, members of the realm *Ribozyviria* that includes human hepatitis delta virus (HDV) and its relatives from other animals,[205] are thought to originate from viroidlike, noncoding infectious agents and encode a single protein that forms the virus nucleocapsid.[128,152] No homologs of this protein have been detected so far. Thus, the entire proteome of this virus realm is dark matter.

In viruses with larger dsDNA genomes, the fraction of protein dark matter differs widely. In the well-characterized poxviruses and herpesviruses, the domain architectures as well as biochemical and biological functions of most proteins are known, and the origins of many from cellular ancestors are apparent, even if not down to a specific host gene, due to the high divergence of most virus proteins. However, in other viruses with large genomes, in particular, the giant pandoraviruses,[154] most of the proteins represent dark matter. An even higher fraction of such ORFans, up to 90% of the (predicted) proteins, has been reported for large dsDNA viruses that currently could not be classified into any of the two major realms, such a nimaviruses[253] and yaravirus,[23] in which all proteins except for a few VHP remain complete unknowns.

The dark matter of virus proteomes can be classified into two categories that can be colloquially dubbed “knowable unknowns” and “unknowable unknowns,” respectively. The first category consists of highly derived descendants of cellular proteins whereas the second one includes proteins that might have originated in viruses *de novo*, from noncoding sequences. For the “knowable unknowns,” light can be shed on their origins through the application of sensitive methods for detection of sequence and structure similarity. A notable case in point is the large group of the so-called crAss-like phages that includes some of the most abundant phages infecting bacteria in the human gut microbiome.[54] When the first crAssphage was discovered, no homologs were detected for more than 80% of its predicted proteins, and even the expected VHP, such as the HK97 fold CP, were not identified.[52] However, subsequent analysis that combined the discovery of numerous related phages and search of their protein sequences using sensitive methods established the identity and likely origins of the majority of these unknowns, leaving only about one-third of the proteins within the dark matter.[267,269] With the decisive progress made in the field of protein structure prediction, with AlphaFold2[107] and RoseTTAFold,[17] it can be expected that numerous knowable unknowns among virus proteins leave the dark matter realm

soon.

Many other virus proteins, however, such as the silencing suppressors in plant viruses and ACRs in bacterial and archaeal viruses, seem to be unknowable unknowns. Typically, these are small proteins that are poorly conserved even among closely related viruses and no homologs detected even using the most sensitive available methods. These proteins can be suspected to have originated de novo although demonstrating this origin definitively is difficult except for proteins that evolve by overprinting, that is, as an alternative reading frame within other genes, for which the *de novo* scenario appears a certainty.[201,202] The lysis proteins of leviviruses are a typical case, and analogous proteins in alternative frames are also encoded by other RNA viruses and some ssDNA viruses.

Exaptation and Recruitment of Host Proteins as Major Routes of Virus Protein Evolution

The massive comparative analyses of virus proteins performed in the last few years provide for some generalizations on the routes of virus proteome evolution. With the apparent exception of the several VHPs that play key roles in virus genome replication and are likely to be direct descendants of enzymes that catalyzed the replication of primordial replicators, the rest of virus evolution appears to be largely a history of exaptation (Fig. 12.9). Exaptation was defined by Gould and Vrba as recruitment of biological structures for roles distinct from their original functions shaped by adaptation.[81] Although originally formulated in the context of organismal biology, the concept of exaptation is readily expandable and is a powerful explanatory framework for many aspects of molecular evolution. In virus evolution, exaptation is traceable back to the earliest stage, the recruitment of cellular carbohydrate-binding proteins as viral CPs, in particular, the SJR domains that apparently were recruited on several independent occasions.[138] Notably, despite the original reconstructions of the evolution of the DJR CP via SJR duplication in a virus genome, a more detailed investigation revealed an independent exaptation, again of a carbohydrate-active enzyme, a glycoside hydrolase.[144] Characteristically, the giant pandoraviruses that lost the ancestral DJR CP of *Nucleocytovirecetes* (and with it, the icosahedral capsid itself) also recruited an inactivated glycoside hydrolase of a different family as their major virion protein.[145] In small viruses, the principal adaptation of the CPs for their role in the virions is the acquisition of positively charged residues that interact with the virus genomic RNA or DNA. Typically, these positive charges reside in terminal extensions of the CPs such that exaptation does not substantially affect the core protein fold.

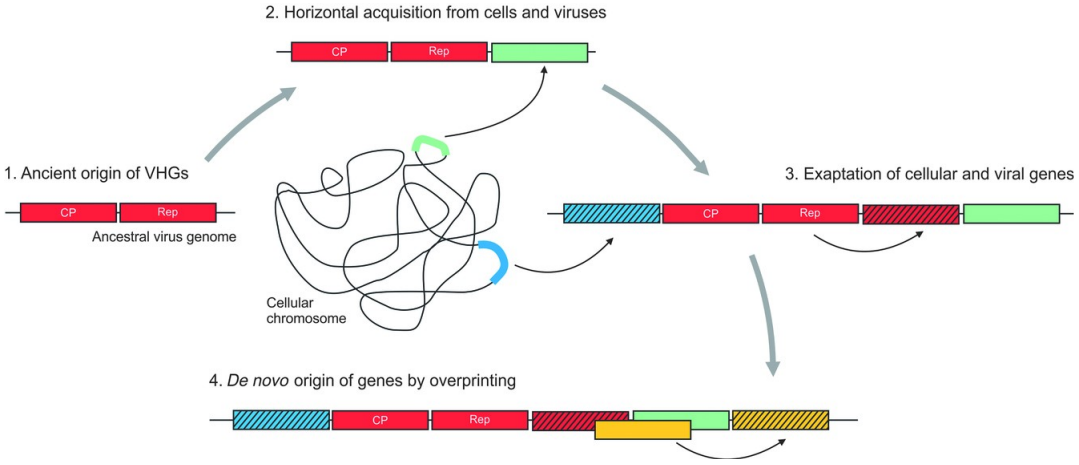

FIGURE 12.9 **Routes of evolution of viral proteins**.

Several other cases of emergence of major virion protein via exaptation of host proteins have been documented.[138] One notable example is the matrix protein of retroviruses, which is a derivative of the DNA-binding helix-turn-helix domain of transposon integrases. Another case in point are the matrix proteins of the viruses in the order *Mononegavirales* (phylum *Negarnaviricota*) that appear to have been derived from cyclophilins, molecular chaperones with peptidyl-prolyl-isomerase activity. When discussing the evolution of CPs above, we already mentioned the CP of alphaviruses, which is a derived chymotrypsinlike protease. In this case, the route of exaptation was apparently complex, with the protease first acquired by members of *Flaviviridae* and employed for polyprotein processing, followed by the gene transfer to alphaviruses, in which exaptation for the CP function occurred. The last two examples illustrate an important trend of exaptive evolution of virus proteins, namely, recruitment of enzymes for structural roles accompanied by loss of the enzymatic activity.

The numerous cases of recruitment of cellular proteins by viruses span a wide range of protein adaptation and evolutionary modification. Some of the recruited proteins effectively retain the same ancestral functions, for instance, enzymes involved in virus DNA replication or nucleotide metabolism. In such directly recruited viral enzymes, not only the protein fold but also the catalytic amino acids are conserved, and accordingly, the similarity to the cellular ancestors remains pronounced. Then, there are many exaptations that involve a limited change to the respective protein, notably, in the cases when a protein recruited by viruses functions as a mimic of a host protein involved in a particular antivirus defense pathway and hence a dominant negative inhibitor of that pathway. Soluble cytokine receptors and DEATH domain functioning as apoptosis inhibitors, both encoded by poxviruses, are good examples of such evolutionary strategy.[9,265] These proteins typically are represented in relatively narrow groups of viruses. The cellular ancestry of such proteins is readily discernible, typically, via straightforward sequence comparison. The CPs discussed above are farther removed from their cellular ancestors on the spectrum of virus exaptations and are only detectable by advanced sequence analysis approaches or by structure comparison. In these cases, there is a clear mechanistic similarity between the original function of a protein and that in viruses, even though the biological roles are quite different. Finally, some virus proteins evolve via exaptation of cellular proteins for functions that are not obviously related to the original ones. The discovery of ancestry is such cases comes as a surprise and often requires the most sensitive and/or structural comparisons. A relevant example is the poxvirus structural protein F12 that turned out to be a derived, inactivated DNA polymerase.[268] Similarly, in herpesviruses, protein UL8 is an inactivated family B DNA polymerase, which was recruited to function as a nonenzymatic, yet essential component of the helicase-primase complex, implicated in multiple protein-protein interactions.[110] It appears likely that the extent of such radical exaptation of host proteins by viruses is substantially underappreciated because of the major changes of the involved protein sequences and even structures. Many more such cases are likely to be discovered through comprehensive prediction of virus protein structures using the new, powerful methods.

Concluding Remarks: Organization of the Virus Pan-proteome and Challenges in its Analysis

The virus pan-proteome, that is, the entirety of proteins encoded by viruses, is the largest protein pool on earth, apparently spanning a much greater region of the sequence space than the pan-proteome of all cellular life forms combined. This is the case because viruses with large genomes encode numerous proteins unique to narrow groups of viruses. Our knowledge of the diversity of viromes appears insufficient for a robust quantitative estimate of the size of the virus pan-proteome, but beyond doubt, there are in the least many millions of groups of related viruses and hence billions of virus proteins. A key common feature of virus proteins is their fast, albeit widely varying, evolutionary change. At coarse grain and with some degree of arbitrariness, the virus pan-proteome can be classified into four classes of proteins that differ in their evolutionary conservation and spread across the virosphere (Fig. 12.10):

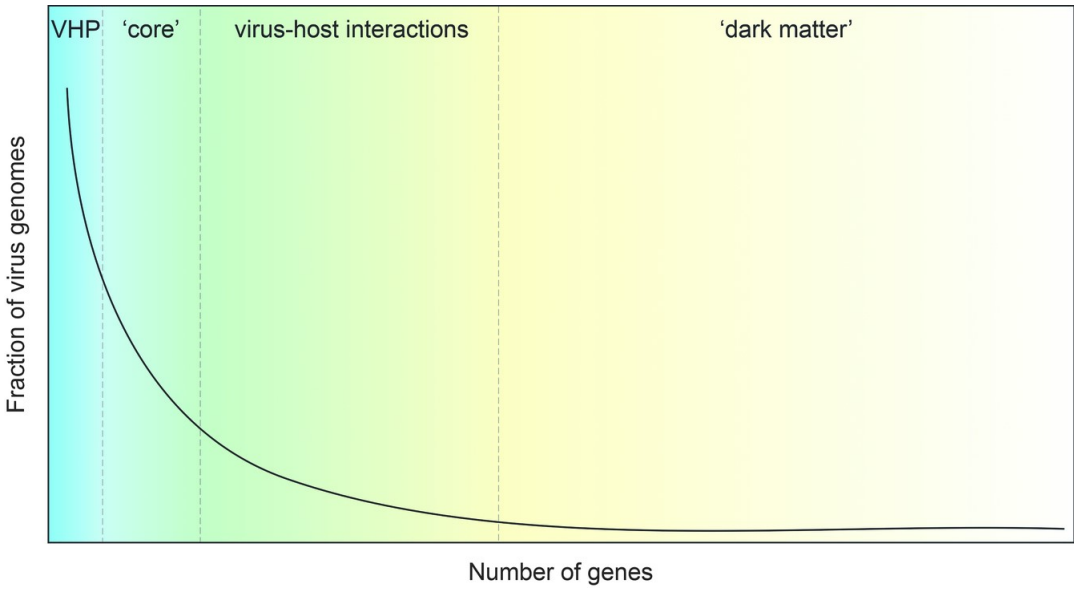

FIGURE 12.10 **Frequency of the four functional gene categories in viral genomes**. The curve is approximate, based on the results of comparative analysis of virus genomes, but not reflecting exact numbers.

i. the VHPs that are broadly conserved across different realms of viruses.

ii. proteins involved in core virus functions, such as replication, expression, and virion formation, but typically represented within a single virus realm or kingdom.

iii. proteins involved in virus-host interactions, primarily, counteracting host defenses, typically, conserved only in narrow groups of viruses and evolving at a high rate.

iv. dark matter, that is, proteins without detectable homologs or known functions, almost in all cases shared only by closely related viruses. The boundary between the latter two classes of virus proteins is, obviously, porous, so that as the provenance and functionality of the dark matter proteins are clarified, they migrate into the virus-host interaction category. Indeed, most of the current unknowns can be expected to be involved in various virus-host interactions.

Apart from the few VHPs that seem to originate from the primordial protein pool, the bulk of the virus pan-proteome is derived from cellular proteins, via direct recruitment of proteins with activities relevant for virus reproduction as well as extensive exaptation. The degree of change to the sequences and structures of proteins acquired by viruses from hosts reflects the extent of functional change. Genes encoding recruited proteins that retain their activities may experience a period of accelerated evolution once integrated into virus genomes, but the magnitude of such acceleration is constrained by the requirement for preservation of active sites, in addition to the protein fold. In contrast, exaptation events cover a broad range of sequence and structure change, from high level of sequence conservation despite a functional switch to extreme divergence, including structural rearrangement that can make the ancestry of virus proteins hard if possible at all to trace. Comprehensive experimental and computational analyses of virus protein structures have the potential to reveal many more cases of radical protein change accompanying exaptation.

In addition to the recruitment and exaptation of host proteins, virus genomes might be a hotbed of *de novo* protein emergence. This route of protein origin is obvious in cases of overprinting, but hard to convincingly demonstrate on other occasions. Nevertheless, *de novo* origin of numerous small proteins encoded by diverse viruses, for example ACRs, appears plausible and could be an important source of new protein folds.

Virus proteomes, clearly, are not random collections of proteins. Rather, the recruitment of cellular proteins for roles in viral reproduction follows a logic dictated by functionalities that are relevant for viruses. Under this logic, different groups of viruses convergently capture distinct, often unrelated proteins providing similar functionalities, for example, helicases and proteases of several different families. Further, viruses acquire and possibly evolve de novo diverse proteins that target the defense systems that are most prominent in their respective hosts, such as CRISPR in bacteria and archaea, RNAi in plants, and apoptosis in animals. An important part of the logic of virus evolution is the "guns for hire" trend whereby viruses capture components of the host defense systems and repurpose them for antidefense, for example, as dominant negative inhibitors.[131]

Concluding the discussion of the major trends in the evolution of virus proteins and proteomes, it seems prudent to mention some serious challenges confronted by the analysis of deep connections among viral proteins. The strongest challenge, arguably, is the fast pace of change of viral protein sequences and even structures, because of which many relationships can remain unnoticed. Comprehensive structural

characterization of viral proteomes is key. With the advent of the latest generation of structure modeling methods, this has become a realistic prospect, but the work itself and careful analysis and interpretation of the results still lie in the future. Fast evolution of viral proteins, especially, perhaps, at times of evolutionary transitions that include emergence of new groups of viruses also seriously compromises the robustness of phylogenetic analyses. Methodological improvements are badly needed and may come from refined methods for phylogenetic tree construction based on direct protein structure comparisons. Further characterization of the diversity of the virus proteomes combined with in-depth structural and functional studies of virus proteins using improved methods can be expected to clarify the architecture of the virus pan-proteome and the logic of virus evolution.

Epidemiology

Epidemiology is the science of measuring patterns of health and disease and the impact of interventions across time, space, and populations. Basic concepts of infectious disease epidemiology, including incubation period, reproductive number, and herd immunity, entered public discourse during the SARS-CoV-2 pandemic and are no longer the special purview of epidemiologists, public health practitioners, infectious disease specialists, and virologists. Epidemiologic patterns of viral diseases, such as smallpox and measles, were recognized and characterized long before their causal agents were discovered, and viral epidemiology was one of the first aspects of the science of virology to be developed. Evolving insights into the molecular biology, genomics, pathogenesis, and host immune responses to viruses have provided an increasingly rational basis for understanding the epidemiology of viruses.

Historically, epidemiology has its roots in infectious diseases, with methods for studying chronic diseases such as diabetes and cardiovascular diseases maturing after World War II. What distinguishes infectious disease epidemiology from chronic disease epidemiology is that the former accounts for *dependent happenings*, a term introduced by Ronald Ross, in which the incidence of a disease depends on its prevalence within a population.[81] Traditional statistical methods that are used in epidemiologic studies to infer relationships between exposure and disease outcome assume that the outcome in one individual is independent of the outcome in other individuals, an assumption that is invalid for communicable viral infections.[66] This dependent nature of viral infections is what makes their epidemiology so dynamic and complex, and their study so fascinating.

Basic Definitions and Methods of Epidemiology

Measures of Disease Burden

The quantification of disease occurrence is the cardinal feature of epidemiology. To accomplish this, the concept of rates was introduced, and rates have become the basic coinage of epidemiology (Fig. 13.1). Rates are fractions in which the numerator is the number of cases of disease and the denominator is a measure of the population. The *incidence rate* (also called the *attack rate* for acute infectious diseases) is used to quantify the number of new infections. A population and a time frame are defined, and the number of new cases in that population during that interval of time is enumerated. The denominator includes both the size of population and the time frame of measurement and is often expressed as person-years (or any other standard interval of time: eg, “thousand person-years” or “hundred person-weeks”). The incidence rate is then expressed as “cases per thousand person-years” or a similar term. The time element may not be explicitly stated, in which case the reader must then determine by context the time frame used.

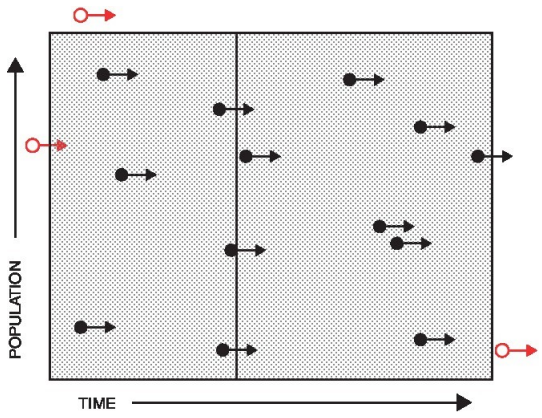

FIGURE 13.1 **Computation of incidence rate and prevalence ratio**. The *shaded area* defines a population and a time frame that can be expressed as person-time units. Cases of disease are indicated by *circles* (placed according to the date of their onset) and *arrows* for duration of illness. *Solid black circles* would be counted for computation of incidence, whereas *open red circles* would be excluded because they had onset outside the designated time frame or were resident outside the population boundaries. Incidence equals the number of cases divided by population-time units. Prevalence would be determined by a *single vertical line* across the hatched area: cases active at that time point would be divided by the size of the population to compute the prevalence.

Prevalence is not a rate but a proportion and refers to the total number of cases present in a defined population within a specified time interval. Thus, the numerator in prevalence includes not just new cases but cases carried forward from the period prior to the specified time interval, a distinction more important for chronic than acute viral infections. When a point or period prevalence is computed, a particular narrow time point or frame is selected (eg, 1 month), and the average population size within that time frame constitutes the denominator. All prevalent cases during that period constitute the numerator. Prevalence is expressed as a ratio, such as “cases per million persons.” Note that there is no time unit in this ratio.

In calculating incidence and prevalence, persons counted in the denominator should be at risk to be a case in the numerator if infected. For instance, if incidence is computed for the population of Baltimore for 2022, a case hospitalized in the city but resident outside the city would not be counted. A case with onset in December 2021 but still ill or infected in 2022 would not be counted as an incident case but would be a prevalent case. Immune individuals are often included in the denominator because their measurement is not possible without additional information, such as from serological surveys. The *force of infection* is the rate at which susceptible individuals are infected.

The relationship between incidence and prevalence depends on the average duration of disease, and changes in incidence and prevalence may be divergent. A control program for human immunodeficiency virus (HIV) infection, for example, could decrease HIV incidence through effective preventative measures but increase the prevalence of HIV infection through access to antiretroviral therapy and improved survival.

Data Sources for Measuring Disease Burden

In practice, accurate data collection for the computation of incidence and prevalence is often a major undertaking, whereas the computations are relatively simple. Such data collection requires access to populations (eg, at health care facilities, the workplace, or at home) and accurate diagnostic tests. Epidemiologists must frequently work with incomplete and inaccurate information, including nonrepresentative study populations and diagnostic tests with imperfect sensitivity and specificity. In some settings, denominator (population) information is accurate and the challenge is measuring the numerator (cases). But in other settings, accurate population data may be unavailable, further hindering efforts to estimate incidence and prevalence.

For infectious diseases, several sources of case data are routinely available. *Passive surveillance* denotes the reporting of disease by health care workers. By law, many viral diseases are designated as "reportable," and in theory, the reporting of all cases is required. Cases are reported by practicing physicians, hospitals, or laboratories to local health jurisdictions, which in turn relay reports to a central state office where they are transmitted to a national center (eg, the U.S. Centers for Disease Control and Prevention). The weakest link is the initial report; in practice, only a small fraction of cases of many common viral diseases present for care, are correctly identified, and are reported to the national center (reflecting the *reporting efficiency*). However, if the proportion of cases reported is consistent between geographic locales and between years, these reports may be used to monitor trends. Consistency of reporting efficiency is important because the proportion of cases reported may increase if the number of cases decreases. Changes in the case definition, for example, also may result in spurious changes in surveillance data. With SARS-CoV-2, increasing availability of home testing with rapid diagnostic tests led to under-reporting.[77] Reporting of certain rare or serious diseases, such as acquired immunodeficiency syndrome (AIDS), is often close to 100%, and reported cases can be used with greater confidence for calculation of rates.

With increasing interest in the pandemic spread of respiratory viruses and the emergence of new zoonotic viral pathogens, passive global disease surveillance networks have been established to provide data on disease incidence and transmission in real time, including the Program for Monitoring Emerging Diseases (ProMED) and the World Health Organization's Global Outbreak Alert and Response Network (GOARN). Such surveillance systems will likely be strengthened in response to the SARS-CoV-2 pandemic but are only as good as the timeliness and accuracy of reporting. Countries should be encouraged to report outbreaks as soon as they are identified.

Active surveillance through epidemic investigation is the traditional approach to collecting information on disease outbreaks. Such investigations are usually initiated by public health authorities but may be instigated by health care workers or patient families. The investigation is tailored to the situation and resources available. The goals of outbreak investigations are to (1) establish a case definition by classifying the illness and determining the causative organism; (2) assess the extent of the outbreak and its economic and health impact; (3) mitigate the outbreak and prevent future outbreaks; and (4) inform accurate and timely health communications with the public. The first recognition of a new disease or isolation of a previously unknown virus results from an epidemic investigation.

Serological surveys may be used to detect the immunologic footprints that a virus leaves in a population. Serosurveys are particularly useful for viruses because most viral infections leave an imprint on all infected individuals—that is, the presence of virus-specific immunoglobulin G (IgG) antibodies that can persist for years and in some cases, such as measles-specific IgG, many decades. Incident viral infections can be identified using assays for immunoglobulin M (IgM) antibodies or antibody avidity, whereas IgG antibodies indicate prior infection or vaccination. Because many viruses cause asymptomatic infections or nondescript illnesses in addition to diagnosable diseases, serological surveys identify inapparent as well as apparent infections. Serological surveys have been critical to understanding the extent of SARS-CoV-2 infection,[6] and repeated serological surveys can be used to track changes in cumulative exposure by age and geographic location over the course of the epidemic as well as to evaluate the impact of nonpharmaceutical interventions. However, household-based serosurveys can be labor intensive and expensive and results are not often available in time for prompt public health decision-making. The use of residual specimens from blood banks or health care facilities can lower the costs associated with serosurveys but may be less representative of the general population.

Cohort and Case-Control Study Designs

Epidemiological investigations not only provide measures of disease burden but also of risk factors for disease. To assess risk factors associated with specific viral infections, comparisons between those with and without the infection are necessary. Different types of study designs are used to make these comparisons, depending on the research question, viral infection, outcomes and exposures of interest, study population, and available resources. In general, epidemiologists attempt to test the hypothesis that one or more population variables influence the occurrence of a specified disease and, if so, to quantify this effect and estimate confidence limits. There are two basic observational designs used for such studies, *cohort* and *case-control* studies, shown in Figure 13.2, although other study designs are also used.

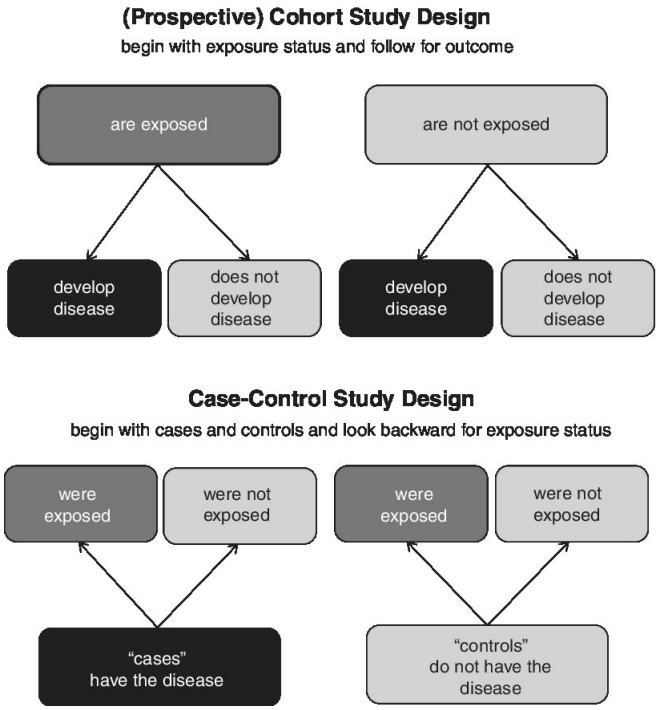

FIGURE 13.2 **Schematic of two basic epidemiological study designs**. **Upper panel**.(Prospective) cohort study design. **Lower panel**. Case-control study design.

Cohort Studies

In a cohort study, the population falls into one of two groups, one with and one without a specified exposure or attribute. Both groups are followed and the *incidence* of the disease under study is measured. Incidence rates for both groups are then computed and compared. In a prospective cohort study, the exposure is measured and participants are then followed into the future. In a retrospective cohort study, the exposure is recorded from past measurements and the disease outcome determined up to the present time. A hypothetical example is shown in Table 13.1. In this example, the population attribute is immunization against a specified viral disease, and the attack rate in the immunized population is one-third the rate in the unimmunized control group. The *relative risk* (RR) associated with immunization is 0.33, and vaccine efficacy is 67%, derived from the equation (1 − RR) × 100. The important assumption underlying the validity of such a study is that the immunized and unimmunized groups are at equal risk of disease. For various reasons, this assumption may not be correct. Differences in the risk of disease between two study groups may be minimized by random allocation of the exposure (in this case, the vaccine) when that is deemed ethical, as done in randomized clinical trials. However, random allocation of exposure is not possible unless the study is of an intervention. Stratifying each study arm according to population characteristics such as age, race, and socioeconomic status and then comparing rates for each subgroup can be used to test the assumption that both groups are at equal risk of disease. More commonly, these variables are adjusted for in a regression analysis.

TABLE 13.1 Hypothetical data to illustrate computations for a cohort and a case-control study of vaccine efficacy

Group	2012 Cases	Population	Incident Cases per 100 000	Relative Risk
Cohort study[a]				
Vaccinated	100	1 000 000	10	0.33
Unvaccinated	900	3 000 000	30	
Group	**Cases**	**Controls**	**Odds**	**Odds Ratio**
Case-control study[b]				
Vaccinated	10	25	10/90	0.33
Unvaccinated	90	75	25/75	

Vaccine efficacy = 1 − relative risk = 0.67.

[a]Cohort study: Two populations, vaccinated and not vaccinated, are followed for 1 year, and incident cases occurring in each group are recorded. Risk for each exposure group is calculated, and the ratio of risks gives the relative risk for those who were vaccinated. In this instance, relative risk is lower for those with than without the attribute (immunization). The validity of this design depends on the assumption that vaccinated and not vaccinated groups would be at equal risk except for the attribute under study.

[b]Case-control study: A group of 100 cases and 100 controls are randomly picked to be representative of the groups from which they are drawn. Subjects in each group are classified as vaccinated or not vaccinated. The odds of a case being exposed (vaccinated) and the odds of the control being exposed are used to compute the odds ratio, which provides an estimate of the relative risk. The validity of the case-control design depends on two assumptions: (1) the case and control groups are representative of the larger groups from which they are drawn and (2) the number of cases is very small (<1/10) relative to the total population.

More complex study designs are used to measure indirect effects of vaccines or other interventions. Indirect effects are when protection is conferred on those who do not receive the vaccine or intervention and is a consequence of the dependent nature of viral infections as described above.[44] Such indirect effects include protection of nonvaccinated individuals through decreased transmission from vaccinated individuals or the decreased probability of an infectious individual encountering a susceptible individual, referred to as herd immunity.[26] Cluster randomized trials—for example, studies in which communities rather than individuals are randomized to receive the intervention—allow measurement of the indirect effects of vaccines by comparing the risk of disease outcomes in nonvaccinated individuals residing in intervention and control communities.[43] If an indirect effect is present, the incidence of disease will be lower among nonvaccinated individuals in the intervention community (eg, the community in which the vaccine was administered) compared to nonvaccinated individuals in the control community with no vaccination.

Case-Control Studies

Cohort studies usually require extensive resources and time because they necessitate the enrollment of large numbers of subjects who must be followed for a period of months or years. The less frequent the expectation of disease, the larger the population or longer the follow-up needed. The costs of prospective cohort studies can be great, limiting them to situations such as the evaluation of a new drug or vaccine, as illustrated in Table 13.2. In contrast, case-control studies can be more cost-effective, particularly if the disease outcome is rare, because they involve smaller numbers of subjects and do not require longitudinal follow-up. Table 13.1 shows a simplified version of such a study. In this instance, 100 cases of the study disease and 100 unaffected control subjects are identified and classified according to the exposure or attribute (vaccination) under study. For both cases and controls, the odds are computed and an odds ratio is estimated. Because, under certain assumptions, the odds ratios have the same relationship as the rates computed in the prospective study shown in the upper half of Table 13.1, the relative risk can be estimated as the ratio of the two odds (0.4/1.2 = 0.33). Two assumptions underlie the validity of the case-control design and analysis, specifically the use of the odds ratio as an estimate of relative risk: the two samples (cases and controls) must be representative of the population from which they are drawn, and the incidence of disease must be low (eg, cases comprise <10% of the total population) so that the odds ratio more closely approximates the relative risk. Because case-control studies are particularly useful to study risk factors for rare diseases, the second assumption is usually correct. The main challenge in designing case-control studies is the choice of valid and representative control groups. Another challenge is accurately measuring the risk of exposure by avoiding information biases, as can occur when cases are more likely to recall or report an exposure than controls.

TABLE 13.2 The 1954 field trial of poliomyelitis vaccine: comparison of attack rates for vaccinated and unvaccinated children[a]

Study Area	Vaccination Group	Population	Paralytic Cases	Attack Rate per 100 000	Estimated Vaccine Efficacy
Placebo areas	Vaccinated Placebo Not inoculated	201 000 201 000 339 000	33 115 121	16 57 36	72%
Observed areas	Vaccinated Controls Not inoculated	222 000 725 000 124 000	38 330 43	17 46 35	63%

[a]Vaccine was administered in the spring of 1954, and children were followed prospectively through the summer poliomyelitis season. Placebo area included volunteers randomized into vaccinated or received placebo inoculations, and nonvolunteers (not inoculated). Observed areas were divided into second-grade volunteers (vaccinated), first and third graders (controls), and second-grade nonvolunteers (not inoculated).

From Francis T Jr, Napier JA, Voight RB, et al. *Evaluation of the 1954 Field Trial of Poliomyelitis Vaccine. Final Report*. University of Michigan; 1957.

A type of case-control study increasingly used to measure vaccine effectiveness is the test-negative design in which the same case definition is used for cases and controls but cases are defined by a positive laboratory test and controls by a negative laboratory test. The test-negative design can be more efficient as both cases and controls are enrolled at the same study site using the same case definition and reduces potential selection biases by ensuring both cases and controls are from the same source population.

Descriptive Epidemiology

Descriptions of epidemic or endemic diseases typically include the parameters person, place, and time. The collection and visualization of these descriptive data is a necessary first step in understanding the epidemiologic processes leading to occurrence, distribution, and course of an epidemic. This simple, systematic approach is a surprisingly powerful tool in analysis.

Person

In tabulating cases of viral infection, the epidemiologist looks for features that distinguish affected persons from the general population to identify risk factors for infection and disease. Clues may exist in demographic features and behavioral characteristics, such as age, sex, gender, race/ethnicity, occupation, residence, or any aspect of personal behavior. Such variables are frequently the most important initial step in understanding an outbreak and designing control measures.

The age distribution of viral infection reflects differences in risk. For many endemic human viruses, the cumulative incidence of infection reaches 100% of the population. In such instances, disease is confined to children or to children and young adults because older individuals are immune because of prior infection. Poliomyelitis prior to the introduction of vaccine is such an example, and differences in age distribution of disease in different regions or in the same population in different eras reflect differing transmission rates.[69] Where this enterovirus was transmitted readily, cases were confined to young children. However, in countries with access to clean water and sanitation, infection may be delayed so that poliomyelitis occurred up to age 30 years or older.[68]

Age-specific differences in case infection ratios can be a key determinant of epidemiologic patterns of disease. In some instances, infants experience much more severe disease than do adults. An important historical example is the outbreak of measles that occurred in the Faroe Islands in 1846,[73] long before measles was known to be caused by a virus. Because measles had not occurred in this isolated site for more than 50 years, women of childbearing age were seronegative, and their infants lacked maternal antibody. During the epidemic, the case fatality ratio was about 20% in infants and below 1% in children and young adults. On the other hand, hepatitis B virus causes inapparent but persistent infection in infants but acute liver disease followed by immunity in adults. In low- and some middle-income countries, infections are frequently transmitted from persistently infected mothers to their newborns, whereas infection in high-income countries is mainly transmitted to older children and adults. These differences account for the paradox that the attack rates for hepatitis B virus are higher in high-income countries, whereas cumulative infection rates are much higher and the virus carrier state is more frequent in low- and middle-income countries.

In addition to identifying individual characteristics associated with viral infection or disease, epidemiologists increasingly are interested in transmission networks critical to the dynamics of viral infections within populations.[54] Network theory and analysis is a complex subject with a long history in mathematics and sociology but has been developed by infectious disease epidemiologists, in part because of the ability to characterize complex social networks, such as large-scale social and sexual networks.[20] The epidemiologic study of social networks is facilitated by unique sampling strategies, including snowball sampling or respondent-driven sampling in which study participants are asked to recruit additional participants among their social contacts. For example, concurrent partnerships (as opposed to serial monogamy) can amplify the spread of HIV and other sexually transmitted infections.[60] Social networks were shown to affect transmission of 2009 H1N1 influenza virus and were responsible for cyclical patterns of transmission between the school, community, and household.[9] For SARS-CoV-2, social networks drove transmission patterns, including superspreading events.[13]

Place

Historically, mapping the distribution of disease preceded the development of epidemiology and became more significant with the introduction of place-specific rates. A famous example is John Snow's mapping of cholera cases during the Broad Street outbreak in London. Mapping spatial patterns of disease distribution remains one of the most powerful aspects of descriptive epidemiology and has been enhanced by remote sensing technologies[80] and sophisticated spatial analysis tools, including patch and network models.[79]

Spatial patterns of viral infections are not static but display complex dynamics, one of which is traveling waves of transmission. Measles virus transmission was shown to exhibit spatiotemporal traveling wave patterns in England and Wales, with regional movement from large cities to small towns.[38] The incidence of dengue hemorrhagic fever, a mosquito-borne disease caused by dengue virus, was characterized in Thailand by a spatiotemporal traveling wave emanating from the capital, Bangkok.[18] The spatiotemporal dynamics of rotavirus infection in the United States prior to the introduction of rotavirus vaccine, which typically started in the Southwest in late fall and ended in the Northeast 3 months later, was explained by spatiotemporal variation in birth rates and thus the introduction of susceptible hosts.[75]

These spatial patterns of viral infections are determined in part by human mobility patterns. Infectious disease epidemiologists use a wide array of tools to measure and characterize human movement patterns, including reported travel histories, GPS loggers worn by individuals, air traffic patterns, and mobile cell phone data.[91]

Time

Many acute viral infections exhibit striking seasonal patterns in incidence.[30] In general, three types of mechanisms have been hypothesized to explain the seasonality of viral infections. First are seasonal cycles in host resistance to infection, including seasonal differences in vitamin D levels.[21] The second involves changes in host behavior and contact patterns, particularly the role of schools as shown for measles virus.[28] Third is the role of climatic factors, particularly temperature and humidity. In temperate climates, some viral infections peak in the winter, whereas others peak in the summer. In general, respiratory infections spread more readily in the winter, although they may peak at different times. Conversely, the incidence of enteric viral infections peak in the summer, although rotaviruses are a striking exception. Arbovirus infections are confined to the summer months when their vectors are active. In the tropics, seasonal patterns of viral infections differ from patterns in temperate climates. Influenza virus transmission in the tropics can be either seasonal or relatively constant throughout the year.[87] Strong seasonal transmission of measles virus in sub-Saharan Africa generates large, irregular measles outbreaks and is an example of nonlinear, chaotic viral dynamics.[25]

Basic Concepts of Infectious Disease Epidemiology

Infectious disease epidemiology, including the epidemiology of viral infections, has its own set of basic concepts and methods, in part due to the dependent nature of communicable diseases.

Susceptibility and Immunity

Some acute viral infections confer lifelong immunity, such as measles and rubella.[7] Upon re-exposure after initial infection, there is often reinfection but with minimal virus replication and an anamnestic immune response. Such reinfections are usually covert and almost never severe, resulting in minimal or no shedding of infectious virus. For certain viruses, such as polioviruses or rhinoviruses, immunity is type specific and confers little protection against exposure to a different serotype. Viral variants, such as seasonal influenza A viruses or the omicron variant of SARS-CoV-2, also can escape immunity conferred by prior infection or vaccination with different variants.[14] Susceptibility may not be present immediately after birth. IgG antibodies are actively transported across the placenta, conferring protective immunity to neonates and young infants. For such viral infections, individuals move from a protected state to a susceptible one in the first year of life. Immunity can then be conferred by vaccination or infection.

These simple facts have profound implications for viral epidemiology. For epidemiologic purposes, a population may be divided into three groups: susceptible, infectious, and immune. For some viral infections, persons infected at any time in the past may be considered immune (recovered) and are protected from reinfection and unable to act as links in a transmission chain, whereas susceptible individuals can be

infected, become infectious, and experience disease. For other viral infections, such as the coronaviruses that cause the common cold, immune or recovered individuals may lose protective immunity and reenter the susceptible group. This compartmentalization of the population is the basis for simple SIR (susceptible, infectious, recovered) models of virus transmission[2] that can explain in part the periodicity ("waves") in incidence of many viral infections as the outcome of the buildup and decline of susceptible individuals.

Persistent viral infections differ from acute viral infections because the infected individual may be capable of transmitting the virus over many years and may develop disease at any time during virus persistence. For persistent viruses, the population may be divided into uninfected susceptibles and immune-but-infectious persons who carry serological markers of prior infection but who are still capable of acting as links in the chain of infection. Important examples are hepatitis B virus, HIV, and several herpesviruses (herpes simplex virus, varicella-zoster virus, and cytomegalovirus) that establish latent infection capable of reactivation.

Parameters That Determine Incidence

For acute viral infections, the following three parameters determine incidence: the proportion of the population susceptible, the proportion of the population that is infectious, and the rate of contact between susceptible and infectious individuals, with *contact* defined as an encounter sufficient for transmission. These three parameters constitute the core of dynamic infectious disease models as described below. The proportion of infected persons who become ill—the case infection ratio—determines the proportion of infected persons detected through case surveillance. This ratio can be high for some infections, such as measles and Ebola virus disease, but low for others, including polio. Table 13.3 shows estimated case infection ratios for five viral infections. Asymptomatic infections hindered SARS-CoV-2 surveillance and led to underestimates of the extent of transmission.

TABLE 13.3 Estimated case infection and case fatality ratios for selected viral infections

Virus	Cases per 100 Infections	Fatalities per 100 Cases	Comment
Smallpox	>95 >95	<1 25	Variola minor Variola major
Measles	>95 >95	0.1 2	United States, 1970 Africa, 1988
Poliomyelitis	<1	5	United States, 1955
Hepatitis B	50 <1	3 <0.1	United States, adults Taiwan, infants
Ebola	high high	42 71	DRC, 2020, Zaire ebolavirus Uganda, 2012, Sudan ebolavirus

Proportion Susceptible

When a population is exposed to an infectious individual with a specific virus, the susceptible part of the population will determine viral spread and account for all new cases. The proportion susceptible will reflect the history of infection with the specific virus in the population, the history of immunization for vaccine-preventable viral infections, and the duration of protective immunity following infection and vaccination. As we saw with SARS-Cov-2, states of susceptibility and protection are not all or none and one must be explicit about the timeframe and outcome of interest: susceptible to infection, disease, hospitalization, or death. For infections that confer life-long immunity, new susceptible individuals largely enter the population through births, and thus the birth rate is a key driver of viral transmission dynamics.

Proportion Infectious

The proportion of susceptibles who become infected, and subsequently infectious, during a fixed period (eg, year or season) can vary widely, depending on the dynamics of transmission, which is influenced by the density of susceptibles and contact patterns between susceptible and infectious individuals.

Rate of Contact Between Susceptible and Infectious Individuals

The rate of contact between susceptible and infectious individuals determines the dynamics of viral spread within a population. This rate depends on the mode of transmission (eg, contact, oral, airborne, or vector-borne), age-specific contact patterns or networks between individuals, and the distribution of susceptible and infectious individuals within a population. Spatial clustering of susceptible individuals can result in outbreaks despite a high proportion of immune individuals within the population.[89] Thus, understanding spatial heterogeneities in susceptibility is critical to understanding outbreak risk.

Case Infection and Fatality Ratios

The proportion of infections resulting in overt disease—the *pathogenicity* of the organism—is characteristic for each virus and is strikingly different for different agents. One of the most important early advances in viral epidemiology was the identification of inapparent or subclinical

infections and the insight that most infections caused by some viruses were asymptomatic. The relative frequency of subclinical infections is expressed as the *case infection ratio*—that is, the number of clinical cases per 100 infections. The lethality of disease is a different parameter that represents the *virulence* of the organism and is designated as the *case fatality ratio*. The case fatality ratio is the number of deaths attributable to an infection per 100 cases. Table 13.3 lists selected common viral infections and shows estimated case infection ratios and case fatality ratios for each. It is noteworthy that there is no regular relationship between the case infection ratio and severity of illness (ie, between pathogenicity and virulence). For instance, measles has a very high case infection ratio (>95:100) but a low case fatality ratio in settings with low levels of undernutrition and high access to care (<1:1000 in the United States). Conversely, poliomyelitis has a low case infection ratio (<1:100) but a higher case fatality ratio (~5:100). Determining the case infection ratio is an important objective of outbreak investigations of novel pathogens, such as SARS-CoV-2, as individuals with asymptomatic infection or mild illness can be important drivers of transmission. Typically, early in an outbreak, only cases that come to clinical attention are counted as incident cases, resulting in an underestimate of the true incidence. Accurate measurement of subclinical infection requires population-based surveys with laboratory confirmation (eg, serological surveys).

Incubation, Latent, and Infectious Periods

The course of infection in a single individual can be divided into several periods (Fig. 13.3).[27] The interval from acquisition of infection to onset of illness is the *incubation period*. Note that "onset of illness" must be explicitly defined for each disease and is often measured by the first day on which pathognomonic signs or symptoms are reported, such as a rash. The interval from acquisition of infection to onset of infectiousness is the *latent period*. For most viral diseases, the latent period is shorter than the incubation period. Consequently, the infected individual begins to shed virus prior to the onset of illness (smallpox was a notable exception) and continues to shed during and sometimes after recovery from the acute illness. The effectiveness of isolation measures is reduced when the latent period is significantly shorter than the incubation period as the infected individual is infectious prior to the onset of symptoms. The period during which the infected person is potentially infectious for others is the *infectious period*.

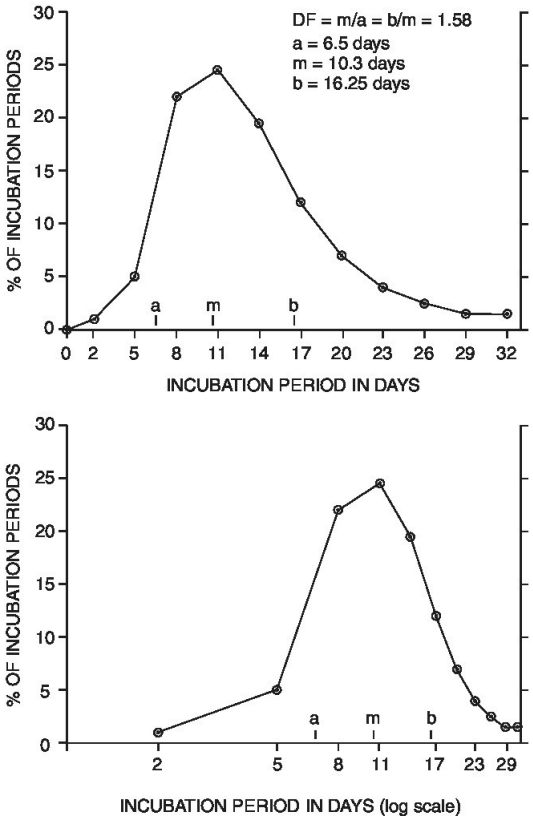

FIGURE 13.3 **Log-normal distribution of incubation periods**. **Upper panel**. Incubation period distribution is shown for poliomyelitis; there is a right-hand tail. **Lower panel**. The same incubation periods when plotted on a logarithmic scale. Logarithmic incubation period approximates a normal distribution, and the standard deviation may be computed (on the logarithmic scale). The dispersion factor (*DF*), a measure of the variation of incubation periods, is the antilogarithm of the standard deviation. The mean (*m*) is shown, together with the standard deviation (points *a* and *b* on the graph). The log DF equals the interval (log *m* to log *a*) or the interval (log *b* to log *m*). In this instance, *m* is about 10.3 days, *a* is 6.5 days, *b* is 16.25 days, and DF is 1.58—that is, about two-thirds of the incubation periods fall into the range (1.58 × mean) to (mean/1.58). (Data from Aycock WL, Luther EH. The incubation period of poliomyelitis. *J Prev Med*. 1929;3:103-120; Casey AE. The incubation period in epidemic poliomyelitis. *JAMA*. 1942;120:805-807; Horstmann DM, Paul JR. The incubation period in human poliomyelitis and its implications. *JAMA*. 1947;135:11-14; Nathanson N, Langmuir AD. The Cutter incident. *Am J Hyg*. 1963;78:16-28; Sartwell PE. The incubation period of poliomyelitis. *Am J Public Health Nations Health*. 1952;42:1403-1408.)

Incubation periods for any viral disease vary around the mean, as illustrated in Figure 13.4. When a frequency distribution of individual incubation periods is plotted, it usually has a longer tail at the high end of the distribution (right skewed). If the frequency is plotted against the logarithm of time, the data often approximate a normal distribution.[82] This log-normal distribution is characteristic of the incubation periods of many viral infections.[52]

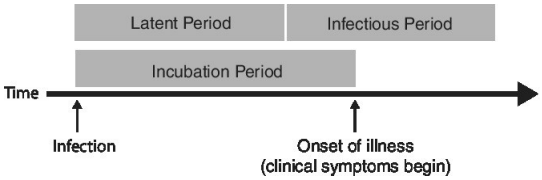

FIGURE 13.4 **Schematic of incubation, latent, and infectious periods**. The relative duration of the periods differs by specific viral infection. In this schematic, the latent period is shorter than the incubation period, implying an infected individual is infectious prior to the onset of symptoms.

The duration of the infectious period is one of the most important determinants of viral transmission dynamics. Acute viral infections are characterized by relatively short infectious periods and excretion of high titers of infectious virus over a short time is necessary to efficiently transmit the virus to susceptible hosts. Examples include measles, smallpox, and influenza viruses. In contrast, viruses with long infectious periods resulting from persistent infection do not require such highly efficient modes of transmission. Examples include hepatitis B virus and HIV. Hepatitis B virus is transmitted to susceptible household contacts at a frequency of <1 per 100 person-years exposure, and HIV is transmitted to sexual contacts at a rate of ~1 transmission per 100 to 1000 contact episodes, with the risk of transmission directly correlated with HIV viral load.[35] Despite inefficient transmission, the number of new infections caused by a persistently infected individual may be high because of the long infectious period. Viral infections can also be persistent due to intermittent periods of activation and latency, such as the herpesviruses (eg, herpes zoster). Thus, an individual may be infected in childhood and transmit infection 50 years later during a recrudescence.

Generation Time and Serial Interval

The average period between infection of an individual and transmission to others is the *generation time* and is primarily determined by the duration of the infectious and latent periods. From studies of selected outbreaks, the average interval between onsets of successive waves of cases (called the *serial interval*) has been determined, and the generation time is often assumed to be equal to this interval as the best approximation available. This is because it is often impossible to know the exact time of infection. These relationships are shown in Figure 13.5 for a typical acute viral infection. Generation time and transmissibility determine the kinetics of the infection. A virus with a relatively short generation time, such as influenza virus, can spread more rapidly than a virus such as poliovirus despite its lower transmissibility (R_0 for influenza virus is ~2 compared to 5-7 for polioviruses).

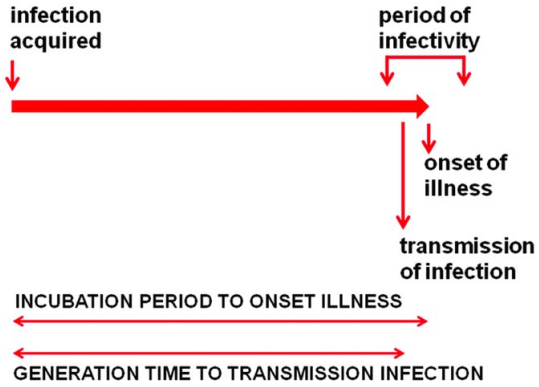

FIGURE 13.5 **Incubation period and generation time**. Incubation period is the interval between acquisition of infection and onset of illness, whereas generation time is the interval between acquisition of infection and transmission to another person. This diagram shows the mean for each parameter; in practice, there is a spread around this mean.

Transmission of Viruses

There are two major patterns of transmission into which viruses may be classified: viruses maintained in a single species and viruses that alternately infect multiple host species. Among multi-host systems, a further distinction important for human hosts are viruses for which transmission is maintained by humans and those in which human cases are sporadic and a dead-end for transmission. There are some viruses that, depending on the setting (eg, urban vs rural), can be both. Examples of these patterns are shown in Table 13.4.

TABLE 13.4 Major transmission patterns of viral infections of humans

Host and Virus Type	Human Transmission Pattern	Maintenance Cycle	Example
Single-host human viruses	Human to human	Human to human	Measles virus Hepatitis A virus Human immunodeficiency virus
Multi-host zoonotic viruses	Animal to human	Animal to animal	Rabies virus Hantavirus Henipaviruses
Multi-host zoonotic viruses	Animal to human or human to human	Animal to animal	Ebolavirus Nipah virus Monkeypox virus
Multi-host zoonotic and vector transmitted viruses	Vector to human	Vector to animal	Japanese encephalitis virus Tick-borne encephalitis virus Yellow fever virus
Multi-host vector transmitted viruses	Vector to human	Vector to human	Dengue virus Yellow fever virus in urban settings Zika virus in urban settings

Viruses Maintained in a Single Host Species

Viruses maintained within a single host population have characteristic modes of transmission: contact, respiratory, oral, or perinatal. Contact transmission includes both direct and indirect contact with infectious individuals, for example, directly through skin or sexual contact or indirectly through infected fomites, blood, or body fluids. Respiratory transmission results from the inhalation of contaminated air, including large respiratory droplets that fall out of the air quickly over short distances and small airborne particles that can remain suspended in the air for several hours. Oral transmission occurs by ingesting contaminated foods or liquids. This includes viruses primarily reliant on the fecal-oral route to maintain transmission, such as rotavirus and polioviruses. Contact, airborne, and oral transmission are horizontal modes. Perinatal transmission denotes transmission from a mother to offspring and is a form of vertical transmission. Perinatal transmission can occur by passage of virus across the placenta, during birth, or from drinking colostrum or breast milk. Germline transmission, another type of vertical transmission, occurs with certain animal retroviruses such as murine leukemia virus, which are transmitted as an integrated provirus that may be transcribed into infectious virus. Although retroviral sequences are carried in the human genome, there are presently no proven instances where these have been shown to function as infectious virions in humans. Selected examples of horizontal and vertical transmission are listed in Table 13.5.

TABLE 13.5 Transmission mechanisms of human viruses maintained by the person-to-person route

General Category	Transmission Mechanism	Examples
Horizontal	Contact	
	Direct	Human papilloma virus, HIV
	Indirect	Influenza virus, hepatitis A virus
	Airborne	SARS-CoV-2, influenza virus
	Oral	Rotavirus, norovirus
Vertical	Perinatal	Rubella virus, cytomegalovirus,
	Via placenta	Zika virus, HIV
	Via maternal parturition	Rubella virus, cytomegalovirus, Zika virus, HIV
	Via maternal breast milk	Herpes simplex virus, hepatitis B virus, HIV

Viruses Maintained in Multiple Host Species

In addition to the four modes of transmission characterized for single-host systems, multi-host systems also include vector transmission. Vector transmission requires a secondary host (ie, vector) to spread the virus. Vector-borne viral infections are usually maintained through continuously cycling between the nonvertebrate host vectors (ie, arthropods such as mosquitos, ticks, sandflies) and vertebrate hosts. In most instances, the virus replicates optimally in a single species or in a few closely related species of arthropods, which constitute the major, if not exclusive, vectors. Most blood-feeding arthropods have a feeding preference for a few vertebrate species, determining the vertebrate species involved in maintaining virus transmission.

Many vectors of human viruses prefer nonhuman vertebrate blood sources for their perpetuation (ie, zoonotic viruses), including birds, rodents, or livestock (eg, Japanese encephalitis virus, tick-borne encephalitis, Rift Valley fever virus). In these systems, humans are infected when the vector "accidently" feeds on humans as an alternate blood meal, and the magnitude of circulating virus among the primary host and vector is a determinant of human risk of infection. However, humans are the major vertebrate host capable of maintaining cycles of other vector-borne viruses, such as dengue virus. In urban areas, humans are the primary reservoir maintaining transmission of some vector-borne viruses such as yellow fever, Zika, and chikungunya viruses. In these systems, transmission and human infection rates differ greatly by setting (ie, urban vs sylvatic vs intermediate).[32] Examples of transmission and maintenance patterns are listed in Table 13.4.

For some vector-borne viruses, there are alternative maintenance cycles limited to the arthropod host, with transovarial or sexual transmission from generation to generation of the arthropod host. These arthropod cycles may be critical in the perpetuation of the virus during adverse conditions, such as overwintering, but otherwise play a minor role in viral dissemination.

Terminal Hosts

A *dead end* or *terminal host* is one not involved in maintaining viral transmission. In these systems, humans are occasional terminal hosts for viruses maintained in animal cycles. These viruses use the range of transmission modes, including vector-borne (eg, Japanese encephalitis virus, West Nile virus), airborne (eg, Hantaviruses), and direct contact (eg, rabies virus). For example, maintenance of the West Nile transmission cycle is primarily within birds. Infected humans do not develop sufficiently high levels of viremia to transmit to mosquitoes and are, therefore, terminal hosts. Rabies virus is maintained in bats and other wildlife and domesticated dogs but can be transmitted to humans most often by dog bite contact. Of course, there are many examples of emerging zoonotic viruses, which initially spread from animals to humans in the recent past and then sustained human to human transmission (ie, HIV, SARS-CoV-2; see section below on viral emergence).

Endemic and Epidemic Patterns of Transmission

Endemic transmission refers to recurring or relatively stable transmission of a virus within a population. Epidemic transmission, on the other hand, refers to the rapid spread of a virus in which incidence exceeds a baseline or expected number of new infections. Less infectious viruses with long generation times tend to have endemic patterns with consistent infection rates over time with little seasonal fluctuation. Examples include sexually transmitted viruses such as HIV. An estimated 40 000 incident HIV infections have occurred each year in the United States over the past decade.[8] Some viruses exhibit seasonal endemic patterns of transmission,[56] that is, seasonal changes in the number of infections within a year but consistent annual number of infections. Seasonal variation in transmission can be driven by host behaviors, immunity, or environmental conditions impacting vector abundance.[34] Examples include viruses that do not induce protective immunity to reinfection, such as dengue virus, rotavirus, or influenza viruses. Viruses that are highly infectious with a short time interval between successive cases will quickly infect a susceptible population. If the viral infection also confers long-term protection against reinfection, we can expect persistent fluctuations or epidemic cycles as a result of the buildup and then depletion of a susceptible individuals born into the population.[29] Examples include many childhood infections such as measles, rubella, or varicella viruses. The duration of the interepidemic period depends in part on the number of susceptible individuals.[4] Human population sizes and birth rates play a critical role in determining the rate of new susceptible individuals, but, for vaccine-preventable viral diseases and settings with high vaccine coverage, vaccination effectively reduces the size of the susceptible population and lengthens interepidemic periods.

Within Host Persistence

Viral diseases can be broadly categorized by their persistence within the host as acute or chronic. Acute infections can be further characterized by the duration of immunity into those that result in long-term protective immunity and those that result in only short-term immune protection. Infections that do not confer long-term protection against reinfection are more common and result from multiple different mechanisms, including rapid viral evolution, cocirculating strains, or variable gene expression. For example, rapid evolution of influenza virus results in short-term immunity to prior strains. High mutation rates of genes encoding surface proteins leads to antigenic drift and viral reassortment during coinfections leads to antigenic shift. Viral infections that result in life-long sterilizing immunity are less common and include infections with measles, rubella, and smallpox viruses. It is not completely understood how and why some viral infections induce long-term protective immunity.

Whether a viral infection is persistent or acute and immunizing or nonimmunizing informs expectations for age-specific incidence and prevalence. Acute viral infections that induce long-term protective immunity mostly occur in infants and young children as most older individuals acquire infection and become immune. As a result, we often call these “childhood” infections even though susceptible adults can become infected. Acute viral infections that do not induce long-term protective immunity, depending on the duration of protection, often have attack rates that are similar across ages, resulting in age-invariant incidence and prevalence. In contrast, the prevalence of persistent viral infections increases with age.

Quantifying Transmission and the Basic Reproductive Ratio

The transmissibility of viral infections may be quantified by the basic reproductive ratio (R_0). R_0 is defined as the average number of secondary infections initiated by a single infectious individual in a completely susceptible population.[45] The basic reproductive ratio is a central concept in infectious disease dynamics. For immunizing infectious diseases in randomly mixing host populations, R_0 can be used to inform (1) the threshold for which the incidence of a viral infection can increase in a population ($R_0 > 1$); (2) the critical threshold for vaccine-induced herd immunity ($p_c = 1-1/ R_0$); (3) the expected final epidemic size in the absence of new susceptible individuals; and (4) the mean age of infection given a specified birth rate.[2] R_0 is determined by the transmissibility of the virus, contact rate between susceptible and infected individuals, and the duration of infectiousness. Examples of R_0 are 12-18 for measles virus, 5-7 for polioviruses and rubella virus, and 1.5-2.0 for influenza viruses, although there is a wide range depending on the setting.[2]

A more realistic measure to quantify the transmissibility of viral infection is the effective (or net) reproductive number (R). R is defined as the average number of secondary infections initiated by a single infectious individual in a partially immune population because of previous virus exposure or vaccination. R is smaller than R_0 because not all individuals in the population are susceptible. When R is >1, the incidence of infection increases; when R is <1, the incidence wanes. When R equals 1, the number of infections is constant. Control programs aim to reduce R to below 1 to achieve disease elimination.

A simple mathematical expression that captures the key parameters for a directly transmitted virus is $R = \beta cXD$, where β represents the transmission coefficient (ie, the probability of infection given contact between a susceptible and infected individual), c is the average number of contacts between susceptible and infectious individuals per unit time, X is the proportion of susceptible individuals, and D is the duration of infectiousness. As can be seen from this simple equation, control of a viral infection could be achieved by reducing the probability of infection

given effective contact (eg, masking), reducing effective contacts (eg, isolation and quarantine), reducing the proportion of susceptible individuals (eg, through vaccination), or reducing the infectious period (eg, treatments to reduce viral load and thus contagiousness).

Modeling Viral Dynamics

Mathematical models of viral dynamics are widely used by infectious disease epidemiologists to understand temporal and spatial patterns of virus transmission and persistence within populations, and to evaluate the potential impact of strategies to control or eliminate transmission. Much of the theory of viral dynamics and disease control has been developed using mathematical models, specifically mechanistic models (eg, the utility of R_0 and R as described above). Mechanistic models differ from statistical models used in other branches of epidemiology because their structure includes proposed mathematical relationships capturing biological mechanisms that drive infection dynamics.

The use of mechanistic models in infectious disease epidemiology has a long history. One of the earliest was a mathematic model of malaria transmission developed by Sir Ronald Ross in the early 20th century. In these early works, Ross laid out a mechanistic description of contagion and evaluated a threshold of mosquito populations below which malaria transmission could not be maintained. Subsequent models of infectious disease dynamics were developed by Wade Hampton Frost and Lowell Reed (the Reed-Frost model), in which the incidence of newly infected persons was based on the probability of contact between susceptible and infectious hosts.[1] The models developed by W. O. Kermack and A. G. McKendrick were the first to divide the population into the three classes of individuals discussed earlier (susceptibles, infectious, and recovered; hence, SIR models) and estimated the number of new infections as a function of the number of susceptible and infectious individuals.[48] These deterministic, compartmental models (based on difference or differential equations depending on whether time is treated as a discrete or continuous variable) were expanded and popularized by Roy Anderson and Robert May[2] and became the basis for much infectious disease modeling. Variations on the basic SIR model include the addition of other compartments or classes of individuals (eg, individuals infected but not infectious and infants protected by maternally acquired immunity), age- and space-specific contact patterns, and stochastic processes.

Mechanistic models can differ by scale, approach, and level of detail but are powerful tools that rely on implicit and explicit assumptions through which interpretation of model output is critical. Useful models balance the goals of the research question and simplicity. Models can provide a conceptual framework for viral transmission dynamics, identify which variables are most important for transmission and require careful measurement, and generate new hypotheses. Models can be used to estimate the likely size of an epidemic, its time course and periodicity, the reproductive number R, the expected impact of various interventions, evaluate strategies for control, and forecast disease burden. More complex models require additional underlying assumptions and parameter estimates and can be less intuitive. Model validation against epidemiologic data is a critical component of model building, use, and interpretation.

Measles is a useful system for infectious disease modelers to showcase dynamic mechanisms of transmission and control because it is a fully immunizing infection that is highly infectious and has a long time-series available because of the readily distinguishable clinical characteristics. Mathematical models of measles virus transmission allow for exploration of the impact of various vaccination strategies, including the optimum age at measles vaccination and the use of mass vaccination campaigns that would otherwise be difficult to evaluate in epidemiologic studies.[19] Model results suggest that the best age at which to vaccinate against measles depends critically on the age distribution of cases of infection prior to the introduction of control measures.[57] Introduction of mass measles vaccination induces a temporary phase of low incidence of infection before the system settles to a new pattern of recurrent epidemics,[58] and frequent, relatively low coverage mass vaccination campaigns are effective in reducing measles virus transmission.[51]

Phylodynamics

Infectious disease epidemiologists are increasingly interested in linking immunological, epidemiological, and evolutionary processes to understand how viruses are transmitted and evolve, a field referred to as phylodynamics.[39] Because of the high mutation rates of viral pathogens, evolutionary and epidemiologic processes take place on a similar time scale.[76] According to this framework, phylodynamic processes that determine the degree of viral diversity are a function of host immune selective pressures and epidemiologic patterns of transmission.

Since the term phylodynamics was introduced in 2004, the field has expanded dramatically, enabled by the decreasing cost of genetic sequencing and increasing availability of viral sequence data[70] Open-source software to analyze viral sequence data (eg, BEAST[22]) has contributed to the expansion of available data, allowing scientists to readily apply nonlinear evolutionary models. Sequence data are used to understand details of virus evolution and transmission, including the frequency and source of virus introductions, or deconstructing the role of “hotspots” to maintain spread.[33,88] The knowledge gleaned can be leveraged to anticipate future spread and develop control strategies. The utility of phylodynamic analysis is also applicable to clinical settings, including linking closely related cases to predict phenotypes such as drug resistance and virulence.[70]

The Zika virus epidemic in the Americas began in May 2015 with the first reported case in Brazil. Zika virus was subsequently reported from many countries throughout Central America, South America, and the Caribbean.[49] Genomic sequencing combined with phylogenetic, epidemiologic, and environmental data were used to understand Zika virus transmission over space and time. These analyses tracked Zika virus transmission across national boundaries and assessed the extent of undetected spread throughout the region.[88] Phylodynamic analyses also informed understanding of biannual peaks of viral transmission, likely driven by environmental conditions that impact the vector *Aedes* sp. mosquitoes, despite the other modes of transmission (eg, blood transfusion, sexual contact, vertical transmission) that were not readily impacted by environmental factors.[88]

Influenza A viruses display endemic seasonal patterns of transmission with annual outbreaks occurring in during “winter” months in temperate climates (November to March in the northern hemisphere and from May to September in the southern hemisphere).[46] As a result of antigenic drift, a large pool of susceptible individuals at risk of infection is present every year. Phylogenetic analysis provided key evidence to inform the underlying causes of seasonal influenza A virus transmission. Rather than the virus remaining local within a host population between seasonal outbreaks, as previously proposed, global migration of infected individuals spreads the virus and contributes to seasonal emergence of influenza A viruses.[71] Countries in the tropics with persistent influenza virus reservoirs can serve as “sources” for “sink” countries in temperate zones.[78]

Viral Emergence

One of the most dramatic aspects of infectious disease epidemiology is the appearance of a new viral disease, as the world is well aware following the emergence of SARS-CoV-2 and the resulting pandemic.[74] This may reflect the true appearance of a new virus in the population; an increase in the case infection ratio so that an endemic infection is associated with a marked increase in disease incidence; or lastly, the recognition of an existing but previously unidentified disease that can now be clearly diagnosed owing to new laboratory tests accompanied by heightened practitioner awareness.

New viral diseases may be emerging as zoonoses at an increasing frequency, with SARS-CoV-2 being the most recent and dramatic example.[93] Several secular trends have enhanced the probability of emergence of new viral diseases (Fig. 13.6).[90] First, the population of the world has inexorably continued to increase, and urbanization has concentrated a higher proportion of people in densely populated areas, facilitating the transmission of any new virus. Second, modern transportation permits the carriage of infections around the globe within a single incubation period. Third, man-made perturbations of the environment are occurring at an increasing pace, thus increasing the likelihood of transmission of zoonotic and arboviral infections to humans. Finally, advances in fundamental virology have made available a new armamentarium of methods for the detection of previously unknown pathogenic viruses. All these factors were in play with the emergence and spread of SARS-CoV-2.

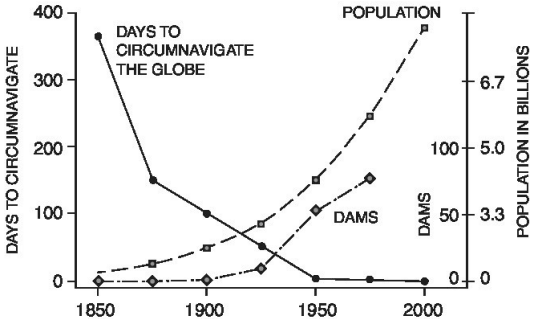

FIGURE 13.6 **Since the middle of the 19th century, many global changes have enhanced the probability of the emergence of new viral diseases of humans and animals**. This chart depicts three examples of such trends. The growth in the human population has been accompanied by a massive increase in large urban populations, markedly increasing the risk of epidemic spread of infection. Dramatic reductions in the time to travel over long distances have increased the possibility of global transport of infectious agents over short periods of time. The number of large dams (dams >75 meters high built in the United States from 1890 to 1975) exemplifies increases in man-made manipulation of the environment. (Data from Anonymous. *Atlas of World Population History*. Penguin Books and Allen Lane; 1978; Anonymous. *Statistical Yearbook*. 38th Issue, 1990/1991. Epidemics

Causes of Epidemics

Epidemics may result from an increase in viral virulence, an increase in the number or proportion of susceptible individuals exposed to the virus, an increase in the number or proportion of susceptible individuals in a population, recent emergence of a new virus, or re-emergence of an existing virus. Expanding knowledge of basic virology provides molecular insights into the determinants of viral epidemics. For example, generation time and transmissibility of a virus, that in turn impact the magnitude and timing of epidemics, are influenced by specific viral genes. Mutations in the gene encoding the spike protein of SARS-CoV-2 resulted in increased transmissibility and shortening of the generation time.[53] In certain instances, it is possible to identify some of the molecular determinants of each of these four mechanisms that are associated with epidemics.

Increase in Viral Virulence

In many instances, an outbreak is clearly associated with a virus strain of high virulence that increases the ratio of reported cases to infections. Such occurrences are probably quite frequent but are rarely well documented. Theoretical models inform our understanding of the selection for viral virulence at the onset of an epidemic, despite selection for less virulent or latent virus later in the epidemic as the susceptible population decreases in size.[3] Most viruses exhibit great natural variation in virulence. One classical example is variola virus, which caused virulent forms of smallpox (variola major) in India and Africa and much milder disease (alastrim or variola minor) in South America (Table 13.3). It was known for many years that natural isolates of poliovirus varied greatly in their neurovirulence, and attenuated isolates were the starting point for the development of avirulent vaccine strains. Molecular analysis identified the genomic determinants of virulence, which are located both in the structural genes and in the noncoding 5′ region of the genome.[67] This natural variation might have been a factor in the severity of poliomyelitis epidemics of the past. SARS-CoV-2 variants have also differed in virulence as well as transmissibility.[41]

Increase in Susceptible Population Exposed to the Virus

An enhanced mode of transmission or a change in factors that increase host exposure can increase the susceptible population exposed to the virus. Ecological factors, in particular climatic conditions (rainfall, temperature, etc.), that maximize the vector population can increase human risk of vector-borne virus infection. Additionally, a change in the interplay between environment and human behavior can increase human exposures to sylvatic disease cycles. Examples include population growth and spatial expansions of farming and agriculture increasing interactions between wildlife, vectors, livestock, and humans.[47]

Increase in Population Susceptibility

Waning immunity or viral variants that escape prior immunity can result in increases in population susceptibility. Susceptible individuals also

increase in a population through births and migration and when transmission temporarily ceases. Viruses that are highly infectious with immunizing infections and short generation times will quickly be transmitted in a susceptible population resulting in fluctuations or epidemic cycles.[29] Measles incidence in Iceland over a 50-year period is shown in Figure 13.7, during which time epidemics alternated with periods with no measles virus transmission. When measles virus invades an isolated island population, the virus spreads widely and quickly and fades out when the density of susceptible individuals drops below the level needed to sustain virus transmission. The virus disappears entirely, allowing susceptible individuals to accumulate as new cohorts of infants are born. Once enough susceptible individuals have accumulated, a single importation of measles virus can initiate a new epidemic.[84]

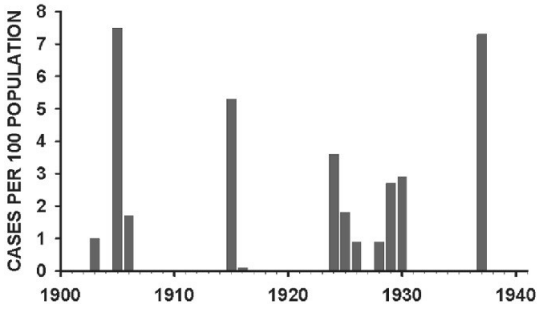

FIGURE 13.7 **Measles incidence in Iceland from 1900 to 1940**. (Data from Tauxe R. Measles incidence in Iceland, 1900-1940. Unpublished report. 1979.)

Emergent or Re-emergent Viruses

SARS-CoV-2 is the most well-known and recent example of a new virus that led to an epidemic (more specifically, a global epidemic or pandemic). Emergent viruses infect and transmit among a completely susceptible population allowing for high attack rates depending on the infectiousness of the virus. A time series of global cases reported to the World Health Organization show the epidemic curve in Figure 13.8 during which different strains of the virus resulted in new waves of cases. SARS-CoV-2 is an epidemic virus likely to become endemic if reinfection is common.[83]

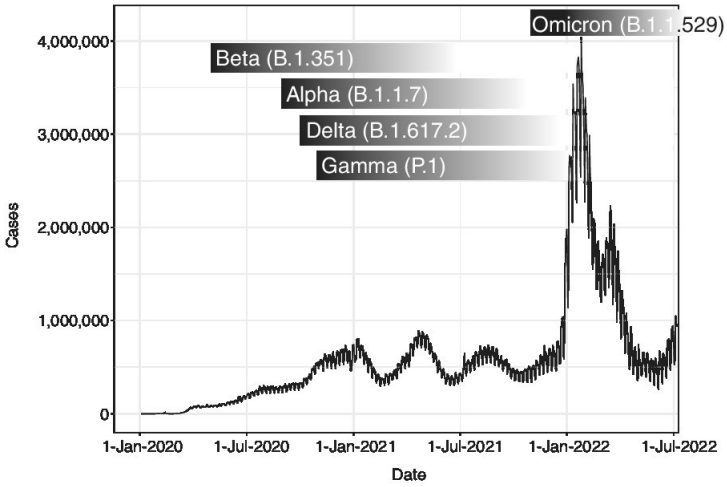

FIGURE 13.8 **Epidemic curve of global SARS-CoV-2 cases reported to the World Health Organization**. Temporal changes in variants of concern are shown with the starting date based on the earliest documented sample. (Data were extracted from World Health Organization website on 11 July 2022, https://covid19.who.int/data, aggregated across countries by day, and plotted as a time series & https://www.who.int/activities/tracking-SARS-CoV-2-variants.)

While seasonal influenza is considered an endemic disease across the world, the segmented genome of influenza viruses enables exchange of entire gene segments when cells are coinfected with two influenza viruses. Reassortment can lead to a major shift in the antigenicity of the virus if the new virus bears a hemagglutinin that is novel for the human population. Reassortment between an avian influenza virus and the previously circulating human influenza virus occurred in 1957 and 1968, with the appearance of the H2N2 and H3N2 pandemic influenza viruses, respectively. Animal influenza viruses also reassort in nature; the 2009 pandemic was caused a complex, triple-reassortant H1N1 swine influenza virus.[72] Such a radical shift in antigenicity provides the newly created virus with a global population that is relatively susceptible and, as a result, an influenza pandemic may occur.

Epidemic Investigation

The primary goal of an epidemic or outbreak investigation is to control the spread of disease. This requires identifying the etiologic agent (including but not limited to viruses), its source, and the mode of transmission. During an outbreak investigation, epidemics can be classified as either point source, common source, or propagated. An epidemic curve (ie, time series of cases) is a useful outbreak investigation tool for delineating these modes (Fig. 13.9).

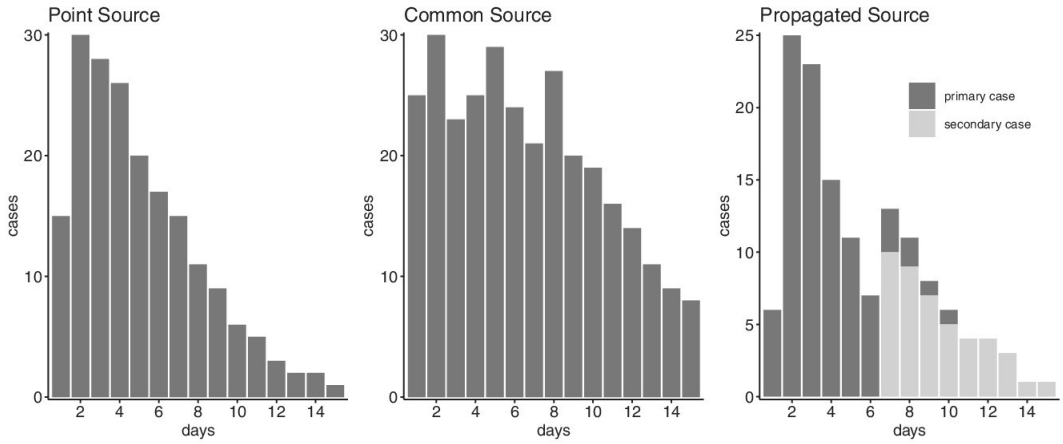

FIGURE 13.9 Examples of epidemic curves showing how the shape of the curves provides insight into the modes of transmission and duration of the incubation period. The three epidemic curves represent a point source (**left panel**), common source (**center panel**) and propagated source (**right panel**).

Point Source Outbreak

Point source outbreaks are those in which a susceptible population is exposed at a discrete point in time. As the name implies, pathogen exposure occurs from a point source, often food, water, or aerosol. Point source outbreaks are explosive because of the simultaneous exposure. The epidemic curve is characterized by the rapid rise and only slightly slower fall in the number of cases, with variation based on individual heterogeneity in incubation periods and clinical phases. The most common point source outbreaks in the United States are those involving contaminated food.[86]

Common Source Epidemic

Common source epidemics are the result of exposure to a pathogen from a common source, including food, water, aerosol, or injected product. But unlike a point source outbreak, a common source epidemic continues to expose individuals to the pathogen. The epidemic curve for a common source outbreak includes a sudden rise in cases but instead of dropping quickly, cases continue as individuals continue to be exposed.

Propagated Epidemic

Propagated epidemics involve host to host spread of the pathogen. A propagated epidemic typically includes an increase in the number of cases following exposure. As the number of susceptible individuals from the initial exposure decreases, so will the number of cases. Secondary cases resulting from person to person transmission result in a secondary rise in the number of cases one incubation period after the initial peak in cases. Propagated epidemics result in the largest number of epidemic cases owing to the perpetuation of transmission. Finally, some epidemics are neither point-source, common-source, nor propagated from person to person, such as epidemics of zoonotic or vector-borne diseases.

Perpetuation and Eradication of Viruses

All viruses, whether they cause acute or chronic infections, are capable of persisting in populations because perpetuation is a requirement for survival. Eradication is the converse of perpetuation and represents the ultimate method for control of an infectious disease. To determine the potential for eradication, it is necessary first to understand the requirements for perpetuation.

The principal ecological patterns of viruses in host populations have been discussed previously, with emphasis on human viruses. In most instances, a virus is perpetuated in a single species, and discussion will be limited to this dominant ecological pattern. Parameters that determine perpetuation include characteristics of the human population and the virus. Population determinants include the size of the population, the rate at which new susceptible individuals are introduced (largely through births), the density of the population, and the proportion of the population that are susceptible. Viral determinants include transmissibility, generation time, and duration of infectiousness (acute or persistent). These three viral variables determine the rate of spread of a virus through a population for a given set of population parameters. Paradoxically, an agent that spreads rapidly may exhaust susceptibles and disappear more quickly from a small population than a virus that moves indolently through the same population. Perpetuation will be discussed separately for large and small populations, because population size is such an important determinant.

Small Populations

For small populations, a crude prediction of sustained transmission may be made by determining the number of susceptible individuals entering the population per generation period. If this number is less than one, persistence will almost certainly not occur.[95] Small primitive human populations that have minimal contact with the outside world are occasionally available for serological study. These populations provide a unique opportunity to determine the ability of viruses to perpetuate in human hosts. There are two principal patterns.[5] Viruses that cause acute short-term infections produce abrupt outbreaks after introduction into human populations and then die out until reintroduced. Viruses that are capable of persisting in individual hosts as chronic infections can sustain transmission in small, isolated groups.

Animal populations differ radically from human populations in their relatively rapid rate of turnover—a critical variable in sustained virus transmission. Mean life expectancy in many animal populations ranges from 6 to 12 months, in contrast to a range of 30-70 years for humans. However, the kinetics of infection is often longer in an individual human than animal host. For instance, the median incubation period (to rash)

is about 14 days in smallpox and 10 days in mousepox. The consequence is that sustained transmission may occur in animal populations with rapid turnover that are much smaller than the minimum human population required to sustain a similar virus.

Laboratory animal colonies have provided an opportunity to document the quantitative impact of population turnover. Perpetuation in such colonies is of more than academic interest because enzootic infections present an important practical problem that frequently confounds biomedical research. One documented example is ectromelia (mousepox) that closely resembles variola in humans.[23] Infection is initiated either by entry through the skin or by inhalation and results in a generalized poxlike rash of the skin from which aerosolized virus is transmitted. As in smallpox, infections can be fatal, although recovered mice are solidly immune. Ectromelia is a relatively infectious agent and a notorious cause of acute and devastating epizootics. When a few infected mice are placed in a larger group of susceptible animals, the virus spreads rapidly, all mice are infected within two incubation periods, and many mice die. In these circumstances, ectromelia would not be expected to perpetuate in a small mouse population. However, a series of classical studies demonstrated that this virus was readily perpetuated in a population of 100-200 animals because of the more rapid population turnover in mice.[36]

Large Populations

To follow the pattern of viral infection in large populations, it is generally necessary to rely on reportable diseases that can be identified by clinical observation and that exhibit relatively high case infection ratios. Measles is one of the few viral diseases that meets these criteria; however, even measles surveillance has its limitations, considering only a fraction (usually 10%-50%) of cases are reported. Table 13.6 shows that in cities of 200 000-300 000, measles faded out for at least 1 month in 56 of the 100 years recorded. Because a population of 300 000 might be expected to experience about 5000 cases of measles in an average year, it is initially surprising that this would be insufficient to maintain measles virus transmission. The explanation becomes more apparent when the seasonal cycle of measles is examined.[95] Data for the city of Baltimore (population 900 000) for 32 years of observation showed that annual reports averaged about 5000 cases, representing about 35% of cases; incidence rates ranged more than 100-fold from the peak in March to the seasonal low in August, when about 10 cases were reported. Because there were about three generation periods per month, this represents no more than 3 cases per generation period, which is barely sufficient to perpetuate the virus. A similar city of 300 000 would experience only 1 case per generation period at the seasonal trough; in such an instance, it is quite plausible that periodic fadeouts would occur.

TABLE 13.6 Fadeouts of measles in North American cities, 1921-1940[a]

Size of City (Millions)	Number of Cities	Average Annual Measles Reports (Thousands)	Years of Study	Years With Fadeout
1.0-7.5	6	3.5-21	120	0
0.5-0.9	9	2.8-4.0	180	1
0.2-0.3	5	0.9-2.1	100	56

[a]Estimate of reporting ranged from 14% to 55% of measles incidence. *Large cities:* New York, Chicago, Philadelphia, Detroit, Los Angeles, Montreal; *medium cities:* Cleveland, Baltimore, Boston, Toronto, Washington, Pittsburgh, Milwaukee, Buffalo, Minneapolis; *small cities:* Vancouver, Rochester, Dallas, Akron, Winnipeg.

Data from Bartlett MS. The critical community size for measles in the United States. *J R Stat Soc A*. 1960;123:37-44; Yorke JA, London WP. Recurrent outbreaks of measles, chickenpox, and mumps. II. Systematic differences in contact rates and stochastic effects. *Am J Epidemiol*. 1973;98:469-482.

This analysis suggests that persistence of a short-cycle infection in a large population depends on the relationship between incidence during the seasonal trough and the generation time. Influenza virus, with a generation time of 1-3 days, is maintained in human populations through the seasonal trough by shuttling between Northern and Southern hemispheres each year.

Requirements for Eradication

Elimination refers to the interruption of virus transmission in a defined geographic area (eg, country or region), and eradication refers to the global interruption of virus transmission. The history of smallpox, and more recently rinderpest virus, demonstrates that eradication is an attainable objective for selected human and animal viral infections. The salient epidemiologic features that made smallpox eradication possible were its relatively long incubation period (about 14 days) and low infectiousness, the near equivalent durations of the latent and incubation periods, its marked seasonality, a case to infection ratio approaching 1, and the lack of a nonhuman reservoir. These features made it possible to abandon mass vaccination in favor of a search and containment strategy in which local outbreaks were identified and aborted by intensive immunization around each focus.[31] The paucity of local outbreaks during the seasonal trough were essential to the success of this strategy.

Eradication of Polioviruses

Two poliovirus vaccines (inactivated poliovirus vaccine [IPV] and oral poliovirus vaccine [OPV]) were introduced in the period from 1955 to 1963 in the United States, and their application led to the elimination of circulating wild polioviruses around 1970.[68] Wild polioviruses were eliminated from the Western Hemisphere by 1990 as a result of immunization programs in Latin America, and the World Health Organization set a goal of global eradication in 1988. Worldwide efforts reduced polio cases from an estimated 350 000 in 1988 to fewer than 1000 in 2000. However, since then, elimination efforts have stalled owing to the persistence of wild polioviruses in Afghanistan and Pakistan. In 2021, a case of paralytic poliomyelitis due to wild poliovirus type 1 was reported in Malawi 1 year after the World Health Organization African Region was certified as free from wild-type polioviruses,[92] a further setback to the Global Polio Eradication Initiative. There have been two major impediments to eradication, first the failure to immunize a sufficiently high proportion of infants and young children in settings where transmission of enteric infections is very intense and, second, a low “take” rate of OPV, owing in part to competition between the three serotypes in the vaccine. However, OPV presents another complicating issue, namely the tendency to revert to a more virulent phenotype on human enteric passage. Vaccine-derived polioviruses have caused outbreaks of poliomyelitis in settings where weak immunization programs have left many children susceptible and capable of spreading OPV shed by those who were immunized. Circulating vaccine-derived poliovirus (cVDPV)

cases were reported from 31 countries during 2020-2021, further hindering polio eradication efforts.[92]

Eradication of Measles Virus

The feasibility of measles eradication has been debated for many years. Measles meets criteria for a disease that can be eradicated: (1) there is no animal or environmental reservoir, and humans are critical to maintaining transmission; (2) accurate diagnostic tests are available; (3) measles vaccine and existing vaccination strategies are effective and safe; and (4) measles transmission has been interrupted in a large geographic area (eg, nationwide) for a prolonged period. The WHO conducted a comprehensive assessment of the feasibility of measles and rubella eradication in response to a request from the World Health Assembly.[61] The report concluded that a time-bound measles and rubella eradication goal should only be set when substantial and measurable progress has been made, and the strategies, resources, and commitment are likely to be in place to interrupt the final transmission pathways.

Several potential biological obstacles to measles eradication should be considered.[62] Persistent infection with transmissible measles virus would pose a biological barrier to eradication. Measles virus is known to establish persistent infection in persons with subacute sclerosing panencephalitis (SSPE); however, virion assembly and budding is defective and multiple mutations occur throughout the measles virus genome.[40] As a consequence, infectious measles virus is not present. Theoretically, selective pressure on measles viruses to mutate neutralizing epitopes and escape protective immune responses induced by vaccines could be a biological obstacle to measles eradication. However, despite the high degree of genetic variation expected of an RNA virus, mutations in the measles virus genome have not reduced the protective immunity induced by measles vaccines.[64] Subclinical infection resulting in sustained measles virus transmission also could pose a barrier to eradication.[63] However, sustained measles virus transmission among partially immune individuals without clinical disease would be highly unlikely.

Eradication of Rinderpest Virus

Rinderpest virus, a pathogen of cattle and many other domestic and wild artiodactyl species, was declared eradicated on May 25, 2011, following widespread vaccination and control efforts coordinated by the Global Rinderpest Eradication Programme.[59] Rinderpest virus is a *Morbillivirus* closely related to measles virus, transmitted by close contact with an infected animal via inhalation of virus-containing nasal, oral, or fecal secretions. Infection resulted in severe diarrhea leading to dehydration and death. Rinderpest impacted human health in Europe and Africa by decimating cattle populations, leading to famine, disease, and death. What is remarkable about rinderpest eradication is that the virus has many potential reservoirs, both domestic and wild, and yet the goal of eradication was achieved through widespread vaccination of cattle and buffalo, establishment of effective surveillance programs, and regional coordination of control efforts.

Applications of Epidemiology

Outbreak Investigation to Identify Etiological Agents

Epidemiology grew out of outbreak investigations of infectious diseases. Early outbreak investigations, such as investigations of cholera by John Snow in the mid-19th century, were conducted before the widespread acceptance of germ theory but nonetheless comprised hypothesis-driven research. The steps of an outbreak investigation through which hypotheses are formed generally consist of defining a case, assessing the distribution of cases over time to inform the mode of transmission (including tracking subsequent cases), characterizing potential risk factors, and investigating possible sources by exploring common exposures among cases. Epidemiologically, it may be difficult to infer whether the cause is a virus or other infectious agent. Epidemiologic observations, however, can suggest the mode of transmission and the period of infectiousness, which are important for collection of specimens for virus isolation.

Viruses that cause more severe disease or death are more readily identified due to their readily noticeable clinical presentation. Hantavirus pulmonary syndrome (HPS) was unknown in 1993 when first identified but later was discovered to be caused by different hantaviruses. The investigation was triggered by an illness characterized by respiratory distress and death in two otherwise healthy, young individuals residing in the same household in New Mexico, USA.[10] As part of the investigation, epidemiologists identified other individuals who died of similar acute respiratory failure, but laboratory tests failed to identify an etiologic agent. Virologists conducted thorough testing of tissue samples from patients with similar clinical histories and were able to identify a previously unknown hantavirus.[11] Throughout the remainder of 1993, investigators trapped as many different species of rodents living near the households and places of occupation of the cases and finally identified the viral reservoir in deer mice.[15] The last step was to investigate the connection between deer mice and cases. A case-control study design was used (given the low incidence of disease) among surviving cases or people and controls matched by geographic location. Cases had more rodents around living near their houses and were more likely to clean around the house and plant in outdoor gardens.[96] National surveillance for HPS began 1995 and 816 cases were reported in the United States through 2019, as seen in Figure 13.10. Most cases (94%) occur in states west of the Mississippi River in states more prone to drought.

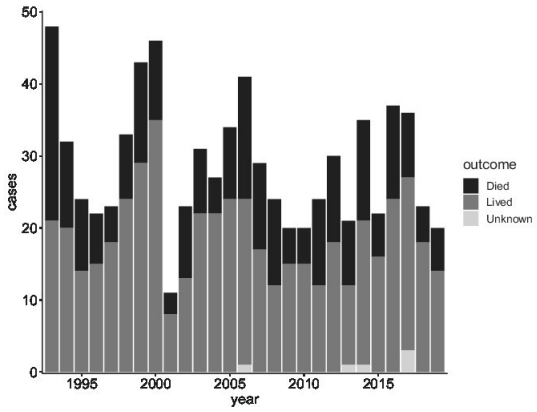

FIGURE 13.10 **Case count of hantavirus disease reported 1993 to 2019 in the United States**. Data were reported to US CDC's Viral Special Pathogens Branch and Collected by the Nationally Notifiable Disease Surveillance System. Annual case count is grouped by the outcome of the case (lived, died, unknown). (Source US CDC. *Reported Cases of Hantavirus Disease*. Accessed April 20, 2022. https://www.cdc.gov/hantavirus/surveillance/index.html)

Epidemiologic observations may also contribute insights into more obscure persistent infections associated with atypical chronic diseases. The spongiform encephalopathies or prion diseases are an example. This group of agents includes scrapie of sheep, kuru and Creutzfeldt-Jakob disease of humans, and bovine spongiform encephalopathy.[17] The initial definitive evidence that scrapie, a chronic degenerative neurological disease, could be transmitted by an infectious agent and occurred as an unwanted complication of the use of louping ill vaccine was made in Scotland in 1935.[37] Table 13.7 shows that three lots of vaccine against louping ill, a flavivirus, were injected into sheep in Scotland. Unexpectedly, there was a very high incidence of scrapie in recipients of one of the three lots. Subsequent epidemiologic investigation showed that louping ill vaccine was prepared by formalin treatment of virus grown in sheep brain and that several of the sheep used were probably incubating scrapie because their parents subsequently came down with the disease. Prions are extremely resistant to inactivation by formalin; thus, contamination of the vaccine was readily explained. Prior to this episode, it was not generally accepted that scrapie was attributable to a transmissible agent with an incubation period of several years.

TABLE 13.7 Occurrence of scrapie in sheep immunized with louping ill vaccine, Scotland, 1935[a]

Vaccine Batch	Number of Sheep Vaccinated	Percentage With Scrapie
1	>22 000	<0.1%
2	18 000	5%
3	>4000	<0.1%

[a]Batch 2 was prepared from 122 sheep infected with louping ill; of these, 8 were offspring of scrapie-affected ewes. Interval between subcutaneous injection of vaccine and onset was 20 months or longer.

Data from Greig JR. Scrapie in sheep. *J Comp Pathol*. 1950;60(4):263-266.

Evaluation of Vaccine Efficacy and Safety

The ultimate test of viral vaccines is their efficacy and safety in humans. Epidemiology provides well-established methods for the design and analysis of prospective studies of vaccine efficacy and effectiveness.[43] Vaccine efficacy estimates come from prelicensure, randomized, double-blind phase three clinical trials, evaluating the direct effect of vaccination on the individual (including individual susceptibility to infection, disease, death, or infectiousness). Vaccine effectiveness estimates, which measure direct protection to the vaccinated as well the indirect effect on the population, come from postlicensure observational studies. These are illustrated by the 1954 field trial of poliomyelitis vaccine.[55] In this trial, a large number of children in the first three grades of elementary school were enrolled. As shown in Table 13.2, the trial comprised two different study designs—namely, placebo and observed. In the placebo design, children fell into three categories: vaccinated, placebo inoculated, and nonvolunteers (uninoculated). In the observational study, the three groups were vaccinated second graders, nonvolunteer second graders (unvaccinated), and controls (all children in the first and third grades). The most valid comparison was between vaccinated and placebo-inoculated children in the placebo areas. This group yielded an estimated efficacy of 72% for paralytic poliomyelitis, whereas the observed control area yielded an efficacy of 63%. The discrepancy was explained by the fact that the nonvolunteer children in both areas experienced an attack rate that was considerably lower than that of the placebo controls or the observed controls. Apparently, volunteer children were at higher risk (presumably because they included a higher percentage of susceptibles) than were nonvolunteer children. Thus, the strict placebo control was the best comparison group. When the placebo study was further refined by limiting the analysis to laboratory-confirmed cases, the estimated efficacy was even higher (85%), underlining the importance of etiology-proven cases in vaccine evaluation. As described above, test negative designs can be a more efficient approach to estimate vaccine effectiveness while reducing selection biases.

Epidemiologic studies can also play a critical role in documenting adverse events associated with vaccines. Postlicensure monitoring of vaccine-related adverse events is conducted using passive surveillance systems, through which individuals, health care providers, and vaccine manufacturers can report suspected adverse events. These passive surveillance systems serve to generate hypotheses regarding potential causal relationships between vaccines and adverse outcomes and thus serve as early warning signals. More rigorous epidemiological studies then need to be conducted to establish causality.

The first rotavirus vaccine was licensed in 1998 (RotaShield), but the CDC recommended health care providers suspend use of the vaccine shortly thereafter in July 1999.[12] Between December 1998 and June 1999, ten cases of intussusception in infants were reported to the US passive surveillance systems for adverse vaccine-related events, and the US CDC conducted epidemiological studies to evaluate a potential causal relationship between the rotavirus vaccine and intussusception. A case-control study in 19 states and a retrospective cohort study in managed care organizations were conducted. In the retrospective cohort study, data on the cases of intussusception and the vaccination status of infants were available from participating managed care organizations. The incidence rate of intussusception among vaccinated and nonvaccinated infants were compared and showed an increased risk of intussusception after administration of the rotavirus vaccine (Table 13.8).[50] In the case-control study, cases of hospitalized infants for intussusception were identified via medical records and were matched by age and hospital of birth to nonintussusception controls. Seventeen and 13% of cases and controls received the rotavirus vaccine, respectively. The risk of intussusception was increased 3-14 days after the first dose of the rotavirus vaccine.[65] As a result of these finding, the vaccine was no longer recommended and production was stopped. However, there are now several licensed rotavirus vaccines used around with world, and two licensed vaccines in the United States, and with a much lower risk of intussusception.

TABLE 13.8 Incidence rate and relative risk of intussusception after rotavirus vaccination

Vaccine Batch	Vaccinated	Never Vaccinated
Number of children	56 253	407 024
Person-years	13 541	126 492
Cases	9	31
Incidence rate	66	25
Relative risk	2.7	1.0 (reference)

Development and Assessment of Control Measures

In addition to vaccines, other control measures are often useful against viral infections. Such approaches seek to reduce the risk of exposure and are usually suggested by epidemiologic studies of transmission. A recent example is the prevention of respiratory droplet and airborne transmission of SARS-CoV-2 through masking, social distancing, and improved ventilation.[16] Other historical examples include reduction in the risks associated with blood or blood products for viruses such as hepatitis B and hepatitis C, HIV, and human T-cell leukemia viruses I and II. Another classical example is the reduction of urban yellow fever and dengue through control of *Aedes aegypti* mosquito populations. The use of epidemiologic management of viral infection is illustrated by a study of Bolivian hemorrhagic fever—an arenavirus that was endemic in certain rural villages.[85] Ecological studies suggested that this virus was enzootic in one species of peridomestic house-dwelling mouse—*Calomys callosus*—and was transmitted by aerosolized fomites. Table 13.9 shows a study in which rodent control was initiated in one-half of a village and then extended to the other half. The dramatic effect of rodenticides confirmed the hypothesis of the virus reservoir and its transmission mechanism and provided a practical approach to control of a serious viral infection. Sophisticated mathematical models have been used to evaluate control measures that cannot be tested in epidemiologic studies, including containment of a potential bioterrorist use of smallpox virus[42] and containment of pandemic influenza virus through vaccination[94] and the use of prophylactic antivirals.[24]

TABLE 13.9 Control of Bolivian hemorrhagic fever by reduction of the rodent reservoir, San Joaquin, Bolivia, 1964[a]

Ten-Day Period Beginning	New Cases, East Sector	New Cases, West Sector
April 1	12	9
11	8	17
21	12	8
May 1	7	18
11	4	14
21	2	9
31	3	12
June 10	0	10
20	5	7
30	0	0
July 10	0	0

[a]Rodents were controlled by trapping and poisoning, beginning in the East sector on May 1 and in the West sector on June 15.

Overview

Medical Value of Antiviral Drugs and Barriers to Their Development

Viruses are a leading cause of disease and death worldwide. As illustrated most recently by the coronavirus infectious disease of 2019 (COVID-19) pandemic, public health measures and vaccines are the most effective ways to control many viral infections. However, such preventive measures achieve only partial success for numerous viral diseases. For some of these diseases, antiviral drugs have been developed. A number of these drugs have been highly successful, saving lives and relieving suffering. This has been most dramatic with drugs active against human immunodeficiency virus (HIV) and hepatitis C virus (HCV). For HIV, a progressive fatal disease can be transformed into a manageable condition in which virus replication can be suppressed presumably for a lifetime as long as antiretroviral therapy is maintained, and for HCV, a progressive fatal disease can be cured by several weeks of antiviral therapy.

Despite these successes, there are relatively few diseases for which highly effective antiviral drugs have been developed. Several factors contribute to this. Most antivirals are designed to hit a specific viral target, limiting their utility to treat other viral infections. Some viruses (eg, herpesviruses, HIV) establish latent infections, so treating active infections does not cure the patient. Different viruses, especially respiratory viruses, can cause similar symptoms, making diagnosis difficult. Often, treatment must begin early to be beneficial, sometimes because the viral diseases are quickly controlled by immune responses. Finally, many viral illnesses present limited market opportunities that have sometimes discouraged pharmaceutical companies from developing antiviral drugs.

The Process of Antiviral Drug Development

Antiviral drugs can be divided into two classes, one comprising small molecules and, less commonly, peptides and oligonucleotides, and a second comprising macromolecules such as antibodies and interferons. This chapter will cover FDA-approved or -authorized drugs in the former class while the latter agents will be covered in a different chapter in this volume. Older small molecule antiviral drugs such as amantadine and acyclovir (ACV) were discovered by testing chemicals, often synthesized for some other purpose, for their ability to inhibit virus replication in labor- and time-intensive assays of viral replication, such as assays of cytopathic effect or plaque assays.[94,389] This approach has now developed into cell-based high-throughput screens that use automation to allow screening of large compound collections (up to millions of compounds) in a relatively short period of time. One advantage of cellular screening is that it can identify new mechanisms to target for effective antivirals. For example, highly potent compounds that target NS5A, a poorly understood function of HCV, to block HCV replication have been discovered this way.[144]

A more rational approach is to screen large compound collections against a specific viral gene product that would make a good drug target (see below for discussion). Such target-based screens can examine over one million chemical compounds even more rapidly than cell-based screens. The first nonnucleoside reverse transcriptase inhibitors (NNRTIs), which are active against HIV-1, were discovered using this approach (eg, nevirapine[300]).

A structure-based approach allows one to exploit detailed knowledge about a viral protein to design drugs that will inhibit its activity. Knowledge of the 3-dimensional structure of the protein can enable visualization of its active site and understanding of its mechanism of action and can also be used to design or refine small molecules that can block the active site and the protein's action. An example of a drug discovered using this approach is the neuraminidase inhibitor, zanamivir, which is active against influenza A and B virus.[452]

The approaches outlined above result in what is called a "hit"; however, a hit is only an inhibitor of the function of a viral protein or of viral replication in cell culture. The next steps involve using medicinal chemistry to convert the hit into a compound with high potency and desirable pharmacological properties (eg, bioavailability, long elimination half-life, low toxicity), not to mention patentability. If the structure of the hit compound bound to its target is available, this information can be used to help generate additional compounds to be tested. This process will be illustrated below with the example of the anti-HCV NS3/4A inhibitors, the anti-HIV protease inhibitor, ritonavir, and the anti-influenza neuraminidase inhibitors. Simultaneously, studies to demonstrate the mechanism(s) of action of the compounds are undertaken (see section on *General Aspects of Antiviral Drug Mechanisms and Drug Resistance* below). A key but often overlooked aspect of drug development is developing optimal methods for synthesis of pure compound on a large scale and formulation of the compound for administration to humans.

When a candidate compound with desirable properties has been developed, clinical trials begin. There is no rigid formula by which an antiviral candidate is assessed after it enters the clinic. Typically, the process of clinical development starts with the administration of drug in escalating doses to small cohorts of volunteers to assess pharmacokinetics and tolerability (phase I trials). With some virus infections, these studies may be performed in patients in whom drug activity can also be assessed, for example, by quantifying reductions of chronic HCMV shedding in the genitourinary tract or of HCV in the plasma (proof of concept studies). Substantial reductions in viral load encourage progression to more advanced clinical trials.

A major advantage of antiviral drug development, compared to drug development for many other diseases, is that quantitative reductions in virus shedding are a precise measure of activity and in general correlate with clinical endpoints. These quantitative reductions can be measured quickly (days or less) and permit determination of whether drugs work and of appropriate doses and dosing intervals. Phase II clinical trials assess this antiviral activity along with the additional pharmacological and safety information in dozens to several hundred subjects. The data from phase II trials permit the design of larger phase III efficacy studies, which provide statistically robust results that fulfill regulatory requirements for drug approval. Trials for certain antiviral drugs (eg, vs influenza and herpesviruses) require clinical endpoints (ie, amelioration of disease), with virological data supporting those. For HIV, hepatitis B virus (HBV), and HCV, the correlations between levels of viremia and disease and the correlations between drug-induced reductions in viremia and improvement of disease have resulted in the acceptance of virological endpoints (eg, the proportion of patients with viremia below the limit of detection or the proportion with sustained virological response) as criteria for drug approval.

Should the clinical trials yield the desired results, the "hit" will have turned into an approved drug. Even then, its efficacy and safety will be put to the test in much larger populations, and new indications or limitations for its use may emerge.

Importance of Antiviral Drugs for Basic Science

Aside from their importance in treating viral diseases, antiviral drugs make excellent laboratory tools. By blocking functions of specific viral proteins and thus specific stages in viral replication, drugs can be crucial for understanding the timing of particular events in the virus replication cycle and which proteins are needed for each step. Studies using selective antiviral drugs, coupled with viral mutations that confer drug resistance, can help dissect the details of how these proteins function. Drug resistance mutations can provide selectable markers for

engineering interesting mutant viruses and performing viral genetics.

An example of how studies of antiviral drugs and drug resistance can illuminate virus biology and biochemistry is the role of amantadine in the discovery of an influenza A ion channel and its function in virus uncoating.[173,352] Similarly, clinical investigation has been greatly abetted by antiviral drugs. For a recent example, insights into the dynamics of HCV infection have been obtained through detailed analysis of the impact of directly acting antivirals on the kinetics of HCV RNA and liver transaminases in serum.[55]

General Aspects of Antiviral Drug Mechanisms and Drug Resistance

Drug Selectivity, Resistance, and Drug Targets

The value of antiviral drugs for both basic science and therapy depends on how selective they are and on how well their mechanisms are understood. Biologically, selectivity is the difference between the dose of the drug that exerts its antiviral effect and the dose that exerts its toxic effect. These doses are often quantified in cells as the effective concentrations that reduce viral activity and the concentration that causes cytotoxicity, respectively, by 50% (EC_{50} and CC_{50}). However, differences between these values can overestimate therapeutic selectivity, as a 50% reduction in viral replication would have little if any clinical benefit, while a 50% toxic effect could make a drug unsafe for humans. Thus, a more appropriate measure of selectivity is likely to include a dose that reduces viral activity much more drastically; that is, 99% or more. Examples of how selectivity is achieved biochemically can be found among the descriptions of the mechanisms of specific antiviral drugs.

It is generally agreed that the best way to understand antiviral selectivity and mechanism is through the study of drug resistance. The detection of resistance to an antiviral drug implies that the drug is selective. That is, the drug acts at least in part by interfering with a virus-specific process, rather than by incapacitating the host cell.[185] In much the same way, a mutation in a viral gene that confers resistance to an antiviral drug (showing that requires a genetic experiment) implies that the gene or its product is necessary for at least part of the selective action of the drug.

In most cases, drug resistance mutations identify targets of antiviral drugs. However, there are exceptions. For example, anti-influenza virus drugs whose target is neuraminidase (eg, zanamivir) can select for mutations in the gene encoding the hemagglutinin.[164,294,412] These mutations would be expected to result in a hemagglutinin that binds less avidly to cell surface glycoproteins. This in turn could result in a reduced requirement for neuraminidase to release the virion from the cell and thus resistance to the neuraminidase inhibitor. Accordingly, genetics alone is not sufficient to identify a drug target. Ideally, one should also show that the drug interacts with the target, and that the resistance mutation results in a target with an altered interaction with the drug that explains the resistance phenotype. This usually requires biochemical studies, and the analyses are not always straightforward.

Mapping a resistance mutation that results in a single amino acid change in the target protein identifies that residue as being necessary for sensitivity to the drug. Other genetic approaches, such as the generation of chimeric genes from closely related viruses that are susceptible or resistant to a drug (eg, HIV-1 and HIV-2, and NNRTIs[89]), can identify residues that are sufficient to confer susceptibility to the drug to an otherwise resistant protein. However, these results do not necessarily identify residues that interact with the drug. Identification of a drug-binding site requires methods such as photoaffinity cross-linking and X-ray crystallography. These two methods identified the binding site for the NNRTI, nevirapine, on HIV-1 RT.[86,220,478] Mapping a drug-binding site is valuable but does not tell us how drug binding exerts its physiological action. In the case of NNRTIs, presteady state kinetic analyses of HIV-1 RT were used to show that the drug slows the enzyme's incorporation of dNTPs into DNA,[373,408] presumably by altering the orientation of catalytic residues, as suggested by the location of the drug-binding site.[220] Thus, solving the mechanism of action of an antiviral drug requires multidisciplinary approaches, and in some cases, we still lack a complete understanding.

General Aspects of Antiviral Drug Targets

There are two major kinds of virus proteins that serve as targets for small molecule antiviral drugs. As, in general, it is easier to inhibit a protein's function (with an antagonist) than to promote its function (with an agonist), the most common antiviral drug target is a virus-encoded protein that can be inhibited by a drug. Ideally, the target is essential for viral replication. Less ideally, it should at least be very important for replication and pathogenesis in the human host. The target should also be sufficiently different from any important host proteins to permit selectivity. Ideally, it should be *druggable*; that is, a small molecule should be able to inhibit it. Enzymes make especially good targets for inhibition, because they are usually at low concentrations inside cells, they are relatively well understood mechanistically, they often interact with small-molecule substrates, and, as catalysts, their inhibition interrupts multiple reactions. A second kind of target, which does not need to be essential, is a virus-encoded protein that can activate the drug to make it inhibitory to the virus (*lethal synthesis*), and that is sufficiently different from host counterparts to permit selectivity. An example is HSV thymidine kinase (TK), which activates ACV and its congeners.[142]

Host proteins may also serve as antiviral drug targets, if they have an activity that is more important for viral replication than for host health. However, targeting host functions is inherently more likely to result in toxicity than targeting viral functions. Additionally, as noted above, given that antiviral efficacy requires orders of magnitude effects on viral replication while meaningful toxicity often only requires twofold effects, there is a high barrier to developing safe and effective antiviral drugs against host targets. Despite that, there are successful examples of this approach in targeting cell surface molecules. The prime example is the host target, CCR5, which led to the development of the anti-HIV drug maraviroc.[248,357] This example is a testament to the value of human genetic studies of subjects carrying a null mutation in the gene encoding CCR5, who remained HIV negative and in good health despite frequent exposure to the virus.[268] However, most host functions do not show such a dichotomy.

It has been argued that viruses should be less likely to develop resistance against drugs that target host functions. Regardless, such mutants certainly can develop (eg, see Refs.[390,442]).

Factors Affecting the Development of Drug Resistance

If a drug acts selectively against a virus, the virus will generally be able to develop resistance to it. However, the frequency of drug resistant mutants in a population and how rapidly they arise depend on several factors: the first is the mutation rate of the virus. The higher the mutation

rate, the more rapidly resistance can develop. Viral mutation rates are largely controlled by the fidelity of the polymerases that replicate the viral genomes. RNA viruses, which replicate using low fidelity RNA polymerases, usually have the highest mutation rates, averaging one mutation per genome per replication cycle,[106,281] while DNA viruses, whose DNA polymerases include proofreading 3′-5′ exonucleases that contribute to fidelity,[199] have lower mutation rates. However, viral and host DNA repair proteins and other factors, including nucleotide pools, which can be modulated by both viral and cellular factors, also affect mutation rate.

The second factor is the target size for mutation. The more sites where mutations can confer drug resistance, the more rapidly resistance can arise. For some drugs, such as ACV, many mutations can confer resistance, as any mutation that substantially reduces viral TK activity results in resistance. Also, some sites within a gene are more or less likely to mutate than others. Homopolymeric runs in the HSV *tk* gene (eg, a run of 7 G's) are hot spots for frameshift mutations that confer ACV resistance.[197]

The third factor is magnitude of replication of the virus. The more copies of viral genomes produced, the more opportunities for resistance to arise. The fourth factor is the preexisting size of the virus population. The more virus present, even in the absence of drug selection, the more likely that drug-resistant mutants will be present among the array of genetic variants. Examples of these two factors that have an impact on HIV drug resistance are provided below in the section on *Drug Resistance in Antiviral Therapy*.

The fifth factor involves fitness (ie, how well a genetic variant reproduces relative to other genetic variants, which can include "wild type"). The fitter the drug resistant mutant, the likelier it is to emerge during treatment. For a virus to cause disease that is resistant to an antiviral drug, it must mutate not only to evade drug action but also to retain pathogenicity. Some drug resistant mutants, such as influenza viruses that are resistant to adamantanes, can be highly fit in cell culture, animal models,[29,427] and in humans (reviewed in Ref.[174]). On the other hand, HCV mutants resistant to sofosbuvir replicate very poorly in cell culture, and this has translated to a major advantage for the clinical use of this drug.[234,244,426] (This illustrates the advantage of designing antivirals to interact with functional sites on essential targets.) Many drug-resistant herpesvirus mutants are highly fit in cell culture but are much less so in animal models, which correlates with the low frequency that these mutants are recovered in immunocompetent humans, while others are less fit in cell culture, yet not so impaired that they do not cause disease in patients[25] (reviewed in Refs.[82,239]). Relative fitness is important both in the absence and the presence of drug. When treatment is stopped, if drug-resistant mutants are less fit in that setting, wild-type virus can return to predominate. These various factors—mutation rate, target size, replication rate, preexisting population, and fitness—can be taken into account in mathematical formulae and used to model the emergence of drug resistance (eg, see Ref.[85]).

These factors also influence how different viral infections are treated. For example, HIV infections are now treated with combinations of antiviral drugs, while HSV infections are treated with single agents. This will be discussed below in the sections on antiviral therapy.

Mechanisms of Specific Antiviral Drugs

This section, with a few exceptions, will consider agents currently authorized or approved by the FDA and marketed for clinical use. No endorsement of the therapeutic value of these drugs is intended. For certain viruses that can be studied usefully in animal models, we will discuss the effects of drug resistance mutations on replication and pathogenesis *in vivo*.

Targeting Drugs to Specific Stages of Virus Infection

As detailed throughout this book, the infection of cells by viruses can be broken down into a common set of steps or stages. Most of these stages have been targeted by approved antiviral drugs; for this chapter, we have divided the stages into entry, uncoating, gene expression, genome replication, and assembly/egress (Fig. 14.1). The order of stages can vary for different viruses, and some viruses have steps within stages that are not shared with other viruses. For example, the replication of HIV and the steps that have been targeted by approved antiviral drugs are illustrated in Figure 14.2. In principle, any stage can be targeted for inhibition. A potential advantage to targeting very early steps such as attachment during the entry stage, or very late steps, such as release during the assembly/egress stage, is that drugs, such as certain peptides, that act at these steps do not have to enter cells to exert activity (most orally available drugs enter cells readily). Stages such as gene expression, genome replication, and assembly/egress often require specific viral enzymes, which, as described above, are attractive drug targets. Indeed, small molecules that inhibit genome replication comprise the largest class of antiviral drugs.

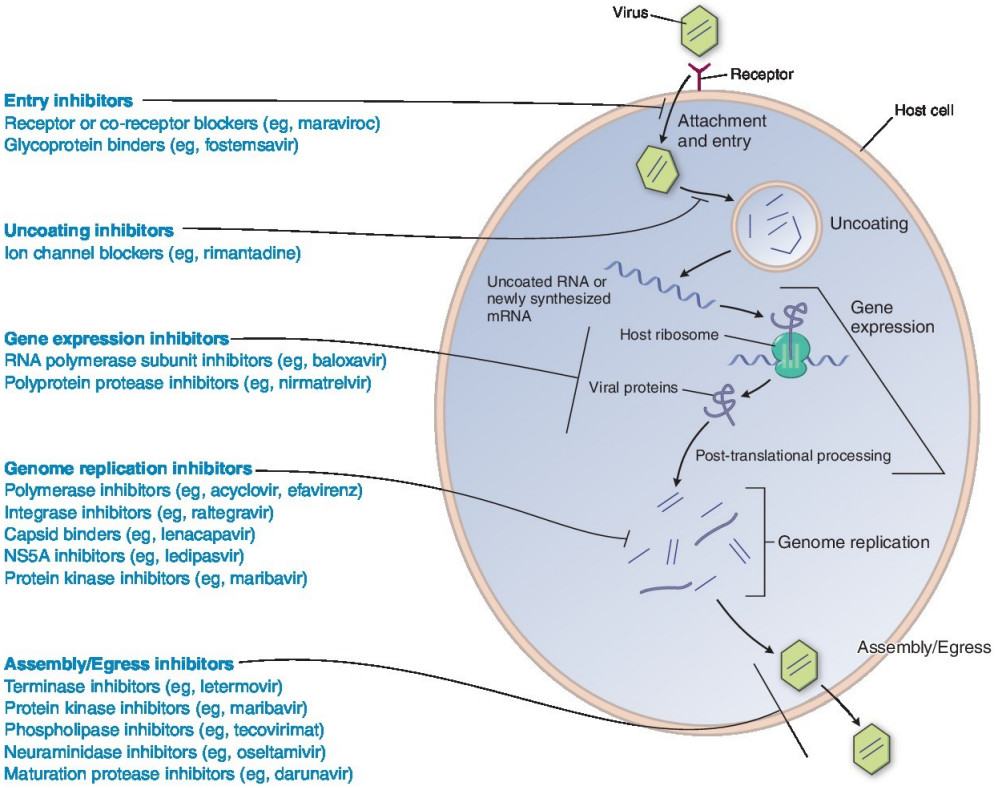

FIGURE 14.1 **Antiviral drugs block various stages of viral replication**. A generic replication cycle of viruses in cells is cartooned, showing the stages of infection, which different drug classes block. These include entry, uncoating, gene expression, genome replication, and assembly/egress. Classes of drugs with examples are provided. For some viruses (eg, HIV), the order of the stages differs from that in this cartoon (see Fig. 14.2, which also highlights different steps within stages). (Modified with permission from Li JZ, Coen DM. Pharmacology of viral infections. In: Golan DE, Armstrong EJ, Armstrong AW, eds. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. 4th ed. Wolters Kluwer; 2017:694-722, Ref.[255])

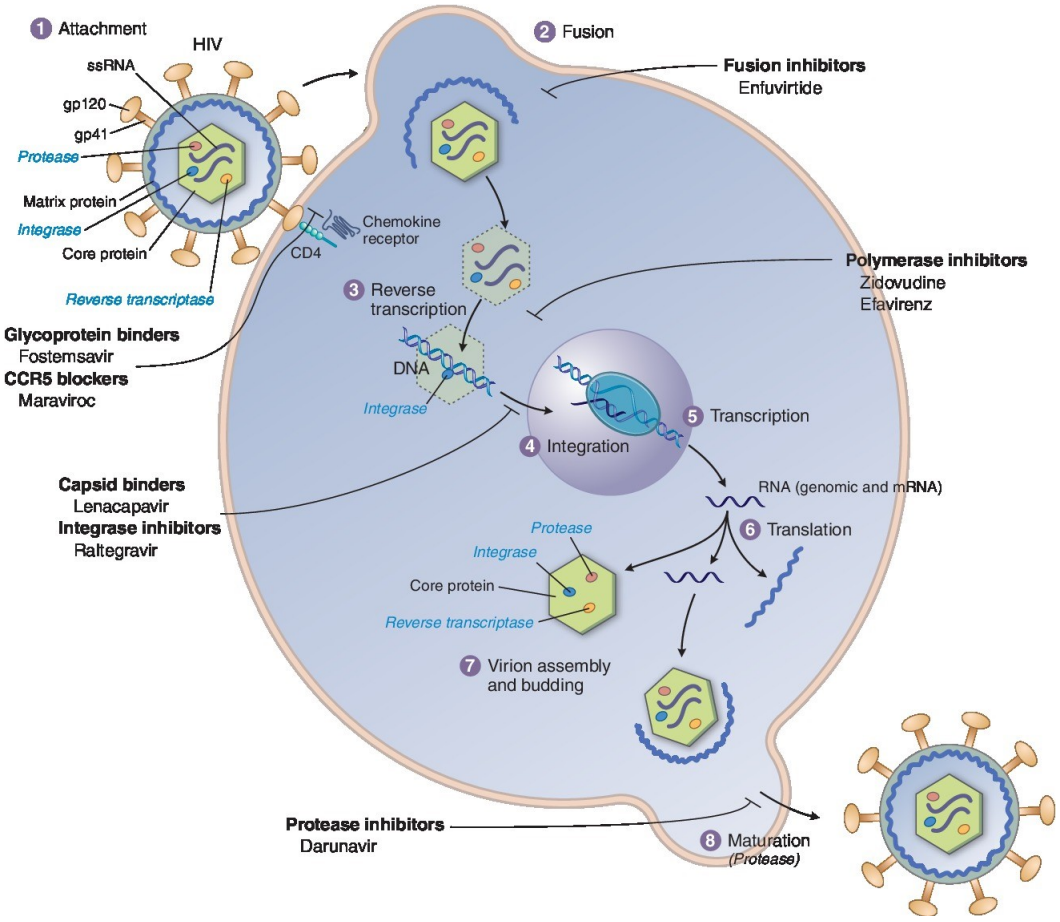

FIGURE 14.2 **Steps of HIV infection blocked by different classes of antiviral drugs**. The life cycle of HIV is cartooned, showing: **1**. Virus attachment is dependent on binding interactions between viral gp160 (composed of gp41 and gp120 proteins) and host cell CD4 and certain chemokine receptors. **2**. Fusion of the viral membrane (envelope) with the host cell plasma membrane allows the HIV genome complexed with certain virion proteins to enter the host cell. **3**. Uncoating permits the single-stranded RNA (ssRNA) HIV genome to be copied by reverse transcriptase into double-stranded DNA. **4**. The HIV DNA is integrated into the host cell genome, in a reaction that depends on HIV-encoded integrase. **5**. Gene transcription and posttranscriptional processing by host cell enzymes abetted by viral gene products produce genomic HIV RNA and viral mRNA. **6**. The viral mRNA is translated into proteins on host cell ribosomes. **7**. The proteins assemble into immature virions that bud from the host cell membrane. **8**. The virions undergo proteolytic cleavage, maturing into fully infective virions. The steps at which classes of anti-HIV drugs act (attachment, fusion, reverse transcription, integration, and maturation) are indicated, with examples from specific drug classes provided. (Adapted with permission from Li JZ, Coen DM. Pharmacology of viral infections. In: Golan DE, Armstrong EJ, Armstrong AW, eds. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. 4th ed. Wolters Kluwer; 2017:694-722.)

Inhibition of Viral Entry

Inhibition of entry prevents all subsequent steps in virus infection and permits the virion to be cleared by immune and other mechanisms. Mechanisms by which viruses enter host cells are reviewed elsewhere in this edition. Briefly, the first step is attachment wherein one or more specific proteins on the virion surface (eg, HIV glycoprotein [gp] 120) bind to one or more specific receptor molecules (eg, for HIV, CD4 and coreceptors CCR5 or CXCR4) on the cell surface. These receptors are usually proteins but are sometimes simpler entities such as modifying groups (eg, sialic acid for influenza virus) on cell surface molecules. The viral protein-host receptor interactions can result in changes in one or both entities. Entry then requires that nucleocapsids cross host membranes to enter the cytoplasm, sometimes directly across the plasma membrane and sometimes following internalization of the virion bound to the receptor. In the case of enveloped viruses such as HIV, entry involves fusion of the viral envelope (membrane) with a host membrane, which often entails dramatic conformational changes (this process for HIV is cartooned in Fig. 14.3).

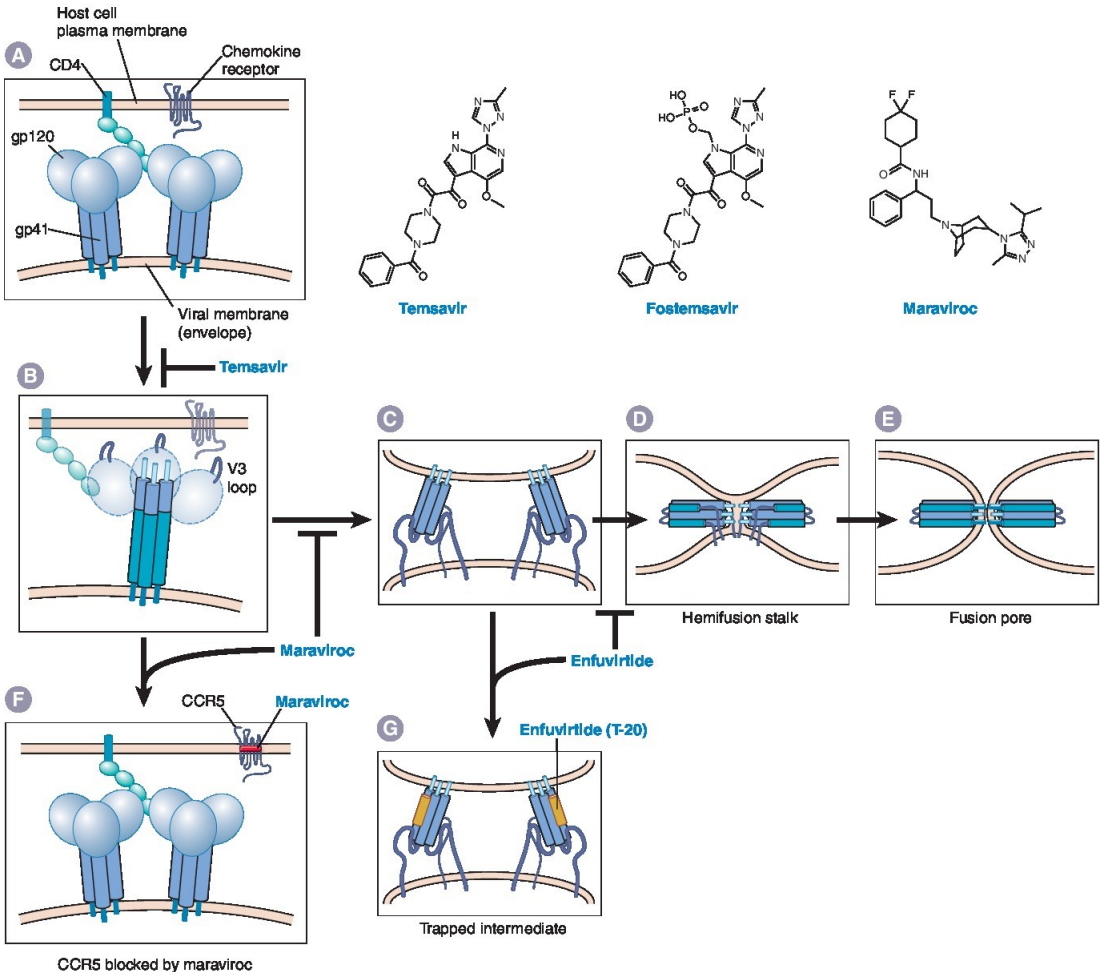

FIGURE 14.3 **Model for HIV gp41–mediated fusion and drug action**. **A**. HIV glycoproteins exist in trimeric form in the viral envelope. Each gp120 molecule is depicted as a ball attached noncovalently to gp41. The CD4 receptor and a chemokine receptor that serves as a coreceptor in the host cell plasma membrane are shown. The structures of temsavir, its orally available form, fostemsavir, and maraviroc are depicted. **B**. The binding of gp120 to CD4 causes a conformational change that results in the V3 loop of gp120 contacting the coreceptor. Temsavir binds to gp120 and blocks this conformational change. Binding of gp120 to the coreceptor causes a conformational change in gp41 that exposes the fusion peptide, heptad-repeat region 1 (HR1) and heptad-repeat region 2 (HR2). The fusion peptide inserts into the host cell plasma membrane. Maraviroc binds to one of the chemokine receptors that can serve as a coreceptor, CCR5, and can block the gp120-CCR5 interaction and thus the gp41 conformational change of HIV strains that use CCR5. **C**. gp41 undergoes further conformational changes, characterized by unfolding and refolding of the HR2 segments. Enfuvirtide is a synthetic peptide that mimics HR2 and binds to HR1. It prevents the HR1-HR2 interaction and blocks further refolding. **D**. Completed refolding of

the HR regions creates a hemifusion stalk in which the outer leaflets of the viral and host cell membranes are fused. **E**. Formation of a complete fusion pore allows viral entry into the host cell. **F**. Maraviroc traps the virus-host cell interaction at the attachment stage, preventing subsequent conformational changes, membrane fusion, and viral entry. **G**. Enfuvirtide traps gp41 so that HR2 cannot fold onto HR1, thereby blocking hemipore formation and fusion. (Adapted with permission from Li JZ, Coen DM. Pharmacology of viral infections. In: Golan DE, Armstrong EJ, Armstrong AW, eds. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. 4th ed. Wolters Kluwer; 2017:694-722.)

Drugs that inhibit entry can target either viral proteins or host proteins. Thus far, efforts to find such drugs have resulted in three approved anti-HIV drugs, fostemsavir, maraviroc, and enfuvirtide (plus a monoclonal antibody drug, ibalizumab), and a drug active against hepatitis B and D viruses (HBV and HDV), bulevirtide, that at this writing is poised for approval. Three of these drugs have unusual properties: maraviroc and bulevirtide target a host protein, and bulevirtide and enfuvirtide are peptides.

Blocking Entry With a Viral Glycoprotein-Derived Peptide: Bulevirtide

HBV and HDV are enveloped viruses displaying three HBV-encoded glycoproteins, S, M, and L, on their surfaces. HDV requires HBV for its propagation; infection with both HBV and HDV causes more serious disease than with HBV alone. A specific segment of HBV glycoprotein L called the pre-S1 domain, which is myrisotylated at its N-terminus, is necessary for infectivity of HBV and HDV, and peptides derived from it are sufficient to bind to liver cells.[254,295,317,422] Pretreatment of cells with myristoylated peptides corresponding to roughly the first half of this segment can specifically inhibit HBV and HDV infectivity with low nM potency, and replacement of the myristate with longer fatty acids resulted in even greater potency.[27,116,161] Starting with a myristoylated pre–S1-derived peptide modified to permit photocrosslinking, Yan et al. identified a host cell protein, sodium taurocholate cotransporting polypeptide (NTCP), as the virus receptor.[482] A myristoylated pre-S peptide can block binding of HDV to cells expressing NTCP[482] suggesting a block at the step of attachment, although effects on subsequent steps leading to virus entry cannot be ruled out. NTCP is crucial for the transport of bile acids, and human genetic studies have indicated that mutations disrupting NTCP function result in substantially elevated serum levels of bile; however, there appears to be much less risk to health than HBV and HDV disease.[449] These findings led to the synthesis and development of an injectable 47 residue peptide (residues 2-48 of glycoprotein L) with an N-tetradecanoylglycyl–modified N-terminus and an amidated C-terminus (bulevirtide), which, at this writing, has been approved in Europe and is under review by the FDA for treatment of chronic HDV infection with compensated liver disease. Given that bulevirtide engages a host protein, one might expect resistance to be unlikely, but not impossible. As of 2020, no resistance to bulevirtide had been detected in treated patients.[123] Continued *in vitro* and clinical studies will be needed to address this possibility.

Targeting a Viral Glycoprotein With a Small Molecule: Fostemsavir

Fostemsavir (Fig. 14.3) was developed starting from a hit that came out of a cell-based screen for compounds that would block an HIV-derived pseudovirus from infecting cells and expressing a reporter gene.[260] Follow-up studies found that the hit compound acted very early in infection and could inhibit the ability of cells expressing the HIV glycoprotein gp120 to fuse with cells expressing CD4 and CCR5.[260] After lengthy medicinal chemistry, preclinical and clinical efforts, as well as studies[166,260] showing that active compounds bind to gp120, and that specific mutations that alter gp120 both reduce binding and confer resistance, the hit was developed into fostemsavir, which is phosphonooxymethyl prodrug of the active 6-azaindole piperazine, temsavir (Fig. 14.3).

Although temsavir and its analogs are frequently described as attachment inhibitors, their mechanism is controversial. Early studies showed that one of these compounds could inhibit binding of gp120 to soluble CD4, supporting a block to attachment.[260] However, the 50% inhibitory dose (IC_{50}) in this assay was ~10-fold higher than in an assay measuring effects on viral replication,[260] and another study found little or no effect on gp120-CD4 binding.[400] Moreover, it was reported that the compounds remain active against HIV strains that can enter cells that don't express CD4.[258] Detailed crystallographic, biochemical, and mutational studies then determined that when members of this class of compounds bind gp120, they interact with a crucial beta-hairpin to stabilize a conformation of gp120 that is still able to bind CD4, but unable to undergo conformational changes that permit engagement of coreceptors that eventually lead to the fusion step of entry (eg, see Refs.[186,342,400]) (Fig. 14.3). It appears then that temsavir has activity at the attachment step, but that its major mode of action is at the subsequent step involving conformational changes and coreceptor interactions.

As noted above, mutations altering gp120 can cause resistance to temsavir in infected cells. As certain of these mutations have been found in patients treated with fostemsavir, they clearly retain some fitness.[226]

Targeting a Coreceptor: Maraviroc

Maraviroc (Fig. 14.3) inhibits binding of HIV to the CCR5 coreceptor. CCR5 is the coreceptor used by the most commonly transmitted HIV-1 strains (R5 tropic), which predominate during the early stages of HIV-1 infection.[47] There are several attractive features to CCR5 as a target for anti-HIV drugs: knockout mice lacking CCR5 and humans with homozygous deletions in the gene encoding CCR5 (CCR5-Δ32) remain healthy albeit with some immune deficits in countering infections other than HIV, suggesting that blocking this host function would not have consequences anywhere near as adverse as HIV disease.[56] Certain of these CCR5Δ32 homozygotes who have been highly exposed to HIV have remained uninfected, and their cells are resistant to R5-tropic strains of HIV *in vitro*.[268] Blockade of CCR5 with a natural ligand (eg, RANTES) or antibody inhibits R5-tropic HIV replication (eg,[81]). These observations suggested that blocking CCR5 could be efficacious against R5-tropic HIV without causing serious toxicity.

Maraviroc was discovered using high throughput screening for small molecules that block binding of CCR5 to a natural ligand, followed by medicinal chemistry efforts to improve upon a hit from the screen.[102] Modeling and mutational studies suggest that maraviroc and several other CCR5 blockers bind to a pocket on CCR5 formed by transmembrane domains,[224] and allosterically inhibit binding to HIV gp120, thereby blocking HIV entry (Fig. 14.3).[17,102,146,460] R5-tropic HIV mutants resistant to CCR5 blockers including maraviroc contain altered gp120 molecules that are able to bind to the drug-bound form of CCR5[442,460] and are often highly fit.[8] Maraviroc was approved in 2007 for use in combination with other anti-HIV drugs in patients with R5-tropic strains. Thus, patients must be tested to determine if they harbor virus that utilizes a different coreceptor (ie, CXCR4). Maraviroc treatment failures are more frequently attributable to preexisting minority populations of CXCR4-tropic virus than to selection of R5-tropic virus that is resistant to maraviroc.[308] Resistance to CCR5 blockers has not resulted thus far

from R5-tropic virus evolving to use a different coreceptor. Nevertheless, this possibility and the effects of antagonizing a host function remain potential issues for the long-term clinical use of maraviroc.

A Fusion Inhibitor: Enfuvirtide

Enfuvirtide was discovered by a rational, directed approach that examined the ability of peptides to inhibit HIV infection in cell culture.[467,468] The peptide that was most potent, enfuvirtide, is similar to a segment of gp41, the HIV protein that mediates membrane fusion. The proposed mechanism for gp41-mediated membrane fusion and enfuvirtide action is illustrated in Figure **14.3**: The gp41 protein in the virion is ordinarily trapped in a metastable conformation so that it cannot fuse membranes or bind enfuvirtide. Binding of HIV to CD4 and then to a coreceptor triggers conformational changes that expose the segment of gp41 thought to insert into host cell membranes (fusion peptide), a helically coiled heptad repeat region (HR-1), and the segment that enfuvirtide resembles, which is a second helical heptad repeat (HR-2). The trimeric gp41 then rearranges, so that the HR-1 and HR-2 helices bind to each other, forming a six-helix bundle. If the fusion peptide has inserted into the host cell membrane, this refolding brings the virion envelope and the cell membrane in proximity, allowing membrane fusion to occur (by mechanisms that remain incompletely understood). When enfuvirtide is present, however, it binds to HR-1 and prevents the refolding process, thereby preventing fusion of the HIV envelope with the host cell membrane.

Although this model requires an exogenous peptide to compete with an intramolecular interaction to bind to a target that is available only transiently, it is supported by a number of observations. These include the crystal structure of the rearranged form of gp41, which shows the HR-1-HR-2 interaction[59,432,458] and evidence that enfuvirtide interacts with HR-1 containing peptides.[60,247,466] Genetic studies show that HR-1 and HR-2 are crucial for fusion.[107,465] Perhaps the strongest evidence that enfuvirtide inhibits HIV replication by binding to HR-1 is that HIV mutations that confer resistance to enfuvirtide alter HR-1 residues, and that these alterations weaken binding of enfuvirtide to HR-1.[372] A number of such mutants exhibit reduced fitness in cell culture, although they have been recovered from patients.[271]

Inhibition of Viral Uncoating: Adamantane Derivatives

The adamantanes, amantadine and rimantadine (Fig. 14.4), were the first successful anti-influenza drugs, although they are no longer recommended for use due to widespread resistance of circulating strains and the availability of more effective alternatives. The adamantanes are active exclusively against influenza A virus (and not influenza B, C, or D viruses) and inhibit virus uncoating. The key to understanding their mechanism was discovered by Hay and colleagues[173] who showed that mutants that could replicate at therapeutic concentrations of amantadine were resistant due to point mutations within the M segment of the influenza RNA genome, in an open reading frame that had only recently been recognized. This open reading frame encodes a small membrane protein known as M_2 (the M segment also encodes the matrix [M_1] protein.) Subsequent biochemical and electrophysiological experiments showed that the M_2 protein forms a tetrameric, pH-gated channel for H^+ ions and that amantadine and rimantadine block this channel.[32,108,189,352,415] Viral mutations conferring resistance to these drugs alter any of five residues in the transmembrane segment of the protein that are predicted to be within the pore of the channel, suggesting that the drugs bind to these residues and "plug" the channel.[172] Structural studies of drug bound versions of M_2, electrophysiological assays using Xenopus oocytes, and assays of engineered viral mutants support this suggestion.[53,206,327,414]

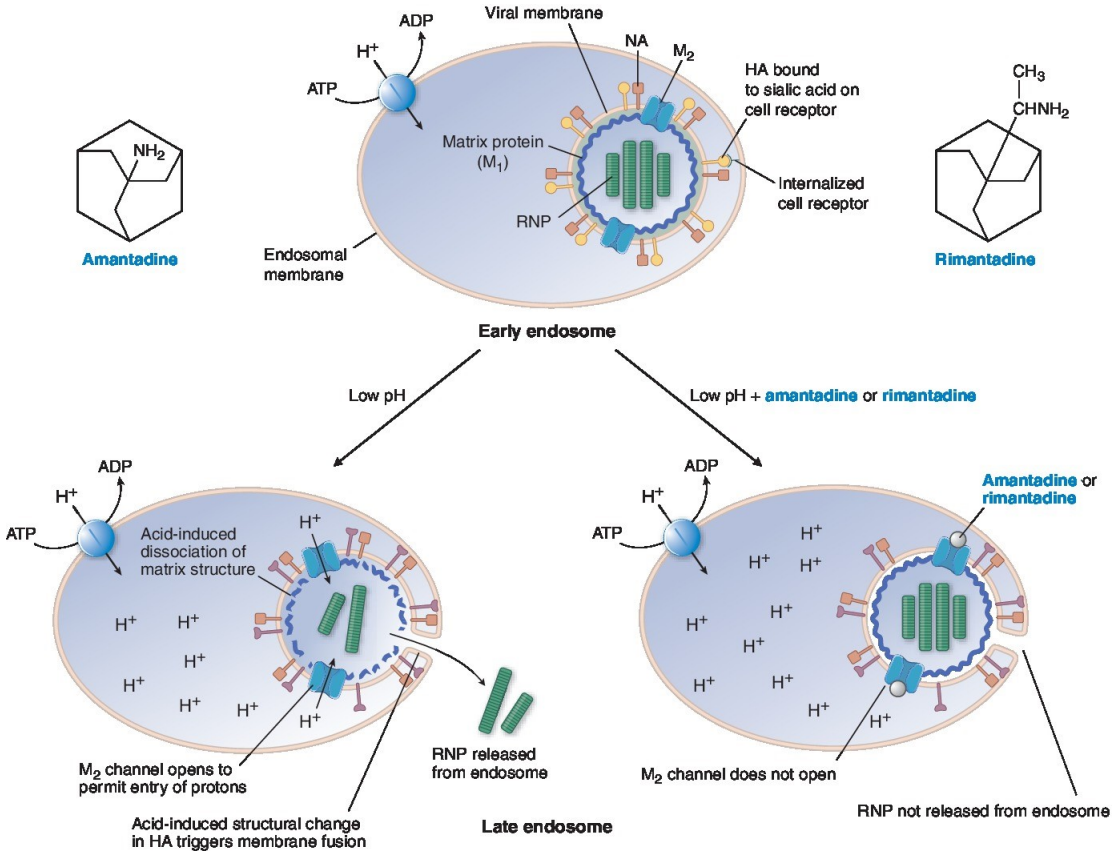

FIGURE 14.4 **Model for uncoating of influenza A virus and effect of amantadine or rimantadine**. The structures of

amantadine and rimantadine are shown. The process of influenza A virus uncoating and drug action is depicted. The virus enters host cells by receptor-mediated endocytosis (not shown) and is contained within an early endosome. The early endosome contains a H^+-ATPase that acidifies the endosome by pumping protons from the cytosol into the endosome. A low pH–dependent conformational change in the envelope protein, hemagglutinin (HA), triggers fusion of the viral membrane with the endosomal membrane. This fusion event, however, is not sufficient to cause viral uncoating. In addition, protons from the late endosome must enter the virion through the M_2 proton channel, which is a virion envelope protein that opens in response to acidification (pH-gated ion channel). The entry of protons into the virion causes dissociation of the M_1 matrix protein from the influenza A ribonucleoprotein (RNP), releasing it into the cytoplasm. The dissociation of matrix is required for RNP to be transported to the nucleus, where it is transcribed and replicated. Amantadine and rimantadine block the M_2 ion channel and thereby inhibit acidification of the interior of the virion, matrix dissociation, and uncoating. NA, neuraminidase. (Adapted with permission from Li JZ, Coen DM. Pharmacology of viral infections. In: Golan DE, Armstrong EJ, Armstrong AW, eds. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. 4th ed. Wolters Kluwer; 2017:694-722.)

How would blocking an ion channel lead to inhibition of uncoating? A reasonable but not completely verified model is diagrammed in Figure 14.4. Influenza A virus attaches to sialic moieties on cell surface glycoproteins, and then, bound to its receptor, is internalized, surrounded by a cell membrane-bounded compartment, the endosome, which normally participates in membrane protein recycling. As part of its normal function, the endosome becomes acidified. During influenza virus entry, this reduction in pH causes a conformational change in the virion hemagglutinin protein and fusion of the virion envelope and the endosomal membrane via a mechanism similar to that of HIV gp41 (Fig. 14.3). By itself, this action would release viral ribonucleoprotein into the cytoplasm. However, in the presence of amantadine or rimantadine, the matrix protein, M_1, does not dissociate from the ribonucleoprotein, which remains in the cytoplasm instead of entering the nucleus.[51,286] Low pH can promote the dissociation of M_1 and allow nuclear entry of the ribonucleoprotein.[50] Thus, M_2 in the virion envelope functions to let H^+ ions from the acidified endosome enter the virion and dissociate M_1 from the ribonucleoprotein. Amantadine and rimantadine would block the entry of H^+ ions, thereby preventing this uncoating event.

With certain influenza A virus strains, amantadine and rimantadine also block late events in virus replication, in particular, maintenance of hemagglutinin in a proper conformation for infectivity.[172]

Influenza virus mutants that are resistant to amantadine and rimantadine due to altered M_2 have been assayed in animal models including mice and ferrets and show little or no diminution in their replication or pathogenesis.[29,336,427] This correlates well with their behavior in human infections.[174]

Inhibition of Viral Gene Expression

Viral gene expression entails not only the transcription of the viral genome into mRNA, the translation of mRNA into protein, and the stabilities of RNA and protein gene products but can also include a variety of processing events including capping, splicing, and polyadenylation of viral mRNAs, and proteolytic cleavage of viral polyproteins into their individual protein units. Many viruses encode functions that execute or abet one or more of these steps in gene expression, and much effort has gone into targeting these functions for development of antiviral drugs. One such function is performed by the cap-snatching endonuclease subunit of influenza virus RNA polymerase, which is crucial for synthesis of viral mRNAs and is targeted by baloxavir. A second function is performed by viral proteases that generate individual viral proteins. This function has been targeted by antiviral drugs against HIV, HCV, and severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), the cause of COVID-19. The activity of one of these, the HIV protease, is not required until the viral particle is fully assembled, and thus will be discussed under *Inhibition of Viral Assembly/Egress* (see below). The activities of the HCV NS3/4A protease and the SARS-CoV-2 main (M) protease, however, are required for proper expression of viral gene products for essentially all subsequent steps in viral infection, and successful antiviral drugs have been developed against these enzymes.

Inhibition of Influenza mRNA Transcription: Baloxavir

Following uncoating, each segment of the influenza virus negative strand genome (vRNA) enters the nucleus associated with a copy of the virally encoded, heterotrimeric (PB1, PB2, and PA subunits) RNA-dependent RNA polymerase (RdRp).[103,436] The RdRp is responsible both for replication of the viral genome and for transcription to generate mRNAs required for viral protein translation. Influenza mRNA production employs a “cap-snatching” mechanism whereby 5′ 7-methyl guanosine–capped host transcripts are captured and cleaved to generate short-capped RNAs that act as primers for transcription (Fig. 14.5): A capped host transcript is first recognized and bound by the PB2 subunit of the influenza polymerase (Fig. 14.5A). The transcript is then cleaved 10-13 residues from the 5′ cap by a cap-dependent endonuclease (CEN) encoded within the PA subunit[103,227,353] (Fig. 14.5A). This capped fragment then acts as a primer, which is elongated by the PB1 subunit in a template-dependent fashion to generate viral mRNAs complementary to the genomic RNA segment to which the RdRp is bound (Fig. 14.5B-E). This mechanism also ensures that influenza mRNAs are capped, so that they are stable and can be translated efficiently by the host translational machinery.

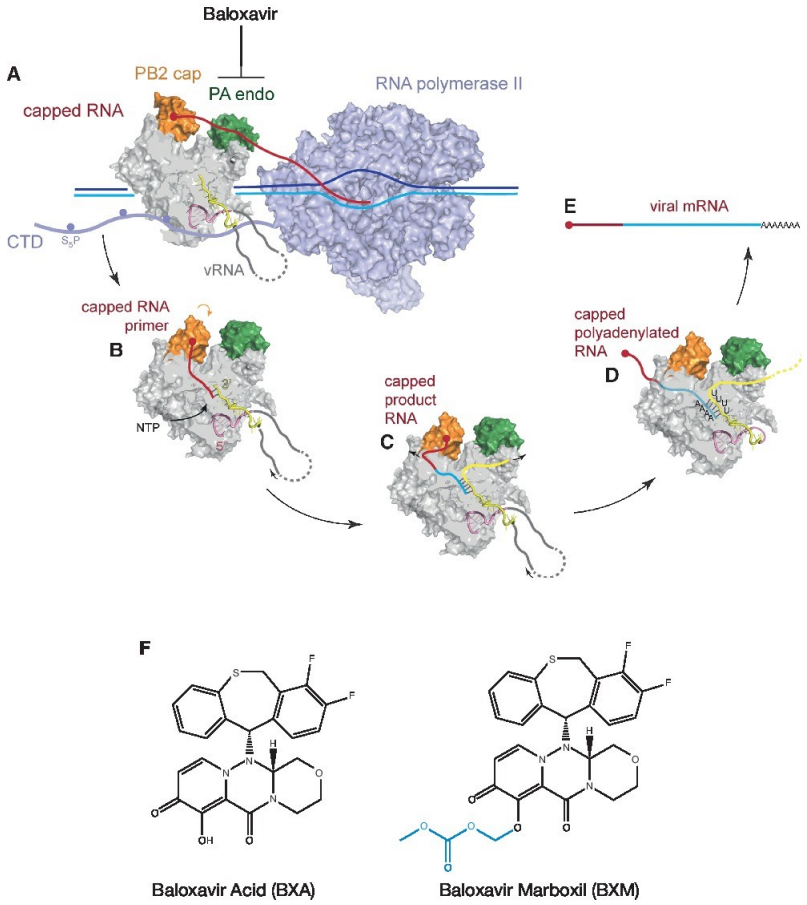

FIGURE 14.5 **Baloxavir, an inhibitor of the cap-snatching step of influenza transcription**. **A**. The three-subunit influenza polymerase (PA, PB1, PB2) associates with a nascent host mRNA and host RNA polymerase II, which permits binding of the host mRNA cap to the PB2 cap-binding domain and cleavage of the nascent transcript by the PA endonuclease (endo). Baloxavir inhibits the endonuclease. **B-E**. In the absence of baloxavir, the cleaved 5′ capped end of the nascent host transcript serves as a primer for the PB1 RNA polymerase, which is bound to viral genomic RNA (vRNA) and elongates the primer in a template-dependent manner, and then polyadenylates the transcript by stuttering on an oligouridine stretch in the vRNA to yield the completed influenza mRNA. **F**. The structures of baloxavir acid, the active drug, and baloxavir marboxil, the prodrug. (Adapted from Krammer F, Palese P. Orthomyxoviridae: The viruses and their replication. In: Howley PM, Knipe DM, eds. *Fields Virology: Emerging Viruses*. Vol 1. 7th ed. Wolters Kluwer; 2021:596-648.)

Baloxavir acid (BXA; Fig. 14.5F) is an inhibitor of the essential CEN function of influenza A and B PA, hence preventing mRNA transcription.[323,440] It was designed to mimic the mechanism of inhibitors of HIV integrase strand transfer (see under *Inhibition of Viral Genome Replication* below), as both enzymes require two divalent cations for their endonuclease function.[323] Critical to the compound design was retention of a di-ketophenol of the oxazino-pyridotriazin-dione (Fig. 14.5F), which acts as a metal chelation site, binding the two required divalent cations within the endonuclease active site.[330] The second “wing” of the molecule (difluoro-dihydro-dibenzothiepine; Fig. 14.5F) makes extensive van der Waals contacts with hydrophobic residues in the active site (eg, Ala20 and Tyr24, Lys34, Ala37, and Ile38 for influenza A).[330,485] BXA demonstrates a low nM IC_{50} for inhibition of endonuclease activity, with no measurable activity on CEN-independent RdRp activity, or human pol II.[323] BXA shows similar potency in inhibiting influenza A and B replication and in decreasing mRNA, complementary RNA for genome replication, and vRNA synthesis in infected cells,[323,330] consistent with a requirement for cap snatching to prime mRNA synthesis that is required for subsequent genome replication.[350]

Studies of mutants derived by *in vitro* selection or emergent resistance in the clinic demonstrate substitutions at isoleucine 38 as conferring resistance to BXA. X-ray crystallographic studies demonstrate that I38 is in the hydrophobic pocket bound by the difluoro-dihydro-dibenzothiepine wing on the molecule.[330] The I38T substitution increased BXA EC_{50} for *in vitro* influenza replication 30-50 fold, with smaller diminutions in activity noted for other position 38 substitutions.[179,323] Acquisition of resistance clinically, correlated with an increase in the median time to symptom resolution.[179] Further characterization of the I38T substitution showed a decreased endonuclease activity as well as *in vitro* replicative viral fitness, potentially through decreased RNA binding.[323,330,485]

To improve oral bioavailability, baloxavir acid is administered as a prodrug, baloxavir marboxil, (BXM) (Fig. 14.5F).

Inhibition of Polyprotein Cleavage: HCV NS3/4A Protease Inhibitors

As noted above, proteolytic cleavage of viral polyproteins into individual viral proteins is an important step of gene expression, and viral proteases that perform this step have been targeted to develop antiviral drugs. Following entry of the flavivirus, HCV, its RNA genome is translated into a single very large (~3000 residue) polypeptide. Subsequent proteolytic processing of the polypeptide to release functional proteins is accomplished through a combination of host cell proteases and two virally encoded proteases—nonstructural protein 2 (NS2) and NS3. Drug discovery efforts have focused on NS3, a serine protease that associates with a second viral protein (NS4a), which both increases its

enzymatic activity and anchors the protein to the membrane to augment processing efficiency.[237] NS3 autoproteolytically cleaves between NS3 and NS4A and then cleaves to generate NS4A (its cofactor), NS4B, NS5A, and NS5B.[310] NS3/4a may also play a role in blunting the host immune response by cleaving cellular substrates involved in double-stranded RNA sensing and induction of the type 1 interferon response.[256,362]

Prior to 2011, the standard of care for HCV infection was treatment with a combination of interferon-α (IFN-α) and ribavirin (a nucleoside analog; see below), which had limited efficacy that varied across the 6 HCV genotypes and had major side effects. The development of NS3/4A inhibitors drugs serves as a case study for how medical need drives medicinal chemistry aided by structural biology.

As a serine protease, NS3 employs the typical serine, histidine, aspartate "catalytic triad" to effect peptide cleavage.[101] Like most proteases, NS3 also has a pocket called the oxyanion hole that stabilizes the negative charge that results following substrate cleavage. All of the approved HCV NS3/4A inhibitors have extensive binding contacts with the catalytic triad both to optimize binding affinity and to ensure that drug resistance mutations that affect these contacts would result in a fitness penalty. Additional interactions also occur with 3-4 substrate recognition sites on the amino terminal side of the bond cleavage site (termed P1-P4 for the inhibitor (see Fig. 14.6A for an example, telaprevir)).

Boceprevir and telaprevir were the first 2 approved direct-acting antivirals for treatment of HCV.[148] They are linear peptidomimetics interacting with the S1-S4 pocket of the protease (Fig. 14.6A and B). Both employ an alpha ketoamide to covalently, but reversibly, engage the catalytic serine. Additional, critical binding interactions include engagement of His 57 of the catalytic triad and residues within the peptide binding site, and hydrogen bonding contacts at positions 155 and 156 (Fig. 14.6C). The compounds possess low nM potency against the genotype 1 NS3/4A enzyme and low triple digit nM potency in cell-based assessments employing subgenomic replicon systems.[191,259,346,450] These molecules represented a significant advance in HCV therapy, substantially increasing the rate of sustained virologic response (cure) and decreasing the treatment duration. However, the first-generation inhibitors were still combined with IFN-α and ribavirin, adding the molecules' side effects to those of IFN-α and ribavirin; their modest potency and suboptimal pharmacokinetics (PK) required three times a day dosing; and resistance mutations developed at six different positions.[216,379,388,416,423] Crucially, they were less potent against nongenotype 1 HCV.[96,158,404]

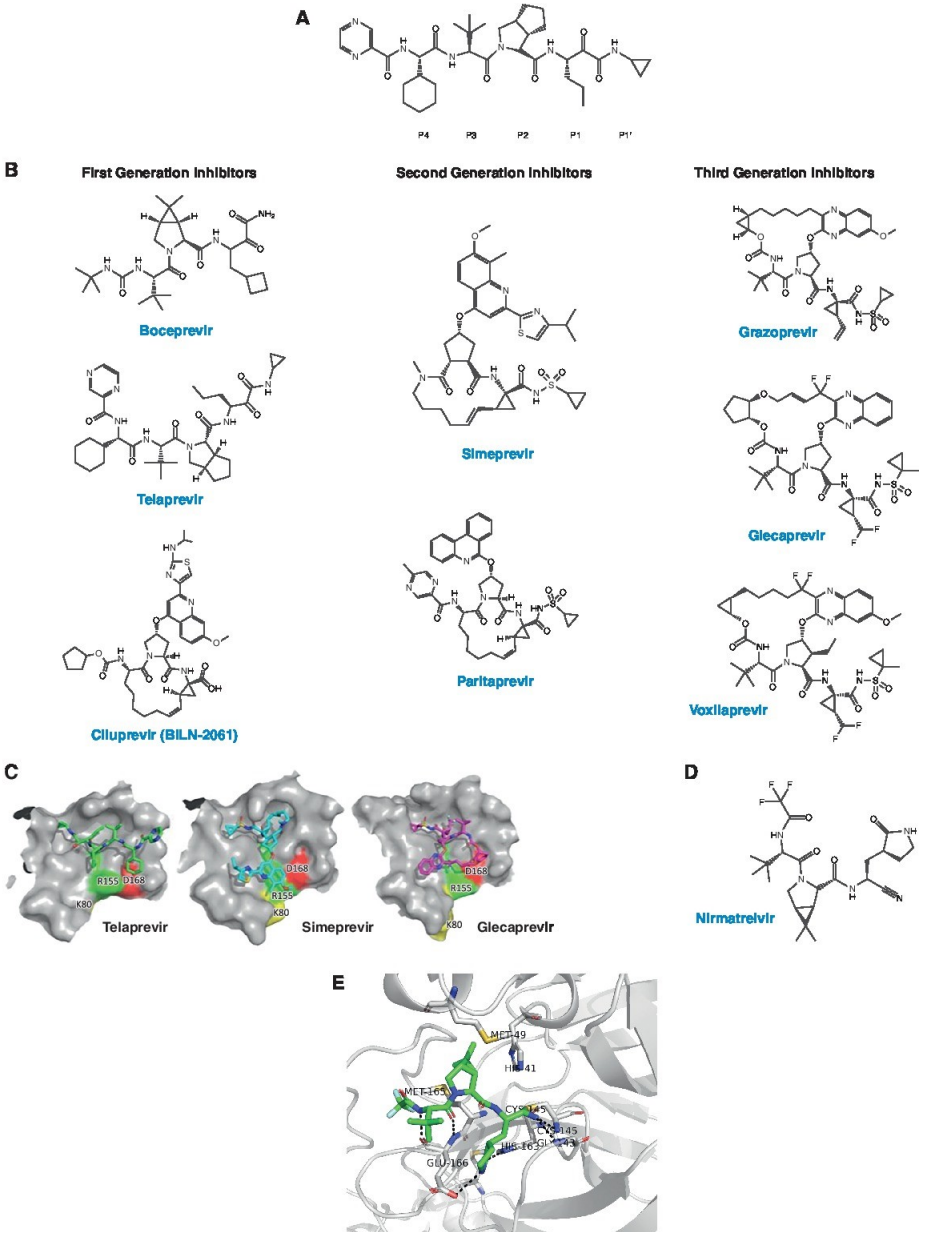

FIGURE 14.6 **Protease inhibitor antiviral drugs that block polyprotein processing of HCV and SARS-CoV2**. **A**. Telaprevir is arranged as a linear peptidomimetic, with moieties P1-P4 and P1' that interact with the corresponding pockets of the HCV NS3/4A protease. **B**. Structures of first-generation approved inhibitors telaprevir and boceprevir along with the investigational drug ciluprevir are shown in the left column; second-generation (simeprevir and paritaprevir) and third-generation (grazoprevir, glecaprevir, voxilaprevir) inhibitors (middle and right column, respectively) were based on ciluprevir. See text for details. **C**. The binding of an example of each generation of inhibitor (telaprevir, simeprevir, glecaprevir) to the HCV NS3/NS4 protease is shown. The positions of amino acids K80, R155, and D168, which bind to some inhibitors, and not others are shown. See text for details. **D**. The structure of the SARS-CoV-2 main protease inhibitor, nirmatrelvir. **E**. Schematic of the binding of nirmatrelvir in the main protease active site. Nirmatrelvir forms a reversible covalent bond via the P1' nitrile with Cys145 as well as hydrogen bonds with the backbone NH of Cys145, Gly143, His163, and Glu166, and hydrophobic interactions with a pocket formed by Met49, His41, and Met165. Panels C and E were kindly provided by Paul Charifson.

Most second-generation inhibitor efforts were based on ciluprevir (also known as BILN-2061), a macrocyclic compound that did not progress to approval but was the first HCV protease inhibitor to demonstrate antiviral activity in humans[236] (Fig. 14.6B). Incorporation of a macrocyclic structure improved compound potency, cellular permeability, and bioavailability.[398] A common modification of ciluprevir that was broadly employed was replacement of the P1 carboxylic acid with a more druglike ketosulfonamide[19,218,376] (Fig. 14.6B). The substitution retains extensive contacts within the oxyanion hole, and like the analogous carboxylate of ciluprevir does not form a covalent bond with the catalytic serine. Similar to ciluprevir, the second-generation inhibitors contain a 14-16 membered macrocyclic ring linking P1 and P3. A third common structural feature was incorporation of a large hydrophobic substituent at P2, which improved target binding through interaction with hydrophobic shelf in that position[293,380] (Fig. 14.6C). Two inhibitors from this structural class, simeprevir and paritaprevir (Fig. 14.6B), progressed to U.S. FDA approval as components of some of the first all oral therapies for HCV, eliminating the use of IFN-α. Both molecules were substantially more potent, were dosed once a day, and the combination therapies were highly effective against genotype 1 within 12-24 weeks.[128,245] However, three of the mutations identified with the first-generation inhibitors, especially those affecting NS3 residues 155 and 168, still conferred resistance to the new drugs, and one of these is a signature polymorphism of genotype 3 (D168Q).[293,451]

The critical change in molecular design of third-generation inhibitors was moving the attachment point for the macrocycle from P1 to position 3 of the P2 proline (Fig. 14.6B).[167,170,434] This allowed decreased interaction with positions 155 and 168 (Fig. 14.6C) and dramatic improvements in potency against genotype 3 and mutants resistant to the first 2 generations of NS3/4A inhibitors.[169,319] A second common design feature was incorporation of a quinoxaline within the macrocyclic ring system (Fig. 14.6B). This resulted in a more extensive pi stacking interaction with His 57 of the catalytic triad, which was critical in improving genotype 3 potency[434] (Fig. 14.6C). These changes provided molecules with sub nM potencies when assessed in subgenomic replicons across the six HCV genotypes, as well as drug resistance mutations identified in the first 2 generations of molecules. Glecaprevir and voxilaprevir (Fig. 14.6B and C) are components of two all oral, multidrug regimens approved for treatment of all HCV genotypes.

Inhibition of Polyprotein Processing: A SARS-CoV-2 Mpro Inhibitor

Following entry of the coronavirus, SARS-CoV-2, its ~30 kilobase viral RNA genome is expressed as 2 large polyproteins, pp1a and pp1ab encoding 11 and 16 viral proteins, respectively.[446] The polyproteins are processed by two essential, virus-encoded cysteine proteases, the papainlike protease (PLpro) and the chymotrypsinlike or main protease (3Clpro or Mpro).[446] Nirmatrelvir (Fig. 14.6D) is a covalent reversible tetrapeptide peptidomimetic inhibitor of the SARS-CoV-2 Mpro. The chemical structure is related to that of the HCV NS3/4A inhibitor, boceprevir (Fig. 14.6B), which was found to inhibit SARS-CoV-2 Mpro.[23,138,274] Optimization yielded nirmatrelvir, which has a 3 nM K_i for inhibition of the SARS-CoV-2 Mpro.[335] The compound forms a reversible covalent bond with the catalytic cysteine (Cys 145) (Fig. 14.6E), but otherwise does not make extensive contact with the oxyanion hole. The P1 cycloglutamine forms a bidentate hydrogen bond to histidine 163 and the carboxylic acid of glutamate 166, while the bridged proline at P2 binds a hydrophobic pocket formed by Met49, His41, and Met165 (Fig. 14.6E).[335] Nirmatrelvir is highly selective for Mpro with no significant binding noted to a broad panel of mammalian proteases, receptors, and enzymes.[335]

Nirmatrelvir exhibits ~100 nM EC_{90} values in various cells infected with SARS-CoV2.[335] Preclinical *in vivo* efficacy was demonstrated in a mouse adapted SARS-CoV-2 infection model dosing 4 hours post infection where nirmatrelvir treatment demonstrated a significant decrease in lung viral titer and virus-associated histopathologic findings.[335] However, nirmatrelvir is poorly bioavailable across various species including humans, prompting coadministration with the HIV protease inhibitor, ritonavir (see under *Inhibitors of Viral Assembly/Egress*), which also inhibits the liver enzyme, Cyp 3A4, that metabolizes nirmatrelvir.[335]

Inhibition of Viral Genome Replication

The largest class of antiviral drugs comprises those that inhibit viral genome replication, most commonly by inhibiting a viral polymerase. Viruses whose genome replication has been successfully targeted to yield FDA-approved or -authorized drugs include the herpesviruses HSV, HCMV, and varicella zoster virus (VZV), the poxvirus variola virus (VV), the lentivirus HIV, the hepadnavirus HBV, the flavivirus HCV, and the coronavirus SARS-CoV-2. Most of the approved drugs are nucleoside analogs that inhibit viral polymerases (Fig. 14.7). Some of these nucleoside analogs mimic nucleoside monophosphates, so they may be considered nucleotide analogs. One nucleoside analog doesn't inhibit a polymerase, but rather a protein kinase. Other inhibitors of genome replication are nonnucleoside inhibitors of a polymerase, inhibitors of a different replication protein of HCV, and inhibitors of HIV integration.

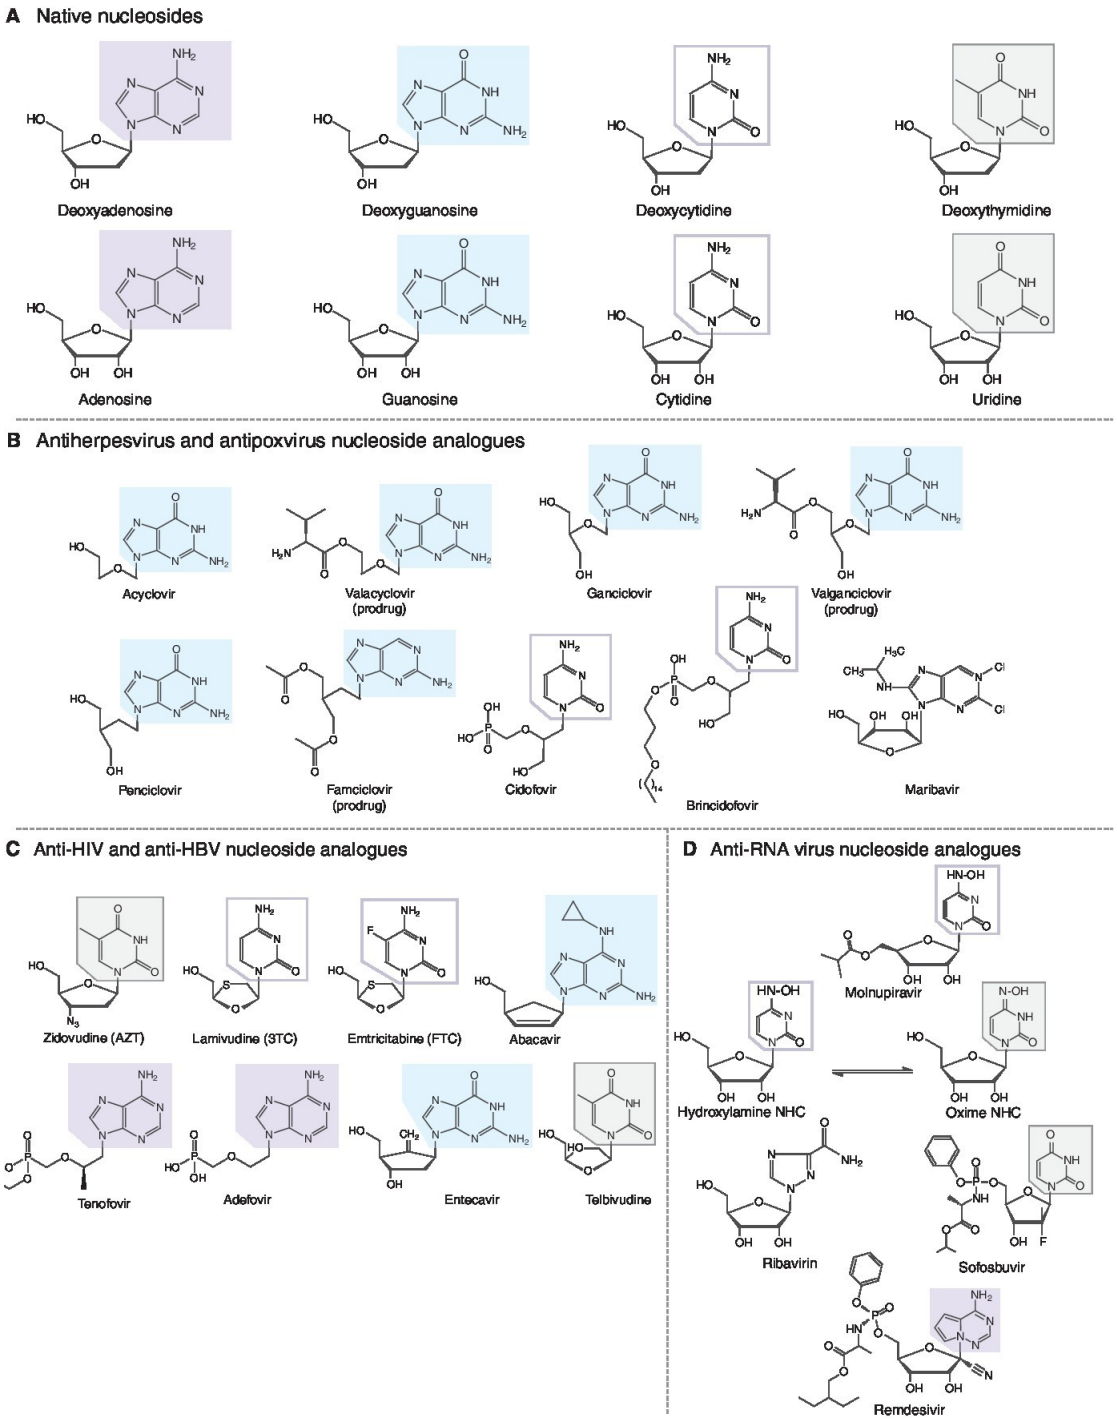

FIGURE 14.7 **Structures of antiviral nucleoside analogs**. **A**. The deoxynucleosides (*top row*) used as precursors for DNA synthesis and the ribonucleosides (*second row*) used as precursors for RNA synthesis are depicted in their *anti* configurations. The base moieties are shaded. **B**. Structures of antiherpesvirus and antipoxvirus nucleoside analogs mimic the deoxynucleoside, deoxyguanosine, except for cidofovir, which mimics the deoxynucleotide dCMP, and maribavir, which contains a purine analog joined to an L-ribose. All but maribavir contain acyclic moieties that mimic deoxyribose. Phosphorylation of all but maribavir results in inhibitors of viral DNA polymerase; unphosphorylated maribavir inhibits the HCMV protein kinase, UL97. Valacyclovir, valganciclovir, famciclovir, and brincidofovir are prodrugs of ACV, ganciclovir, penciclovir, and cidofovir, respectively. **C**. Anti-HIV and anti-HBV nucleoside analogs are obligate chain terminators except the anti-HBV drugs entecavir and telbivudine. The drugs in the top row plus tenofovir are approved for use against HIV. The drugs in the bottom row plus lamivudine are approved for use against HBV. Zidovudine and telbivudine mimic dT, lamivudine and emtricitabine mimic dC, tenofovir and adefovir mimic dAMP, and abacavir and entecavir mimic dG. Lamivudine, emtricitabine, and telbivudine are l-stereoisomers, while the other nucleoside analogs are d-stereoisomers. **D**. Anti-RNA virus nucleoside analogs include molnupiravir, which is a cytidine analog prodrug that is converted to β-D-N4-hydroxycytidine (NHC), which can exist in two tautomeric forms, an oxime and a hydroxylamine, and has been authorized for use against SARS-CoV-2. NHC-triphosphate is not a chain terminator. Other anti-RNA virus nucleoside analogs include ribavirin, which contains a purine mimic attached to ribose, and is approved for use against the RNA viruses HCV and respiratory syncytial virus; sofosbuvir, which is a cytidine monophosphate analog prodrug containing a 2′ fluoro group in place of the usual hydroxyl and is approved for use against HCV; and remdesivir, which is an adenosine monophosphate analog prodrug containing an azido-modified ribose active against SARS-CoV-2 and has been authorized for use against SARS-CoV-2. Nucleoside Analogs Targeting Polymerases: General Considerations and Specific Examples

Nucleoside analogs that clearly target viral polymerases are approved or authorized for treatment of certain herpesviruses, VV, HBV, HIV, HCV, and SARS-CoV-2. These drugs must be activated by phosphorylation to mimic nucleoside triphosphates to exert their effect. Host enzymes are generally responsible for phosphorylation of nucleoside analogs, with the exception of most nucleoside analogs active against herpesviruses where a viral kinase is responsible for the first phosphorylation. Selectivity of nucleoside analogs is largely dictated by the relative efficiency with which the nucleoside analog triphosphate can inhibit viral replication vs cellular functions.

Phosphorylated nucleoside analogs can act on viral polymerases in multiple ways. All compete with binding of the natural substrate (deoxynucleoside triphosphate (dNTP) for DNA polymerase, ribonucleoside triphosphate (NTP) for RNA polymerase) to the polymerase, and all are also incorporated into the growing nucleic acid chain. Either or both of these features—inhibition and incorporation—can be important for antiviral activity. Incorporation of the analog can result in three outcomes: (1) obligate chain termination where the analog is unable to be extended by the polymerase because it lacks a 3′ hydroxyl (OH) group; (2) nonobligate chain termination where the analog retains a 3′ hydroxyl group yet DNA synthesis is terminated, sometimes following incorporation of one or more additional nucleotides (delayed termination); and (3) relatively unimpeded elongation.

These and other principles of nucleoside analogs are illustrated for each kind of outcome by two older drugs, acyclovir and ganciclovir, and a newer drug, molnupiravir.

Acyclovir, an Obligate Chain Terminator Phosphorylated by a Viral Kinase

Acyclovir (ACV) and its more orally available valine ester, valacyclovir (Fig. 14.7B), are approved for treatment of diseases caused by HSV and VZV. ACV consists of a guanine base attached to an acyclic sugarlike molecule that lacks the 2′ and 3′ moieties found in deoxynucleosides (Fig. 14.7B). The mechanism of ACV action[114] is presented in Figure 14.8. The TK encoded by HSV and VZV phosphorylates ACV (Fig. 14.8A). Crystal structures of HSV TK in complex with thymidine or ACV[48,58,469] show that the guanine moiety of ACV interacts with the same residues as does the thymine moiety of thymidine. The HSV or VZV TKs phosphorylate ACV more efficiently than host kinases leading to 30- to 100-fold more phosphorylated ACV in infected cells, which accounts for much of ACV's antiviral selectivity.

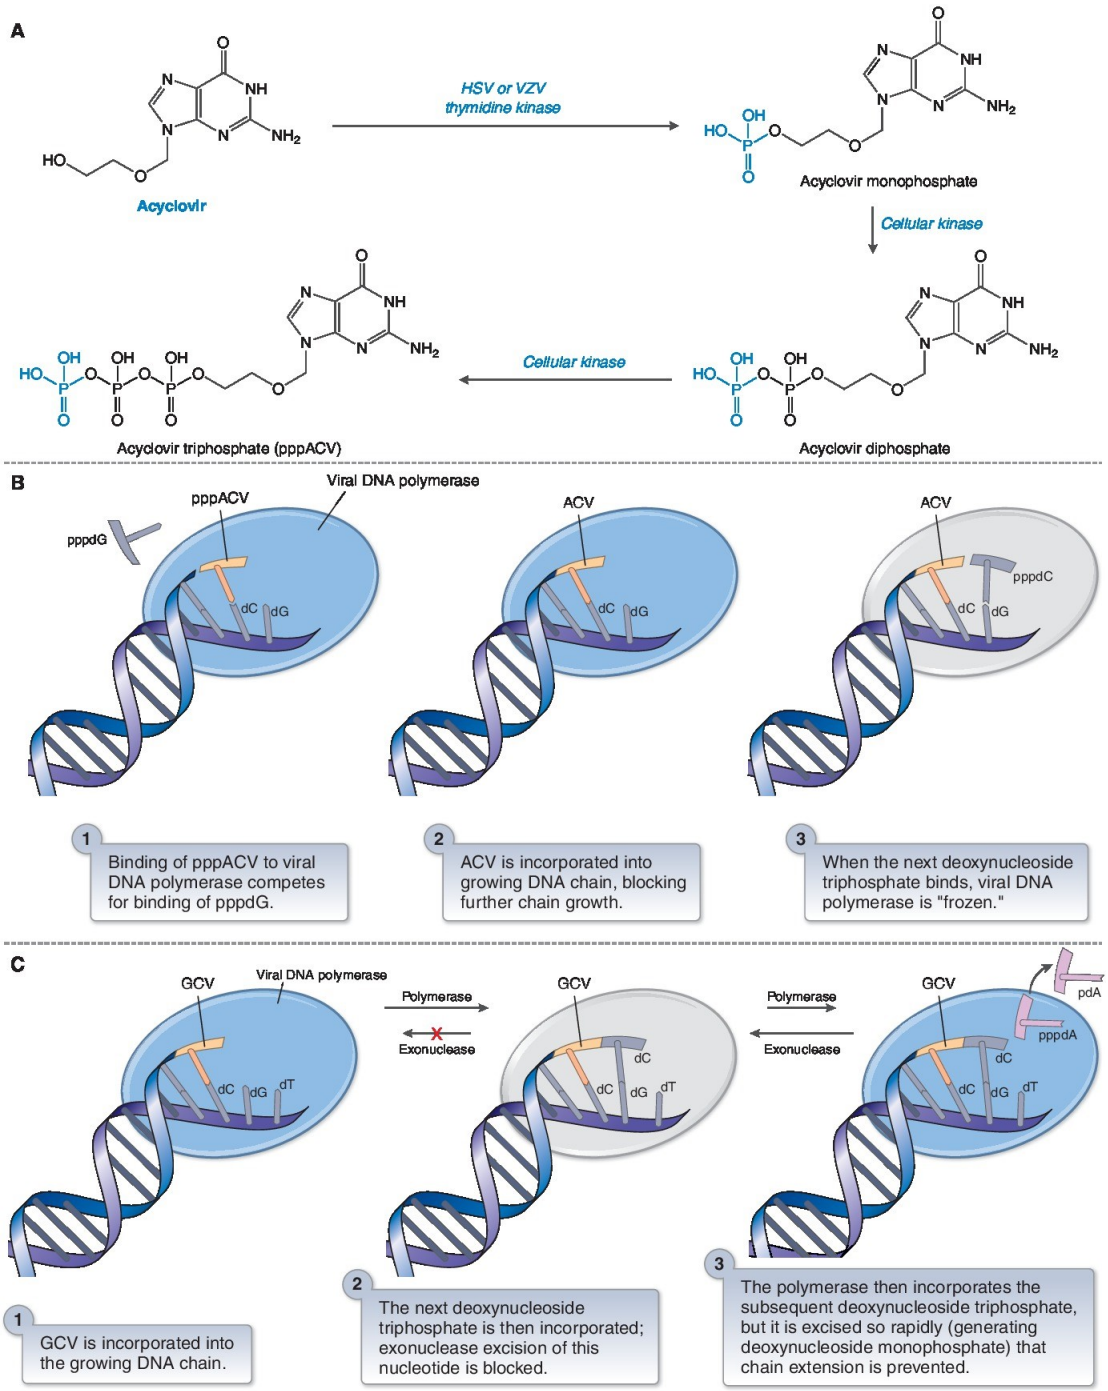

FIGURE 14.8 **Mechanisms of action of ACV and GCV**. **A**. ACV is selectively phosphorylated by herpes simplex virus (HSV) or varicella zoster virus (VZV) thymidine kinase to generate ACV monophosphate. Host cellular enzymes then sequentially phosphorylate the drug monophosphate to the diphosphate and triphosphate (pppACV) forms. **B**. ACV triphosphate has a three step mechanism of inhibition of herpesvirus DNA polymerase *in vitro*: (1) the drug triphosphate acts as a competitive inhibitor of dGTP (pppdG) binding; (2) the drug triphosphate acts as a substrate and is incorporated into the growing DNA chain across from dC in the template, terminating elongation; and (3) the polymerase becomes trapped on the ACV-terminated DNA chain when the dNTP binds (here shown as pppdC, dCTP, which would be templated by dG). **C**. Ganciclovir triphosphate (GCV-TP) is a nonobligate chain terminator. In the model for its multistep mechanism of action, GCV-TP is incorporated into the growing DNA chain across from dC in the template (*forward arrow*) more efficiently than it is removed by the polymerase's exonuclease activity. The next deoxynucleoside triphosphate (dNTP) is incorporated across from its templating base; the exonuclease is unable to remove this incorporated nucleotide (*reverse arrow* with an x through it). When the subsequent nucleotide is incorporated, it is rapidly removed by the exonuclease, generating dNMP in a process known as idling, and preventing further chain extension. (Modified with permission from Li JZ, Coen DM. Pharmacology of viral infections. In: Golan DE, Armstrong EJ, Armstrong AW, eds. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. 4th ed. Wolters Kluwer; 2017:694-722.)

Phosphorylation of ACV by the viral TK produces the compound ACV-monophosphate, which is converted sequentially to ACV-diphosphate and ACV-triphosphate (ACV-TP) by cellular enzymes[305,306] (Fig. 14.8A). ACV-TP then inhibits HSV and VZV DNA polymerases. Inhibition of HSV DNA polymerase *in vitro* is a three-step process (Ref.[361]; Fig. 14.8B). In the first step, ACV-TP competitively inhibits dGTP incorporation. Next, ACV-TP acts as a substrate and is incorporated into the growing DNA chain opposite a C residue. Finally, the polymerase translocates to the next

position on the template but cannot add the next dNTP because ACV contains no 3′-hydroxyl; hence, ACV-TP is an obligate chain terminator. Provided that the next dNTP is present, the viral polymerase freezes at this final step in a "dead-end complex," leading to apparent inactivation of the enzyme. This mechanism appears to be common among obligate chain terminators and may be due to the polymerase becoming locked in its closed conformation induced by binding to dNTP and primer template, in this case terminated by ACV. There is biochemical and genetic evidence for selectivity at each of these steps.[193,202,285,360]

There is considerable variety in ACV-resistant mutants. ACV selects mainly for *tk* mutations[83,387,425] that ablate (TK-negative) or reduce (TK-partial) TK activity, or alter TK so that it fails to phosphorylate ACV but continues to phosphorylate dT (TK-altered). ACV-resistance mutations can also alter the viral polymerase catalytic subunit (Pol) to be less inhibited by the drug (reviewed in[239]). Structural studies have provided details on how *tk* and *pol* mutations affect binding and catalysis of ACV and ACV-TP, respectively, and suggest further that *pol* mutations can confer resistance by disfavoring the closed complex[48,58,134,193,269,469](Protein Data Bank ID: 7M5R).

Nearly all ACV-resistant HSV mutants exhibit some degree of attenuation in assays of pathogenesis in animal models, with TK-negative mutants being the most attenuated and TK-partial and certain *pol* mutant being the least (reviewed in Refs.[82,239]). Interestingly, certain nonsense and frameshift mutations that might be expected to inactivate TK do not do so, due to translational mechanisms that permit low levels of TK that suffice for aspects of pathogenesis.[160,198,341] Additionally, mixtures of drug-resistant mutants with each other or with drug-sensitive virus can complement each other for drug resistance and pathogenicity.[82,239] Thus, it is important to consider heterogeneity as a factor influencing drug resistance and pathogenicity.

Ganciclovir: A Nonobligate Chain Terminator Phosphorylated by a Viral Kinase

A congener of ACV, ganciclovir (Fig. 14.7B), was the first drug approved for use against HCMV. Ganciclovir (GCV) is now also produced as the more orally available valine ester, valganciclovir, with the same valyl modification as valacyclovir (Fig. 14.7B). GCV, unlike ACV, has the equivalent of a 3′-OH moiety (Fig. 14.7B). Much as viral TK phosphorylates ACV in HSV- and VZV-infected cells, an unusual viral protein kinase, UL97, phosphorylates GCV in HCMV-infected cells.[181,265,301,417,431] Cellular kinases can convert GCV monophosphate to GCV triphosphate.

Like ACV triphosphate, GCV triphosphate is both a selective competitive inhibitor and substrate for viral DNA polymerase.[38,151,282,285,363,410] However, due to its equivalent of a 3′-OH, GCV triphosphate is not an obligate chain terminator. Nevertheless, after incorporating GCV, HCMV DNA polymerase terminates synthesis after incorporating one additional nucleotide.[363] Such termination following incorporation of subsequent nucleotides is called delayed termination. For GCV, this requires the 3′-5′ exonuclease (Exo) activity of viral DNA polymerase.[62] A model for nonobligate chain termination by GCV is shown in Figure 14.8C: HCMV DNA polymerase incorporates GCV readily, and then the next dNTP. Of note, once that dNTP is incorporated, even the Exo of wild-type enzyme is unable to excise it. Wild-type enzyme can then add the subsequent dNTP to this primer template, but only slowly, and the Exo removes it before it can be used for further extension, a process known as idling[62,63] (Fig. 14.8C), explaining delayed nonobligate chain termination. Loss of Exo activity eliminates idling, permitting extension, thereby overcoming chain termination and conferring GCV resistance, which might require DNA repair, too.[62] Consistent with this model, a different mutant polymerase extends GCV-containing primers more rapidly to overcome chain termination.[63] Several other nucleoside analogs are nonobligate chain terminators; where known, their mechanisms of termination will be discussed (see below).

Biochemical and genetic studies indicate that selectivity of GCV at the phosphorylation step and the DNA polymerase inhibition step for HCMV are not as great as the selectivity of ACV against those steps for HSV. Accordingly, the drug is more toxic than ACV. Toxicity is most commonly manifested in patients as bone marrow suppression, especially neutropenia.[322]

Most GCV-resistant mutants contain *UL97* mutations, but these have a limited distribution in the gene,[24,153] suggesting that they alter substrate specificity. Unlike HSV TK, HCMV UL97 protein kinase is very important for viral replication in cultured cells[355]; see discussion of maribavir below. Numerous different *pol* mutations have been shown to confer ganciclovir resistance (reviewed in Refs.[24,153]). As noted above, some lie in regions important for Exo activity, while other lie in regions important for DNA polymerase activity. As these mutants cause disease in humans, they clearly retain fitness.

Molnupiravir: A Nonchain Terminating Analog Phosphorylated by Host Kinases

Molnupiravir is a 5′ isopropyl ester prodrug of β-D-N4-hydroxycytidine (NHC, Fig. 14.7D) that is authorized for the treatment of SARS-CoV-2. Upon oral administration, molnupiravir is rapidly converted to NHC by hydrolysis of the isopropyl moiety, and after cellular uptake, NHC is phosphorylated to the nucleoside triphosphate by host kinases (reviewed in Ref.[338]). NHC has antiviral activity against SARS-CoV-2 and multiple other coronaviruses in cell culture and in animal models, with submicromolar EC_{50} values.[91,397,454]

NHC can exist in two tautomeric forms (Fig. 14.7D), allowing it to pair with either G or A. *In vitro* biochemical studies with the RdRp from SARS-CoV-2 demonstrate that NHC-TP competes most effectively with CTP when incorporated in a growing RNA strand opposite a template G, although NHC-TP can also be incorporated opposite a template A. Unlike the triphosphates of ACV or GCV, NHC-triphosphate does not cause chain termination.[155,209,279,299] Efficient incorporation and extension may allow NHC to avoid excision via the coronavirus proofreading exonuclease, which associates with the RdRp.[5]

Several lines of evidence suggest incorporation of NHC results in full-length, but less functional viral RNAs. Studies with a rodent coronavirus (murine hepatitis virus, MHV) and SARS-CoV-2 suggest that NHC has substantially larger effects on infectivity of supernatant virus than on total or supernatant viral RNA.[5,397] Studies of molnupiravir in SARS-CoV-2–infected patients are also consistent with greater effects on infectivity than on production of RNA.[137] The most popular hypothesis for how this occurs is "error catastrophe," wherein NHC incorporation causes an accumulation of mutations within viral RNAs until the resulting virus is not viable.[397] This mechanism was first proposed for another ribonucleoside analog, ribavirin (see below). For molnupiravir, not only can NHC be incorporated opposite both G and A as noted above, but both G and A can form base pairs opposite NHC in the template, resulting in mutagenesis even more efficiently than when NHC is incorporated opposite A.[155,209,279,299] Studies in cells infected with SARS-CoV-2 demonstrate that NHC causes an increase in error frequency with a preference for all four transitions,[397] which implies that NHC is incorporated into both positive and negative strands during genome replication.

Increased frequencies of transition mutations have also been observed in SARS-CoV-2–infected people treated with molnupiravir.[137]

Error catastrophe may not account for all of the antiviral activity of molnupiravir. For example, in an MHV study,[5] G:A and C:U transition frequencies increased only ~40% at concentrations that decreased infectivity 100 000-fold, whereas in other MHV studies, a mutation that inactivates a proofreading exonuclease was reported to increase mutation frequencies 1500%, yet decreased peak viral yields only ~10-fold.[113,159] Presently, as transition error frequency only serves as an indirect measure of the degree of incorporation of NHC into viral genomic and mRNA, it cannot be excluded that insertion of NHC into viral mRNA could result in mistranslation, alter ribosomal frameshifting, and/or impair posttranscriptional modifications important for RNA stability or translation, in which case molnupiravir might, at least in part, inhibit viral gene expression. An additional possibility is that NHC or its metabolites affect other viral functions. Regardless, molnupiravir is the best example of a nucleoside analog that acts against the virus for which it is used via a viral polymerase yet is not a chain terminator.

NHC appears to have a high barrier to resistance in that coronavirus variants with only ~twofold decreases in susceptibility have been isolated, and changes in drug sensitivity have not been correlated with any signature mutations.[5] NHC retains activity against mutants resistant to remdesivir (see below), another nucleoside analog active against SARS-CoV-2.[397] At this writing, there is little information regarding resistance in treated patients.

Antiherpesvirus Nucleoside Analogs Other Than ACV and GCV and an Antipoxvirus Nucleoside Analog

Aside from ACV and GCV, a number of antiviral nucleoside analogs have been developed against herpesviruses. These include vidarabine, idoxuridine, and trifluridine, which have been primarily used as topical treatments for ocular HSV infections. These drugs have been superseded by more selective compounds and/or have poorly understood mechanisms and will not be discussed further.

Penciclovir and Famciclovir

Penciclovir (Fig. 14.7B) is approved for topical use for cold sores caused by HSV, and its orally available prodrug, famciclovir, which is a diacetyl ester of 6-deoxypenciclovir (Fig. 14.7B), is approved for use against cold sores, genital herpes, and shingles (caused by VZV). Penciclovir's mechanism of action is overall similar to that of ACV, but penciclovir triphosphate is a nonobligate chain terminator of DNA synthesis, due to its 3' hydroxyl-like moiety similar to that of GCV, although it does permit at least some extension of primers following incorporation.[111] Penciclovir-resistant mutants are similar to ACV-resistant mutants with some subtle differences.[68,387]

Cidofovir and Brincidofovir

Cidofovir, a phosphonate-containing acyclic cytosine analog, is approved for use against HCMV retinitis. With its phosphonate group, it is, in effect, a nucleotide analog that mimics dCMP (Fig. 14.6). This charged moiety likely accounts for the relatively poor uptake of cidofovir into cells[188] and poor oral bioavailability. Once inside the cell, cidofovir is metabolized via cellular enzymes to its monophosphate (akin to a diphosphate) and diphosphate (akin to a triphosphate), and to a third phosphorylated form that contains a choline adduct.[76,188] These phosphorylated forms have very long intracellular half-lives, which may be due in part to the choline metabolite serving as a reservoir.[2,188] This property contributes to the prolonged antiviral activity of cidofovir,[309] which provides the therapeutic advantage of infrequent dosing. Also, because cidofovir uses cellular kinases for its phosphorylation, it is active against *UL97* mutants that are resistant to ganciclovir,[272] although this also removes the selectivity gained by requiring a viral kinase for efficient phosphorylation.

The diphosphorylated form of cidofovir is an analog of dCTP that inhibits HCMV DNA polymerase more potently than it does various cellular DNA polymerases.[67,188,480] It is a nonobligate chain terminator, which when incorporated into DNA, slows elongation, and, when two cidofovir residues are incorporated in a row,[479,480] causes chain termination. Many of the *pol* mutations that confer resistance to ganciclovir confer resistance to cidofovir, suggesting similar mechanisms of chain termination due to exonuclease-mediated idling[62,63] and similar fitness.

Efforts to overcome the lack of oral availability and nephrotoxicity of cidofovir led to the development of a hexadecycloxypropyl ester, conjugated to the phosphonate, brincidofovir (Fig. 14.7B). This not only increased oral availability but also cell uptake and conversion to the diphosphate.[190] Brincidofovir shows activity in cell culture against many double-stranded DNA viruses that encode their own DNA polymerases, including submicromolar potency against orthopoxviruses, including variola virus (reviewed in Ref.[133]), which is the cause of smallpox. Clinical trials of brincidofovir for HCMV and adenoviruses did not succeed, but those studies and others provided safety information in humans, while animal studies of the drug's ability to reduce mortality from various orthopoxviruses in animal models provided efficacy data for treatment of smallpox, for which human trials are not deemed practical or ethical (reviewed in Ref.[133]). Related orthopoxviruses readily develop resistance to brincidofovir due to alterations in DNA polymerase, but thus far, those mutants show reduced virulence in animal models.[9,109] Still, the recovery of cidofovir-resistant HCMV mutants from patients suggests that fit, disease-causing brincidofovir-resistant smallpox viruses could arise. The FDA approved brincidofovir for treatment of smallpox in 2021.

A Nucleoside Analog That Inhibits HCMV Protein Kinase to Impair Genome Replication

As discussed above in the section on ganciclovir, HCMV encodes an unusual protein kinase, UL97. This enzyme, although not strictly essential for production of infectious HCMV, is very important, especially in nondividing cells where it plays a role in viral DNA synthesis.[37,211,355,364,473] Maribavir is the L-stereoisomer of a benzimidazole riboside nucleoside analog (Fig. 14.7B), which was found to inhibit HCMV replication and viral DNA synthesis at submicromolar concentrations.[37] Its toxicity in animal models, and subsequently in human clinical trials, was found to be less severe than that of older HCMV drugs, and it is orally available.[225,471] Maribavir inhibits UL97 kinase activity with low nM IC_{50}, and *UL97* mutations were shown to confer maribavir resistance.[37] The locations of resistance mutations and maribavir's resemblance to a nucleoside suggest the hypothesis that the drug binds at or near the ATP-binding pocket of UL97.[73] Consistent with this hypothesis, maribavir has been reported to inhibit UL97 autophosphorylation competitively with ATP.[395] However, another study reported that maribavir inhibits competitively with a nucleoside analog substrate for phosphorylation.[150] Resolution of these seemingly

discordant results may require structural analyses.

How does maribavir inhibit HCMV DNA synthesis? Although UL97 can phosphorylate a subunit of HCMV DNA polymerase, UL44, substitution of UL44's sites of phosphorylation by UL97 with alanine had no more than modest effects on viral replication.[403] On the other hand, UL97 mimics host cyclin-dependent kinases to phosphorylate retinoblastoma protein (Rb), which controls transcription of genes for host proteins important for cellular DNA synthesis.[194,211,356] Expression of a papillomavirus oncoprotein that leads to degradation of Rb family proteins compensates for the loss of UL97 for viral DNA synthesis in nondividing cells, while a mutant form of this protein that is specifically disrupted for Rb degradation does not.[211] These results and the lack of HCMV-encoded enzymes that increase nucleotide pools such as ribonucleotide reductase and TK support a hypothesis where HCMV UL97 inactivates Rb family members to activate corresponding host enzymes to increase dNTP pools. Although there is a publication that argues against this hypothesis[231] and although no direct measurements of the effects of UL97 on nucleotide pools have been reported, this remains an appealing hypothesis to explain how maribavir inhibits DNA synthesis. Nevertheless, which Rb family–controlled proteins are crucial for HCMV DNA synthesis remain unclear, and it remains possible that phosphorylation of other substrates of UL97 also contribute to its role in viral DNA synthesis. Notably, loss of UL97 activity has little effect on HCMV DNA synthesis in dividing cells; in that setting, UL97 appears to be particularly important for viral nuclear egress (see under *Inhibitors of Viral Assembly/Egress*).[211,364]

In HCMV-infected cells in culture, resistance to maribavir can arise not only from *UL97* mutations but also from mutations in the *UL27* gene.[223] Loss of *UL27* function results in increased cyclin-dependent kinase activity, which appears to account for the modest resistance observed.[365] Maribavir was approved by the FDA in 2021 to treat patients with posttransplant HCMV disease that is refractory to treatment with ganciclovir, valganciclovir, foscarnet, or cidofovir. Maribavir resistance due to *UL97* mutations arose in ~20% of treated patients in the clinical trials and was associated with treatment failures; *UL27* mutations were less common and their clinical relevance remains unclear.[74]

Anti-HIV and HBV Nucleoside Analogs

As discussed elsewhere in this edition, the lentivirus, HIV, and the hepadnavirus, hepatitis B virus (HBV) replicate their genomes through DNA and RNA intermediates, respectively, using a DNA polymerase that can copy RNA. The HIV reverse transcriptase (RT) and the HBV DNA polymerase are thus essential for viral replication and differ substantially from cellular polymerases, making them excellent targets for antivirals. The success of antiherpesvirus nucleoside analogs provided a rationale for the development of nucleoside analogs active against HIV and subsequently HBV.

Numerous nucleoside analogs have been approved to treat HIV (Fig. 14.7C), all of which are obligate chain terminators. Thus, many of the principles that govern their mechanisms of action and resistance are similar to those of ACV, although there are important differences. For the sake of brevity, this chapter will dwell only on the anti-HIV nucleoside analogs, AZT, and two drugs closely related to each other, lamivudine and emtricitabine, to illustrate principles of this class of antivirals.

Zidovudine

Zidovudine, (3′-azidothymidine, AZT), which was first reported to have anti-HIV activity in 1985,[307] is a thymine base attached to a sugar in which the normal 3′ hydroxyl has been replaced by an azido group (Fig. 14.7C). Although rarely used now in wealthy countries, zidovudine (3′-azidothymidine, AZT) is still on the WHO essential medicines list. AZT is an excellent substrate for cellular TK, which phosphorylates ZDV to its monophosphate (AZT-MP).[140] The monophosphate is then converted to the diphosphate form by cellular thymidylate kinase and to the triphosphate form (AZT-TP) by cellular nucleoside diphosphate kinase.[140] The activity of AZT and other anti-HIV nucleoside analogs can vary depending on the activity of cellular kinases in the infected cell. For example, activated lymphocytes upregulate thymidine kinase, which is needed for DNA replication and cellular proliferation; thymidine analogs are thus more potent in activated than in quiescent CD4 lymphocytes.[399]

AZT-TP is a substantially more potent inhibitor of and substrate for HIV RT than of the human DNA polymerases that have been tested.[66,140,411] This biochemical selectivity is reflected in the degree of resistance of AZT-resistant mutants, which can be >100-fold in some cell types.[240] Nevertheless, its toxicity in particular cells is a serious clinical issue. In particular, AZT causes bone marrow suppression that manifests most commonly as neutropenia and anemia.[370] AZT toxicity appears to be due not only to the effects of AZT-TP on cellular polymerases but also to the effects of AZT-monophosphate, which is both a substrate for cellular thymidylate kinase and an inhibitor of this essential enzyme.[140] For a number of other anti-HIV nucleoside analogs, a key determinant of toxicity appears to be the mitochondrial DNA polymerase (DNA polymerase γ[61,249,285]).

AZT-resistance mutations accumulate in the HIV *pol* gene that encodes RT[43,77,212,242] (Fig. 14.9). Interestingly, four or more mutations are required to confer high-level resistance, but some of the mutations confer little or no resistance on their own.[212,241,242] These latter mutations appear to be selected because they boost resistance by the other mutations or compensate for fitness costs of certain mutations. The requirement for multiple mutations for high-level resistance likely explains the relatively slow emergence of AZT resistance in patients and during selection in cell culture.[145,238] Based on sequencing of virus isolated from patients following cessation of AZT therapy or in individuals newly infected with resistant virus, and of virus from replication competition experiments *in vitro*, AZT-resistant mutants appear to be modestly less fit than wild-type virus.[97]

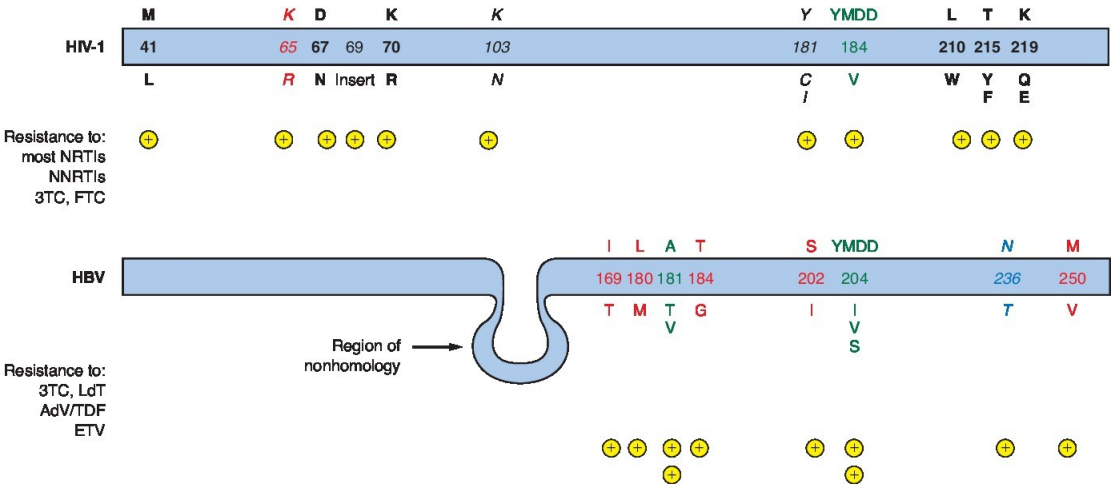

FIGURE 14.9 **Locations of drug resistance alterations in the HIV-1 and HBV polymerases**. The HIV-1 reverse transcriptase (RT) (*top*) and the HBV DNA polymerase (*bottom*) are related enzymes with sequence and predicted structural homology and are cartooned as bars. The HBV enzyme has a segment that is unrelated to the HIV enzyme, which is depicted here as looping out. The positions of selected substitutions and insertions that confer drug resistance are indicated in single letter code with the wild-type residue above the bar, the residue number within the bar, and mutant residues or inserts below the bar. Methionine 184 in HIV RT and methionine 204 in HBV polymerase are embedded within a YMDD motif (*green*) that is important for polymerase catalysis. Alterations in this methionine confer resistance to 3TC and related L-stereoisomer drugs, as does alteration of alanine 181 in HBV polymerase (also *green*). Boldfaced residues in HIV RT indicate the positions of mutations that affect susceptibility to most anti-HIV nucleoside analogs. An insertion at residue 69 in HIV RT (*blue*) together with other alterations including M41L, K70R, L210W, T215Y, and K219Q also affect susceptibility to these drugs. Substitution of arginine for lysine 65 (*purple*) in HIV RT confers resistance to all nucleoside analogs except AZT. Substitutions of lysine 103 and tyrosine 181 (*italics*) confer resistance to nonnucleoside reverse transcriptase inhibitors. Alterations of isoleucine 169, threonine 184, serine 202, or methionine 250 (*orange*) together with a leucine to methionine substitution at residue 180 (*orange*) plus a methionine 204 substitution in HBV polymerase can result in entecavir resistance. A threonine for asparagine 236 substitution in HBV polymerase (*blue*) can result in resistance to adefovir (high-level) and tenofovir (intermediate).

The mechanism of AZT resistance stems from chain elongation by 3′-5′ phosphodiester bond formation being a reversible process, so that in the presence of pyrophosphate or ATP, RT can catalytically excise the terminal nucleotide by a process termed pyrophosphorolysis (Fig. 14.10).[12,302] Given the K_m's of pyrophosphate and ATP for this reaction, and the concentrations of these species in cells, ATP is the likely substrate *in vivo*. The viral DNA chain is now free to resume elongation with the removal of the chain terminating nucleoside analog. AZT resistance mutations facilitate this reverse reaction of excision repair.[252,303] Crystal structures of wild-type and AZT-resistant RTs bound to either AZT-TP or the excision product indicate that resistance mutations alter the way that the AMP moiety of the excision product binds without affecting the AZT-TP–binding site.[443]

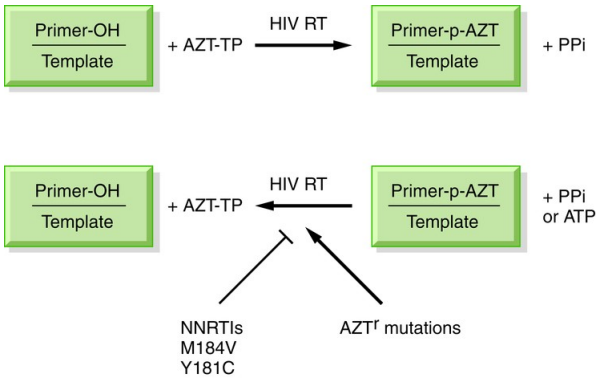

FIGURE 14.10 **Biochemical mechanism of resistance to AZT**. During synthesis of HIV DNA by HIV RT, AZT-TP is incorporated into the growing primer strand (primer-p-AZT), generating pyrophosphate (PPi). This reaction is reversible, so that RT can excise AZT-MP from the primer terminus and combine it with PPi, regenerating AZT-TP and primer/template. ATP can substitute for PPi in this excision reaction by donating two phosphates to AZT-MP. The excision reaction is enhanced by AZT resistance mutations but impaired by NNRTIs and certain HIV RT substitutions that confer resistance to 3TC (eg, M184V) and NNRTIs (eg, Y181C).

This resistance mechanism of excision repair applies to most, if not all anti-HIV nucleoside analogs; thus, these mutations have been termed *nucleoside-associated mutations* (NAMs) and account for many examples of cross resistance of HIV toward various nucleoside analogs.[462] Regardless of mechanism, various combinations of mutations affecting HIV RT can confer resistance to every approved nucleoside analog (Fig. 14.9; Ref.[207]).

The limited clinical effectiveness of AZT and problems with toxicity and resistance led to the development of other anti-HIV drugs and the use of combination chemotherapy.

Lamivudine and Emtricitabine

Lamivudine (3TC) was reported to exhibit anti-HIV activity in 1992.[78,79,391] Lamivudine and its close relative emtricitabine (FTC) appear to exhibit the least toxicity of the anti-HIV nucleoside analogs. This may be related to their unusual sugar moiety that contains a sulfur atom and is an l-stereoisomer, not the standard d-stereoisomer of normal nucleosides (Fig. 14.7C). Lamivudine is sequentially phosphorylated by cellular enzymes to its triphosphate.[54] Like AZT-triphosphate, 3TC-triphosphate is both a competitive inhibitor and a substrate for RT, and once incorporated, is an obligate chain-terminator of DNA synthesis. It is a more potent inhibitor of HIV RT than cellular polymerases.[171] The relative lack of toxicity of 3TC may be due to the negligible inhibition of host polymerases including mitochondrial DNA polymerase by 3TC-triphosphate.[171]

High-level resistance to 3TC develops rapidly both in cell culture and in patients treated with this drug alone (reviewed in Ref.[100]). A single mutation at codon 184 from Met to Val (M184V) or to Ile (M184I) confers a high degree of resistance to 3TC. M184 is within the conserved YMDD motif, in which the two Asp (D) residues are involved in catalysis of polymerization (Fig. 14.9). Both mutants are less fit than wild-type virus, which may be due to decreased processivity, primer usage, or initiation by the mutant enzyme or some combination of these (reviewed in Ref.[100]). The crystal structure of a 3TC-resistant RT was used to develop a molecular model that posits that codon 184 mutations result in steric hindrance that obstruct incorporation of 3TC-triphosphate, but not normal nucleotides.[386]

The M184V mutation has a number of other interesting effects, including conferring low-level resistance to some (eg, abacavir, Fig. 14.6) or hypersensitivity to other nucleoside analogs (eg, AZT and tenofovir; reviewed in Ref.[100]). This hypersensitivity to AZT and other drugs in the absence of other mutations is also observed in the presence of known drug resistance mutations such that levels of resistance are reduced with the addition of M184V. This phenotypic suppression is best explained by the M184V mutation reducing the excision repair of AZT-terminated primers (Fig. 14.10; Ref.[100]). Nevertheless, an accumulation of multiple mutations can result in high-level resistance to both AZT and 3TC, and other single mutations such as K65R can confer resistance to 3TC (and most other nucleoside analogs) (Fig. 14.9; Ref.[304]).

The mechanisms of action and resistance of FTC are very similar to those of 3TC; however, it may be slightly more potent and have a longer intracellular half-life.[369] Its coformulation with tenofovir (see below) has made this combination a backbone of combination antiretroviral therapy.

Other Anti-HIV Nucleoside Analogs

There have been numerous other anti-HIV nucleoside analogs approved over the years, but several of them have been discontinued. Two that are still used are abacavir and tenofovir. Abacavir contains an altered guanosine and an altered sugar that lacks both 2′ and 3′ OH and the ether oxygen (Fig. 14.7C). Following uptake into cells, abacavir is phosphorylated to its monophosphate, and then the 6-cyclopropylamino alteration on the base is removed, resulting in guanine linked to the modified sugar (carbovir), followed by further phosphorylation to the triphosphate.[124] Abacavir is also notable as an example of the use of pharmacogenomic tests to exclude patients likely to suffer adverse events, in this case those with the HLA-B*-5701 allele, which predisposes to a severe hypersensitivity reaction.[276] Tenofovir is an acyclic deoxyadenosine monophosphate analog (ie, a nucleotide analog) lacking a 3′OH and the entire 2′ moiety (Fig. 14.7C). It is administered as an orally available prodrug, either tenofovir disoproxil or tenofovir alafenamide (structures of these prodrugs not shown). These formulations have the advantage of being administered just once daily, making them attractive as constituents of long-term combination therapies.

Anti-HBV Nucleoside Analogs

Five nucleoside analogs—lamivudine (3TC), tenofovir, telbivudine, adefovir, and entecavir—have been approved for the treatment of HBV. Lamivudine and tenofovir have been described above under anti-HIV nucleoside analogs. Telbivudine is simply l-thymidine, thus sharing this isomeric configuration with 3TC and FTC, but has been withdrawn so will not be discussed further. Adefovir, like tenofovir, is a nucleotide analog with an adenine linked to an altered sugar similar to that in acyclovir, but containing an additional methylene moiety (Fig. 14.7C). Also, like tenofovir, it is administered as an orally available prodrug, in this case as adefovir dipivoxil. Entecavir is an unusual deoxyguanosine nucleoside analog in which the ether oxygen of the sugar is replaced with an exo carbon-carbon double bond (Fig. 14.7C). The mechanisms of action of anti-HBV nucleoside analogs are very similar to those of anti-HIV nucleoside analogs: They are converted to triphosphates by cellular enzymes, are incorporated into the growing DNA chain by HBV DNA polymerase (also a reverse transcriptase), and cause chain termination. Notably entecavir is a nonobligate chain terminator. Termination occurs two or three bases after its incorporation,[392] but precisely how this occurs remains unclear. Of note, entecavir-triphosphate has a higher affinity for HBV polymerase than does dGTP.[392]

The similarities in mechanisms of action of these drugs against the two viruses extend to some similarities in mechanisms of resistance but also important differences.[270] For example, a mutation in the methionine codon in the HBV *pol* gene that corresponds to codon M184 in the HIV *pol* gene can confer high-level resistance to 3TC (Fig. 14.9); however, in this case, the methionine to isoleucine mutant retains fitness, whereas methionine to valine or serine substitutions are usually only found in the presence of additional mutations. There is little if any evidence for HBV drug resistance mutations resulting in increased excision of incorporated drug as do AZT resistance mutations of HIV; rather, the mutations appear to affect incorporation of drug-triphosphate by various mechanisms. Interestingly, drug resistance that requires only a single mutation develops relatively quickly, but still more slowly *in vivo* with HBV than with HIV. In at least some cases, this may be because sites of mutation also encode residues in an overlapping reading frame that affect HBV surface antigen.

As is the case with AZT resistance, multiple mutations are required to confer high-level resistance to entecavir, and some of these mutations confer little resistance on their own.[270] This correlates with slow development of resistance *in vivo*. The greater potency and slower rates of resistance to entecavir and tenofovir has led to these drugs becoming preferred for treatment of HBV.[270] FTC and tenofovir are often used in patients who are infected with both HIV and HBV, because they are active against both viruses (even though FTC is not FDA approved for treating HBV infections).

Anti-RNA Virus Nucleoside Analogs

With all the nucleoside analog drugs against DNA viruses and retroviruses, it may seem surprising that there are so few anti-RNA virus nucleoside analogs. One possible contributor to this outcome may be the higher concentrations of competing ribonucleotides in cells relative to deoxyribonucleotides. Nevertheless, there is one long-standing nucleoside analog, ribavirin, that was approved for use against certain RNA

viruses; sofosbuvir, which is a mainstay anti-HCV drug; and now, two new ones, molnupiravir (see above) and remdesivir, which have received emergency authorization against SARS-CoV-2.

Ribavirin

Ribavirin is a nucleoside analog unlike the other nucleoside analogs discussed thus far in that it has a normal D-stereoisomer sugar (ribose) attached to a baselike moiety (Fig. 14.7D). It exhibits activity against many viruses in cell culture, but it has been approved only as monotherapy for severe respiratory syncytial virus (RSV) infections, and in combination with interferons for chronic HCV infections. Its routine use against RSV is not recommended except in certain complicated cases,[444] and its use against HCV has been superseded by newer, much more effective drugs. In both cases, it is not clear if it exhibits meaningful antiviral activity in patients.[41,99] Moreover, even in cell culture, its antiviral mechanism of action against RSV and HCV is still not well understood with multiple mechanisms proposed, including "error catastrophe,"[106] which, as discussed above, is a leading hypothesis for the mechanism of molnupiravir. However, in HCV replicons, ribavirin resistance was found to be due to mutations affecting a protein other than polymerase,[348] and studies of viral mutagenesis in patients treated with ribavirin have not provided definitive answers.[277,345] Further investigations of the mechanisms of ribavirin action and resistance may yield interesting new insights into virus biology and biochemistry.

Sofosbuvir, an Anti-HCV Nucleoside Analog

Sofosbuvir is a prodrug of β-D-2′-deoxy-2′-R-fluoro-2′-β-C-methyluridine monophosphate. Its corresponding nucleoside was initially identified as a metabolite of another drug[313,407] but did not show appreciable activity in cells, potentially due to slow formation of the nucleoside monophosphate.[275,407] Compound optimization efforts, therefore, focused on cell permeable prodrugs of the nucleoside monophosphate that could be selectively activated in the liver to mitigate potential off target toxicity.[141,407] These efforts lead to the discovery of the phenoxy phosphoramidate prodrug sofosbuvir[407] (Fig. 14.7D).

Postcellular uptake, the prodrug is cleaved by either carboxyesterase 1, or cathepsin A, and subsequently undergoes an intermolecular attack to release phenol.[314] Generation of the active nucleoside triphosphate is completed through hydrolysis of the alaninyl moiety to generate the monophosphate by histidine triad nucleotide-binding protein1 (Hint1), followed by di- and triphosphorylation by uridine/cytidine monophosphate kinase nucleotide diphosphate kinase, respectively.[141,314] Biochemical studies demonstrated sofosbuvir triphosphate is a selective substrate/inhibitor of the HCV RNA–dependent RNA polymerase vs human DNA and RNA polymerases.[11,235,275,313] Following incorporation into the growing RNA strand, sofosbuvir acts as a nonobligate chain terminator, terminating extension without addition of other nucleotides,[275] but how it induces termination is unclear. In cellular systems, sofosbuvir demonstrates similar activity across genotypes with 20-40 nM EC_{50} values in genotype 1-3 replicon assays.[234,235,374] *In vitro* resistance selection with sofosbuvir and nucleosides with a similar structure identified S282T mutation within the polymerase, which causes a 10-fold decrease in replicon sensitivity to sofosbuvir in the genotype 1 background.[234] A more complex resistance picture emerged upon resistance selection in the genotype 2 background where T179A, M289L, I293L, M434T, and H479P mutation were observed in addition to S282T; these mutations in combination with S282T were required to generate significant resistance to sofosbuvir.[234] Decreased replication fitness was observed with the S282T mutation across genotypes.[234] Treatment emergent clinical resistance to sofosbuvir is extremely rare consistent with a high barrier to resistance.[244,426] Sofosbuvir is a component of several HCV therapies (see under *Therapy of Viral Hepatitis*).

Remdesivir, an Anti–SARS-CoV-2 Nucleoside Analog

Remdesivir is a prodrug of 1′cyano 4-aza-7,9-dideazaadenosine (Fig. 14.7D). The compound was initially identified by examining a series of modified 1′-substituted 4-aza-7,9-dideazaadenosine C-nucleosides.[69] To improve cell permeability and potency, the nucleoside was converted to the monophosphoramidate prodrug.[69,457] Subsequently, remdesivir demonstrated <100 nM potency against SARS-CoV-2 in cell-based assays[75,455,488] and demonstrated efficacy in a nonhuman primate model of SARS-CoV-2 infection.[470]

Postcellular uptake, remdesivir is converted to its triphosphate (RTP) through a multistep mechanism. Initially, esterase cleavage leads to release of a free carboxylate, which cyclizes liberating the phenoxide. The resulting cyclic anhydride hydrolyzes to an alanine intermediate that is subsequently converted to the nucleoside monophosphate via phosphoramidase-mediated cleavage and then phosphorylated by cellular nucleotide kinases to yield RTP.[112,195,402] Mechanistic studies show that RTP is an excellent substrate and is incorporated selectively and rapidly by viral RdRps as an ATP analog, with kinetics similar and perhaps superior to those of ATP.[93,156] The efficiency of incorporation likely allows remdesivir to retain antiviral activity despite the presence of the coronavirus proof-reading exonuclease.[4] After incorporation of remdesivir, in ensemble assays, RNA strand elongation proceeds for 3-4 additional nucleotides before stalling; thus, remdesivir has been described as a delayed nonobligate chain terminator, although some elongation can be observed past the initial stall point, especially in the presence of higher concentrations of NTPs.[156,222] Interestingly, in single molecule studies, where numerous individual RdRps can be assessed, elongation following incorporation of remdesivir was found to proceed for as many as 30 additional nucleotides, followed by pausing and then diffusion backward of the RdRp, which led to the proposal that remdesivir incorporation leads to dissociation of the product strand in a process termed backtracking,[393] which may be promoted by the SARS-CoV-2 exonuclease.[222] For either proposed mechanism, cryoEM, mutational, and biochemical studies suggest that stalling arises from a translocation barrier where the C-1′nitrile of remdesivir sterically clashes with serine 861 of the RdRp when remdesivir is incorporated into the appropriate location (N-4) in the primer strand, precluding addition of the subsequent nucleotide and rendering the 3′ end of the primer less susceptible to the SARS-CoV-2 exonuclease.[156,222,435,456] It has also been suggested that remdesivir acts by incorporation into template, where it causes reduced UTP incorporation opposite its template position.[435]

In vitro resistance selection conducted against SARS-CoV-2 have resulted in substitutions in the viral polymerase that increase the EC_{50} in cells by roughly 2- to 10-fold.[413,429] One mutation is hypothesized to cause a structural rearrangement, which decreases the steric clash preventing binding of the remdesivir at the N-4 site postincorporation.[429] Others affect binding or incorporation of RTP.[413] The mutations are associated with a decrease in viral fitness and are not observed in sequence data bases of isolates.[413,429] Clinical resistance to remdesivir in treatment of COVID-19 has been rare, though a case study of an immunosuppressed patient whose infection rebounded during and after remdesivir treatment noted the emergence of virus with ~sixfold resistance and reduced fitness.[143]

Nonnucleoside Inhibitors of Polymerases

As described above, viral polymerases are excellent targets for antiviral drugs, and nucleoside analogs, for all their successes, can inhibit cellular as well as viral enzymes, and viruses can mutate to resist these drugs. As a result, efforts have been made to discover compounds that inhibit viral polymerases by other mechanisms.

Foscarnet, an Antiherpesvirus Nonnucleoside Polymerase Inhibitor

The first of these to be approved for clinical use was foscarnet (phosphonoformic acid, PFA; structure in Fig. 14.11). Although it is not orally available so that intravenous administration is required, and it is nephrotoxic, it is approved for treatment of severe HSV, VZV, and HCMV infections that are resistant to front-line drugs.

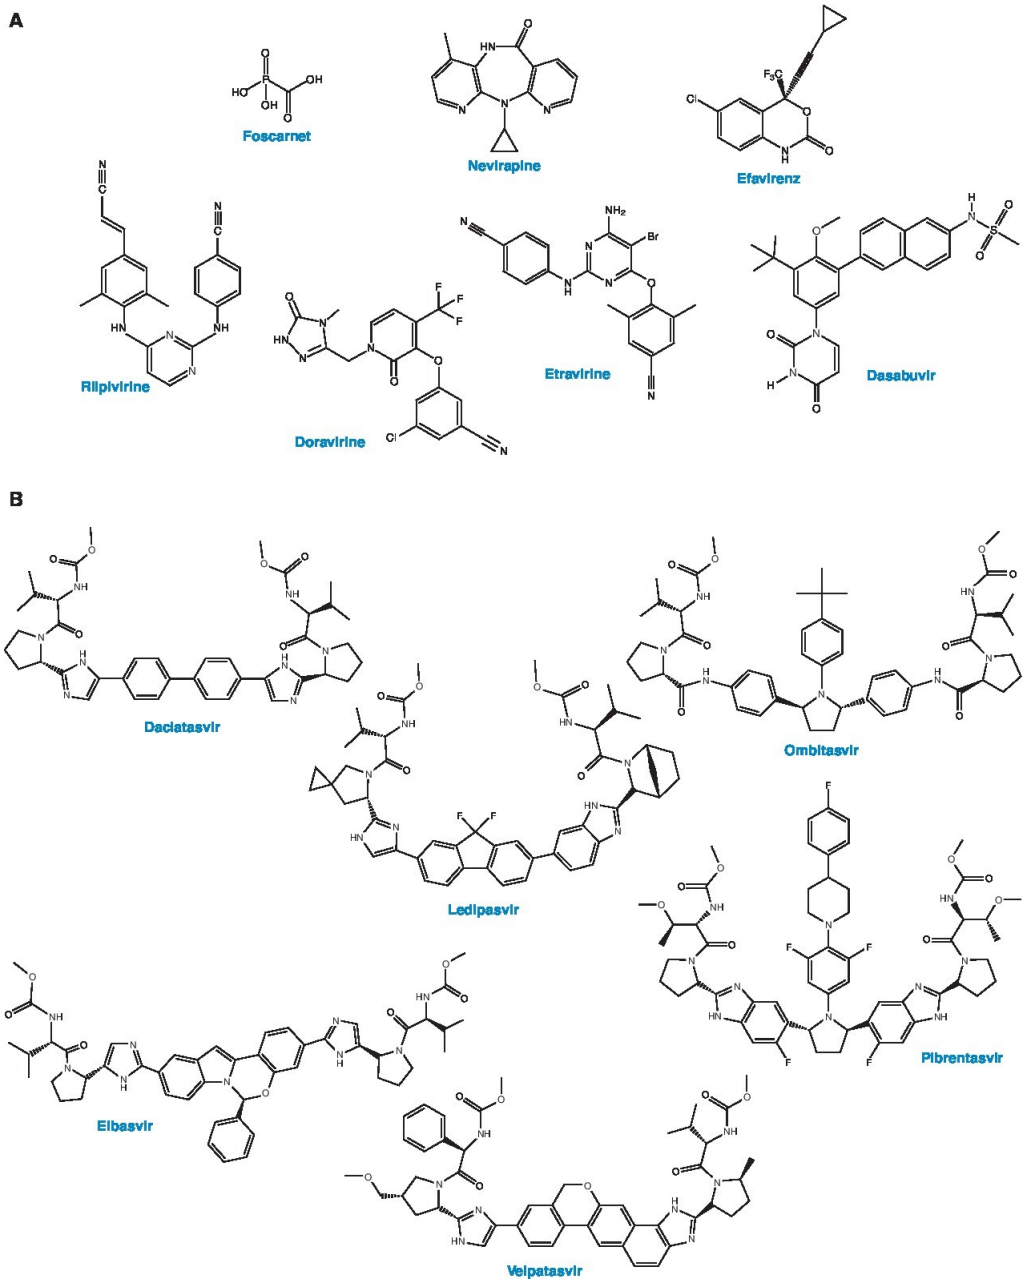

FIGURE 14.11 **Nonnucleoside DNA polymerase inhibitors (foscarnet and NNRTIs) and NS5A inhibitors**. **A**. Foscarnet is a pyrophosphate analog that inhibits viral polymerases. It is approved for treatment of HSV, VZV, and HCMV infections that are resistant to other drugs. NNRTIs, nevirapine, efavirenz, etravirine, rilpivirine, dasabuvir, and doravirine, which do not mimic any known ligands of DNA polymerases, inhibit HIV-1 reverse transcriptase and are approved for treatment of HIV-1 in combination with other drugs. **B**. Daclatasvir, ledipasvir, ombitasvir, elbasvir, velpatasvir, and pibrentasvir bind to and inhibit HCV NS5A and are approved for treatment of HCV in combination with other drugs. (Modified with permission from Li JZ, Coen DM. Pharmacology of viral infections. In: Golan DE, Armstrong EJ, Armstrong AW, eds. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. 4th ed. Wolters Kluwer; 2017:694-722.)

Foscarnet is an analog of pyrophosphate, which is a product of polymerization of nucleic acids. Unlike the nucleoside analogs described above, it does not require activation by either cellular or viral enzymes but rather inhibits herpesvirus DNA polymerases directly and selectively.

Inhibition is *not* competitive with deoxynucleoside triphosphates. Rather, it appears that foscarnet acts as a product analog, preventing normal pyrophosphate release so the polymerase cannot complete the catalytic cycle.[119,332] The structure of foscarnet bound to a DNA polymerase that is a chimera of a bacteriophage DNA polymerase and a segment of HCMV polymerase that is important for foscarnet sensitivity has been determined.[487] In the structure, the drug binds to highly conserved basic residues in a closed form of the enzyme that has not translocated to the next base on the template. The drug occupies the position of the beta and gamma phosphates of an incoming dNTP. The structure suggests that foscarnet may stabilize this closed, untranslocated state, thus stalling the polymerase.

Because foscarnet is not a nucleoside analog, HSV and VZV *tk* mutants and HCMV *UL97* mutants are not resistant to it. However, although foscarnet inhibits DNA polymerase by a mechanism that differs substantially from the nucleoside analogs, many *pol* mutants that are resistant to nucleoside analogs are resistant to foscarnet. Moreover, most foscarnet-resistant mutants are resistant to one or more nucleoside analogs (reviewed in Ref.[153]). This has been an impetus to further drug development.

Anti-HIV Nonnucleoside Reverse Transcriptase Inhibitors

There are currently six FDA-approved nonnucleoside reverse transcriptase inhibitors (NNRTIs)—efavirenz, nevirapine, etravirine, rilpivirine, dasabuvir, and doravirine (Fig. 14.11)—that are used for treatment of HIV infections. The first NNRTIs were discovered using high-throughput screening for inhibition of HIV-1 RT (eg, nevirapine[300]). The compounds that emerged were then chemically modified to improve their antiviral activities, stabilities, and pharmacokinetics and reduce their toxicities. The NNRTIs are highly specific, inhibiting HIV-1 RT at low concentrations while not inhibiting human DNA polymerases or even the RT of the closely related virus HIV-2.[300] This biochemical selectivity is reflected by the high-level resistance conferred by HIV-1 *pol* mutations.[368] These drugs directly inhibit RT. The NNRTIs do not mimic a natural ligand of a polymerase. Each NNRTI appears to share a polycyclic structure that tends to form a “butterfly wings” conformation upon binding to RT. NNRTIs bind to a pocket near the catalytic Asp residues of RT.[220] This pocket is not observed in structures of RT in the absence of drug but rather is stabilized by drug binding.[375] Thus, NNRTI binding causes a substantial conformational change in RT, including distortion of the catalytic Asp residues, and slows the enzyme's incorporation of dNTPs into DNA.[373,408] NNRTIs inhibit pyrophosphorolysis and the excision of AZT from primer termini by RT (Fig. 14.10; see Ref.[326]), which likely accounts for synergy of these drugs against HIV.[367]

As with 3TC, resistance to NNRTIs develops quickly both *in vitro* and in patients, with single amino acid substitutions conferring high-level resistance.[296,368,371] Some common resistance mutations arise in codon 181 (Fig. 14.9), changing Tyr to Cys (Y181C) or to Ile (Y181I), and cause high-level resistance.[296,368] This change alters a residue known to interact with NNRTIs[86,220,478] and thus reduces drug binding. The Y181C mutant is relatively fit in infected cells[87,200] and in patients. Some but not all other NNRTI-resistant mutants exhibit reduced fitness in cells and in patients.[264] The Y181C mutation, like the M184V mutation, sensitizes otherwise AZT-resistant mutants to AZT due to suppression of excision repair (Fig. 14.10, see Ref.[394]). The newest NNRTI, doravirine, retains activity against Y181C and certain other common NNRTI-resistant mutants.[127] The different mechanisms of action and resistance of the anti-HIV nucleoside analogs and NNRTIs help provide the rationales for various combinations of these drugs in treating HIV (see section on *HIV Therapy*).

Inhibitors of Hepatitis C Virus NS5A Protein

The evolution of NS5A inhibitors for the treatment of HCV followed a similar path to what was previously described for NS3/4A inhibitors. To date, six NS5A inhibitors have been approved by the U.S. FDA (Fig. 14.11B). The first generation of approved therapies (daclatasvir, ledipasvir, and ombitasvir) were components of some of the first all oral regimens for the treatment of genotype 1 HCV. The main liabilities of these compounds were resistance profile and the lack of pangenotypic coverage. These molecules were rapidly supplanted by molecules with pangenotypic activity and superior resistance profiles (elbasvir, velpatasvir, pibrentasvir).

NS5A inhibitors were originally discovered through a one million compound screen in cell culture for activity against genotype 1b genome replication using a subgenomic replicon assay, which discovered a series of molecules whose activity could not be related to inhibition of the known enzymatic targets such as polymerase or protease.[31,144] Selection and identification of resistance mutations suggested that the target was the viral protein NS5A.[144,251] NS5A is essential for viral replication but does not have a known enzymatic function.[310,344,381]

Despite extensive study, particularly on daclatasvir, the mechanism of action of NS5A inhibitors is not fully understood. To date, resistant mutants to NS5A inhibitors have all contained alterations within the first 100 amino acids of NS5A within domain one, which forms a symmetrical dimer capable of RNA binding, contains an amphipathic alpha helix that anchors the protein to cellular membranes, and plays a role in genome replication.[13,192,310,381,437] Biochemical studies demonstrated that daclatasvir can bind to domain one with nM affinity, and that binding is diminished by a resistance mutation (Y93H) or the addition of RNA.[13] Furthermore, NS5A inhibitors can disrupt the formation of subcellular structures of the “membranous web,” a subcellular structure associated with formation of the replication complex.[33] Synergy has been noted with different NS5A inhibitors, including the ability to rescue daclatasvir susceptibility in the presence of the Y93H mutation using a second NS5A inhibitor that shows no activity as a single agent.[419] These data along with studies demonstrating, remarkably, that NS5A is present in vast molar excess to NS5A inhibitors at their effective concentrations in infected cells have led to the suggestion that the inhibitors may act to disrupt the function of NS5A oligomers or distinct pools of NS5A in different complexes.[325,419]

Both the first- and second-generation NS5A inhibitors share a similar molecular topology, containing a hydrophobic core flanked by two largely identical substituents whose symmetry reflects the dimer structure of NS5A (Fig. 14.11B). The second common pharmacophoric feature is a chiral substituted pyrrolidine terminating in an isopropyl carbamate. In all cases, the molecules are larger and more hydrophobic than traditional oral small molecule therapies. NS5A inhibitors are among the most potent small molecule antivirals that have been developed to date with potencies in subgenomic genotype 1 replicon assays below 31 pM for all of the approved compounds.[65,80,144,228,267,318,474]

Resistance substitutions selected in cell culture are relatively consistent across genotypes and include M28T/V, Q30E/H/K/R, L31M/V, H58D, Y93C/H/N, and well as highly resistant Q30, Y93 double mutants. Mutations at positions 28, 31, and 93 are the most prominent. Complex interactions between mutations have been shown to drive high-level resistance even when a single mutation conferred little drug resistance on its own.[324] Sequencing of virus in patients treated with various NS5A inhibitors as a single agent, whose virus loads rebounded, showed a similar constellation of mutations with common mutational hot spots observed at position M28, Q30, L31, and Y93.[136,228,246,267,474] Notably,

the majority of genotype 2 HCV patients possess the L31M polymorphism at baseline,[492] which helped drive development of second-generation NS5A inhibitors. Optimization of the next-generation NS5A inhibitors, such as pibrentasvir and velpatasvir, led to molecules that exhibit sub nM to low pM EC_{50} values against wild-type replicons across all 6 genotypes, including genotype 2 replicons possessing the L31M polymorphism and dramatic improvements in the resistance profile including against Y93H.[318,324]

All of the NS5A inhibitors are used clinically in combination with another antivirals.

Inhibitors of HIV Integration

Inhibitors of HIV Integrase

A crucial stage in genome replication of HIV and other retroviruses is integration of the linear, double-stranded DNA product of reverse transcription into the host genome. The enzyme that carries out this step, integrase, is an essential enzyme. Integrase assembles onto sequences from the ends of HIV DNA, cleaves dinucleotides from each 3′ strand, and transfers these strands to covalently link them with target DNA (Fig. 14.12A). The catalytic core of integrase includes three conserved acidic residues called the DDE motif (Fig. 14.12C), which binds Mg^{++} that is essential for integrase activity. Discovery of integrase inhibitors was propelled by the development of an assay selective for DNA strand transfer,[180] which identified inhibitors that act much more potently at this step than at prior steps (Fig. 14.12A). Medicinal chemistry studies of various classes of diketoacid scaffolds led to the development of raltegravir (Fig. 14.12B).[418] Its diketoacid moiety binds to the metal coordinated by the DDE motif, and additional moieties bind to the enzyme and, evidently, DNA (Fig. 14.12C).[7,64,292] Raltegravir was tested against a variety of enzymes that are Mg^{++} dependent (eg, HIV RT) and was highly selective for integrase. Its selectivity for the strand-transfer step seems to depend on binding to a conformation of integrase that is stable only after processing of 3′ ends.

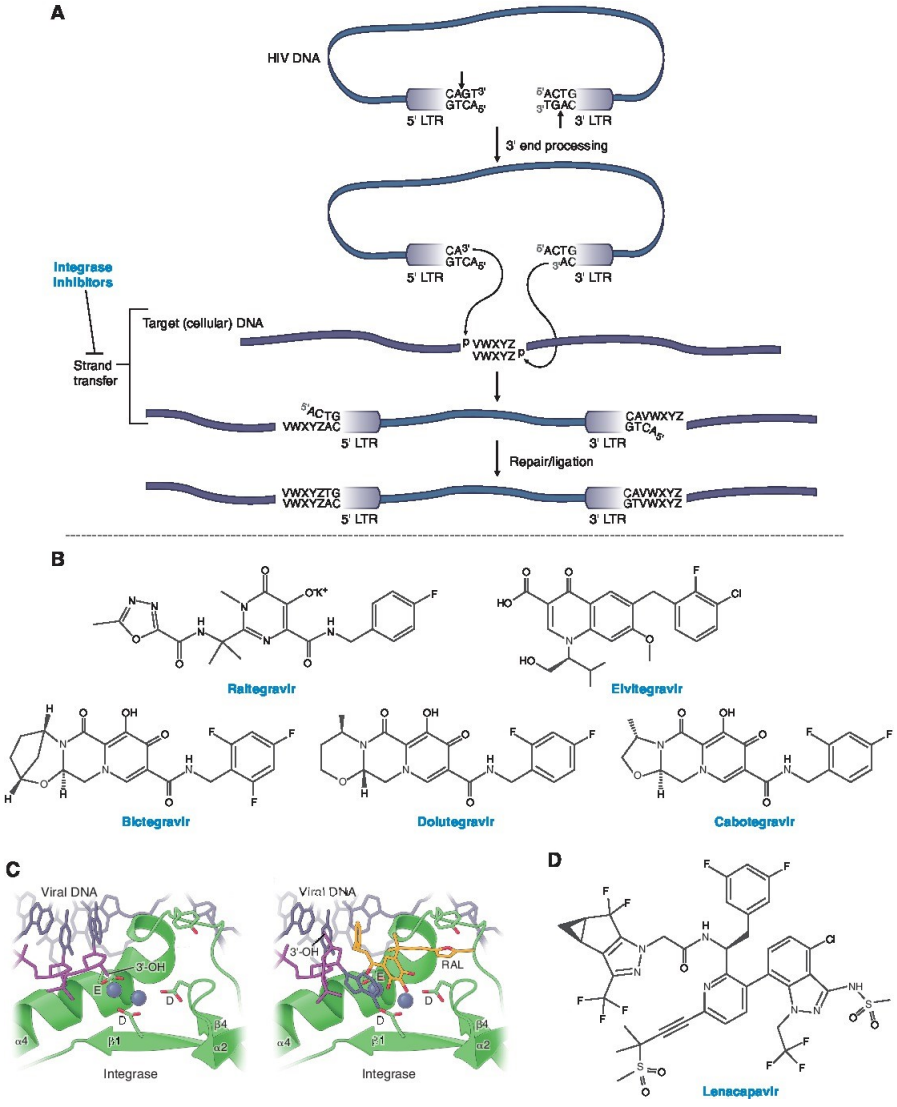

FIGURE 14.12 **HIV integrase, raltegravir action, and lenacapavir**. **A**. Linear, double-stranded HIV DNA, generated by reverse transcription, contains a four base sequence at each of its ends, as part of its long terminal repeat (LTR). Integrase (IN), which contains an N-terminal zinc-finger domain important for DNA binding, a C-terminal domain, and an internal core domain containing three acidic residues (DDE) that coordinate magnesium ions important for catalysis, binds to HIV DNA (as part of a larger complex), and cleaves a dinucleotide from the 3′ strand at each end of viral DNA (3′ end processing). The integrase-viral DNA complex then catalyzes the attack of the recessed 3′ ends of viral DNA on phosphodiester bonds of target (cellular) DNA (strand transfer). The product results in 5′ flaps of viral DNA and gaps in cellular DNA. Integrase releases and host enzymes remove the flaps and repair the gaps, resulting in integrated

viral DNA flanked by duplicated host sequences. Raltegravir inhibits the strand transfer step of this process. **B**. Structures of raltegravir, elvitegravir, bictegravir, dolutegravir, and cabotegravir. **C**. The mechanism by which raltegravir inhibits integrase. The left panel shows the active site of a retroviral integrase bound to viral DNA in the absence of drug, while the right panel shows the same active site in the presence of raltegravir. The integrase protein is shown in *green* with alpha helices shown as helical ribbons and beta-strands as arrows. Asp and Glu residues that coordinate magnesium ions, the viral DNA, and raltegravir (RAL) are shown as stick models, and the magnesium ions as *gray* spheres. The 3′ hydroxyl group of DNA is adjacent to the magnesium ions in the absence of drug but angled away from the ions when raltegravir is bound. (This figure panel was kindly provided by Peter Cherepanov.) **D**. Structure of the capsid binding drug lenacapavir, which blocks HIV replication at the step of integration. (Modified with permission from Li JZ, Coen DM. Pharmacology of viral infections. In: Golan DE, Armstrong EJ, Armstrong AW, eds. *Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy*. 4th ed. Wolters Kluwer; 2017:694-722.; Freed EO, Martin MA. HIVs and their replication. In: Knipe DM, Howley PM, Griffin DE, et al., eds. *Fields Virology*. 5th ed. Wolters Kluwer Health/Lippincott Williams & Wilkins; 2007. Ref.[135])

Raltegravir inhibits HIV replication at low nanomolar concentrations. As expected, HIV mutants resistant to raltegravir contain mutations in sequences encoding the integrase, with most mutations that confer resistance altering residues close to the inhibitor binding site.[292] Of mechanistic interest, one mutation alters a residue that, in the crystal structure, makes contact with a nucleotide corresponding to the 5′ terminus of viral DNA. There are also mutations that do not themselves confer resistance but increase the effects of other mutations. Similar mutations are selected by raltegravir in cell culture and in patients. Single mutations seem to be sufficient to confer clinically significant resistance, but most of these mutations decrease HIV fitness at least modestly.[292]

Since the development of raltegravir, four other integrase strand-transfer inhibitors have been FDA approved—elvitegravir (administered with a cytochrome P450 inhibitor, cobicistat, to boost serum drug levels), dolutegravir, bictegravir, and cabotegravir (which can be administered as a long-acting injection) (Fig. 14.12B). Some of these drugs are less prone to resistance than raltegravir. Integrase inhibitors are now key components of several anti-HIV combination therapies and prophylaxes.

A Capsid-Binding Drug That Blocks HIV Integration—Lenacapavir

A different way of blocking HIV integration has been revealed by studies of a new drug, lenacapavir (Fig. 14.12D). This drug was approved by the FDA in late 2022 as an every 6-month injectable in combination with other antiretrovirals for treatment of otherwise untreatable HIV infections. Lenacapavir was developed starting from a small molecule that accelerates self-assembly of HIV capsids from capsid protein p24 monomers.[261,484] Structural information from X-ray crystal structures of various related small molecules bound to cross-linked hexamers of p24 was used to optimize potency and metabolic stability, and a similar structure of the p24 hexamer-lenacapavir complex revealed that lenacapavir binds to and bridges interfaces between p24 monomers.[34,261] Accordingly, it binds much more tightly to p24 hexamers (subnanomolar K_d) than to monomers, and this very tight binding translates to highly potent antiviral activity in cells (subnanomolar ED_{50}) accompanied by cytotoxicity only at much higher concentrations.[34,261]

Based on its ability to accelerate HIV capsid assembly, one might anticipate that lenacapavir could inhibit capsid disassembly and/or other functions during the uncoating stage and subsequent steps culminating in the integration step of the genome replication stage.[481] Indeed, lenacapavir stabilizes capsids within HIV particles[34] and inhibits multiple steps of HIV infection. Early steps are inhibited with much higher potency—similar to that seen for viral replication—than later steps such as capsid assembly and maturation.[34,261] At concentrations that block viral replication, the drug has little effect on production of viral reverse transcripts (cDNA), so does not block uncoating but does block integration.[34,261] This appears to be due, at least in part, to impairing the import of complexes that contain DNA, p24, and integrase into the nucleus, as there are reductions in the amounts of integrase and viral DNA in that compartment with concomitant increases in the cytoplasm.[34,261] These effects can be explained by inhibition of dissociation of these complexes but likely effects on interactions of complexes containing DNA, p24, and integrase with host factors important for transit to the nucleus, nuclear import, and/or integration likely also contribute.[34,261,481]

Lenacapavir resistance mutations have been selected in cell culture and map, as expected, to the sequences that encode the binding site for the drug on p24.[261] Interestingly, most affect highly conserved residues and reduce replication in cell culture except one that confers relatively modest resistance and also arose in a patient during a clinical study.[261] Further study of the mechanisms of lenacapavir resistance and its clinical impact are needed.

Prospects for New Inhibitors and Targets of Viral Genome Replication

Given the successful development of numerous antiviral drugs targeting multiple steps in genome replication, it is not surprising that work continues on finding new drugs against established targets and against new targets that function at this stage. New nucleoside analog and nonnucleoside inhibitors of viral polymerases and other replication enzymes continue to be developed. One that has progressed to phase 3 clinical trials is pritelivir. This drug acts on the trimeric helicase-primase complex of HSV, which unwinds DNA ahead of the DNA polymerase on the leading strand and lays down primer for the polymerase to extend on the lagging strand.[219]

Inhibition of Viral Assembly/Egress

The processes by which viruses assemble infectious virions and egress from cells are closely intertwined and are attractive targets for drug discovery because they are unique to virus biology. As will be detailed below, certain steps in assembly are crucial for egress and certain steps in egress are crucial for assembly. Moreover, certain steps in assembly can occur after egress and certain steps in egress can occur prior to completion of assembly. Thus, for the purposes of this chapter, assembly and egress are considered together as a single stage of infection. FDA-approved drugs that target different steps during this stage are letermovir targeting DNA packaging into HCMV capsids, maribavir targeting nuclear egress of HCMV prior to completion of assembly of the virion, tecovirimat targeting assembly of a poxvirus glycoprotein that is crucial for egress, various HIV protease inhibitors targeting the final step of assembly—maturation into infectious virions—which can occur following egress, and various influenza neuraminidase inhibitors targeting release of virus particles from the extracellular surface of cells.

Letermovir—an Inhibitor of HCMV DNA Cleavage During Packaging

A major step in the assembly of all viruses is incorporation of viral genomes into capsids. For herpesviruses, the current model (reviewed in Ref.[182]) posits that replicated viral DNA is in the form of long concatemers made up of unit-length monomers arranged head-to-tail, and that a closed precursor called the procapsid is formed from a set of capsid and scaffold proteins and a viral protease. Then, additional capsid proteins involved in DNA packaging are assembled onto the surface of the procapsid, viral DNA is inserted into the capsid through a portal at a capsid vertex in a process preceded or accompanied by protease cleavage of the scaffold protein, and then the concatemerized DNA is cleaved at the genome terminus to yield the mature nucleocapsid (also known as C-capsid) containing a unit-length linear DNA. The cleavage activity, known as terminase, has three subunits, all of which are essential for viral replication.

Several different drug classes have been shown to inhibit HCMV DNA packaging. One class is comprised of 3,4-dihydro-quinazoline-4yl-acetic acid derivatives that were identified in a high throughput screen for anti-HCMV activity. One of these derivatives, now known as letermovir (Fig. 14.13A), was found to have ~50 nM potency against HCMV replication with orders of magnitude higher concentrations required to observe cytotoxicity or antiviral activity against other viruses, including HSV.[262,284] The target was revealed by isolation of drug-resistant mutants, whose mutations mapped to the *UL56* gene, which encodes a subunit of the terminase[154] thought to interact with DNA sequences required for cleavage and packaging.[42,182] Consistent with inhibition of terminase, letermovir-treated infected cells contained wild-type levels of replicated DNA, but a large decrease in unit-length genomes.[154] Which specific step in cleavage/packaging is inhibited by letermovir is unclear, as it has been difficult to reconstitute these activities *in vitro*.

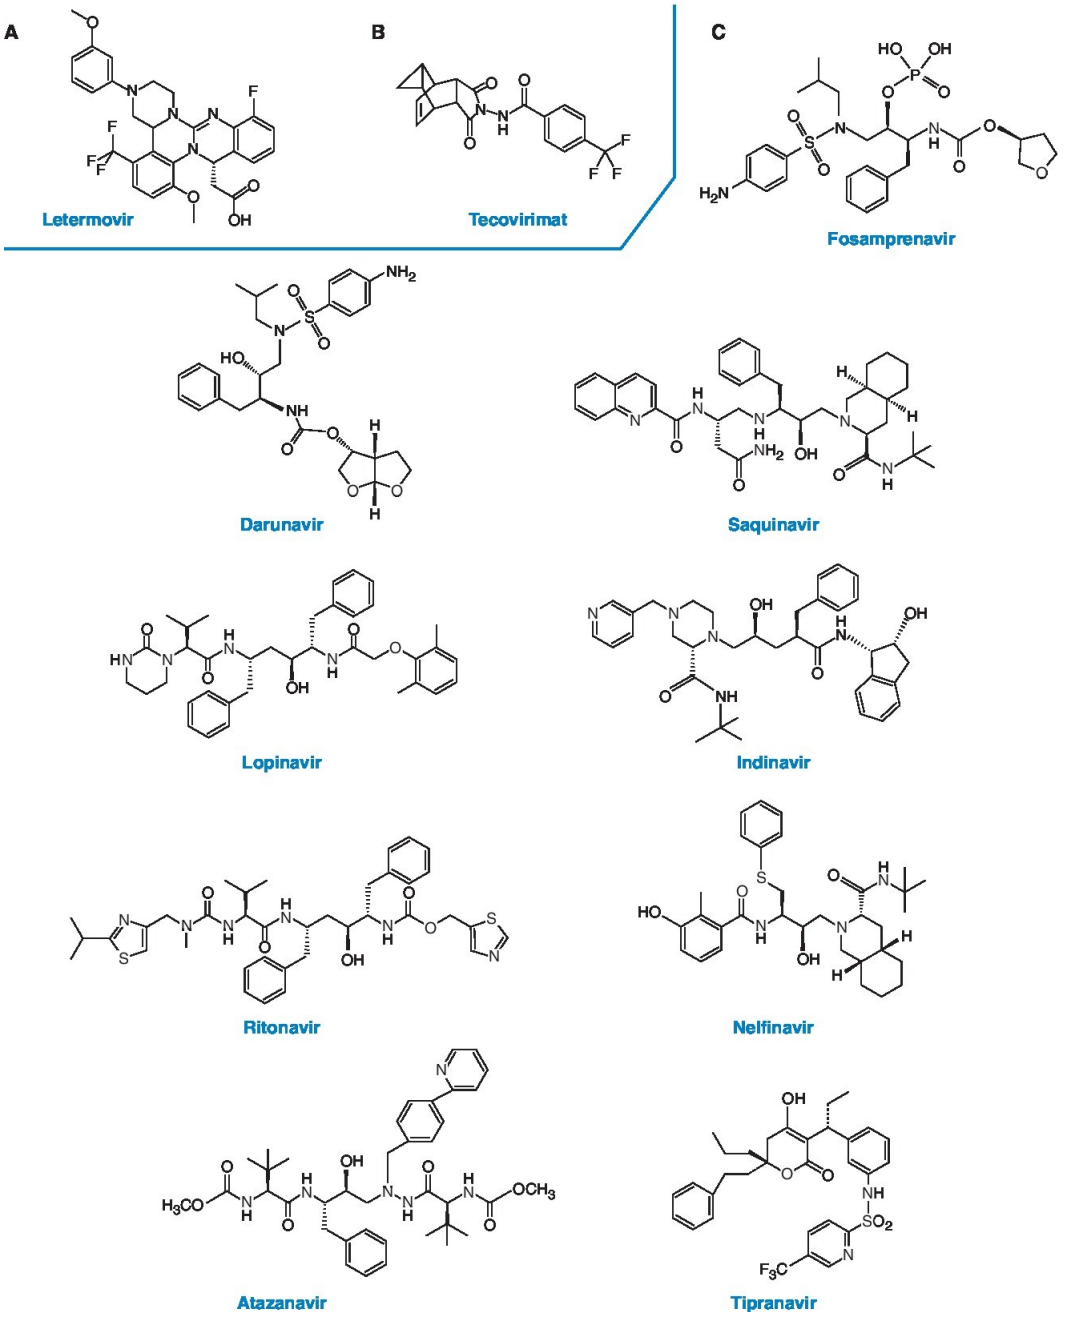

FIGURE 14.13 **Letermovir, tecovirimat, and anti-HIV protease inhibitors**. **A**. Structure of the anti-HCMV packaging inhibitor, letermovir. **B**. Structure of the antipoxvirus envelopment and egress inhibitor, tecovirimat. **C**. The structures of approved and marketed anti-HIV protease inhibitors fosamprenavir, darunavir, saquinavir, lopinavir, indinavir, ritonavir, nelfinavir, atazanavir, and tipranavir are shown.

Letermovir is orally available, causes less severe adverse events than older anti-HCMV drugs, and is active against most mutants resistant to such drugs.[262,287] HCMV mutants resistant to letermovir can evolve rapidly in cell culture with little effects on fitness.[70,72] Most such mutants have *UL56* mutations, but mutations in the *UL89* and *UL51* genes that encode different terminase subunits can confer slight resistance on their own and more substantially augment resistance conferred by *UL56* mutations.[71,72] Prophylaxis failures occurred in ~40% of treated patients,[287] but a relatively small fraction of those failures were associated with letermovir-resistant viruses, most of which had mutations in *UL56*.[104] At the time of this writing, work is ongoing to better understand the clinical importance of letermovir resistance, both in a prophylactic setting and in settings where the drug might be used to treat active HCMV infections, where resistance would be more likely to arise.

Maribavir, a Protein Kinase Inhibitor That Blocks HCMV Nuclear Egress

As summarized above in the section on inhibitors of genome replication, maribavir (Fig. 14.7B) is a nucleoside analog inhibitor of the protein kinase encoded by HCMV, UL97. Aside from inhibiting genome replication in nondividing cells, in both dividing and nondividing cells, maribavir (or a mutation inactivating UL97) also inhibits an unusual process during the assembly and egress of HCMV (and other herpesviruses), known as nuclear egress.[229,364] Indeed, in dividing cells, maribavir's inhibition of nuclear egress (~30-fold) is similar to its inhibition of virus yield.[229]

During herpesvirus nuclear egress, nucleocapsids migrate from their sites of assembly in the nuclear interior toward the nuclear periphery, where they cross the nuclear lamina that underlies the inner nuclear membrane, bud through the inner nuclear membrane, acquiring an envelope, and then fuse with the outer nuclear membrane to be released, envelope-less, into the cytoplasm.[36,273] During subsequent steps in assembly and movement through the cytoplasm, the capsid acquires a new envelope and envelope proteins, as well as tegument proteins that reside between the capsid and envelope. The completed virion can then egress from the cell.

What step in nuclear egress is inhibited by maribavir? During wild-type HCMV infection, the nuclear lamina becomes disrupted with gaps visible by confocal light microscopy, but in the presence of maribavir, the lamina remains intact.[168] Expression of active UL97 in cells following transfection also disrupts nuclear lamina,[283] and UL97 can phosphorylate the lamina component, lamin A/C *in vitro* on the site phosphorylated by cyclin-dependent kinase 1 that is crucial for disruption of nuclear lamina during mitosis.[168] Maribavir blocks phosphorylation at this site both *in vitro* and in HCMV-infected cells.[168] Expression of a dominant negative lamin A/C mutant that disrupts nuclear lamina in the place of UL97 alleviates the loss of UL97 function for replication in dividing cells.[396] Thus, the model is that maribavir blocks nuclear egress by inhibiting UL97 phosphorylation of lamin A/C, thereby preventing nucleocapsids from crossing the nuclear lamina. It remains unclear whether UL97 has functions other than disruption of the nuclear lamina during nuclear egress. Maribavir resistance is discussed in the section on this drug under *Inhibition of Viral Genome Replication*.

Tecovirimat—an Inhibitor of Envelopment and Egress

Concerns about the use of variola virus as a biological weapon led to efforts to develop antipox virus drugs. The first of these to achieve FDA approval (in 2018) was tecovirimat for treatment of smallpox disease. Tecovirimat (Fig. 14.13B) was discovered following a high throughput screen for inhibition of cytopathic effect induced by vaccinia virus. The screen identified a series of tricyclononine carboxyamides whose subsequent optimization resulted in tecovirimat.[22] Tecovirimat is potent against a variety of poxviruses including variola and vaccinia viruses in cell culture with EC_{50}s < 100 nM, and selective as it fails to inhibit other viruses or cell viability at concentrations more than 400-fold higher.[110,483] It also shows antiviral activity, and good tolerability and pharmacokinetics in animal models,[483] which form the basis for FDA approval as clinical trials for antivariola drugs are neither ethical nor practical.

Poxviruses assemble two kinds of infectious particles—intracellular virions, which have a single envelope, and are only infectious following mechanical lysis of cells, and, following wrapping of these particles with a second membrane, virions that can transit to the plasma membrane where the outer membrane fuses with the cell plasma membrane to release infectious virus that can infect neighboring cells and disseminate.[311] Interestingly, tecovirimat inhibits formation of extracellular infectious virus with little effect on intracellular virus.[483] The target of tecovirimat was revealed by the mapping of tecovirimat resistance mutations to the F13L gene of vaccinia virus, which encodes the major viral protein exclusively found in the outer membrane.[483] Inactivation of this gene results in a phenotype similar to that of tecovirimat—greatly reduced production of extracellular virions.[39] Interestingly, there is also evidence that those virions that are produced are less infectious,[49] but whether tecovirimat also has that effect is not yet known.

How tecovirimat inhibits the F13L gene product is unclear. The protein contains a motif that is conserved among a family of phospholipases, and substitutions in this motif blocks formation of the outer wrapping membrane and plaque formation.[378,420] Additionally, the protein has been reported to have lipase activity.[20] Tecovirimat treatment alters the localization of this protein as well as a second outer envelope protein.[110] Docking of tecovirimat to a putative model of the protein based on the structure of a bacterial phospholipase identified a potential pocket to which the drug binds; this predicted pocket also contains residues altered by tecovirimat resistance mutations.[110] It has been proposed that binding of drug to this pocket could affect a nearby loop-bearing residues in the motif conserved among phospholipases.[110] Further investigation is required to test this proposal and the putative model of the structure of the protein.

As noted, tecovirimat resistance mutations can arise in cell culture. The initial isolation of such mutants was obtained simply by plating virus in the presence of high concentrations of tecovirimat,[483] while a subsequent study found that multiple passages in the presence of drug were required.[110] Regardless, resistant vaccinia viruses that replicate as well as wild-type virus in cell culture were obtained although these mutants exhibited smaller plaque sizes. It would be interesting to know if these mutants had altered pathogenicity in animal models, which could shed light on possible outcomes of resistance in humans.

HIV Protease Inhibitors That Block Maturation

For many viruses, including HIV, mere assembly of proteins and nucleic acid into particles is not sufficient to produce an infectious virion. For such viruses, an additional step, maturation, is required. In most cases, these viruses encode proteases that are essential for maturation. The approved antiviral drugs that target HIV protease and are still marketed are saquinavir, ritonavir (which is now used mainly at low dose to boost

plasma drug levels of other protease inhibitors), lopinavir, fosamprenavir, indinavir, nelfinavir, atazanavir, darunavir, and tipranavir (Fig. 14.13C). This class of drugs is a paradigm of rational drug design.

The cleavage sites in the viral polypeptide substrates of HIV protease are conserved and somewhat unusual[347,354] and, unlike the human proteases most closely related to it, HIV protease is a symmetric homodimer, suggesting both specificity and a starting point for drug design.[316] For simplicity, only the development of ritonavir will be detailed. Ritonavir's design began with the recognition that a natural substrate of the protease contains a phenylalanine-proline (Phe-Pro) bond; mammalian enzymes rarely if ever cleave at such a site. The transition state of this substrate during cleavage was then modeled (Fig. 14.14A). Knowing that HIV protease is a symmetric dimer, an analog of the transition state was modeled, using the same residue, phenylalanine, on both sides, and with a CHOH group that mimics the transition state as the center of symmetry. This molecule, A-74702, was a very weak inhibitor of HIV protease, but adding groups symmetrically to both ends to form A-74704, resulted in a >40 000-fold increase in potency (K_i ~ 5 nM[118]). Attempts to modify A-74074 to improve solubility reduced potency, so a related potent inhibitor, A-75925, in which the center of symmetry was a C-C bond between two CHOH groups, became the scaffold for further additions to both ends.[215] This resulted in a soluble, highly potent inhibitor, A-77003 (Fig. 14.14B). However, this compound was not orally available.[214] It was modified by removing a central OH group and altering other moieties at each end (Fig. 14.14B). This resulted in less solubility but improved antiviral activity and good oral bioavailability.[213] These improvements took advantage of the X-ray structure of HIV protease complexed with each version of the inhibitors (reviewed in Refs.[10,472]). By examining these structures, chemists were able to make informed guesses about what groups to add or subtract. The result was ritonavir.

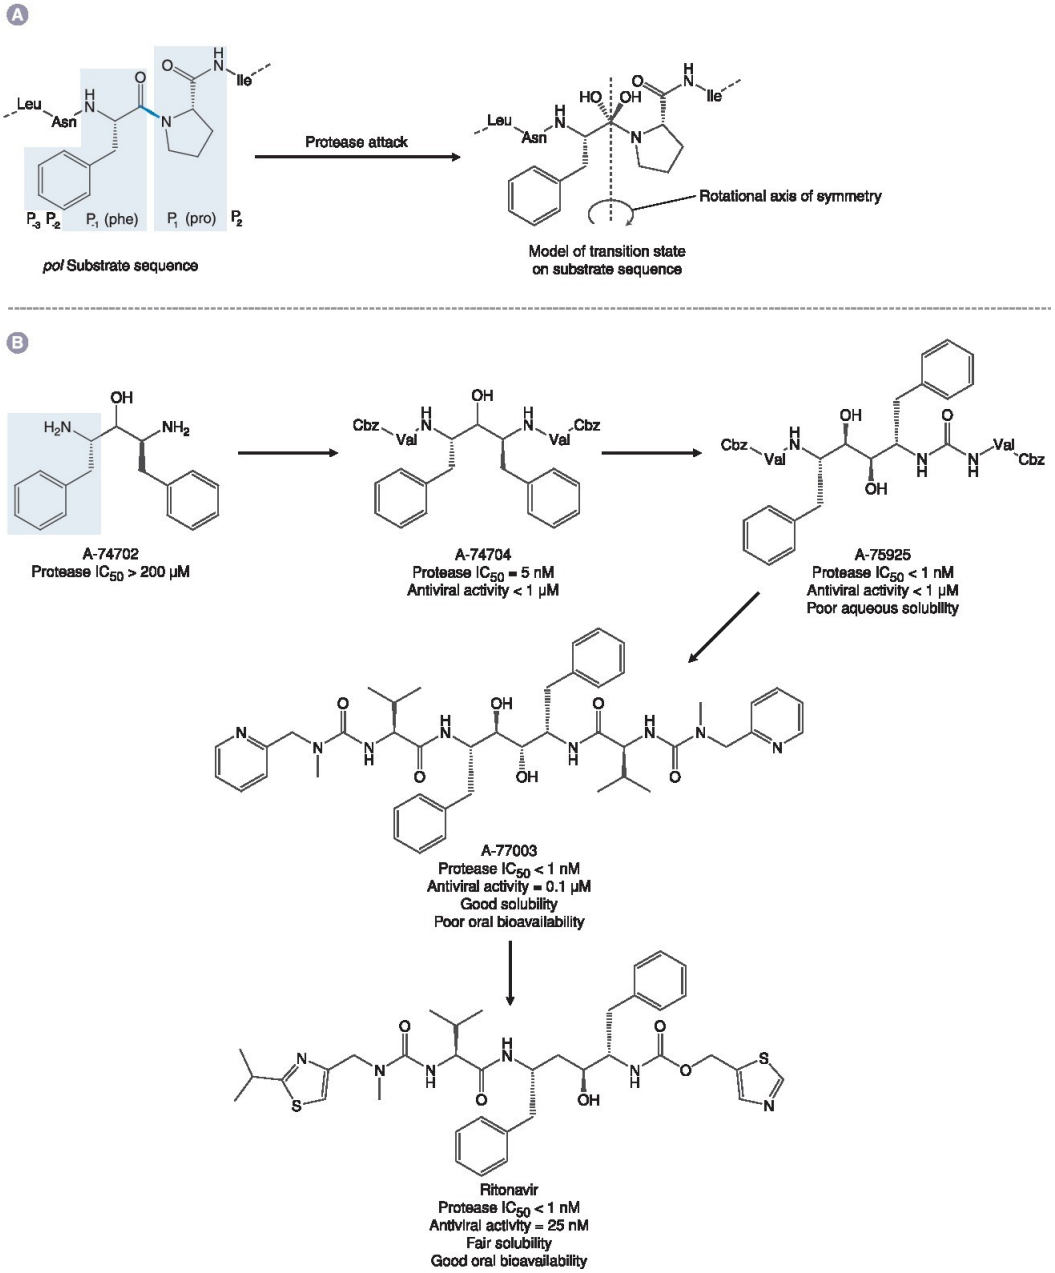

FIGURE 14.14 **Steps in the development of ritonavir**. **A**. On the left is shown a substrate sequence that is cleaved by HIV protease between a phenylalanine (phe) on the N-terminal side of the cleavage (P_{-1}) and a proline (pro) on the C-terminal side (P_1). On the right, the transition state of this sequence during protease cleavage is modeled. The transition state contains a rotational axis of symmetry. **B**. Structure-based development of ritonavir began with A-74072 (*top left*) that mimics the transition state with a single CHOH moiety between two phenylalanines (to maximize symmetry). This compound, which had weak inhibitory activity, was modified by symmetric

addition of other groups (CBZ = carboxybenzyl) to yield A-74074, which was more potent, but was insufficiently soluble. This was modified to mimic the transition state with CHOH groups on each side of the axis of symmetry (A-75925, *top right*). This was also poorly soluble but could be improved by adding more groups (A-77003, *middle*). That compound was not very orally available, so additional modifications, including the removal of a central OH group, were made, resulting in ritonavir (*bottom*). The choices of modifications were aided by crystal structures of intermediate compounds bound to HIV-1 protease. For each compound, the inhibitory potencies against HIV-1 protease *in vitro* (IC_{50}) and against HIV in infected cells (antiviral activity) are provided.

Crystallographic studies reveal that upon binding of protease inhibitors, the enzyme assumes a conformation with closed "flaps" that are unable to undergo conformational changes that help form the active site (Fig. 14.14C; reviewed in Refs.[10,472]). The drugs work in cell culture as expected: HIV-infected cells exposed to protease inhibitors continue to make viral proteins, but these proteins are not processed efficiently.[92] Viral particles bud from the infected cells, but they are immature and noninfectious.[149] Mutations conferring drug resistance map to HIV sequences encoding the protease, confirming that protease is the target.[333]

Mutations in over 30 of the 99 amino acid residues of protease have been selected with the different protease inhibitors, with as many as 24 conferring resistance to any one drug.[459] Some of the mutations affect the active site or sites known to interact with the inhibitors, and thus the mechanism of resistance can be readily understood. However, other mutations affect more distal sites, and it is not clear how they confer resistance, although several lines of evidence raise the possibility that these mutations affect the dynamics of the protease to weaken drug binding ([250] and references therein). Resistance is often cumulative. In some patients, after failing multiple regimens containing protease inhibitors, over 20 of these mutations have accumulated in their virus, demonstrating the remarkable plasticity of this enzyme.[459] There is even an example of a virus whose replication is enhanced by subinhibitory concentrations of a protease inhibitor.[290]

Different protease inhibitors tend to select different mutations, at least initially. Thus, although the drugs all work by similar mechanisms, the first mutation selected for resistance to one protease inhibitor often does not confer resistance to another. This can be understood by considering that although the different drugs tend to share similar functionalities that interact with the protease active site, each drug has a different functionality that confers high affinity binding via interactions with a particular site specific to the drug. Thus, a single mutation that interferes with binding of one drug will not necessarily affect binding of the other. As mutations accumulate, however, cross resistance develops among the protease inhibitors. Mutations affecting protease cleavage sites can also confer resistance.[105] These result in more easily cleaved precursor substrates for the protease. Different protease mutations also have differing impacts on viral fitness. Certain mutations can be readily found in untreated patients, suggesting high fitness, while others are not detected except following drug treatment, and often decrease fitness. Cleavage site mutations can improve the fitness of protease mutants.[105,280,489] These different features of resistance to protease inhibitors have important clinical implications (see section on *HIV therapy*).

Inhibition of Viral Release: Influenza Virus Neuraminidase Inhibitors

Inhibitors of influenza virus neuraminidases block viral release of influenza A and B viruses. The rationale for their action follows from the mechanism of viral attachment. Influenza attaches to cells via interactions between the virion hemagglutinin and sialic acid, which is present on many cellular membrane glycoproteins. However, upon egress of influenza virus from cells at the end of a round of replication, hemagglutinin on nascent virions again binds to sialic acid and tethers virions, preventing release and initiation of new rounds of infection. To overcome this problem, influenza virus encodes a virion neuraminidase, which cleaves sialic acid from the membrane glycoproteins. Studies using influenza virus mutants or an early neuraminidase inhibitor showed that without neuraminidase, the virus remains tethered and cannot spread to other cells.[266,339,340] In 1992, structures of the neuraminidase-sialic acid cleavage product were solved (Fig. 14.15A).[52,448] The structure showed that sialic acid occupied two of three well-formed pockets on the enzyme (Fig. 14.15C). Based largely on this structure, a new sialic acid transition state analog was designed to make energetically favorable interactions in all three of the pockets, principally by adding a guanidino group[452] (Fig. 14.15C). This compound, zanamivir (Fig. 14.15B), inhibits neuraminidase with a Ki of about 0.1 nM. Zanamivir is active against both influenza A and influenza B viruses with potencies of about 30 nM. However, it is not orally bioavailable and must be administered as an aerosol.

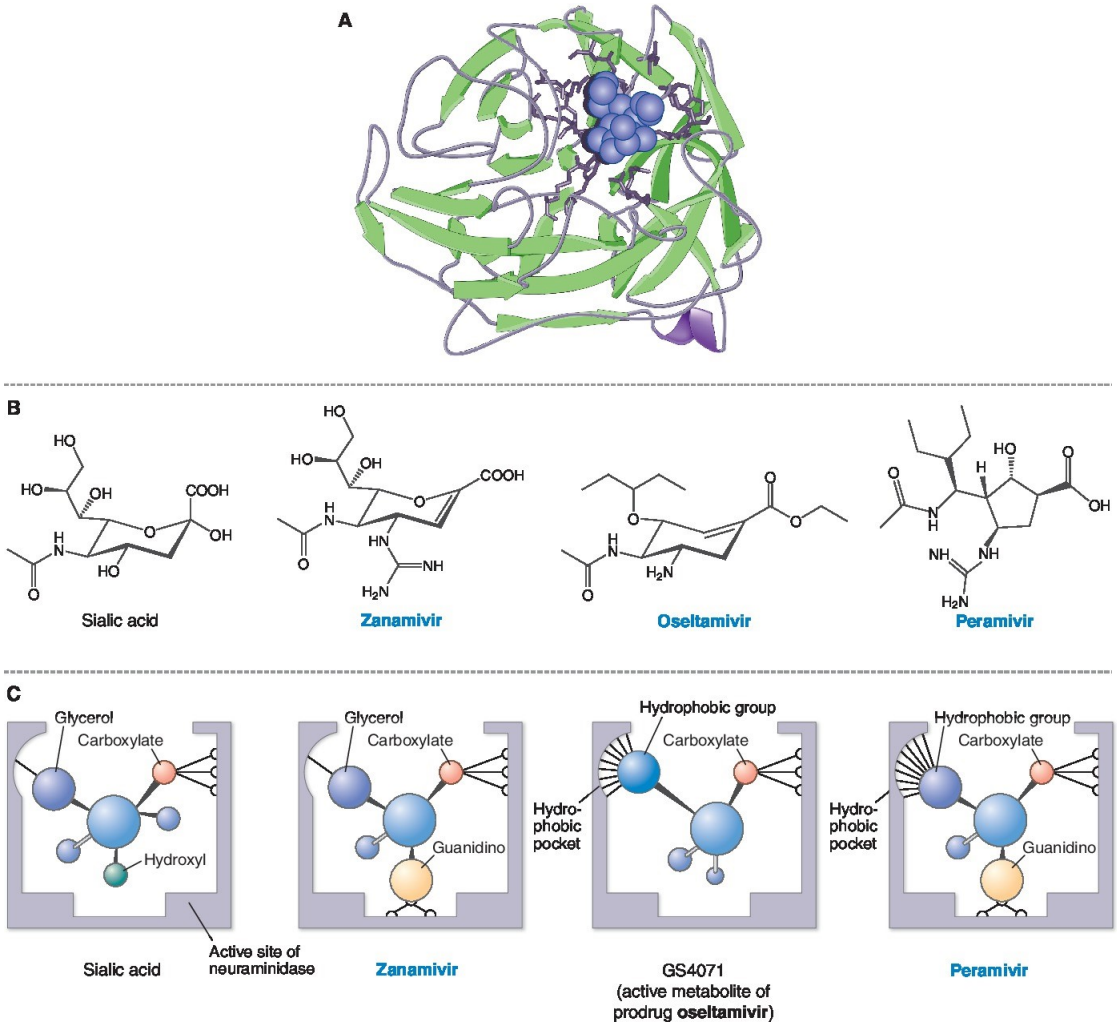

FIGURE 14.15 **Structure-based design of inhibitors of influenza A and B virus neuraminidase**. **A**. Shown is a model of sialic acid (space-filling structure in *dark purple*) bound to the influenza neuraminidase (*green* and *light purple*), with the amino acids that bind sialic acid shown in stick form. This structure was used to design transition state inhibitors that bind with higher affinity than sialic acid. **B**. Structures of sialic acid and the neuraminidase inhibitors oseltamivir, zanamivir, and peramivir. **C**. Diagram of the active site of influenza virus neuraminidase, showing the binding of sialic acid, zanamivir, GS 4071 (oseltamivir is the ethyl ester of this compound), and peramivir showing how the different ligands interact with pockets in the active site. Note that the compounds in **C** are flipped 180° relative to how they are shown in **A** and **B**. (Modified with permission from Li JZ, Coen DM. Pharmacology of viral infections. Wolters Kluwer; 2017:694-722. **C** is modified from Bryan Christie: Source: R. Scott Rowland, *BioCyst Pharmaceuticals, Inc.*)

Efforts to obtain a neuraminidase inhibitor with better pharmacokinetic properties than zanamivir resulted in oseltamivir (Fig. 14.15B).[217,257] Oseltamivir makes use of a carbocyclic ring based on a transition state analog of sialic acid. Rather than use a guanidino group to occupy a third pocket, it makes stronger contacts with one of the two pockets bound by sialic acid by adding a hydrophobic group (Fig. 14.15C). Oseltamivir's high oral bioavailability depends in part on its being an ester prodrug, which when cleaved gives rise to the active carboxylate (Fig. 14.15B).

Peramivir, which is administered by injection, replaces the 6 membered ring of oseltamivir and zanamivir with a cyclopentane (Fig. 14.15B). Despite the change in core structure, peramivir maintains a similar binding mode for the carboxylate to the other NA inhibitors, as well as occupying the hydrophobic pocket of oseltamivir and the guanidino binding pocket of zanamivir[6,18,486] (Fig. 14.15C). Peramivir has similar NA potency to that observed with zanamivir and oseltamivir.[26,28,165]

Most neuraminidase resistance mutations result in an enzyme that is less inhibited by the drug.[298] As would be expected by the differences in drug binding to the enzyme (Fig. 14.15), mutants resistant to one drug are not necessarily resistant to the other. For example, the H274Y mutation causes a 2-3 order of magnitude decrease in NA IC_{50} for oseltamivir, but a 1-2 order of magnitude decrease in NA affinity for peramivir.[21,165] Still, compared with amantadine, for many years, it was relatively difficult to generate mutants resistant to zanamivir or oseltamivir in the laboratory, and they appeared less frequently in the clinic. This was due in part to most such mutants being less fit than wild-type virus.[203,278] However, fit H275Y viruses have since arisen; their fitness can be attributed to secondary mutations that allow increased expression of the H275Y mutants on the surface of the infected cell.[40,358] As described in the Overview section of this chapter, another class of mutants resistant to the neuraminidase inhibitors contains altered hemagglutinins.

With increasing concerns regarding influenza pandemics, the mechanisms of action and resistance of neuraminidase inhibitors have become very important, as has the development of new anti-influenza drugs such as baloxavir that are active against mutants resistant to neuraminidase inhibitors.

Antiviral Therapies That Target Immune Processes

Two types of drugs approved for treatment of viral infections—imiquimod and interferons—do not inhibit virus replication directly. Rather, they enhance innate host immune responses to viral infection (see Chapter 9). Imiquimod, which is approved for treating certain diseases caused by human papillomaviruses, interacts with Toll-like receptors TLR7 and TLR8 to boost innate immunity, including secretion of interferons.[152,183,208] Interferon alpha is approved for treating HCV, HBV, condyloma acuminata, which is caused by certain human papillomaviruses, and Kaposi sarcoma, which is caused by Kaposi sarcoma–associated herpesvirus (human herpesvirus 8). The actions of interferons are reviewed in Chapter 9. However, which of the many activities induced by interferons contribute to their therapeutic effects (eg, against HCV; reviewed in Ref.[125]) remain poorly understood. Interestingly, genetic polymorphisms in a region encoding certain type III interferons, which are induced by interferon alpha, are associated with response of HCV infections to interferon alpha and ribavirin, with lower expression of these interferons associated with lower responses to therapy.[147,421,433] Follow-up studies of this observation and greater understanding of mechanisms by which viruses inhibit interferon action (eg, HCV; reviewed in Ref.[125]) may facilitate the development of more targeted therapies.

Principles of Antiviral Therapy

General Concepts

Different viruses can have very different dynamics of infection, and these differences have major impacts on the goals and effects of antiviral therapy. Many of these differences relate to the interplay between antiviral therapy and the immune system. Acute viral infections of immunocompetent patients usually are cleared by the immune system in a matter of days. It is not surprising then that antiviral treatment of most such infections in immunocompetent patients reduces the duration of symptoms by only a day or so; as a corollary, treatment must be started as soon as possible to obtain clinical benefits. Indeed, antiviral prophylaxis can be more effective than treatment.

Many of the same considerations apply to recurrent disease caused by reactivation of latent viral infections in immunocompetent patients. In the case of frequently recurring herpes genitalis, suppressive therapy is much more effective than treating each episode. Another issue in acute infections can be the extent to which symptoms are due to viral replication rather than the immune response to the virus. For example, many of the later manifestations of severe COVID-19 are the consequence of the host immune response to SARS-CoV-2 and respond more effectively to treatment with corticosteroids and other immunomodulators than to antivirals.[163,210,366,401,464] Conversely, in the absence of an effective immune response, antiviral therapy may fail to control viral replication, leading to emergence of drug-resistant virus as in the case of HSV, VZV, and HCMV in patients with late-stage AIDS.

Many of the viruses for which antiviral drugs have been developed cause persistent infections. The primary goal in the management of persistent viral infections with antiviral therapy is sustained suppression of viral replication. In contrast with acute infections, treatment of chronic viral infections can be effective even when initiated well after symptoms have appeared. In some cases, such as HCV infections, persistent viral replication occurs in the face of an immune response that usually is incapable of clearing the virus by itself. However, because HCV does not establish latent infection, complete inhibition of viral replication for a sufficient period results in cure. In other cases, such as HCMV reactivation in recipients of stem cell or solid organ transplants, the immune system often cannot control virus replication. Antiviral drugs cannot cure HCMV infections but can suppress viral replication, thereby preventing disease until an effective immune response is restored. The benefits of suppressive prophylactic treatment of HCMV in immunosuppressed patients must be weighed carefully against the toxicities of anti-HCMV drugs and risks of drug resistance (see below).

Drug Resistance in Antiviral Therapy

As summarized earlier in the chapter, the rate at which mutants that are resistant to a given drug will emerge is a function of mutation rate, size of the genomic target for resistance, relative fitness conferred by a particular resistance mutation, replication rate, and size of the preexisting population of virus.[84] All of these factors can have clinical impact. For example, HIV has high mutation and replication rates, and patients have enormous populations of virus by the time they are treated, so resistance can emerge in most patients even with a single codon target whose mutation reduces fitness.[84] By contrast, HSV has lower mutation and replication rates and lower populations of virus, so resistance is less common even with larger target sizes for ACV resistance. In both cases, drug-resistant mutants can recur from latent reservoirs.

Of particular relevance to antiviral drug resistance is the relationship between drug concentrations attained in patients and the suppressive effect on viral replication. At very low levels of drug exposure, minimal viral inhibition is achieved and thus selective pressure favors persistence of wild-type virus. As drug exposure and viral inhibition increase, so too does selection pressure favoring emergence of drug-resistant variants. At higher levels of drug exposure, only variants carrying mutations that confer high-level drug resistance can persist. Achieving complete suppression of viral replication through appropriate drug dosing or use of combination antiviral therapy substantially reduces the risk of drug resistance. For example, combination ART regimens that include the HIV protease inhibitor (PI) atazanavir select for the I50L substitution in HIV protease, which confers modest levels of resistance.[88] By contrast, when atazanavir is coadministered with a low dose of ritonavir, an HIV PI that potently inhibits hepatic drug metabolism, thereby leading to sustained high levels of atazanavir, resistance is rarely observed.[253] The ultimate goal of antiviral therapy, especially for viruses like HIV, HBV, and HCV, which have high mutation rates, high replication rates, and high preexisting populations, is to apply drug regimens that completely inhibit virus replication.

Clinical Impact of Drug Resistance

It may seem obvious that drug resistance is important clinically. However, many treatment failures are not due to drug resistance, and many drug-resistant viruses do not cause treatment failures. For acute infections like influenza, which are largely controlled by the immune system, antiviral drug resistance is generally not a major problem for the patient in whom it arises. Therefore, during monotherapy with neuraminidase inhibitors, variants probably emerge in all patients within a week, but in immunocompetent patients, that is when the infection has largely resolved. Transmission of resistant virus to others can occur, however, and the antiviral efficacy will be impaired in these secondary cases. By contrast, in persistent infections, accumulation of resistance mutations progressively reduces the efficacy of antiviral regimens. Continued replication in the presence of drug selects for even greater levels of resistance to each administered drug and progressive cross resistance to

drugs of the same class. These factors drive a vicious cycle of treatment failure and yet more difficult treatment challenges.

Drug-resistant herpesviruses and HIV can establish latent infections. Drug-resistant HIV, HBV, and influenza A viruses have been transmitted to other individuals.[117,139,297] In the case of HIV, resistant virus in blood or genital secretions can be transmitted during sex, needle sharing, or childbirth.[263] In the United States, one or more transmitted drug resistance mutation was detected in HIV from nearly 20% of newly diagnosed persons during the period 2014-2018.[291] Antiretroviral drug resistance in lower- and middle-income countries has become increasingly appreciated with the rollout of treatment access.[476]

Strategies to Combat Drug Resistance

The increasing prevalence of antiviral drug resistance raises challenges to the effective treatment of individuals and to the public health similar to those that have resulted from widespread antibiotic resistance. One strategy to combat this problem is to test viruses for drug resistance before choosing antiviral regimens. Resistance testing can help determine which drugs will not work (thereby diminishing cost, toxicity, and inconvenience) and which drugs are most likely to be effective. These tests can be performed most rapidly if they are genotypic (ie, detecting mutations at the level of DNA or RNA) rather than phenotypic (ie, measuring changes in drug susceptibility). Because the turn-around time for obtaining resistance test results may delay treatment initiation by days to a few weeks, resistance testing for individual patients is more feasible for chronic viral infections (eg, HIV) than for acute infections (eg, influenza). For this reason, active surveillance to assess the prevalence of resistance to first-line drugs among circulating viruses is essential.

A second potential strategy is combination chemotherapy. This strategy combats resistance on several levels. First, the probability of a virus being resistant to multiple different drugs (with different mutations conferring resistance) is the product of the probabilities of resistance to each drug. This approach makes it much less likely that a preexisting virus in the patient will be resistant to all of the drugs. Second, the combination is likely to suppress replication more completely than would any single drug alone, thereby reducing the chance for resistance to develop. Third, members of the combination might synergize, thereby providing even greater efficacy. It is crucial that drugs in the combination not antagonize each other's activities by mechanism of action or pharmacologic interaction. Fourth, a mutation conferring resistance to one drug in a combination might yield clinical advantages, for example, by making the virus less fit or by sensitizing otherwise resistant viruses to a second drug. Such advantages have been invoked for the M184V mutation in HIV and the M204V/I mutation in HBV that confer resistance to 3TC and FTC.[100,232]

Drug resistance is relatively uncommon with certain virus infections, such as herpesvirus infections in immunocompetent persons, which, together with the various downsides of adding additional drugs, explains why combination chemotherapy is rarely used for treating herpesvirus or influenza virus infections.

HIV Therapy

Since AZT was first approved for clinical use, more than 30 drugs or drug combinations have been approved for treating HIV (Fig. 14.16). This remarkable drug development experience helped elucidate many of the principles of antiviral therapy described above. A review of the clinical evaluation of each of the anti-HIV drugs and each of the combinations of these drugs for patients in various stages of disease is beyond the scope of this chapter. Guidelines summarizing the practical use of currently available antiretrovirals are frequently updated.[343,383]

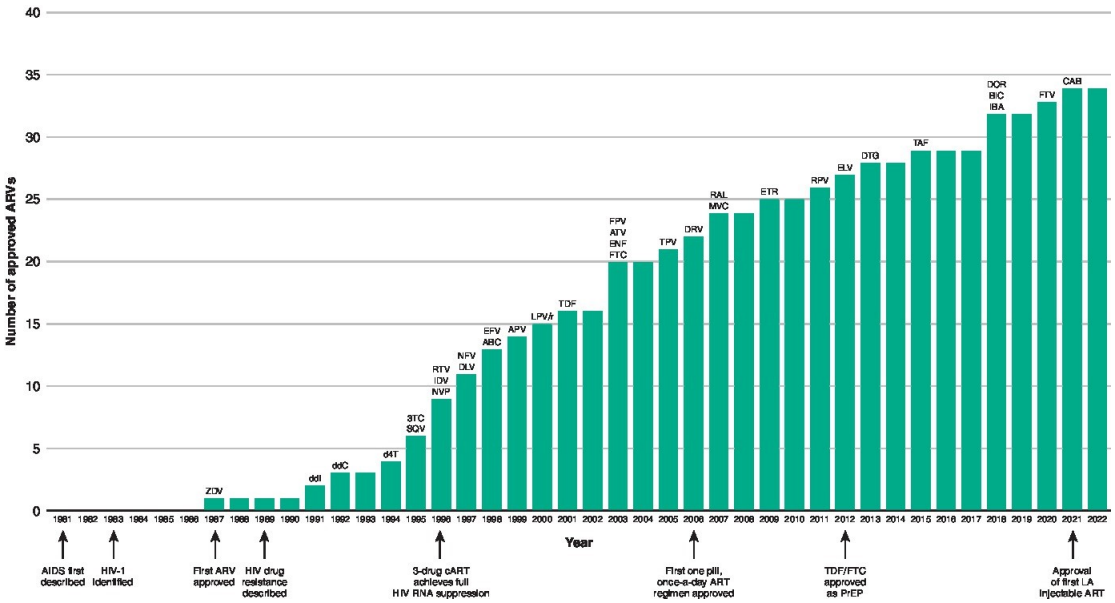

FIGURE 14.16 **Time line of AIDS therapies**. The dates of important events in the understanding and therapy of AIDS are provided together with the dates of FDA approval of antiretroviral drugs. The bars represent the progressive accrual of approved drugs. Abbreviations: ZDV, zidovudine (AZT); ddI, didanosine; ddC, zalcitabine; d4T, stavudine; 3TC, lamivudine; SQV, saquinavir; RTV, ritonavir; IDV, indinavir; NVP, nevirapine; NFV, nelfinavir; DLV, delavirdine; EFV, efavirenz; ABC, abacavir; APV, amprenavir; LPV/r; lopinavir/ritonavir; TDF, tenofovir; FPV, fosamprenavir; ATV, atazanavir; ENF, enfuvirtide; FTC, emtricitabine; TPV, tipranavir; DRV, darunavir; RAL, raltegravir; MVC, maraviroc; ETV, etravirine; RIL, rilpivirine; ELV, elvitegravir; DTG, dolutegravir; TAF, tenofovir alafenamide; DOR, doravirine; BIC, bictegravir; IBA, ibalizumab; CAB, cabotegravir; ARV, antiretroviral; cART, combination antiretroviral therapy; PrEP, preexposure prophylaxis; LA, long acting. After this figure was completed, lenacapavir was approved (late 2022). (Adapted from a figure created by Douglas R. Richman.)

A large body of data from randomized controlled trials and longitudinal cohort studies informs treatment guidelines developed by various groups. The general principles are clear: to be effective, treatment must be sufficiently potent to suppress plasma viremia to below the limits of detection of sensitive assays and must be sufficiently simple and well tolerated that patients will be capable of adhering to the prescribed regimen with a minimum of missed doses. Because current therapy is incapable of eradicating HIV-1 infection, once such therapy is started, most patients will require it lifelong.

Since 2016, the World Health Organization HIV treatment guidelines have recommended initiation of ART for all persons with HIV infection regardless of CD4 count or stage of HIV infection. As of this writing (2022), regimens preferred by the U.S. Department of Health and Human Services *Guidelines for Use of Antiretroviral Agents in Adults and Adolescents with HIV* include an integrase strand transfer inhibitor (INSTI; either bictegravir or dolutegravir) in combination with tenofovir plus FTC or 3TC.[121,343,383,477] The approval of long-acting formulations of the INSTI cabotegravir plus the NNRTI rilpivirine as monthly or bimonthly injectable agents provides an alternative to daily oral therapy in appropriate patients.[331,334,428] Newer drugs in novel classes such as ibalizumab and fostemsavir generally are reserved for highly treatment-experienced patients with limited treatment options due to multidrug-resistant HIV.[115,226]

Therapy of Herpesviruses

HSV and VZV Therapies

ACV, the mechanism of which is detailed in this chapter, set the standard for the development of antiviral drugs. Randomized, controlled trials demonstrated efficacy of the intravenous drug for serious systemic infections such as herpes encephalitis, neonatal herpes, and disseminated varicella zoster in immunocompromised hosts.[463] The oral formulation, which has negligible toxicity, is used widely for the treatment of primary and recurrent HSV-1 and HSV-2, the prophylaxis of recurrent HSV, and the treatment of uncomplicated VZV. The earlier in the presentation of symptoms, the more effective the treatment, and prophylaxis is more dependable than treatment. The appearance of resistant isolates has been remarkably rare in immunocompetent patients and occurs in a minority of immunocompromised patients. ACV-resistant HSV and VZV did become a significant challenge in patients with AIDS before the availability of combination antiretroviral therapy.[120,337] The expanded number of resistant infections reflected the number of patients with AIDS, the prevalence of recurrent HSV and VZV infection in these patients, and the duration and magnitude of these opportunistic infections because of the severely reduced antiviral immunity in these hosts. Foscarnet shows activity against some ACV-resistant infections,[384] but resistance to this DNA polymerase inhibitor has developed as well.[385]

Two limitations of oral ACV have been its limited oral bioavailability (~15%) and short half-life. These limitations require administration of large pills as often as every 4 hours. As described earlier in this chapter, valacyclovir and famciclovir overcome these limitations. Both valacyclovir and famciclovir can be used in place of oral ACV. In most situations, valacyclovir is preferred due to dosing convenience. In addition, once-daily administration of the ACV prodrug valacyclovir reduces the risk of transmission of genital HSV.[90] Because of the more prolonged maintenance of higher levels of antiviral activity, valacyclovir and famciclovir are also used in place of intravenous or high-dose oral ACV for the treatment of uncomplicated herpes zoster in the immunocompromised host.[35,445]

HCMV Therapies

As reviewed earlier in the chapter, the lack of potency of ACV against HCMV led to the development of ganciclovir. Ganciclovir is more toxic than ACV. However, it is the first-line therapy for HCMV disease in the immunocompromised host. The eventual development of valganciclovir has now provided an orally bioavailable drug for HCMV that can achieve levels approaching those of intravenous ganciclovir without the cost, inconvenience, and complications of intravenous dosing.

Although ganciclovir and valganciclovir initially were used for the treatment of retinitis and other end-organ disease due to HCMV in patients with HIV, the incidence of these infections has diminished drastically since the introduction of effective combination ART. Consequently, use of ganciclovir and other anti-HCMV agents is now directed principally to the prevention and treatment of HCMV disease in recipients of stem cell and solid organ transplants. In the setting of stem cell transplantation, preventive therapy may be preemptive (guided by the level of HCMV viremia as measured by quantitative PCR) or prophylactic (given in the immediate posttransplant period to high-risk patients regardless of HCMV viremia). Previously, the benefits of prophylaxis with ganciclovir or valganciclovir needed to be balanced against the risk of prolonged neutropenia, the principal toxicity of these agents. The approval of letermovir for HCMV prophylaxis in this setting is changing practice, given the absence of myelotoxicity or nephrotoxicity associated with this drug.[287]

Foscarnet and cidofovir are also approved for the treatment of HCMV. Although equally effective, foscarnet is used only for ganciclovir-resistant HCMV infections because of inconvenience and nephrotoxicity.[439] Cidofovir also is used for the treatment of ganciclovir-resistant HCMV. It has the advantage of requiring administration only once every 1 or 2 weeks due to its very prolonged intracellular half-life but shares with foscarnet the disadvantage of renal toxicity. Maribavir is approved for treatment of HCMV infections in transplant recipients who fail to respond to other available antiviral agents. Although a phase 3, double-blind, randomized controlled trial failed to show a benefit of maribavir with respect to incidence of CMV disease,[288] a subsequent open-label phase 3 trial that used a higher dose of maribavir in patients with HCMV refractory to treatment with ganciclovir (or valganciclovir), foscarnet, or cidofovir demonstrated that a significantly greater proportion of participants achieved clearance of HCMV viremia in the maribavir arm as compared to the investigator-assigned treatment arm.[16]

Antiviral therapy has not yet been shown in randomized trials to significantly alter disease attributable to the other human herpesviruses including Epstein-Barr virus (EBV) and human herpesvirus 6 (HHV6), HHV7, and HHV8. Retrospective analyses and case reports suggest a possible clinical benefit of treating HHV6 encephalitis in the setting of stem cell transplantation with foscarnet, ganciclovir, or cidofovir, each of which shows activity against HHV6 *in vitro*,[187] but even when started promptly survivors may suffer significant neurologic sequelae. No available antiherpesvirus drug effectively addresses the problem of viral latency.

Therapy of Viral Hepatitis

HBV Therapy

The complex natural history of HBV infection is described elsewhere in this text. Criteria based on disease stage and level of HBV viremia, and the availability of more effective drugs, have increased the treatment indications and the long-term success of therapy.[122,475] An important complication is that chronic HBV infection implies that immune responses toward the virus are impaired. In addition, chronic HBV entails the existence of large numbers of cells containing covalently closed circular HBV DNA, a situation akin to herpesvirus latency. For all practical purposes, this factor may preclude eradication of HBV infection. In this context, for therapy to be successful, the immune response must be restored, chronic antiviral suppression must be maintained, or both.

A significant proportion, but not all, carriers of HBV progress to cirrhosis, hepatic failure, or hepatocellular carcinoma. Antiviral therapy has been shown to prevent the development of these complications and, in fact, to reverse cirrhotic histopathology.[424] Whom, when, and how to treat are decisions based on risk of progression and therapeutic index of the various treatments.[122] Treatment efficacy is affected by the regimen used as well as viral genotype, disease and virologic status, age, and comorbidities such as HIV coinfection. Because treatment interruption can lead to a serious flare of acute hepatitis, once initiated anti-HBV treatment generally must be continued lifelong.

Five nucleoside analogs have been approved for the treatment of hepatitis B. The experiences with these drugs recapitulate many of the experiences of HIV therapy. Whereas 3TC, telbivudine, and adefovir are effective at reducing plasma HBV DNA, continued use is associated with increasing proportions of patients with resistant mutants who experience treatment failure.[270] Entecavir and tenofovir (formulated as one of two prodrugs) have displaced other drugs for HBV infection because of their high rates of virus suppression with monotherapy and the low rates of emergence of drug-resistant virus during treatment.[122,406,438,475] The combination of tenofovir and emtricitabine, which is active against HBV, has been approved for the treatment of HIV and is used routinely in patients who are coinfected with HIV and HBV.

HCV Therapy

A critical difference between HBV (or HIV) and HCV is that HCV has no DNA intermediate that precludes eradication; hence, HCV is curable. Whereas treatment previously depended on the combination of IFN-α plus ribavirin, such treatment has been supplanted entirely by combination therapy with orally bioavailable small molecule antivirals targeting the NS3/4A protease, NS5A, or the NS5B RNA polymerase (so-called “directly acting” antiviral drugs) that have revolutionized the treatment of HCV. Regimens including various combinations of these drugs are able to effect cure (as assessed by sustained virologic suppression) in nearly all patients with HCV after just 8-12 weeks of treatment. The choice of regimen depends on presence or absence of cirrhosis, HCV genotype, and whether or not the patient has received prior treatment for HCV. Specific guidance from the American Association for the Study of Liver Diseases and the Infectious Diseases Society of America can be found at www.hcvguidelines.org. The combination of the NS3/NS4A protease inhibitor glecaprevir plus the NS5A inhibitor pibrentasvir administered daily for 8 weeks is recommended for patients with or without compensated cirrhosis regardless of genotype[14,15,130,233,490]; the combination of NS5B RNA polymerase inhibitor sofosbuvir plus the NS5A inhibitor velpatasvir administered daily for 12 weeks can also be used,[126,131] but addition of voxilaprevir or weight-based dosing of ribavirin is necessary in patients with infection due to HCV genotype 3 carrying the NS5A inhibitor resistance–associated mutation Y93H.[45,46,204,351] Regimens including combinations of ledipasvir plus sofosbuvir[3,44] or elbasvir plus grazoprevir[132,491] may also be useful in some patients depending on HCV genotype.

Influenza Therapy

Treatment of influenza relies on the neuraminidase inhibitors (oseltamivir, peramivir, and zanamivir) and the cap-dependent endonuclease inhibitor baloxavir. Each of these drugs is effective in treating both influenza A and B[178,179,221,315,321,359,441]; oseltamivir, zanamivir, and baloxavir are also effective for postexposure prophylaxis.[175,177,201] Oseltamivir and baloxavir are dosed orally, whereas zanamivir must be administered by inhalation and peramivir is available only for intravenous administration. Although the adamantanes amantadine and rimantadine were the first antiviral drugs used for prevention of influenza A, because of widespread resistance to these M2 inhibitors, they no longer are recommended for use.

Because of its oral bioavailability, oseltamivir is preferred among the neuraminidase inhibitors for treatment and prevention of influenza, except when a high proportion of circulating influenza A strains are oseltamivir resistant. The inhalational administration of zanamivir risks uneven distribution in the respiratory tract and occasionally bronchospasm. Baloxavir has the advantage of requiring only a single dose and has greater activity against influenza B as compared to oseltamivir.[179] Although baloxavir retains activity against influenza A strains resistant to neuraminidase inhibitors, emergence of I38T, M, or F substitutions in the polymerase PA subunit that confer resistance to baloxavir occurred in 9.7% of participants assigned to baloxavir in a phase 3 trial.[179] For this reason, oseltamivir generally is preferred over baloxavir. In theory, a combination of oseltamivir and baloxavir might prevent emergence of resistance in influenza A while providing optimal activity against influenza B, but limited clinical trials conducted to date have not shown improved outcomes.[230] Because experience with baloxavir in patients with severe influenza is limited, oseltamivir is preferred in this setting as well. Use of peramivir typically is reserved for patients unable to take oral therapy. An intravenous formulation of zanamivir is available in the United Kingdom and Europe Union, but as of this writing is not approved for use in the United States.[405]

High-level resistance due to His to Tyr mutation in codon 275 of the N1 neuraminidase has emerged during treatment of H1N1 in children and in patients treated for H5N1 infection.[95,377] This mutation confers cross resistance to peramivir but not to zanamivir.[164,320,461] By itself, the H275Y (H274Y in N2) mutation reduces fitness *in vitro* and *in vivo*,[203] although these mutants are transmissible to ferrets.[184] However, as reviewed earlier in the section on neuraminidase inhibitor mechanisms, oseltamivir-resistant H1N1 viruses containing H275Y together with secondary mutations that increase fitness emerged during the 2007-2008 influenza season and became the predominant influenza A strain circulating in 2008-2009[98,176]; those oseltamivir-resistant viruses showed no loss of fitness, transmissibility, or pathogenicity.[297] In that setting, zanamivir was recommended as the preferred antiviral for treatment and prevention of influenza A (baloxavir was not yet available). Fortunately, the prevalence of oseltamivir resistance has been infrequent in subsequent influenza seasons.

SARS-CoV-2 Therapy

The explosion of the SARS-CoV-2 pandemic in early 2020 prompted an urgent search for antiviral drugs that might prevent disease progression and reduce mortality of COVID-19. Two years into the pandemic, three agents have emerged as small-molecule inhibitors of SARS-CoV-2 with demonstrated clinical efficacy, including remdesivir, nirmatrelvir, and molnupiravir. These agents have broad activity against SARS-CoV-1,

MERS, and SARS-CoV-2. In contrast to mAbs, these drugs retain potency against a wide range of SARS-CoV-2 variants.[430,447] As with treatment for influenza, antiviral therapy for SARS-CoV-2 has the greatest impact when initiated as soon as possible after symptom onset.

The RdRp inhibitor remdesivir is approved for treatment of persons with SARS-CoV-2 infection. Clinical trials have shown its effectiveness in preventing disease progression among outpatients with symptomatic SARS-CoV-2 and risk factors for severe COVID-19, and in shortening the time to recovery among patients with COVID-19 and evidence of lower respiratory tract infection.[30,409] Although comparison with contemporaneous control groups suggest a survival benefit for hospitalized patients treated with remdesivir, randomized, controlled clinical trials have failed to demonstrate a reduction in mortality.[1,312,328,329,464] When administered to symptomatic outpatients at risk for severe COVID-19, remdesivir reduces the risk of COVID-19–related hospitalization or death by 87%.[157] The need to administer remdesivir intravenously has proven to be a logistical barrier to its use in the outpatient setting. Although resistance to remdesivir can be selected by serial passage *in vitro*, to date clinical use has not been accompanied by emergence of resistance.[129,413,429]

Nirmatrelvir, an orally bioavailable inhibitor of the chymotrypsinlike (CL) "main" protease of SARS-CoV-2, is highly effective in preventing disease progression among outpatients with symptomatic infection who are at risk for progression to severe COVID-19.[349] To achieve adequate plasma concentrations, nirmatrelvir is coadministered with a low dose of the cytochrome P450 3A/4 inhibitor ritonavir (an HIV protease inhibitor). Inclusion of ritonavir with nirmatrelvir potentially limits its use due to interactions with certain drugs that eligible patients may require for coexisting medical conditions (eg, clopidogrel; amiodarone; rifampin).[289] The nucleoside analog molnupiravir has more modest activity, reducing the risk of hospitalization or death by 31%.[205] It is approved for the treatment of confirmed SARS-CoV-2 infection in adults who are at high risk for progression to severe COVID-19 for whom alternative COVID-19 treatment options are not accessible or clinically appropriate, but its properties as a teratogen limit use among women of child-bearing potential.

Poxvirus Therapy

Although smallpox has been eradicated as a human disease, the continued maintenance of stocks of variola virus leave open the possibility of renewed outbreaks of smallpox, resulting either from accidental laboratory transmission or, more ominously, due to purposeful release as an act of bioterrorism or biological warfare. Two agents, tecovirimat and brincidofovir, have been approved for use in the treatment of smallpox.[57,453] Both drugs were approved under the FDA's "Animal Rule," which allows approval of drugs for human use based on results of appropriate animal trials when clinical trials in humans cannot be conducted.[162] Given the nature of their approval and the intended circumstances for their use, tecovirimat and brincidofovir are available only through the United States Government's Strategic National Stockpile. Although approved for variola, both drugs have been used anecdotally for treatment of severe complications of vaccinia administration (smallpox vaccination). Data from animal models suggest that tecovirimat and brincidofovir would also be useful for treating mpox (formerly known as monkeypox); indeed, tecovirimat proved to be highly effective in treatment of mpox during the 2022 outbreak.[196,382]

Conclusion and Future Directions

Antiviral drugs ameliorate viral disease and save lives. Understanding viral replication and virus-host interactions is crucial for understanding the mechanisms of antiviral agents and for the discovery of new ones. Likewise, antiviral agents provide excellent tools for investigating viral biology and biochemistry and virus-host interactions. Despite the remarkable progress in antiviral therapeutics made since publication of the previous edition of this textbook, effective treatment is available for only a small number of the clinically important viruses discussed in subsequent chapters. Viruses for which treatment is needed include respiratory syncytial virus, adenovirus, enteroviruses, flaviviruses other than HCV, alphaviruses, and rabies virus, to name a few. There remains a considerable unmet medical need that can be served by antiviral drugs, and we continue to learn how to use them.

Acknowledgments

Summary

Acknowledgments

Both innate and adaptive immune responses mediate host resistance to virus infection. Elements of the innate immune system, especially type I interferons, strongly influence the clinical outcome of a virus infection. Many viruses have evolved mechanisms to inhibit or evade innate immune responses, indicating the importance of those defenses in limiting virus infection. Innate immune responses also mediate important effects during the induction phase of an immune response and may influence the magnitude and composition of adaptive immune responses. The capacity for somatic diversification of B cell receptors and selection and long-term memory for B and T cells are central properties of

adaptive immunity. Therefore, vaccine-induced immunity that is established in advance of virus infection relies primarily on adaptive immune responses for protective efficacy. Vaccination depends critically on the properties of Ag recognition, activation, expansion, memory, trafficking, and effector functions inherent to lymphocytes. Complex influences of vaccination on the timing, magnitude, specificity, quality, and location of responding lymphocytes and their effector molecules determine whether exposure to a viral pathogen results in infection, protection, subclinical infection, mild disease, or exaggerated disease expression. The extent to which vaccine-induced immunity is successful in an individual can determine the spread of virus within a population (e-Fig. 15.1). Thus, vaccines have a profound effect on public health through the control of epidemics (e-Fig. 15.2). An antigenic stimulus that elicits a virus-specific adaptive immune response that can be recalled during subsequent virus infection defines it as an immunization. A vaccination is an antigenic stimulus delivered by intention. Natural exposures to circulating viruses (in vaccinated or antigen-naive individuals) also can induce immunity and may contribute to establishing or maintaining population immunity, even if the resulting infections are subclinical.

e-FIGURE 15.1 **Points where vaccination can interrupt the dynamics of viral spread in an individual and the population.** Vaccination of an individual not only provides direct benefit by producing immunity to prevent disease but also has a profound indirect effect on public health by interrupting the cycle of transmission. As transmitters and susceptible hosts are removed from a population, the spread of infection becomes less likely. To be successful, a virus must reach a susceptible host, attach to a susceptible cell, enter that cell, and evade clearance by host defenses long enough to be transmitted to another susceptible host. Each step in the process represents an opportunity for vaccine-induced immune responses to limit spread of the virus.

e-FIGURE 15.2 **Vaccine-mediated control of epidemic viral infection.** The spread of infectious diseases within a population can be described largely by (1) transmission efficiency, (2) rates of contact between infected and susceptible people, and (3) duration of viral shedding or contagiousness of the transmitter. These factors support the proverbial 3-legged stool that represents the expansion or contraction of an epidemic, and each is influenced by different aspects of vaccine-mediated immunity.

History of Viral Vaccine Development and Future Prospects

The history of discovery and development for each viral vaccine is unique and instructional. Although space limitations prevent the full description of each vaccine, some of the major events are outlined below. Although each vaccine development story is different, there are common events and themes that have been catalogued in a supplementary table (e-Table 15.1) that includes the following: (1) disease description and virus discovery, (2) vaccine discovery and/or proof-of-concept, (3) vaccine licensure or first human use, and (4) unique or unanticipated events.

Origins of Vaccinology

Origin of Live Virus Vaccination

Most viral vaccines were developed because of both fortuitous events and empirical findings. The origin of modern vaccinology, and particularly live virus vaccination, is based on the practice of variolization (mechanical attenuation and intentional low-dose infection) to reduce the virulence of subsequent smallpox infection, which was initiated more than 1000 years ago in India and China. From this practice arose the concept of vaccination (using an alternative agent to provide immunity against an infectious disease), and the first vaccine used in humans, live cowpox virus. In 1796, Edward Jenner inoculated 8-year-old James Phipps with purulent material taken from a cowpox pustule on the hand of milkmaid Sarah Nelmes and introduced it into an incision on the boy's arm. Jenner subsequently proved that the boy was protected from an inoculation of material from a smallpox lesion. He published the work in 1798 and coined the word vaccine from the Latin *vacca* for cow and designated the process vaccination. For 80 years, live virus was transferred almost exclusively from human arm to arm by collection of purulent material. Subsequently, vaccine was propagated on the skin of calves using serial inoculation resulting in vaccinia virus as the distinct vaccine strain.[277] This vaccine was used successfully to eradicate smallpox from the population, and smallpox remains the only human viral infection to be validated as eradicated through a vaccination campaign (Fig. 15.1). A concerted effort to eradicate polioviruses is ongoing.

FIGURE 15.1 **Origins of live attenuated viral vaccines**. **A**. Edward Jenner is credited for performing the first vaccine experiment in which he demonstrated that inoculation of a boy with purulent material obtained from a cowpox lesion on the hand of a milkmaid protected him against subsequent challenge with variola. This event launched the formal concept of vaccination and established the prototypical approach for developing live attenuated viral vaccines. **B**. The implementation of smallpox vaccination faced many of the same issues of fear and misunderstanding that are prevalent today and impede the deployment of effective vaccines as illustrated by a political cartoon published in 1804. **C**. The successful eradication of smallpox yielded many lessons about the value of simple, low-cost, local production of vaccine as illustrated by the collection of vaccine material from the hide of a cow during the initial phases of the WHO-sponsored eradication campaign. There were also lessons on the importance of product stability and simple delivery approaches. **D**. Once vaccinia was lyophilized, it could be reconstituted on site and was not as dependent on maintenance of the cold chain. The bifurcated needle **(D)** was an innovation that provided a simple standardized approach to inoculation without the need for needles or mechanical devices and allowed vaccination to penetrate remote locations. (**A and B**, courtesy of the National Library of Medicine; **C**, courtesy of J. Mohr, WHO; **D**, courtesy of James Gathany/CDC.)

Origins of Inactivated Virus Vaccination

In the 1880s, Louis Pasteur and his colleagues attributed rabies to virus replication in the central nervous system. Next, they discovered that drying rabies-infected tissue at room temperature attenuated the infectivity of the tissue. The dried rabies-infected tissue was determined to be noninfectious, yet serial inoculation of dogs with the tissues provided protection against an otherwise lethal rabies virus challenge. Inoculation of dried rabies-infected central nervous system tissue was tested in a single human postexposure case in 1885 when Pasteur serially inoculated Joseph Meister, a 9-year-old boy bitten by a rabid dog more than 2 days earlier. The initial inoculations contained highly attenuated virus from rabbit spinal cord dried for 15 days, followed by inoculations with less attenuated virus-infected tissue. In total, the regimen included 13 immunizations over 10 days. The boy was fully protected from disease, and this intervention represents the beginning of an era in which inactivated vaccines were used for other viral diseases following Pasteur's paradigm of identification, inactivation, and inoculation (Fig. 15.2; e-Table 15.1).

FIGURE 15.2 **Origins of inactivated viral vaccines**. Louis Pasteur is pictured here as the person responsible for the inactivated viral vaccine concept. His work on the rabies vaccine produced by desiccation of spinal cords from rabid dogs also anticipated the public debates that still occur involving the balance of risk and benefit to the individual and the public from the implementation of vaccines. (Courtesy of the National Library of Medicine.)

Critical Events in the History of Viral Vaccines

Since the introduction of vaccinia virus, licensed vaccines have been developed for nearly 30 virus strains from 16 types of viral pathogens (Table 15.1). Notable advances in viral vaccine development over the past century include semieradication of many viral infections, processes for optimization of manufacturing cell lines for next-generation vaccines, utilization of human immune correlates to establish efficacy for licensure, and improvements in vaccine safety monitoring, which is important for public safety but also serves to keep safe and efficacious vaccines from unwarranted negative assessment. The COVID-19 pandemic saw a major increase in the rapidity of vaccine development. Prior to 2020, the 4-year mumps vaccine development process was the fastest ever from obtaining a virus sample to approval of a vaccine. In 2020, the first SARS-CoV-2 virus genome sequences were reported on January 10 and by December 2 (<11 months later) the Pfizer/BioNTech COVID-19 mRNA vaccine was approved for emergency use in the United Kingdom after being fully tested in clinical trials.

TABLE 15.1 Viral vaccines licensed in the United States[a]

[a]See individual chapters for specifics on target populations and immunization schedules for individual agents, which may vary or change from this overview. In addition, see the following website for a list of licensed vaccine products, including combination products: http://www.fda.gov/cber/vaccine/licvacc.htm.

[b]RotaShield tetravalent vaccine is no longer available. RotaTeq pentavalent and Rotarix monovalent vaccines are available.

[c]Zoster vaccine live (Zostavax) is no longer available for use in the United States, as of November 18, 2020.

VLP, virus-like particle; WT, wild-type; IM, intramuscular; SQ, subcutaneous; ID, intradermal.

Goals of Immunization Against Viral Diseases

Prevention of Disease or Infection

The major goals of immunization against viruses are the prevention or modification of disease in an individual and the control of epidemic infection within populations. Most viral vaccines prevent or modify disease without necessarily preventing infection. The ways in which this objective is achieved are diverse. Whereas most viral vaccines are administered before infection occurs, prevention of CNS disease in individuals inoculated with rabies virus by an animal bite can be achieved by administration of a vaccine regimen initiated shortly after infection has occurred. This *postexposure prophylaxis* is possible because the long incubation period of the infection permits the development of an effective immune response in time to modify infection and prevent disease. Similarly, infants born to untreated hepatitis B–infected mothers are treated with postexposure vaccination and antibody treatment. Interestingly, even for viruses with a more rapid course, like variola, individuals can be protected against a fatal outcome if vaccinia virus vaccine is administered up to 4 days after the initial exposure to the virus. This effect may be due to augmented innate immune responses or more rapid induction of adaptive immune responses.

The major goal of immunization against rubella virus is prevention of fetal abnormalities caused by intrauterine infection. To achieve this goal, both males and females are immunized in the United States. Immunization of males has little direct benefit to the vaccinee other than prevention of the relatively mild illness caused by the rubella virus, and males are not targeted in all national vaccine programs. The fetus of a vaccinated female is protected by immunization of the mother before pregnancy. Community (herd) immunity resulting from extensive immunization of males and females provides some protection to the fetus of an unvaccinated female by decreasing the circulation of virus in the community. An example of community immunity was seen early after introducing the mumps vaccine. The incidence of mumps declined precipitously before vaccine coverage was significantly expanded. A modest reduction in the number of susceptible persons and transmitters had a significant impact on the epidemic.91a

In addition to reducing the frequency of susceptible persons and transmitters, some live viral vaccines can improve community immunity by the spread of vaccine from recipients to contacts. This phenomenon has been observed with oral live poliovirus vaccine[406] resulting in the indirect immunization of a significant proportion of the population and a marked reduction in the incidence of poliomyelitis in both vaccinated and "unvaccinated" individuals. Spread of vaccine virus has been viewed by many as a desirable property because this transmission confers the benefits of immunization on many individuals who were not vaccinated. However, spread of vaccine in the population also raises concern because of the rare occurrence of vaccine-associated paralytic disease among contacts of vaccinees, and immunization of persons without their prior consent presents ethical issues. For instance, wild poliovirus type 2 transmission stopped in Africa in the mid-1990s, but hundreds of cases of circulating vaccine-derived poliovirus type 2 (cVDPV2) were reported in Nigeria in 2021 during the COVID-19 pandemic, and cases are still occurring in 2022.

Although most vaccines in use today are effective in preventing disease, they usually are inefficient at completely preventing infection. Prevention of infection is a desirable property for specific vaccines such as HBV and HIV. The vaccine for human papillomavirus (HPV) was licensed based on its ability to prevent cervical neoplasia.[382] In addition to preventing the acute effects of viral infection, the HBV vaccine is also given with the goal of preventing hepatomas.[212] Infection with HBV during the neonatal period is associated with an increased risk of progression to the chronic carrier state and associated with the development of chronic liver disease and hepatocellular carcinoma later in life. Therefore, a major goal of HBV vaccination is to prevent transmission of infection from persistently infected mothers to their infants during the neonatal period. Considerable success in this effort has been achieved using HB surface antigen (sAg) vaccine or hyperimmune HBV antiserum plus vaccine immediately after delivery.[212] HIV is a lentivirus, and the possibility of progression to AIDS can occur many years after initial infection. Therefore, it is desirable to develop a vaccine that induces immunity to prevent infection or result in an abortive or transient HIV infection. We have not successfully created a vaccine for HIV, however, because of the extreme genetic diversity of HIV genome sequences, the difficulty of eradicating infected cells in which virus genome has integrated into host DNA but is not replicating, and other factors. We also have failed to develop licensed vaccines for respiratory syncytial virus (RSV), because the target populations of infants and the elderly mount less effective immune responses to immunizations, mucosal immunity is hard to maintain at high levels for prolonged periods, and additional barriers.

Immunotherapy

HSV-1 or HSV-2 as well as VZV produce latent infections in sensory ganglia that periodically reactivate, resulting in development of new lesions and increased opportunity for transmission of virus. Therefore, a goal of immunization of persons previously infected with these viruses is to prevent or ameliorate recurrent disease caused by reactivation of their latent infection.[38] This form of immunization is referred to as immunotherapy. Other illnesses that are candidates for immunotherapeutic vaccines include warts and cancer caused by HPV and chronic hepatitis caused by HBV or HCV. HIV-1 has also been considered as a target for immunotherapy to prevent the long-term consequences of chronic infection or to reduce the requirements for ongoing antiretroviral drug therapy. Because of the extent of repeated Ag exposure and damage to many elements of the adaptive immune system resulting in immunodeficiency, it may be difficult to elicit new immune responses to effectively control virus infection and the associated disease.[67] Effective immunotherapeutic vaccines for recurrent HSV face a similar challenge since the vaccinees previously infected by wild-type virus are repeatedly reimmunized during each recurrence. However, for a related herpesvirus, VZV, where recurrence is relatively uncommon, immunization with live attenuated vaccine reduces the incidence of herpes zoster and postherpetic neuralgia.[108]

Eradication or Elimination

Appropriate use of a highly effective vaccine can help to eradicate a major disease when humans are the only natural host for the virus, and there is no natural reservoir or intermediate host. During the 1970s, this goal of eradication was achieved for smallpox largely using live vaccinia virus vaccine. This campaign ranks as one of the major public health achievements in all history. Two other human viruses have been targeted similarly for eradication, namely poliovirus and measles virus, and significant progress toward these goals has been made for both viral pathogens. The United Nations officially declared eradication of the morbillivirus animal pathogen rinderpest in 2011, after a concerted worldwide eradication program. Unfortunately, eradication of viral pathogens usually is an elusive goal because of setbacks from social instability, antivaccine sentiments, the threat of bioterrorism, and the potential for intentional reintroduction or resurrection of previously eradicated viral pathogens. Therefore, it will be prudent to find ways of maintaining immunity to serious virus pathogens even after eradication of virus in the natural reservoir has been achieved. The new technologies that have improved our ability to identify and perform research on emerging pathogens have also created the capacity to synthetically recreate pathogens (ie, to "rescue" infectious viruses from synthetic DNA copies of virus genomes). Elimination of a virus pathogen suggests that epidemic and endemic disease is controlled, and no active cases are present. However, setting the goal of elimination acknowledges the possibility of reemergence and may include maintenance of active vaccine-induced immunity. For instance, wild poliovirus type 2 was declared eradicated by the Global Commission for the Certification of Eradication of Poliomyelitis (GCC) in September 2015, and in May 2016, the world stopped using oral polio vaccine type 2 (OPV2) for routine vaccination of children. Many specimens stored by researchers however, such as stool or respiratory secretion specimens collected at times and in geographic areas where wild poliovirus type 2, vaccine-derived poliovirus type 2, oral polio vaccine type 2, or Sabin type 2 viruses were circulating, are likely to contain these viruses. The World Health Organization (WHO) Global Action Plan (GAPIII) for eradication of poliovirus states that each country is required to complete a national inventory of poliovirus-containing materials. Thus, authorities currently are surveying nonpoliovirus facilities to help them identify specimens potentially infected with poliovirus types 1, 2, or 3 and to implement appropriate measures for their destruction or safe and secure handling and storage.

Semieradication Secondary to Effective Vaccine Campaigns

Several vaccines have resulted in regional semieradication of the virus disease or dramatic reduction in the incidence or morbidity from infection (polio, measles, mumps, rubella, rabies, and VZV). Other vaccines are highly effective and have been reduced to use only for travelers to endemic areas of the world (yellow fever, Japanese encephalitis). Licensed vaccines for hepatitis A and B are highly effective and for influenza are moderately effective, and their impact on frequency of infection has been improved by new strategies for distribution (Table 15.2).

How Vaccines Work

The general strategy of vaccination is to cause an antigenic exposure that faithfully mimics exposure to the antigens of a pathogen to induce protection against infection or disease on subsequent exposure, while causing the least side effects possible. Virus vaccines can be live attenuated (weakened) strains that cause infection but not disease, or they can be created by incorporation of inactive components of the virus (antigens) or the genes encoding such antigens. The key to efficacy of a vaccine is induction of robust and durable vaccine-induced immunity.

Correlates of Protection

The goal of studies of correlates of protection (CoPs) is to define the immune responses that are responsible for the efficacy of a vaccine. CoPs enable the selection of the most appropriate and protective antigens and the monitoring of a parameter that tracks with protection in individuals or populations after vaccination. If an efficacy trial in not feasible (or a simple vaccine strain change is warranted) CoPs help manufacturers to obtain licensure, measure lot-to-lot consistency of vaccines, and bridge from one formulation or construct to another. The eminent vaccinologist Stanley Plotkin has written summaries of CoPs that shape the field by simplifying the concepts,[372] distinguishing biological from statistical CoPs,[375] and pointing out that CoPs are complex because the immune system is complex and often exhibits redundant capacity to respond to infection.[373] Plotkin defined three principal terms relating to CoPs: A *CoP* is a marker of immune function that statistically correlates with protection after vaccination, which may be mechanistic (*mCoP*) or nonmechanistic (*nCo*P). The nCoP is defined as an immune factor that does not cause protection but nevertheless predicts protection through its (partial) correlation with another immune response(s) that mechanistically protects. Diverse immune factors have been noted as CoPs for vaccines (e-Fig. 15.3), including (1) antibodies (binding, infection neutralizing, mucosal IgA or IgG, antibody-dependent cellular cytotoxicity (NK cells), antibody-dependent cellular phagocytosis, histoblood group antigen blocking); (2) CD4+ T cells (cytokine production [IFN-γ, IL-2, TNF-α], help to antibody production, effector memory, central memory); and (3) CD8+ T cells (cytotoxicity, effector memory, central memory, Th17+ T-cell secretion of IL-17 on mucosa).[374] Traditionally, the assessment of vaccine efficacy has been made by determining whether infection or disease has been prevented. In the process of establishing vaccine efficacy, the use of a human immune CoP is potentially more efficient and has been implemented successfully in the yearly approval process for influenza vaccines. Influenza vaccines typically are approved based on the accepted surrogate of protection, a hemagglutination inhibition (HAI) titer ≥1:40 or a fourfold increase over the prevaccination HAI titer. In this case, the immune response serves as a surrogate marker that is predetermined to predict clinical benefit, and therefore, the lengthier process of assessing the presence or absence of influenza infection in a clinical trial is not always needed.[462] Similarly, assessing the result of infection (or absence of), rather documenting an effect on the virus itself can also be used to assess protective efficacy. The HPV vaccines were licensed based on efficacy derived from the prevention of cervical and

vulvar cancer, precancerous lesions, and dysplastic lesions.[461]

e-FIGURE 15.3 **Relative importance of vaccine-induced immune responses to different stages of viral life cycle.** Ab is the only component of the adaptive immune response that provides a defense against a cell-free virion. In contrast, T cells can only recognize virus-infected cells because of the requirement for host cell MHC-restricted Ag presentation. Ab has some mechanisms involving the Fc portion that can bind complement or Fc receptors on NK cells to mediate killing of virus-infected cells. If a virus has the capacity for latency (eg, HSV or HIV), or sequestration (eg, HIV harbored in extracellular space of lymph nodes bound to follicular dendritic cells), or infection of immunoprivileged site (eg, brain or eye), it can remain hidden or protected from immune responses. Antibody Fc regions also interact with other cells to mediate diverse activities, including antibody-dependent cellular phagocytosis (ADCP) mediated by monocytes, antibody-dependent neutrophil-mediated phagocytosis (ADNP), antibody-dependent cell-mediated viral inhibition (ADCVI), and antibody-dependent complement-mediated lysis (ADCML) of cells or virions.

Mechanisms of Vaccine-Induced Immunity

Immune mechanisms have evolved to protect the host against a diverse assortment of viral pathogens. Viruses and their hosts co-evolve; viruses find ways to evade host defenses and hosts adapt mechanisms to control virus replication. The host is equipped with three principal toolsets to resist infection: (1) physical or mechanical barriers (such as skin or gut, genital, or respiratory tract mucosa), (2) innate immune mechanisms that can limit the initial encounter with a virus, and (3) adaptive immune mechanisms that provide immunity against repeated exposures to the same viral pathogen. Although innate responses are important during the induction phase of vaccine-induced immunity, humoral and cellular adaptive responses are the primary effector mechanisms of protection from future infection (e-Fig. 15.4). Humoral and cellular responses are complementary in that Ab prevents infection by cell-free virus, but when infection occurs despite innate defenses and the presence of neutralizing Abs, T-cell responses and antibodies that bridge infected cells and Fcγ receptor–bearing immune cells are designed to eliminate virus-infected cells and diminish the subsequent release of infectious virus. The repertoires of B- and T-cell receptors have also evolved complementary strategies to deal with genetic variation in viruses. For a given antigenic site on a viral protein, most hosts can expand a B-cell population that can recognize the structure through clonal lineage development of variant antibodies using somatic hypermutation (SHM). This mechanism may lead to population-wide protection against reinfection with a particular virus or minimally drifted virus variants. This immune pressure may cause selection of escape viruses bearing major antigenic changes, sometimes resulting in a new clade, subgroup, group, subtype, or serotype, which is not recognized by the original antibodies. Therefore, the host must start over in the generation of antibody-mediated type-specific protection. In contrast, T-cell epitopes are not shared between hosts unless they happen to share the same MHC-restricting allele. Consequently, each infected host generates T-cell responses against a limited number of viral epitopes that are largely determined by HLA haplotype. Unlike antibody epitopes, T-cell epitopes are often cross-reactive between viral serotypes and thereby provide the antigen-experienced host with partial protection against new virus strains until the antibody responses can adapt.

e-FIGURE 15.4 **Virus infection engages the major components of the adaptive immune response. A.** The principal components of the adaptive immune system are B cells and T cells. The surface structures of virions are accessible to antibodies (ie, B-cell receptors) that are important for virus recognition and neutralization. Production of virus proteins in the cytoplasm leads to processing of virus-derived peptides in the proteasome and transport to the endoplasmic reticulum where they can associate with MHC class I molecules for display on the cell surface and recognition by CD8 T cells. Virus particles and proteins that are endocytosed can associate with MHC class II proteins in lysosomes for presentation to CD4 T cells. **B.** Timing is everything. In a prototypical viral infection, the virus penetrates physical and innate immune barriers to infection to establish a local infection that progresses to infect the target organ of disease. This can occur through local or systemic spread. Natural immunity occurs after these acute events and in most cases successfully clears or controls infection to limit disease. In some cases, virus infection can become persistent. **C.** The virological and clinical consequences of viral infection and the host immune response are shown for persistent viral infections like HIV or for a self-limited viral infection like influenza or dengue. Note that the clinical manifestations of a persistent or cytolytic virus infection are congruent with the viral load, while in self-limited infections, the peak illness can occur at the time of peak viremia or may be temporally associated with the timing of innate or adaptive immune responses.

When a virus breaches the physical and innate barriers and infects a target cell, several rounds of replication may occur in a primary infection before the adaptive immune responses are established (e-Fig. 15.4B). Depending on the virus, this exposure may result in spread to the target organ of disease and/or establishment of a persistent infection. The timing, magnitude, location, and qualitative features of the host response determine the clinical outcome of infection. In persistent virus infections (eg, HIV, HCV, or HSV), disease manifestations are often congruent with virus replication. In self-limited infections (eg, those caused by influenza, RSV, or dengue), the bulk of disease often occurs after the peak of viral replication, although in some cases, disease is worst near the peak in viral load (e-Fig. 15.4B). In cases of persistent or latent virus infection, the immune response attempts to limit virus replication or spread. Control of the magnitude and composition of complex immune responses is critical to avoid immunopathology. Fortunately, there is considerable redundancy inherent in immunity to viruses (e-Fig. 15.4C). For example, while CD8+ T cells are the primary mediator of cytolytic activity, this function may also be accomplished by complement or by NK cells targeting the Fc portion of Ab labeling virus-infected cells. Another well-studied example of this redundancy involves CD4 and CD8+ T cells, either of which are sufficient to achieve clearance of virus, as shown in studies of influenza A virus or poxviruses in mice. Animals lacking CD8+ T cells readily clear influenza virus or vaccinia virus from the lungs, indicating that CD4 T cells and Ab are sometimes sufficient for viral clearance.[289,418] The therapeutic efficacy of Abs acting in the absence of other immune functions has also been demonstrated in experimental influenza A virus infection of mice. Abs to the influenza A virus surface HA cleared virus from the lungs of persistently infected SCID mice.[418] While CD8+ T cells are specialized in recognition and clearance of virus-infected cells, CD4 T cells (plus the Abs secreted by B cells for which they provide help) and CD8+ T cells can mediate viral clearance independently. The relative importance of these two arms of the immune response varies in the resolution of viral infections. Even in the case of lymphocytic choriomeningitis virus (LCMV), the prototypic arenavirus, which in the murine model is a paradigm for CD8+ T-cell–mediated immunity, Abs and CD4 T cells each make a significant contribution to the resolution of primary viral infection.[19] In general, Abs are the major mediator of resistance to reinfection with virus, and CD8+ T cells are the major mediator of clearing virus-infected cells. CD4 T cells are critical for the induction of robust Ab responses and important for “helping” memory CD8+ T-cell responses and have potential for direct antiviral effector functions. Abs work best when the target organ for disease pathogenesis is distinct from the initial site of infection, particularly in cases where the virus must travel through the bloodstream to reach its target organ. For example, in diseases like measles, polio, hepatitis, or most viral encephalitides, where viremia must be established to cause disease, it often takes very small concentrations of preexisting Abs to achieve clinical protection. Since it is rarely possible to elicit sufficient Ab through vaccination to prevent virus infection completely, other immune mechanisms must contribute to vaccine-induced immunity.

One reason that live virus vaccines are so effective is that many components of both innate and adaptive immunity are engaged. The protein,

nucleic acid, carbohydrate, and lipid components of viruses induce innate responses through a variety of Toll-like receptor (TLR) and other pathogen-associated molecular pattern (PAMP) receptor interactions. Virus infection induces all components of the adaptive immune response—Ab responses are induced against viral surface proteins in their native conformation, CD4 T cells are stimulated, and viral proteins are produced in the cytoplasm, processed, and presented in MHC class I molecules for induction of CD8+ CTL responses. All these responses contribute to the clinical outcome from a virus infection. Abs and innate defenses provide the initial barrier to infection by neutralizing incoming virus. After the virus has infected a cell, however, it is then incumbent on the innate defenses to control the virus until the adaptive cellular immune response can be activated, expand, and traffic to the affected tissues. In the immune host, preexisting antibody prevents or limits the number of infected cells, and rapid mobilization of memory T-cell responses rapidly clears virus-infected cells. While cytolytic T cells are potent in their ability to clear virus-infected cells and reduce the spread of virus, this activity often comes at a cost. The T-cell response can injure the host as it clears the virus and is thus tightly regulated. Turning the immune response off as virus infection resolves is just as important as turning it on for the well-being of the host. The system is biased toward controlling inflammation and that may be a reason why the T-cell response is regulated to require several days to activate and expand. Influencing the events in this period between virus exposure and the fully activated primary T-cell response is one of the key factors in determining the efficacy of vaccine-induced immunity, for which the goal is to prevent, abort, or control viral infection to avoid clinical disease. The cytokine environment in which T cells are induced stimulates diverse patterns of differentiation (e-Fig. 15.5).

e-FIGURE 15.5 **Vaccine-induce cytokine milieu influences patterns of T-cell differentiation.** The primary effectors of adaptive immunity are regulated by earlier events in the immune response. The virus-infected cell produces chemokine gradients to recruit the cells needed for the initial wave of innate immune responses and Ag processing by professional Ag-presenting cells (APCs). These cells also produce cytokines and engage in cognate interactions to influence the function of cells involved in the inflammatory response. APCs also can produce a variety of cytokines and cognate interactions to initiate the adaptive immune response. This is largely orchestrated by CD4+ T cells that have been characterized phenotypically and functionally distinct subpopulations. The pattern of CD4 T-cell response elicited by the initial Ag exposure to vaccination or infection has a significant influence on functional properties of the adaptive immune response on subsequent exposure to Ag.[174]

The aggregate data suggest that a successful strategy of immunoprophylaxis against most virus infections requires the generation of an immune response to the surface Ags displayed on virions and on virus-infected cells. Other viruses (such as poxviruses, herpesviruses, filoviruses, some respiratory viruses, and lentiviruses) that have a more complex pathogenesis may require vaccines that induce more complex immune responses for protection from infection or control of disease. Many of these viruses possess the capacity for persistence, infection of immunoprivileged sites, use sophisticated immune evasion strategies, directly infect their target organ without a requirement for viremia, or cause disease by eliciting an aberrant host response. Vaccine development for these viruses probably will require the induction of neutralizing Abs against surface proteins to protect against infection in addition to T-cell responses against structural and regulatory proteins to control virus spread and to modulate the composition of the immune response.[178]

Vaccine-Induced Humoral Immunity

The correlates of immunity that have been established to date for licensed viral vaccines have been associated with Ab responses. In fact, the rationale for development of many of the vaccines in use today was the evidence derived from clinical trials of Ab treatments showing that Abs could mediate protection against disease. Passive transfer studies established the efficacy of Abs in preventing or treating viral infections and disease caused by a wide variety of viruses belonging to diverse RNA or DNA virus families that include the orthomyxoviruses, paramyxoviruses, alphaviruses, flaviviruses, arenaviruses, lentiviruses, picornaviruses, hepadnaviruses, and herpesviruses. Examples of the licensed clinical use of immune globulins include preparations for hepatitis A and B viruses, measles virus, varicella-zoster virus, rabies virus, RSV, and cytomegalovirus (CMV). Many new human monoclonal antibodies (mAbs) have been discovered in the last decade, and some have been licensed or authorized for prevention or treatment of RSV, Ebola virus, HIV, and SARS-CoV-2.

A long history of Ab treatments laid the groundwork for current vaccine strategies. Commercial human gamma globulin, which usually contains 16%-18% immunoglobulin G (IgG), is highly effective in preventing hepatitis A disease and was used widely for that purpose during the past 50 years, even though only a small proportion of the Abs in the preparations are specific for that virus.[97] Currently, inactivated vaccines for hepatitis A are licensed and thought to work by inducing serum Abs to the virus. An historic double-blind, prospective clinical trial performed in 1951-1952 showed that human IgG also was effective in preventing paralytic disease caused by poliovirus.[196] Intramuscular inoculation of 0.3 mL of IgG/kg conferred significant resistance that lasted for at least 5 weeks. This seminal observation showed that Abs alone can confer resistance to poliomyelitis and suggested that vaccines that induced such Abs might protect against the disease. Subsequent field trials of inactivated vaccines by Salk and live attenuated vaccines by Sabin validated this view, leading to implementation of universal immunization against poliovirus and ultimately the current worldwide campaign for elimination of polio disease (Fig. 15.3). Before the live measles virus vaccine was licensed for routine use in immunization of young children, human IgG was used for passive prophylaxis and was the mainstay for prevention of disease. IgG given at a dose of 0.5 mL/kg prevented measles, even when administered to exposed individuals as late as 3 days after inoculation with virus.[219] Human IgG prepared from pooled plasma selected for a high titer of varicella-zoster virus Abs (varicella-zoster immune globulin or VZIG) is licensed in the United States for use in prevention of severe varicella in immunosuppressed children.[507] Most of the exposed immunosuppressed children receiving treatment still become infected, but the majority exhibit attenuated disease or subclinical infection. Live attenuated varicella virus vaccine was licensed and recommended for universal immunization in 1995. Human IgG was effective in preventing chronic hepatitis B virus (HBV) infection in high-risk infants following maternal exposure.[31] Hepatitis B immune globulin and subunit vaccine are now used in concert to protect infants in this setting.

FIGURE 15.3 **Polio vaccine development**. The development of vaccines for polio brought the process of vaccine development into the public eye and was the first licensed vaccine that relied on mammalian cell culture. Jonas Salk **(A)** spearheaded the development of the inactivated polio vaccine (IPV) **(B)**. The development of the oral polio vaccine (OPV) **(C)** was headed by Albert Sabin **(D)**. These two vaccines are still in use today, and over the last 50 years have nearly eliminated poliovirus making the goal of global eradication feasible. (**A**, ©AP Wide World Photos; **C courtesy of Division of Medicine and Science, National Museum of American History, Smithsonian Institution. D**, courtesy of the Hauck Center for the Albert B. Sabin Archives, Henry R. Winkler Center for the History of the Health Professions, University of Cincinnati Libraries.)

Preclinical studies in animals suggested that serum RSV neutralizing Abs above a threshold titer were protective against lower respiratory tract infection, and this observation was validated during a clinical trial of human IgG containing a high titer of RSV neutralizing Abs that led to licensure in 1995.[379,387] Of interest, the level of serum RSV neutralizing Abs required for reduction of hospitalization was like that needed to

prevent infection in cotton rats. A second-generation approach, the use of a humanized murine neutralizing mAb to RSV, palivizumab, was licensed in 1998.[349] Palivizumab was the only mAb licensed for prevention of a viral disease for many decades. These clinical applications strongly suggest that neutralizing Abs is an important correlate of protection for RSV vaccines, which are under development. A second-generation long-acting RSV mAb (nirsevimab) was tested in a clinical trial in about 1500 healthy late-preterm and term infants and caused a 75% reduction in medically attended RSV-associated lower respiratory tract infection but unfortunately failed to show a statistically significant effect on hospitalization rates.[195]

One mAb has been approved for treatment of HIV infection, although it is directed to a host factor not to the virus. Ibalizumab is a humanized IgG4 mAb that binds to CD4 on host T cells and blocks virus entry. It functions as an entry inhibitor at a postattachment stage by blocking HIV binding to CCR5 and CXCR4 coreceptors. The mAb is used in combination with small molecule antiviral drug treatments, and in the phase III clinical trial, 59% of patients achieved viral suppression.[133]

The emergency period of the large West Africa Ebola outbreak in 2013-2016 led to the testing of new medical countermeasures against Ebola virus disease (EVD), including mAbs. An initial randomized controlled trial using a combination of three humanized murine mAbs to the Ebola glycoprotein (ZMapp) suggested benefit, but the study was inconclusive. In a subsequent outbreak of EVD in the Democratic Republic of Congo, where an outbreak began in August 2018, the Pamoja Tulinde Maisha (PALM) trial showed two mAb products (the three-mAb combination called REGN-EB3 [atoltivimab, maftivimab, and odesivimab-ebgn] and a monotherapy called mAb114 [ansuvimab-zykl]) demonstrated efficacy as compared to the ZMapp control arm.[316] In 2020, these mAbs became the first FDA-approved treatment for Zaire ebolavirus infection in adult and pediatric patients.

As of April 2022, four mAb products for SARS-CoV-2 had received Emergency Use Authorization (EUA) from the U.S. FDA; the issuance of an EUA does not constitute FDA approval but allows use during declared emergencies. Bamlanivimab plus etesevimab, casirivimab plus imdevimab, sotrovimab, and bebtelovimab received EUAs during 2021-2022 for the treatment of mild to moderate COVID-19 in nonhospitalized patients with laboratory-confirmed SARS-CoV-2 infection who are at high risk for progressing to severe disease and/or hospitalization. Distribution of bamlanivimab, bamlanivimab plus etesevimab, casirivimab plus imdevimab, and sotrovimab was ended because the products had reduced activities against some variants of concern. The FDA issued an EUA for the long-acting anti-SARS-CoV-2 mAb combination tixagevimab plus cilgavimab in December 2021, for using in preexposure prophylaxis in individuals who do not have SARS-CoV-2 infection, who have not been recently exposed to an individual with SARS-CoV-2 infection, and who are at risk for an inadequate immune response to COVID-19 vaccination or have a documented history of severe adverse reaction to an available COVID-19 vaccine.

Mechanisms of Antibody-Mediated Virus Neutralization

Abs may render free virus noninfectious, principally through neutralization of infectivity. Virus neutralizing activity typically is measured by *in vitro* assays in which Ab and infectious virus are incubated and then inoculated onto cell culture. Residual infectivity is quantified by plaque count, infectious foci marked by colorimetric or fluorescent markers, signal from recombinant reporter virus, percent of infected cells detected by flow cytometry, cell impedance measurements reflecting cytopathic effect, or other methods and compared to untreated suspensions. Viruses are neutralized *in vitro* by Abs by a wide variety of mechanisms. Important Ab characteristics include affinity/avidity, isotype, concentration, Ab to virus ratio, valency, state of polymerization, ability to bind the polyimmunoglobulin receptor (pIgR), ability to fix complement, ability to engage Fcγ receptors, and specificity for the virus protein and epitope of interest. Virus-related factors important to neutralization include general aspects of the replication cycle of the virus under consideration (receptor use, mode of entry into the cell, pH dependence of fusion, site of replication) and individual characteristics of the specific virus strain (antigenic subgroup and amino acid sequence of viral surface proteins). Host factors influencing the mechanism of neutralization include the type and origin of cells and the level of expression of membrane receptors. The most potent mechanisms of neutralization act prior to infection of cells. First, free infectious virions in solution can be aggregated by multivalent Abs directed against surface glycoproteins.[13,347] The consolidation of multiple infectious virions into an aggregate reduces the number of available infectious units. Second, Abs can inhibit virus attachment to cells, usually by binding directly to virus attachment proteins. Abs to attachment proteins often are poorly neutralizing *in vitro*, effecting only partial neutralization even at high concentration.[227] This effect may be caused by virus heterogeneity due to a variable extent of glycosylation that occurs during posttranslational processing at the numerous glycosylation sites on these proteins or because of multiple routes of entry or mechanisms of attachment. Third, viruses can be neutralized following attachment, at the cell surface prior to cell entry, suggesting that immune serum contains Abs capable of inhibiting virus-cell membrane fusion or other early steps of virus entry into the cell. For example, antibodies to HPV can interrupt infection at two stages of attachment and entry, the first an initial association with the acellular basement membrane that induces conformational changes in the virion and second the association of virus with the keratinocyte cell surface.[115] Some neutralizing Abs decrease infectivity by inhibition of virus-cell fusion at the plasma membrane. Fusion inhibition (FI) activity for some Abs has been inferred from *in vitro* assays in which Ab is incorporated into overlay medium after virus absorption and penetration, and activity measured by inhibition of postinfection cell-to-cell fusion. Additionally, Abs can reduce the release of progeny viruses from infected cells ("egress-inhibiting" antibodies). Antibodies to influenza neuraminidase (NA) surface glycoprotein are a prime example of such inhibitors, as many NA mAbs inhibit the enzymatic cleavage of sialic acid on the cell surface in the region of particle budding and release. An antibody to the "vestigial esterase domain" on the side of the influenza virus HA head domain also has egressing inhibiting activity, probably by tethering virus to the cell surface.[22] The influenza M2 ion channel protein participates in the formation and budding of new influenza A virions, and some antibodies that recognize the extracellular domain of M2 (M2e) inhibit the virus. M2e-based universal influenza vaccine candidates are being developed on this basis.[298] There is evidence that some influenza and Ebola virus–specific Abs inhibit virus replication by preventing the primary uncoating of virus that is associated with low-pH membrane fusion in the endosome or at the step of the secondary uncoating of the virion core structure, a step required for primary transcription of the virus genome. This principle was harnessed to create "Trojan Horse" bispecific antibodies that bind to viral or host proteins by one arm of the IgG to deliver the antiviral arm of the IgG for activity in the endosome.[481]

Structural and Biochemical Features of Antibodies Important to Affinity

Abs induced by primary infection or immunization are generally of low affinity for the target Ag. Affinity maturation of Abs is mediated by somatic mutation of the genes encoding B-cell receptors, which occurs in germinal centers, most prominently following second infections or booster doses of vaccine. SHM coupled with B-cell selection results in the promulgation of high-affinity Abs in the antiviral repertoire. Increases in affinity likely increase neutralizing potency for most antiviral Abs directed to surface proteins. Although the molecular basis for affinity maturation during secondary responses was not understood during the development of early vaccines, the enhanced efficacy of multiple-dose vaccine regimens in clinical trials pointed the way to a practical use of this principle. Most licensed viral vaccines are administered using

multiple-dose regimens to enhance the quality, magnitude, and durability of the immune response.

Increased affinity is widely believed to confer enhanced functional competence upon Abs. Work using HIV-1–specific Abs derived from combinatorial phage display Ab libraries demonstrated improvements in neutralization associated with affinity maturation caused by SHM.[456] The fusion (F) protein, the major protective Ag of RSV, has at least six major antigenic sites, each with a differing capacity as a target for virus neutralization.[32] Recombinant derivatives of a humanized RSV mAb containing random mutations in the combining site showed that mutations enhancing the association rate improved neutralization and efficacy, while mutations improving the dissociation rate did not, despite their contribution to improved steady-state affinity.[494] Somatic mutations in human rotavirus antibodies have been shown to enhance affinity and inhibitory function, with individual mutations in Ab combining sites conferring several hundred-fold increases in affinity and function.[227] The broadest and most potent human antibodies to HIV and influenza virus isolated to date are distinguished by exceptional numbers of somatic mutations in the Ab sequences (on the order of about 1/3 of nucleotides altered).[503,510] Hypermutation introduces not only point mutations that enhance function but in some cases nontemplated insertions of sequences encoding new amino acids that mediate neutralization.[250] In the vesicular stomatitis virus (VSV) mouse model, investigators have shown only modest increases in the affinities of hypermutated Abs compared with those in germ-line configuration over the course of infection and after repeated booster injections.[226] The VSV G glycoprotein is unusual in that it contains only a single immunodominant antigenic site that reliably induces neutralizing Abs. Many instances, however, have now been reported of neutralization by human antibodies lacking somatic mutations (created recombinantly by reverting inferred mutations to the germ line–encoded forms, termed reverted unmutated ancestor [RUA], or unmutated common ancestor [UCA] antibodies). Neutralization activity also is determined by the number of times the neutralizing determinant is displayed on the surface of the virion. HIV is interesting in this regard in that the number of envelope glycoproteins on the virus particles is remarkably sparse. Some studies suggest that certain types of virion particles may be dynamic in their display of epitopes.[124] The recognition of epitopes in the hidden interface regions of virus protein oligomers that are recognized by antibodies with antiviral activity implies a high level of dynamic excursion of the proteins in relation to one another. Examples of this pattern are the influenza HA trimer interface antibodies[21,478] and some neutralizing antibodies for henipaviruses.[121] Dengue viruses clearly exhibit “breathing” patterns involving the entire virus particle.[141] Understanding the relationship of affinity and neutralization is needed so that we can better appreciate the B-cell response to exposure with foreign Ags in a physiologic context. Furthermore, elucidation of the role of affinity in antiviral Ab function is critical for designing new active and passive immunization strategies against pathogenic human viruses. The absence of somatic mutations in the virus-specific Ab sequences of infants probably accounts for the difficulty in inducing high affinity high-potency Abs in this population after a single vaccination.[482]

CDR3 Loops of the Antibody Variable Region in Antigen Binding

A combining site formed by the variable heavy (V_H) and variable light (V_L) domains of the Ab fragment (Fab) mediates Ag recognition. Both the heavy and light chains have three noncontiguous linear sequences of greatest variability termed the CDRs (complementarity-determining regions) that result in flexible loops in the immunoglobulin (Ig) protein and form the classical Ag-binding site. The heavy-chain CDR3 (HCDR3) shows the greatest variability in terms of length and sequence, particularly in human Abs. Some crystal structures of Abs have demonstrated that human CDRs tend to adopt a limited number of canonical conformations, except for HCDR3.[80] In each of the crystal structures of human Abs complexed with Ags, the HCDR3 has been shown to make important contacts in every case.[25,429] Diverse CDR length and gene family usage have been shown to be essential features of immunologic health and functional antiviral immune responses.[167,246,417] Vaccinations that induce a broad Ab repertoire that is rich in CDR diversity are more likely to succeed than highly focused vaccinations inducing limited Ab repertoires. Although not universal, long HCDR3 regions are common in highly active Abs to HIV, and they may facilitate high-affinity binding to complex viral antigenic sites. For example, the crystal structure of the 17b mAb complexed with CD4-triggered HIV gp120 reveals a complex interaction that is accomplished only by the unique long HCDR3 region of this Ab.[255] High-throughput screening for broadly reactive high-potency HIV neutralizing Abs isolated two unusual antibodies with extremely long CDRs,[470] and the HCDR3s of these Abs possess fascinating secondary structural elements.[361] In contrast, identification of another broadly neutralizing mAb specific for the CD4-binding site has a CDR3 loop of only 13 amino acids, but the variable region of the heavy chains is more than 30% somatically mutated from germ line.[495] Many interesting sites of vulnerability for broad and potently neutralizing antibodies have now been identified, including antibodies that recognize the membrane-proximal external region (MPER), antibodies to the fusion peptide that blocks viral entry by inhibiting conformational changes in gp120 and gp41,[243] neutralizing CD4-binding site antibodies that mimic binding to CD4, and antibodies targeting the V3 glycan supersite on Env. Several mAbs have been evaluated in clinical trials including CD4-binding site antibodies VRC01 and 3BNC117 and V3 glycan supersite mAb 10-1074. The clinical approach to demonstrate benefit of antibodies in HIV infection involves testing in viremic persons infected with HIV-1 or in infected individuals during transient treatment interruption.

The Role of Isotype in Additional Mechanisms of Antibody-Mediated Virus Neutralization

The complement system is activated by the classical (Ab-dependent), alternative (Ab-independent), and lectin-binding pathways. Viral neutralization by specific Abs is concentration-dependent and is often enhanced by complement activation. It has been reported that even apparently “nonneutralizing” Abs can acquire neutralizing activity with the addition of complement, for example, a nonneutralizing RSV murine mAb was shown to exhibit complement-enhanced neutralization *in vivo* in the presence of complement.[101] Complement fixation is mediated by the C_H2 region of the Ab Fc domain of IgM, IgG1, and IgG3 subclasses in human and the IgM, IgG2a, and IgG2b subclasses in mice.[343] Understanding the role of complement in enhancing the functional capacity of Abs to neutralize viruses has broad implications for vaccine design, since the cytokine milieu induced by infection or immunization affects the isotype and subclass of the Ab response to the viral Ags by activating selective promoters in the appropriate Ig heavy chain locus. B cells triggered in an environment with high IFN-γ concentrations tend to produce IgG1 and IgG3 Abs. In contrast, in the presence of a dominant interleukin-4 response, B cells produce IgE and IgG4 Abs. IgE participates in allergic diseases, and it is generally considered desirable to avoid strong IgE responses following vaccination. The Fc region of Abs also mediates some cellular activities, termed Ab-dependent cell-mediated cytotoxicity (ADCC), which are discussed below.

Structural Features of Antigens Critical for Inducing Efficient Antibody Interactions

The conformation of epitopes on viral surface proteins often is critical to the ability of vaccine Ags to induce or bind neutralizing Abs. Most neutralizing Abs bind to conformationally dependent epitopes on surface proteins. Linear peptide vaccine candidates derived from the sequence of the natural Ag rarely recapitulate the conformation of the protective Ag, which is why most peptide-based vaccines are poor immunogens for

humoral immunity. Many subunit Ags comprising purified or recombinant viral proteins that have been developed as vaccine candidates contain the full polypeptide sequence of the Ag, but the protein emerges from the purification process in a conformationally relaxed state that resembles the natural Ag only in part. Such Ags may induce high levels of Abs that bind the vaccine Ag, but low levels of Abs that bind or neutralize virus.[409] Some viruses appear to present highly antigenic surface loops to the immune system that are structurally nonessential, causing immune focusing on hypervariable domains of viral proteins, such as the influenza HA variable loops surrounding the sialic acid receptor-binding domain (RBD) or the third variable (V3) region of HIV gp120. Some individuals make broadly neutralizing antibodies that recognize these hypervariable domains.[169] Many structurally critical domains of viral surface proteins are hidden from B cells because they are buried in the interior of viral molecules or oligomers of molecules, or they are exposed only briefly during rapid conformational changes required for virus attachment or virus-cell membrane fusion. For example, viral hydrophobic fusion peptides, RBDs, heptad repeats, and other critical regions of fusion proteins usually are not accessible to Abs. Most fusion proteins require cleavage by proteases before they are competent to fuse, and Abs to the precursor protein may not bind the cleaved protein in the mature virus particle.[352] Posttranslational modifications of surface proteins, especially glycosylation, can present a challenge for Ab recognition of protein because of the highly varied nature of the glycoprotein population. Deglycosylated protein Ags may enhance induction of protein-specific Ags, but these Abs may not efficiently recognize glycosylated proteins *in vivo*. Some virus neutralizing Abs are directed specifically to carbohydrates on virus glycoproteins, however.[61] Some broadly resulting antibodies to HIV, such as PG9 and PG16, recognize a conformational epitope that is dependent on glycosylation at specific variable loop N-linked sites.[123] Posttranslational modification of Abs also can affect the interaction of Ab and virus. For instance, several human Abs to HIV gp120 are sulfated in the combining site, which allows the Ag-combining sites to mimic the structure of the virus coreceptor CCR5, which is sulfated.[79] These Abs inhibit infectivity by binding to the coreceptor-binding domain on HIV gp120.

Antigens Recognized by the Humoral Immune Response

Development of an immune response to Ags present on the surface of virions or virus-infected cells is often critical for immunity against virus infection. Antibody (Ab) responses to surface viral protein or glycoprotein Ags often effectively limit infection of new cells and thus spread of the virus. The following generalizations can be made about the nature of Abs and their interaction with virus surface proteins. First, antiviral Abs against the extracellular domain of surface proteins predominantly recognize conformational epitopes that are often quaternary in nature, with extensive posttranslational modifications. Such conformational epitopes are difficult to mimic with peptides or proteins that have had the structure of antigenic sites modified by vaccine preparation and formulation. Presentation of the native Ag structure in its authentic conformation is critical for induction of neutralizing Abs. Even when the structure is mimicked with atomic level precision and elicits Abs that bind the epitope, the property of viral neutralization may not be achieved.[292,340] Most viral surface proteins assemble into oligomeric states on virions, typically dimers, trimers, or tetramers, but the monomeric form of the protein is also present in cell debris or shed proteins. The principal neutralizing determinant may be present only in quaternary structures, so that Abs binding to monomeric protein do not recognize or neutralize virions. In addition, many surface proteins that are targets of neutralizing Abs are fusion proteins that are present in a metastable state on virions. During the attachment and fusion process, the fusion proteins transition from prefusion to postfusion forms, in some cases drastically altering the structure of neutralizing epitopes. Recent protein engineering techniques have allowed rational design of recombinant viral surface proteins that are stabilized in a prefusion conformation to enhance immunogenicity, such as the prefusion RSV F protein candidate vaccine DS-Cav1.[364] Second, Abs recognize many major antigenic sites on each viral protein, and within each of these antigenic sites, there may be multiple epitopes. For example, the parainfluenza virus attachment glycoprotein (HN) has at least six antigenic sites, three of which are recognized by neutralizing Abs.[92] Antibodies to internal proteins that are not accessible on intact virions or to proteins that are present only in infected cells and not virions (nonstructural [NS] proteins) occur commonly. For some viruses, especially flaviviruses, antibodies to NS proteins can reduce or prevent disease, for example, antibodies to the NS1 proteins of West Nile virus or dengue virus. After infection, individuals often develop Abs only to a subset of the antigenic sites of the infecting virus.[93] After one or more reinfections, the Ab response usually broadens to recognize more antigenic sites. These findings provide a partial explanation for the failure of immunization to induce complete immunity in certain circumstances and provide a rationale for recommending multiple immunizations to achieve optimal protection. However, in the case of influenza, repetitive immunization or infection in a population may lead to narrowing of the recognition of virus variants due to immunodominance of certain antigenic sites.[515] This immune focusing is dangerous because frequent introductions of glycans on the surface of hemagglutinin (HA) can abrogate recognition of whole antigenic sites, which is especially unfortunate if the egg-adapted vaccines do not possess that same glycan.[514] The influenza NA protein also is susceptible to such major antigenic changes. For example, the NA of the circulating A(H3N2) viruses since 2016 are antigenically distinct from those in the prior vaccine strains due to amino acid mutations in NA introducing an N-linked glycosylation site.[472] Third, the large size of Ig molecules often precludes direct access to functional sites on viral surface proteins, such as the receptor-binding site, sites with enzymatic activity, or fusion peptides. Such domains can be buried within the protein structure of the surface protein or masked by carbohydrate molecules, variable loops, or conformational flexibility.[253] Consequently, the critical sites vulnerable to Ab-mediated neutralization can remain relatively inaccessible. Furthermore, some occult sites of vulnerability are hidden in the interface between multimer oligomers of a surface protein. Some highly conserved antigenic sites on viral surface glycoproteins are membrane-proximal, such as a class of bNAbs that target a discrete membrane-proximal anchor epitope of the influenza HA stalk domain[187] and/or similar epitopes on gp41 of HIV, the GP of filoviruses, and others. Therefore, Abs may exert their antiviral activities by mechanisms other than direct inactivation of functional sites on the surface proteins. Instead, Abs most often act directly or indirectly to impede attachment of virus to a host cell receptor, block virus fusion to the cell, or prevent uncoating of virus that has attached to or entered the cell. Unfortunately, effective Ab-mediated protection against virus infection is not always achievable. For example, the Ab response to the envelope glycoprotein of HIV evolves over time like the response elicited by repeated infections with parainfluenza virus, but the elaboration of the envelope-specific Ab repertoire is not able to keep pace with the rapid genetic evolution of HIV. The Abs present at a given point in time may neutralize virus isolated from the subject 6 months earlier but have very low neutralization activity against current strains that have mutated extensively.[390] Sufficiently high levels of passively administered broadly neutralizing mAbs can prevent simian-human immunodeficiency virus (SHIV) infection of macaques in some settings.[283] SHIV is a chimeric lentivirus with the internal and regulatory proteins of simian immunodeficiency virus (SIV), and the surface glycoprotein (gp160) of HIV-1. However, immunization with most currently available HIV-1 envelope antigens does not elicit Abs with these broad neutralizing properties.

Antibody Escape Mechanisms

Viruses, especially RNA viruses with error-prone RNA-dependent RNA polymerases, exhibit facility in generating genetic diversity during multiple replicative cycles. During chronic infections, such as those with hepatitis B or C viruses or retroviruses such as HIV, viruses that accumulate amino acid changes in epitopes that are targets of Abs due to point missense mutations in the corresponding genes can escape

neutralization by reduction or loss of binding. Some viruses easily shed surface glycoproteins (eg, HIV gp120 or Ebola GP)[203] or encode soluble forms of surface glycoproteins using alternative start codons (eg, RSV G protein),[391] in part as a decoy mechanism, targeting Abs away from infectious virions. The immunity induced by experimental vaccine candidates that are narrowly targeted to single epitopes or single proteins are susceptible to rapid viral escape. To avoid such Ab resistant mutants, optimal vaccines should induce broad humoral responses to a diversity of antigenic sites. The risk of narrow immunity is illustrated by the phase 3 trial failure of the RSV mAb suptavumab that failed to meet its primary end point of preventing medically attended RSV infections in infants in a study due to naturally occurring mAb-resistant antigenic subgroup B variant that circulated during the trial.[431] The suspension of EUA for therapeutic COVID-19 mAbs due to emergence of mAb-resistant variants of concern also exemplifies the risk of escape from narrow immunity, especially when RNA viruses circulate at large scale. So many variants have occurred during the COVID-19 pandemic; new vocabulary was developed by government interagency groups to organize discussion of the viral diversity observed and its impact. The CDC provides definitions[98] as follows: A *mutation* refers to a single change in a virus's genome that happens frequently, but only sometimes changes the characteristics of the virus. A *lineage* is a group of closely related viruses with a common ancestor. A variant is a viral genome that may contain one or more mutations. In some cases, a group of variants with similar genetic changes and shared characteristics may be designated by public health organizations as a *Variant Being Monitored (VBM)*, *Variant of Interest (VOI)*, *Variant of Concern (VOC)*, or *Variant of High Consequence (VOHC)* depending on the level of need for public health attention or action. Nextstrain is an open-source effort to display publicly available virus genome data for SARS-CoV-2, seasonal and avian influenza, Ebola virus, and chikungunya virus in real time coupled with tools for analysis and visualization (www.nextstrain.org). Viruses also may evade the action of neutralizing antibodies by accomplishing cell-to-cell transmission through passage in extracellular vesicles, exosomes, or nanotubes. In these structures, viruses may pass from one cell to another in a manner that is not accessible to recognition by antibodies.

Antibodies Active Against Virus-Infected Cells

Viruses that mature at the cell surface by budding or that insert viral glycoprotein(s) into the cell surface membrane render the infected cell susceptible to lysis by Ab-dependent complement-mediated lysis or Ab-dependent cell-mediated cytotoxicity (ADCC) mechanisms. This lysis is mediated by cytolytic cells including NK cells, neutrophils, and eosinophils, in an Fc region–dependent manner. Ab-dependent cell-mediated virus inhibition (ADCVI) activity is similar but is typically measured with a readout of reduction of virus replication instead of lysis of target cells. Abs that bind cell surface Fc receptors may arm leukocytes in the ADCC reaction, which has been shown to be important in the resistance of infant mice to herpes infection and for clearance of a retrovirus.[95,241] Fc receptor–mediated mechanisms appear important to neutralization of HIV[207] and many other viruses. Some studies show that the process of SHM is affected by the Fc glycan composition within antibody-antigen immune complexes, such as for antibodies recognizing the conserved stem region of influenza HA.[476] High-throughput methods for measuring surrogates of Fc-mediated functions have been developed to monitor the functions of antibodies, an approach sometimes dubbed systems serology.[83] These methods have been used to investigate the activity of nonneutralizing antibodies in vaccinees in the one human HIV vaccine trial that has demonstrated efficacy[84] and to suggest Fc-mediated effector functions also contribute to Ebola virus immunity in animal models, especially for mAbs with low neutralizing potency.[414] A challenge is how to validate that these putative CoPs function *in vivo* as they are modeled to do so *in vitro*.[267] There is currently a lack of standardization of Fc effector function assays in the field. Antibody effector functions have been shown to contribute to antiviral T-cell–mediated immunity against SHIV *in vivo*.[333] Some antibody Fc-mediated effects may enhance antigen presentation to T cells, inducing what has been termed a vaccinal effect.[48]

Some herpesviruses encode an IgG Fc receptor homolog, which enables the virus to evade ADCC by binding Abs, especially virus-specific Abs if they bind virus proteins on infected cells, suggesting the importance of the ADCC effector or other Fc-mediated mechanisms *in vivo*.[127] Since infection of cells must occur for these Fc-mediated immune mechanisms to act, these mechanisms represent a second line of defense against infection or disease.

Inadvertent Induction of Antibodies to Host Antigens

Immunization of monkeys with formalin-inactivated SIV produced in human cells induced Abs directed at Ags originating from the cells used to produce the virus.[435] These anticellular Abs can neutralize the infectivity of SIV produced in human cells, but not virus produced in monkey cells, by interacting with human Ags incorporated into the virion outer membrane. This form of neutralization, which is mediated by complement-mediated virolysis, can yield an overestimate of vaccine immunogenicity. Hence, an effort should be made to avoid immunization with virions into which foreign host-cell Ags have become incorporated.[435] In some cases, even the native virion proteins may mimic structures associated with host cell proteins. Polyreactivity (the property of binding to diverse structurally unrelated antigens) or autoreactivity (cross-reactivity to self-antigens) is commonly observed in the B-cell response to certain human viral infections like hepatitis C, Epstein-Barr virus (EBV), and HIV. For example, many of the original broadly neutralizing mAbs specific for the HIV-1 gp160 envelope glycoprotein cross-react with host cell proteins.[206] Certain HIV antibodies may exhibit low affinity of the antibody combining site for the HIV envelope but increase the avidity of the antibody by simultaneously binding with the second arm of the antibody to a host cell antigen, a process that has been termed heteroligation.[312]

Inhibitory Antibodies That Lack Classical *In Vitro* Neutralizing Activity

Some Abs that do not exhibit neutralizing activity *in vitro* can mediate resistance to viral infections, but typically, they are less effective than neutralizing Abs.[314] Such Abs can be directed against Ags on the surface of virus particles or against virion or nonstructural proteins displayed on the surface of infected cells. *In vivo*, these Abs mediate antiviral activities by several different mechanisms. First, virus particles coated with nonneutralizing Abs can undergo accelerated clearance from the bloodstream. Second, Abs directed at surface glycoproteins such as the NA of influenza A virus or the hemagglutinin-esterase protein of coronavirus can decrease the level of virus replication in the target organ, by inhibiting the release of virus from infected cells.[50,502] Third, Abs may lyse virus-infected cells via IgG Fc-dependent mechanisms.[101,419] Many antibodies to the nonstructural protein 1 (NS1) of diverse flaviviruses lack neutralizing activity, yet they protect *in vivo*; the diverse mechanisms mediating these protective effects are the subject of intense current research.[39,484]

Antiviral Activity of Antibodies *In Vivo*

Resolution of infection generally depends on cytotoxic T lymphocytes (CTLs), which reduce infection by lysing virus-infected cells. However, virus-specific Abs also can exert a therapeutic effect. Dramatic clinical therapeutic effect of viral Abs has been observed in patients with

Argentine hemorrhagic fever, which is caused by Junin virus, an arenavirus. This disease has a high mortality, but death can be prevented with a preparation of pooled human serum with a high titer of Junin virus neutralizing Abs administered within 8 days of onset of symptoms.[136,279] Mucosal virus infections that are limited to the cells that line the lumen of the respiratory tract also can be cleared by specific Abs that are delivered by parenteral inoculation or by direct instillation into the lungs. RSV immune globulin or RSV neutralizing Abs protect against severe lower respiratory tract disease.[349,387] These antibodies also reduce established infection in animal models, but therapeutic trials in humans have not revealed a clinical benefit of treatment of active infection. Influenza A virus hemagglutinin-specific IgG Abs cleared the lungs of influenza-infected SCID mice, in the absence of other recognized immune functions.[350] Abs can exert a therapeutic effect in privileged sites where CD8 CTLs are not active. Central nervous system neurons are not good targets for CD8 CTLs, because they have highly regulated expression of class I MHC glycoproteins. Nevertheless, in SCID mice, persistent infection of brain neurons mice by the alphavirus Sindbis virus can be cleared rapidly by parenteral inoculation of envelope-glycoprotein–specific Abs without causing obvious cell damage.[266] Evidence suggests that induction of IFN-γ may contribute to noncytolytic clearance of Sindbis virus from neurons by suppressing viral genomic RNA synthesis and reactivating cellular protein synthesis activation, leading to antiviral effects associated with activation of the Jak/Stat pathway. Some patients with underlying X-linked agammaglobulinemia complicated by chronic enteroviral meningoencephalitis have been treated successfully with human IgG that contains Abs specific for the infecting virus. A therapeutic effect was achieved with IgG administered by the intravenous or intraventricular routes.[130,293] Failure of human IgG to alter chronic enteroviral meningoencephalitis in some patients suggests that the concentration of enterovirus-specific Abs in human IgG is often inadequate. Under normal physiological conditions, the blood-brain barrier prevents most large molecules including antibodies from entering the brain.[23] Most biologics used to treat brain conditions are given intrathecally or they act in the periphery. New methods for delivering antibodies to the central nervous system are needed.

Mucosal Antibodies

Antibodies have been shown to function within mucosal epithelium.[286,287] Dimeric IgA secreted at the basolateral surface of cells or from plasma is transcytosed to the apical surface in association with polymeric Ig receptor to which dimeric IgA with J chain binds. During transcytosis through cells infected with the Sendai virus, virus-specific IgA can reduce intracellular virus and infectivity. The mechanism responsible for this effect is not clear, but it is possible that the endocytic pathway used for IgA transport and the exocytic pathways used for transport of viral glycoproteins intersect at some location within the cell, possibly the apical recycling endosome.[155] Similar studies with IgA Abs to rotavirus and measles virus suggest IgA molecules may inhibit viruses inside epithelial cells or after transcytosis.[54,498] Induced IgA molecules to HIV gp41 appear to block transcytosis across genital epithelial surfaces.[44] The FcRn receptor for IgG also is present in some epithelial cells and could participate in transport or retention of IgG at mucosal surfaces.

Antibodies present in the systemic circulation efficiently protect visceral organs against viruses that are introduced directly into the bloodstream (eg, HBV, HIV, etc.) or that spread via the bloodstream from primary sites of replication such as the respiratory or gastrointestinal mucosa. As mentioned above, diseases produced by viruses that fall into the latter category (measles, polio, hepatitis A, rubella, smallpox, and varicella) can be prevented or modified by Ig prophylaxis, even with concentrations of Ab that are so low they difficult to detect in the serum of recipients, and such Abs are relatively easy to induce by parenteral immunization with live or inactivated virus vaccines. To be fair, the efficacy of some parenteral immunization or direct immunization of mucosal surfaces with vaccines is often comparable in human trials, despite theoretical benefits of enhanced mucosal immunity from topical immunization, for example, for influenza or poliovirus vaccines. Nevertheless, Abs present in the systemic circulation may not provide efficient protection against viral diseases that are limited to mucosal surfaces unless these Abs are present in high titer. This is because only a small proportion of such Ig molecules traffic from the plasma to the luminal surface of the mucosal epithelium by transudation. Bronchoalveolar lavage (BAL) fluids have been reported to be contain about 1000 times lower levels of IgG than that in serum after systemic administration of IgGs. It is interesting that an Fc-engineered form of the RSV mAb motavizumab led to a 10-fold increase in *in vitro* FcRn binding at pH 6.0 for both humans and monkeys, and bioavailability in the lungs was also increased fourfold.[114] Therefore, to prevent viral diseases that are limited to mucosal tissue by vaccination, two different strategies can be employed. The first is to induce Abs such as secretory IgA at the mucosal site by virus replication or immunization at that site. The second, and less efficient, strategy is to stimulate a high titer of serum IgG Abs that can protect mucosal surfaces following transudation.

When IgG Abs present in the blood are passively transferred to mucosal surfaces by transudation where they can exert antiviral activity, there is a gradient regarding the ability of serum IgG-derived Abs to restrict virus replication on mucosal surfaces. This gradient is less in lung than it is in the nasopharynx. IgG Abs, if present in the serum in high enough titer, can provide almost complete resistance to pulmonary replication of RSV, but resistance in the upper respiratory tract is more difficult to achieve. Transudation of IgG also probably occurs in the intestine, especially in inflammatory states, but IgG is more easily subjected to proteolytic degradation in the intestinal lumen than in the respiratory tract. Immunization of the female genital tract with a live virus vaccine can induce the local synthesis of IgG antiviral Abs such that the specific activity of mucosal IgG Abs significantly exceeds that of serum, indicating that IgG Abs present on a mucosal surface can come either from serum via transudation or from IgG Ab secreting cells present in the submucosal tissues.[356] Although passively transferred IgG Abs can provide mucosal immunity in the lower respiratory tract, the major mediators of resistance to viral infection of the upper respiratory tract, the larger airways of the lungs, and the gastrointestinal tract are mucosal Abs, many of which are IgAs selectively transported across mucosal surfaces to exert antiviral effects on the luminal surface. Both nonneutralizing[54] and neutralizing[402] IgA Abs have antiviral effects on mucosal surfaces with the former active intracellularly during transcytosis and the latter active both intracellularly and on the luminal side of the epithelium. Antiviral IgA Abs function to clear viral infections, to modify the severity of disease on reinfection, and to prevent infection on re-exposure to virus. The level of antiviral IgA Abs and the number of virus-specific IgA secreting cells often correlates with resistance to viral infection.[89,505] The advantages of IgAs in the mucosal fluids are that they are transported more efficiently, they resist proteolytic degradation better than IgG, and the dimeric nature of secretory IgA enhances avidity.

The primary mucosal IgA response peaks within the first 6 weeks after infection and usually decreases to a low, often barely detectable, level by 3 months. The transient nature of the primary mucosal Ab response is a factor in the ability of many viruses to reinfect mucosal surfaces and underlies the need for two or more doses of vaccine to efficiently immunize mucosal surfaces. The virus-specific IgA Ab response is greater at the site of virus replication or of Ag administration than at distal sites, suggesting that mucosal immunity is best induced by antigenic stimulation of sites directly involved in replication of the wild-type virus.

Adverse Effects of Antibodies

Antibodies may contribute to the potentiation of disease. For example, heterotypic Abs to the envelope glycoprotein of dengue virus appear to

play a role in severe dengue.[248] Dengue viruses replicate primarily in cells of the mononuclear phagocyte lineage, and subneutralizing amounts of dengue virus Abs enhance dengue virus infection of these cells *in vitro* by increasing uptake of virus via IgG Fc receptors present on these cells.[194] However, the mechanism by which augmented disease results from enhanced access of dengue virus into mononuclear cells remains unclear.[400] Some model systems suggest enhanced dengue virus replication in the presence of nonneutralizing antibodies, and other studies suggest an association with enhanced cytokine production and vascular leakage. Immune complexes were detected in the lung tissues of fatal cases of influenza during the 1957 and 2009 pandemics, suggesting a potential role for enhancing antibodies in severe influenza disease.[304]

Vaccine-Induced Cellular Immunity

Major histocompatibility complex (MHC) class I–restricted CD8+ cytotoxic CTLs and MHC class II–restricted CD4 helper T cells (Th cells) each function independently as Ag-specific antiviral effector cells, and they also work cooperatively in most immune responses, for example, CD4 T cells often provide signals that facilitate optimal CD8 memory responses (see Chapter 10). Intact cellular immunity is critical for protection against progression of infection by some types of viruses. For example, most herpesvirus infections become more severe and destructive when cellular immunity is compromised. The attenuated virus vaccinia is used as the vaccine to prevent smallpox or monkeypox disease but also can cause progressive tissue invasion in persons with cell-mediated immune deficiencies or eczema. RSV and parainfluenza type 3 often become lethal infections in the setting of severe combined immunodeficiency or in patients who have undergone bone marrow transplantation. In contrast, patients with Ab deficiencies experience more severe disease only from selected viruses, particularly picornaviruses.

CD8 T Cells

CD8 T cells are the major T-cell effectors of antiviral activity. They are often referred to as CTLs, although they can clear virus-infected cells by both lytic and noncytolytic mechanisms. Classically, the CD8 T-cell receptor (TCR) recognizes a short peptide derived from an endogenously produced viral protein in the context of the MHC class I β2-microglobulin heterodimer expressed on the surface of an infected cell. Ag presentation by the MHC class I β2-microglobulin heterodimer is restricted to viral peptides that are produced and processed during infection. Therefore, the major CTL functions are to eliminate infected cells[146] or to inhibit virus replication by the elaboration of soluble mediators such as cytokines[151,317,455] or chemokines.[82,499] Dendritic cells (DCs) and some other professional antigen-presenting cells can take up extracellular protein antigens, process them as peptides, and present those with MHC class I molecules to CD8 T cells, a process that has been termed cross-presentation. Naive CD8 cells can be cross-primed in this way to become activated cytotoxic CD8+ T cells. Also, lymphocytes engaged in an immunological synapse with an antigen-presenting cell can capture membrane fragments containing surface molecules from presenting cells and express these molecules on their own surface, a process termed trogocytosis. The net effect of CTL activity is to prevent further spread of virus and to terminate infection in cells that are already infected. The importance of CTLs in recovery from viral infection is indicated not only by the association of cellular immune deficiencies with severe virus infection but by the diverse strategies that viruses use to escape from CTL immunity.[437] Viruses like herpesviruses, poxviruses, and lentiviruses have evolved strategies for interfering with Ag presentation pathways or CD8 T-cell effector molecules that compromise CTL activity. Lentiviruses are prototypes for escaping CTL killing by genetic variation and selecting mutations of key epitopes. CD8+ T-cell activity is critical for controlling SIV replication.[420] When that control is mediated by a dominant CTL response to a single epitope, immune control of viremia is lost when that epitope is altered by mutation.[26]

Although CTL antiviral activity generally is associated with the clearance of virus and the reduction of virus-associated pathology, disease enhancement can be observed under experimental conditions in which CTLs have been transferred passively to virus-infected recipients.[63,134,310] Therefore, one can view the immunopathology caused by the T-cell response to virus infection as the cost for virus clearance. A major goal of vaccination is to induce CD8 T cells with properties to clear virus-infected cells efficiently and rapidly to minimize the immunopathology associated with virus infections.

The time course of CTL activation during viral infection in the lungs is consistent with its important role in clearance of primary virus infection. Primary CD8 CTL activity in the lung peaks at about day 7 during acute virus infection, such as that produced by influenza A virus, LCMV, or RSV.[10,146,225] There is a subset of a long-lived memory T cells in mucosal and epithelial tissues with distinct phenotypes and specializations for the relevant tissues, and these have been termed tissue-resident memory T cells. These cells do not recirculate but persist in these extralymphoid tissues and provide protection against infection in those tissues. The naive CD8 T cell in the LCMV model undergoes a process of activation and expansion during that time of 10 000- to 50 000-fold.[42] After about 40 days, the level of detectable virus-specific memory CD8 CTL is about 10% of that during acute infection and is then maintained at constant levels for years even in the absence of Ag.[225] Each successive virus infection adds an expanded set of specificities to the pool of memory CD8 T cells over time and shapes the capacity of the host to respond to selected viruses.[425,426] The memory CD8 T-cell pool not only has an increased precursor frequency against virus-specific epitopes but those cells have a faster response time. The influence of CD8 CTL memory on the outcome of a subsequent virus exposure can be subtle and may depend on the absence or presence of other components of the immune response. For viruses in which a significant component of the clinical syndrome is related to the immune response clearing the virus, having memory CD8 T-cell responses will result in reduced virus replication a day or two earlier than in primary infection, an earlier peak illness time point, and a lower peak magnitude of illness.[151,179] In a setting where there is a large virus load (eg, high inoculum challenge) and an absence of preexisting neutralizing Abs to diminish the number of virus-infected cells, a large CTL response or infusion of excessive CD8 T cells can result in more severe disease.[62] During chronic virus infection, virus-specific CD8+ T cells may become exhausted as marked by upregulation of the inhibitory programmed death-1 (PD-1) pathway. Blockade of the PD-1 pathway in combination with therapeutic vaccination enhanced CD8+ T-cell immunity and resolution of chronic LCMV clone 13 infection in mice,[189] raising the possibility for a combinatorial therapeutic vaccination strategy to synergistically enhance epitope-specific CD8+ T-cell responses and accelerate viral clearance.

To date, the CD8 T-cell response has not been used successfully as a correlate of immunity that is the basis for licensure of a vaccine. However, the incorporation of CTL epitopes into viral vaccines has been considered valuable because of the important role CTLs play in clearance of established viral infections. The following characteristics of the CTL response *in vivo* should be kept in mind when designing a vaccine for viruses that may require a CTL component of immunity. First, the ability of a CTL epitope to induce an immune response is MHC dependent. Therefore, the incorporation of large antigenic content is important so that multiple CD8 T-cell specificities can be elicited by the vaccine to allow selection of epitopes by the diverse repertoire of human MHC class I alleles and to reduce the possibility of immune escape through genetic mutation. Second, when considering vaccine-induced immune protection, CTLs represent a second line of defense against virus infection because they cannot prevent infection and are only effective against infected cells. The localization and phenotype of CD8 T cells can influence

the timing and efficiency of viral clearance. For example, immunization of macaques with a recombinant CMV vector that induces a sufficiently high frequency of intraepithelial effector memory CD8 T cells that rapidly cleared virus-infected cells following SIV challenge leading to abortive infection.[200] Technologies such as polychromatic flow cytometry,[363] MHC class I tetramer reagents that provide the means to sort epitope-specific T cells,[119] the ability to define functional subsets of T cells with more precision,[116] sequencing technology that allows single-cell clonotyping of epitope-specific cells, and correlation of the TCR-peptide-MHC biophysical interaction and structure with T-cell functions[40] may provide the necessary information to harness CD8 T cells more effectively in the future. Indeed, investigators have developed methods using TCR sequences from peptide+ MHC-tetramer-sorted cells along with structural data to cluster TCRs with a high probability of sharing specificity, based on contact points with the antigenic peptides.[164] Impressive efforts have been made to standardize cellular immune assays that can be used in the context of clinical trials, for example, the IFN-γ ELISPOT assay for T cells.[218,278] The NIH has sponsored development of a publicly available curated comprehensive database of epitopes, MHC restrictions, and epitope prediction tools (The Immune Epitope Database and Analysis Resource [IEDB]) that facilitates such predictions.[411]

CD4 T Cells

CD4 T cells provide a variety of functions including help to B cells and CD8 T cells, thereby augmenting the two major effector mechanisms of the adaptive immune response. CD4 T cells can also mediate direct antiviral activity *in vivo*,[204,280,313,454] but this is not their major function as it is for CD8 T cells. The MHC class II, αβ heterodimer, which is the restricting element for CD4 T cells, is present predominantly on Ag-presenting cells such as DCs, macrophages, monocytes, and B cells. However, during inflammation even epithelial cells can express MHC class II molecules, and CD4 T cells have been shown to have compensatory viral clearance capacity in the absence of CD8 T cells. In addition to having antiviral and helper activity, CD4 T cells can mediate immunopathology[8,295,451] and have been shown to have regulatory and other specialized functions[512] (e-Fig. 15.5).

The CD4 T-cell response to certain internal viral proteins may play a cooperative role in the development of effective resistance by augmenting the Ab response to a major surface protein.[403] For example, immunization with the membrane (M) protein of influenza A virus can prime for a subsequent augmented Ab response to the HA glycoprotein on virus particles.[403] In this manner, the entire CD4 T-cell repertoire developed against the viral surface and internal proteins can be called into play to amplify a B-cell response to a surface protein. Because MHC class II–restricted T-cell epitopes tend to be more numerous on viral proteins than MHC class I–restricted epitopes,[251] the repertoire of CD4 T cells capable of augmenting the Ab response is large. While CD4 T cells are typically thought to provide indirect helper functions to improve CD8 T cell and Ab responses, there is evidence that they may also contribute direct effector functions to virus clearance. CD4 T cells have been shown to have cytolytic function against HIV.[345] Viral Ags can induce a protective immune response mediated by CD4 T cells in the absence of B cells or CTLs,[280] indicating that this arm of the immune response can make an independent contribution to resistance against both acute and chronic viral infections.[204] CD4 T cells also secrete IFN-γ, TNF-α, and other soluble factors that may directly inhibit virus replication.[338,339] For these reasons, it is advisable to include virus Ags capable of inducing CD4 T-cell responses in viral vaccines to achieve maximal immunogenicity.

The processes involved in CD4 T-cell memory induction differ from those involved in establishing CD8 T-cell memory responses[424] and are more complex in some ways. Ag processing and presentation in MHC class II molecules can occur through the endocytic pathway so unlike CD8 T cells, CD4 T cells can be induced by killed virus vaccines or even purified proteins and do not require live virus or gene delivery approaches to allow Ag to reach the cytoplasm. The zoster virus subunit vaccine induces CD4 T cells, which are thought to be the correlate of protection for this vaccine. CD4 T cells do not proliferate to the same extent as CD8 T cells during primary infection, and those producing IFN-γ do not survive as long-lived memory cells.[508]

CD4 T cells have traditionally been considered “helper” T cells (Th) and indeed their activities can improve the potency of B-cell and CD8 T-cell responses. Generation of high-affinity antibodies usually depends on cognate T-cell help based on physical contacts between T and B cells, mediated through interactions between the T-cell receptor and its cognate peptide presented on major histocompatibility class II molecules on the B-cell surface. Major subsets of CD4 T cells have been defined based on differentiation pathways and surface markers (e-Fig. 15.5). Th1, Th2, Th17, and Treg cell subsets express, respectively, the specific transcription factors: T-box expressed in T cells (T-bet), GATA3, retinoic acid–related orphan receptor gamma t (RORγt), or Forkhead box P3 (Foxp3). Th1 helper cells typically secrete effector cytokines IFN-γ and IL-2 that enhance cell-mediated responses performed primarily by macrophages and cytotoxic T cells. Th2 helper cells classically enhance humoral immune responses. In addition, to the original subsets Th1 and Th2, there are now many subpopulations of T cells defined with distinct functions, some of which can alter or diminish effector function. T regulatory cells (or Tregs) identified as CD4+FoxP3+ T cells have inhibitory effects on other immune effector functions, hence the name.[33] The extent to which vaccines induce CD4+FoxP3+ T cells with T regulatory activity is still poorly understood. Th17 helper cells are a subset of T helper cells distinct from the Th1 and Th2 lineages that produce interleukin-17 (IL-17). Th cells produce IL-17 and other proinflammatory cytokines that have been associated with immune-mediated pathology but are also important for immunity against some pathogens.[201] A CD4+CXCR5+ subset of CD4 T-cell–designated T follicular helper (Tfh) cells has been identified that resides primarily in lymph node germinal centers and promotes B-cell memory and plasma cell differentiation.[104] THαβ helper cells (triggered by IFN-α/β or IL-10) mediate antiviral immunity in some settings by secreting the effector cytokine IL-10 that alters the activity of many other immune cells. Newly defined T-cell subsets such as Th9 cells (an interleukin-9–producing T-cell subset) Th22 (interleukin-22–producing) cells occur, but their role in antiviral immunity is not clear. The role of each CD4 T-cell subset in vaccine-induced protection and optimal balance is an area that needs more investigation. Currently there is relatively little actionable information on how to control induction of optimal ensembles of CD4 T-cell subsets by vaccination.

Obstacles to Immunization in Special Populations

Immunization of Infants

The developmental immaturity of the immune response to viruses in the very young is seen clearly in the difficulty to immunize neonates and infants.[430] Young infants are a preferred target population for immunization, because most children present to health systems with the highest frequency at birth or shortly after. A high level of access to infants allows universal immunization, and many viral diseases are most severe early in life. Many obstacles arise, however, in attempts to immunize infants in the first several weeks or months of life against disease caused by viruses.

First, most infants possess maternal Abs that can interfere with response to infection or the infectivity or immunogenicity of primary immunization. Live attenuated measles virus cannot be given effectively prior to 1 year of age because many infants possess maternal Abs until that time that reduce or eliminate immunogenicity of the vaccine.[5] Ab-mediated suppression can be overcome in some instances by increasing the dose of the vaccine, for example, the inactivated hepatitis A vaccine or a replicating influenza vaccine.[90,111] The immune suppression by maternal Abs is more potent against B-cell responses than against induction of virus-specific T cells possibly because the Ab response is generally more dependent on Ag dose than T-cell responses.[106] Increasing dose of vaccine must be considered carefully, however. Measles vaccines that were 10-fold (medium titer) or 100-fold (high titer) greater than standard titer were given at 6-11 months of age in some African trials, and increased mortality was associated with high-titer vaccine for girls but not for boys.[210]

Second, the ability to respond to viral surface proteins with a protective Ab response is acquired gradually over the first year of life, reflecting developmental maturation of the neonatal immune system. Responses of seronegative infants to live measles vaccine remain relatively poor during the second 6 months of life.[157] Responses to live varicella-zoster virus vaccine also are reduced in the first year of life.[466] The youngest infants mount Ab responses to experimental mucosal immunization with live influenza, RSV, or parainfluenza virus vaccines that are low in magnitude, quality, and durability.[90,230,231] The molecular and cellular basis for immunologic immaturity is not fully defined. Infant virus-specific Ab sequences are characterized by marked lack of somatic mutations, resulting in low-affinity Abs of low function.[482] Infant B cells exhibit limited capability to switch isotype from IgM to IgG2 Abs, and the isotype profile of circulating Abs differs from adults until age 5-6 years. Infants possess reduced levels of some components of the complement cascade, especially C8 and C9 that participate in membrane attack complexes, leading to impaired complement-mediated reactions. Infants exhibit a high proportion of transitional immature B cells and poor organization of the splenic marginal zone.

The Ab responses that young infants make to respiratory virus surface glycoproteins are significantly lower in quality than those of adults. Studies have described a dissociation of the level of neutralizing and binding Abs in the very young infant.[493] This dissociation may be of functional significance since neutralizing Ab titers correlate well with protective efficacy in studies of protection for viruses. Dissociation between neutralizing and binding Abs also characterized the serum Abs induced by the ill-fated formalin-inactivated RSV experimental vaccine of the 1960s and probably accounts for the lack of protective efficacy of Abs induced by that vaccine candidate.[322] Ab responses induced by infections of infants are less durable than those of older subjects. Postinfection serum Ab levels to respiratory viruses often wane significantly several months after primary infection, especially if infection occurs at a very young age. Animal models suggest that B-cell priming occurs effectively early in life or in the presence of suppressive Abs,[105,106] but the deficient maintenance of long-lived plasma cells in the bone marrow may lead to rapid waning of humoral immunity.[365] Reduced humoral immunity to vaccines early in life also may reflect reduced T helper cell function and altered DC function. Neonatal CD4 T cells exhibit reduced ability to secrete IFN-γ, reflecting limited secretion of IFN-α and IL-12 by DCs.[117] Given the challenges of directly immunizing neonates against specific pathogens, some experts suggest integrated approaches using alternative strategies including vaccinating pregnant women and using vaccines that broadly alter neonatal immune status in a pathogen-agnostic manner.[242] For instance, the live attenuated bacille Calmette-Guérin (BCG) vaccine for tuberculosis has been much studied for its potential to induce heterologous beneficial effects that may protect against virus diseases. Current studies do suggest that BCG vaccination may affect ("train") innate immune cells in ways that alter some subsequent immune responses and metabolic and epigenetic reprogramming of those cells. But the heterogeneity of populations and their diverse environmental exposures makes it challenging to develop predictable and controllable effects of BCG for specific viral diseases.

Immunization of the Elderly

Obstacles to effective immunization also arise late in life due to immune senescence. Immune senescence in the elderly is marked by a decrease in the magnitude, quality, and duration of Ab responses and a reduction in functional T cells, especially CD8 T cells. T cells in the elderly are distinguished by alterations in cytokine production, costimulatory molecule expression, susceptibility to apoptosis, and changes in the level of DNA damage and repair and telomerase length.[158] Chronic virus infection may contribute to immune senescence. For example, CMV-specific T cells progress to a differentiated state in the elderly due to chronic antigenic stimulation.[359] This syndrome has been described as an "immune risk phenotype" in the elderly, reflecting the accumulation of a high percentage of circulating CMV-specific CD8 T cells at a terminal stage of differentiation that may detract from the flexibility of the T-cell repertoire to respond to other Ags. The CD4 T-cell responses of healthy elderly individuals appear to sustain a good level of function until late in life. Waning immunity to latent viruses may be boosted in the elderly in some cases. Immunization of the elderly with the zoster subunit vaccine reduces the incidence of shingles in that population.[108]

Aging has varying effects on the response to different Ags. For example, the immunogenicity of recombinant hepatitis B vaccine is reduced starting in the fifth decade and is poor in the elderly.[490] Ab responses to influenza virus vaccine also are reduced in the elderly. Practically speaking, however, while vaccination in the elderly may be reduced in efficacy and may require frequent boosters or other alterations in strategy, the effectiveness of many vaccines such as influenza virus vaccine are reasonable enough to support vaccination of this group. Higher-dose antigens have been licensed for use in those aged 65 years or older, and it also may be possible to improve the immune responses in the elderly by using new adjuvants or alternative vaccination strategies. Investigational gene-based vaccines have been shown to be highly immunogenic in older adults compared to the typical age-related decrease in responses seen with many traditional vaccines.[261]

Immunization of Pregnant Women

In the past, by default, pregnant women typically were excluded from vaccination programs due to safety concerns. However, immunization for many diseases has been shown to benefit both pregnant women and their children. Therefore, increasingly experts recommend the *presumption of inclusion* so that pregnant women would be included in vaccine development and deployment unless their exclusion can be justified from a scientific and ethical standpoint.[407] The CDC recommends that pregnant women get the inactivated influenza vaccine during every pregnancy. Pregnant people are more likely to suffer severe illness with COVID-19 compared with nonpregnant people and can receive a COVID-19 vaccine. Some vaccines should be given a month or more before pregnancy, such as the measles, mumps, rubella (MMR) vaccine, and hepatitis A and B are considered for pregnancies in which there would be risk for becoming infected with hepatitis viruses during delivery. Some vaccines are not recommended during pregnancy, including the MMR, HPV, live influenza, and varicella vaccines, and certain travel vaccines such as live yellow fever, typhoid fever, and Japanese encephalitis virus (JEV). It is generally safe to receive routine vaccines right after giving birth, even when breastfeeding, although yellow fever vaccine is not preferred in this setting.

Immunization of the Immunocompromised

Individuals with primary immunodeficiency or acquired immunodeficiency from immunosuppressive therapies face unique challenges with vaccines. First, there are increased safety concerns during vaccination for some individuals. Patients with phagocytic cell disorders, such as chronic granulomatous disease or with complement deficiencies can be immunized with standard protocols. However, people with T- or B-cell immunodeficiencies, such as severe combined immune deficiency, Bruton agammaglobulinemia, and common variable immune deficiency, may contract disease following inoculation with live virus vaccines such as MMR, varicella, oral rotavirus, live intranasal influenza, oral polio, or yellow fever virus. Immunodeficient patients also can acquire infections from close-contact spread following contact in public, home, clinic, or hospital with otherwise healthy subjects with infection or who are shedding live virus vaccine–derived strains. Patients who have received therapeutic hematopoietic stem transplantation are at exceptional risk prior to immune reconstitution and during periods when they receive immunosuppressive agents to prevent or treat graft vs host disease. These individuals should avoid live viral vaccines themselves. Second, immunodeficient patients often are unable to develop protective immunity following vaccination. For people with antibody deficiencies, Ig replacement therapy is the standard of care. Maintaining community ("herd") immunity in the population at large and especially in family members of patients with reduced T-cell and B-cell–mediated immunity protects these patients. COVID-19 proved a unique clinical scenario for testing options to protect immunodeficient individuals, as most people can safely get any of the three COVID-19 vaccines with emergency use authorization since they do not contain live virus. COVID-19 vaccination, including extra booster doses, was recommended for immunodeficient subjects. This population is quite heterogeneous, however, comprising individuals with primary vs secondary immunodeficiency, HIV infection, solid tumors or solid organ transplant, autoimmune conditions, and hematologic cancers (leukemia and lymphoma). A comprehensive approach to protecting these individuals includes vaccination and boosting, nonpharmacologic interventions to avoid exposure, and prophylaxis by passive immunization with a combination of two long-acting mAbs (tixagevimab/cilgavimab).

New Conceptual Approaches to Rational Vaccine Design—Structure-Based Vaccines

In recent decades, major advances in viral vaccine development have coincided with the emergence of new technologies (Fig. 15.4, e-Fig. 15.6A and B). Therefore, selected technologies that are likely to influence future vaccine design are discussed briefly.

FIGURE 15.4 **History of virus vaccines**. Viral vaccines can be organized by the major technology that made their development feasible. Licensed viral vaccines are listed on the left axis in chronological order. They are color-coded indicating the major development era or technology with which they were associated. Significant advances since the initial age of empiricism have been coincident with the development of cell culture techniques and molecular biology. One can envision that advances in some of the technologies discussed in the text such as structural biology, advances in sequencing, and gene expression vectors may facilitate vaccine development for unmet and unanticipated future needs for prevention of viral diseases.

e-FIGURE 15.6 Evolution of viral vaccine concepts. **A.** The progression of viral vaccine platforms has followed the availability of new technologies as shown in Figure 15.5. Live attenuated virus vaccine approaches were followed by inactivated virus vaccines. Subsequently, genes encoding specific vaccine Ags were derived from the virus of interest, first by extraction and now by using sequence information for *in vitro* synthesis. **B.** Impact of molecular biology on vaccine development options. Modern approaches to vaccine development virtually all use genes encoding viral proteins and molecular biology techniques to produce vaccine Ags and delivery vehicles. Licensed vaccines utilizing these approaches include VLPs for HBV and HPV and live attenuated virus vaccines for influenza and rotavirus.

Advances in Monoclonal Ab Isolation

The neutralizing determinants on vaccine Ags are *de facto* the epitopes recognized by human antibodies that mediate antiviral function. The study of the molecular and structural basis for neutralization was limited in the past by the difficulty in isolating human mAbs. Breakthroughs in this field using enhanced EBV transformation with CpG,[37] human hybridoma formation,[503] plasmablast sorting and cloning,[492] single B-cell sorting and expansion,[470] B-cell immortalization with lentiviruses transducing BCL6 and Bcl-xL,[252] massively parallel single B-cell interrogation in microfluidic devices,[513] LIBRA-seq,[427] and other techniques have increased the numbers of human antibodies for study by several orders of magnitude. Structural studies of complexes of human Abs with viral Ags have begun to yield fascinating insights into the features of protective Ab epitopes, which often are conformational, quaternary, and otherwise complex.[254]

Advances in Structural Biology Coupled With Computational Biology

The ability to design optimal antigenic surfaces for induction of neutralizing Abs has long been a dream of vaccine scientists. The goal is to develop synthetic constructs that elicit Abs with predetermined structural specificity. Induction of Abs against epitopes that are hidden in the native viral protein has been a challenge for vaccine design. Investigators working in the areas of structural biology and computational modeling have made significant progress in this regard. Computationally designed epitope-scaffolds that are immunogenic have been developed for the HIV-1 gp41 epitopes of the broadly neutralizing mAbs 2F5[340] and 4E10[102] and the RSV F motavizumab epitope.[292] Structural information from HIV gp120 CD4-binding site epitope recognized by the neutralizing Ab b12 has been used to design gp120 reagents to select additional CD4-binding site antibodies that have broad neutralizing activity against HIV.[510] Stabilization of the prefusion conformation of RSV F protein has led to a more immunogenic RSV vaccine candidate.[364] Fragments of influenza HA have been expressed to focus the immune response to conserved epitopes in the HA stem region.[43] The NIH Vaccine Research Center is testing a vaccine candidate composed of the HA stem domain from influenza A/New Caledonia/20/l999 (H1N1) genetically fused to the ferritin protein from *Helicobacter pylori*, which displays eight HA trimers that resemble the native HA stem region.[501]

Computational prediction tools are being used to design vaccine candidates with optimal properties. The Rosetta molecular modeling suite, maintained and developed by the RosettaCommons international collaboration, has been used extensively in docking and design application cases for antibody and antigen modeling.[422] Both side chain and backbone grafting have been applied successfully in multiple cases to place epitopes into scaffolded antigen frameworks. Computational and structural tools also can be used for design of viral inhibitors, for example, the design of proteins targeting the influenza HA stem that mimic the action of neutralizing Abs.[143] Small (<65 amino acid) protein designs that bind their targets with nanomolar to picomolar affinities have been designed using only information in the three-dimensional structure of influenza HA or SARS-CoV-2 spike proteins.[64] AlphaFold, a deep learning system based on an artificial intelligence (AI) program developed by

Alphabet's/Google's DeepMind, performs predictions of protein structure with increasing power to predict or design structures.[224] These computational design methods are optimal for propelling the field of rational vaccine design, which incorporates the concepts of antibody germline targeting and epitope-focused and antibody lineage–based immunogen design.[55] It seems likely that computationally designed immunogens will increasingly influence viral vaccine design.

Sequence-based methodologies are also being used for design of more broadly immunogenic antigens, for example, using the COBRA (computationally optimized broadly reactive antigen) method that has been used for sequence consensus building to generate influenza vaccine HA immunogens for H1, H3, and H5 influenza subtypes.[7] Some HIV vaccine candidates have been designed *in silico* to target multiple viral subtypes using what are termed recombinant mosaic antigens, which constructed from natural sequences to include common broadly protective conserved epitopes while reducing rare sequences, which appear more broadly protective in nonhuman primate studies.[28]

Types of Vaccines

Live Virus Vaccines

History of Methods for Isolating Attenuated Strains

Varying methods have been used to achieve attenuation for live virus vaccines. Type 2 poliovirus, strain 712, one of the three poliovirus vaccine strains in the live vaccine preparation, is a naturally occurring attenuated human poliovirus that was identified by its lack of virulence for the brain and spinal cord of monkeys.[405] Adenovirus vaccine strains (types 4 and 7) are wild-type human respiratory viruses that were developed for use in the U.S. military that produce an asymptomatic infection following oral administration that was restricted in replication to the intestinal tract.[73] The remaining attenuated vaccine viruses were derived from wild-type human viruses by serial passage in cell cultures prepared from an unnatural host, leading to the emergence of mutants that were partially restricted in humans at the portal of entry and/or the target organ(s). In this manner, attenuated mutants of rubella virus and types 1 and 3 poliovirus were selected after passage in monkey kidney tissue culture. Vaccine strains of yellow fever virus (17D strain) and measles virus were generated by multiple passage using cells in tissue from embryonated chicken eggs, whereas mumps virus was attenuated by multiple passages in embryonated eggs. Vaccinia virus was used to eradicate smallpox, but after eradication, its safety profile was considered suboptimal. A highly attenuated derivative strain of vaccinia virus called modified vaccinia Ankara (MVA) virus was developed by more than 500 serial passages in chicken embryo fibroblast cells of a wild strain of vaccinia isolated by the Turkish Vaccine Institute of Ankara. MVA lost ~10% of the vaccinia genome and consequently the ability to replicate efficiently in primate cells,[12] but it is highly immunogenic in humans.

A critical feature of most successful live vaccine development programs is the identification of preclinical laboratory predictors of attenuation. For the yellow fever virus and poliovirus vaccines, promising vaccine strains were identified by their attenuation for experimental animals. In monkeys, the vaccine based on the 17D strain of yellow fever virus exhibited decreased tropism for the liver, suggesting that this mutant might be suitably attenuated for humans,[452] a hypothesis that was confirmed during subsequent clinical trials. Naturally occurring or tissue culture–passaged strains of poliovirus were evaluated for neurovirulence in monkeys by intraspinal inoculation, a central innovation that allowed Sabin to identify attenuated strains.[404,405] This testing system was selected because several observations suggested that the spinal cord of monkeys was more permissive than that of humans to the neuronolytic effect of poliovirus.[405] Viruses that caused the least neurovirulence in monkeys were identified, and these strains then were cloned and recloned biologically by the plaque technique to yield progeny with the lowest possible level of monkey neurovirulence. These candidate vaccine strains then were subjected to additional cycles of selection, which led to the identification of mutants that replicated with high efficiency in the intestinal tract without significant increase in neurovirulence for nonhuman primates. These viruses were evaluated in clinical trials and shown to be satisfactorily attenuated and immunogenic.

Experimental animal systems were not available for evaluating virulence of the other vaccine viruses. Therefore, these viruses were tested for attenuation directly in humans. Initial candidate measles and rubella virus vaccines were insufficiently attenuated, but further passage of rubella virus in monkey kidney cell culture and selection of a cold-adapted, temperature-sensitive mutant of measles virus yielded satisfactory vaccine strains. Attenuation of mumps virus passaged in eggs also was determined in humans. Interestingly, the Jeryl Lynn strain of mumps virus vaccine developed by Maurice Hilleman as a clinical isolate from his daughter was found to be a mixture of two closely related strains of mumps virus.[2] Several other vaccines have been found to be mixtures of virus strains, including the yellow fever virus vaccine and some vaccinia stocks used for smallpox vaccination.

Poliovirus and adenovirus vaccines are administered orally, while yellow fever, rubella, measles, and mumps virus vaccines are given parenterally. Each of the currently licensed live virus vaccines is directed against a virus that has a complex pathogenesis of infection in which virus is introduced by inoculation (yellow fever) or by implantation on a mucosal surface (measles, mumps, rubella, and poliovirus) with subsequent spread systemically to the target organ(s). The requirement of such viruses to pass through blood to reach the target organ of disease makes them generally susceptible to serum antibodies. It is more difficult to protect against infection by viruses that cause disease at a mucosal portal of entry without need for viremia.

Advantages of Live Virus Vaccines

The major advantage of live virus vaccines is the activation of all components of the immune system yielding both a balanced systemic and local immune response and a broad humoral and cell-mediated response. This type of comprehensive induction of immune effectors is particularly important for infections in which cell-mediated immunity plays an important role and for mucosal infections in which both local and systemic immunity are required for optimal resistance. As noted, mucosal infection with a live virus vaccine is much more effective in stimulating a local response in the unprimed host than inactivated virus vaccines administered parenterally.[319] Live virus vaccines also can stimulate an immune response to each of the protective Ags of a virus, and this obviates the difficulties that arise from selective destruction of one of the protective Ags that may occur during the inactivation process and can lead to disease potentiation. This advantage is especially important for complex viruses encoding many protective Ags since it is prohibitively difficult and expensive to immunize with multiple purified proteins or to construct multivalent vectors. Furthermore, immunity induced by live virus vaccines is generally more durable and more effective.[220] There are practical advantages to many live virus vaccines, such as relatively low cost of production and ease of administration. Live viruses contribute to protection in populations because of the induction of herd immunity, sometimes facilitated by transmission of vaccine viruses from a recipient to a contact. The effectiveness of live vaccines in settings of high transmission is illustrated using adenovirus vaccines. Adenovirus vaccines reduced military

respiratory disease morbidity significantly over the last three decades. In 1995, however, the manufacturer of these vaccines ceased production due to budgetary constraints. Major outbreaks of serious adenovirus infections occurred in military facilities, therefore.

Disadvantages of Live Virus Vaccines

The major concerns with live virus vaccines are that they (1) can contain adventitious agents, (2) can cause illness directly, (3) can lose their attenuation during manufacture or during replication in vaccinees by reversion or by second-site compensatory mutations, (4) can spread to contacts, and (5) can lose infectivity during storage, transport, or use. The potential for contamination with live adventitious agents always exists as discussed above. Sources include the original clinical sample from which the virus was isolated, cell culture substrates, laboratory reagents of animal origin (such as serum supplements and trypsin), and contamination from laboratory workers or environments. Cross-contamination of vaccine lots with other viruses in a laboratory facility is possible. Fortunately, contamination of clinical lots of vaccine with major human pathogenic adventitious agents has rarely been a problem in the modern era. Some of the early lots of live poliovirus vaccine were contaminated with live SV40, and the live yellow fever virus vaccine was initially contaminated with an avian leukosis virus. Follow-up of individuals who were given live vaccine contaminated with SV40 or avian leukosis virus has failed to identify any long-term adverse effect, including cancer, associated with exposure to these adventitious viruses.[308,441,479]

Some live virus vaccines, such as the measles virus, rubella virus, and yellow fever virus vaccines, retain a low level of residual virulence. The reactions produced by these vaccines generally are minor and have not interfered with acceptance and widespread use of these products. A more serious problem is that of restoration of a varying degree of virulence during infection by vaccine virus. This occurs with the poliovirus vaccine at an extremely low frequency, that is, about one in 10^6 to 10^7 immunizations.[334] Most vaccine-associated cases of paralysis in vaccinees or their close contacts occur after the first dose and involve the type 3 vaccine strain.[334] A significant proportion of the paralytic illnesses associated with poliovirus vaccine occurs in individuals who are immunocompromised, but this may not represent a manifestation of genetic alteration of vaccine virus.[334]

The genetic basis for the very rare increase in virulence of the poliovirus vaccine strains during replication *in vivo* is relatively well understood. However, a paradox exists in that mutation toward a higher level of virulence for the CNS occurs rapidly and frequently during replication of poliovirus in the intestinal tract of vaccinees. During manufacture of vaccine, the mutations that are associated with restoration of virulence can be detected at variable low frequency by sequence analysis, and neurovirulence of the final product can be held to a low level by rejecting vaccine lots that exceed the accepted standard for frequency of these mutations.[81] Genetic instability was also a problem with the 17D yellow fever virus vaccine during early field trials. Encephalitis was observed in 1%-2% of young vaccinees administered virus that had been passaged 20 times beyond the original seed lot.[149]

The problem of genetic instability of live attenuated virus vaccines following replication *in vivo* is an even larger concern for viruses that can cause latent or persistent infection *in vivo* such as herpes viruses or lentiviruses, for example, HIV. Despite this concern, successful vaccines have been developed for VZV, a herpes virus that causes chickenpox and zoster, indicating that a successful live attenuated vaccine can be developed for a virus that causes a lifelong infection in humans. This vaccine was licensed first for prevention of childhood chickenpox and was shown to significantly reduce the risk of VZV reactivation or shingles.[348]

Rubella virus can be recovered from the lymphocytes of immunologically normal individuals with arthritis up to 6 years after immunization or natural infection,[74] but the rubella virus vaccine does not appear to be associated with chronic arthritis.[385] Interestingly, persistence of measles vaccine virus has not been detected nor has the vaccine virus been implicated in subacute sclerosing panencephalitis.[297] Instead, widespread use of live measles vaccine has almost eradicated this rare but serious sequelae of persistent wild-type measles virus infection.

Several other concerns have been identified for live attenuated virus vaccines. First, there is a theoretical risk that infection of the fetus could occur following vaccination during the first trimester of pregnancy. For rubella vaccine, there is concern that vaccination might lead to development of the congenital rubella syndrome; however, the actual risk appears to be negligible.[355] Second, naturally occurring wild-type viruses may interfere with infection by a live virus vaccine resulting in a decrease in vaccine efficacy. Such interference has been observed primarily with live poliovirus vaccine strains and is caused by a wide variety of enteric viruses. This phenomenon has also been seen with experimental live attenuated alphavirus vaccines.[288] To overcome this viral-viral interference, multiple doses of polyvalent live virus vaccines are required to assure a protective immune response to each component. Third, defective interfering particles have been identified in preparations of live virus vaccines,[60] and it is likely that they are present in all live virus vaccines to some degree. Fourth, live attenuated measles virus vaccine has been associated with a generalized immunosuppression that was observed to be directly correlated with the level of immune response to the vaccine.[215]

Finally, it should be noted that stability is a serious practical problem with thermolabile vaccine viruses such as measles virus. The need for storage and transport of measles vaccine at low temperature (4 °C) has limited its usefulness in some tropical areas where maintenance of a "cold chain" for transport and storage is difficult. Some simple solutions for stabilizing other live virus vaccines have been identified such as lyophilization of vaccinia virus or using deuterium oxide for water in live poliovirus or influenza vaccine formulations,[216,300] but additional work is needed.

Genetic Basis for Attenuation of Live Viruses

Mutants selected by passage in an unnatural host accumulate many mutations, often making it difficult to define in a precise manner the genetic basis for their attenuation. In some cases, the molecular basis of attenuation has been defined. The genetic basis of this neuroattenuation of each of the three poliovirus vaccine strains has been partially defined.[182] Surprisingly few mutations are involved. Analyses have identified attenuating nucleotide substitutions in 5′ noncoding sequences and other attenuating in the 3′ noncoding region or in the structural or nonstructural coding regions of type 1, type 2, or type 3 polioviruses.[47,160,389] These mutations can now be monitored during manufacture and following replication *in vivo*. Vaccine lots with an increased frequency of reversion at some residues have been shown to exhibit increased neurovirulence, and such lots can be discarded as unacceptable for human use.[81] Thus, it is now possible to use molecular virological techniques to control the manufacture of vaccines by identifying the presence of the desired attenuating mutations as well as the absence, or low frequency, of unwanted reversions.[81]

The Jennerian approach to the development of live attenuated viruses involves the use of a virus strain of mammalian or avian origin to immunize humans against a human virus that is related antigenically to the animal or avian strain. Mammalian and avian viruses that are well adapted to their natural host often do not replicate efficiently in humans and hence are attenuated. This host-range restriction of course was the original principle used by Jenner for the first vaccine. At present, we lack a complete understanding of the genetic basis for this form of host-range restriction. However, those mammalian or avian viral genes that have been identified as being responsible for host-range restriction in humans exhibit significant divergence of nucleotide sequence from that of the corresponding human viral genes. Quadrivalent and pentavalent rotavirus vaccine are examples of the Jennerian approach to vaccine development in which a nonhuman rotavirus strain, the rhesus rotavirus (RRV) or bovine rotavirus (BRV), were found to be attenuated in humans. Since there was a need for a multivalent vaccine that would induce resistance to each of the major human rotavirus serotypes, the Jennerian approach was modified by constructing three reassortant viruses, each of which contained 10 RRV or BRV genes plus a single human rotavirus gene encoding one of the major neutralization Ags of the targeted serotypes.

Conventional techniques for attenuation of viruses such as passage of virus at low temperature, mutagenesis followed by selection of mutants with the desired phenotype(s), or passage of virus in heterologous tissues continue to play a significant role in the development of live virus vaccines. These techniques have been used to generate candidate vaccine strains for CMV, ortho- and paramyxoviruses, alphaviruses, flaviviruses, HAV, and arenaviruses. Selection for a combination of phenotypes (such as cold-adapted [*ca*] and temperature sensitive [*ts*]) is thought to be desirable because the different mutations can have synergistic effects on the stability of the attenuation phenotype *in vivo*.[321]

The function of viral proteins can be altered by missense mutations, insertions, or deletions. Classically, attenuated viruses were identified using biologic phenotypes: (1) *ts* mutants, (2) cold passaged (*cp*) or cold-adapted (*ca*) mutants, (3) small plaque mutants, (4) protease activation (*pa*) mutants (also designated as cleavage mutants), and (5) mutants with altered interaction with host cell receptors. With modern molecular techniques, virulent viruses also can be attenuated by a wide variety of creative approaches including gene deletion, shuffling of gene order, alteration of noncoding regulatory regions contain cis-acting signals required for efficient replication, use of gene incompatibility in chimeric genomes, and the insertion of genes that encode proteins with known antiviral activities or with known immunoregulatory functions. Viruses bearing stable, molecularly defined, identifiable attenuating mutations or attenuating gene constellations represent the vaccine strains of the future because the genetic basis for attenuation will be known and can be monitored directly during all phases of vaccine development, manufacture, and use in humans. An interesting synthetic approach to attenuating viruses uses synthesis of nucleic acid copies of viral genomes that alter the genetic code using synonymous codons, thus increasing the number of suboptimal codon pairs.[94] This method has been termed *codon pair deoptimization*. Suboptimal codon pairs cause attenuation by reducing mRNA stability and translation efficiency and thus reducing the amount of viral protein produced.[181]

Inactivated Virus Vaccines

Inactivated virus vaccines are available in the United States for the prevention of disease caused by nine separate viral agents (Table 15.1). The available vaccines are based on either whole inactivated virus or viruslike particles (VLPs) produced from purified protein. The viruses are grown in a variety of cell substrates including eggs (influenza types A and B), a continuous monkey kidney cell line (poliovirus types 1, 2, and 3), human diploid fibroblasts (rabies, hepatitis A), or mouse brain (JEV vaccine). Virus is then inactivated with a chemical such as formalin or disrupted with a detergent (influenza). The level of efficacy of inactivated viral vaccines differs—inactivated poliovirus vaccine is highly effective in preventing disease, whereas influenza virus vaccine is only partially protective.

Features of Inactivated Virus Vaccines

Inactivated virus vaccines offer the advantage of immunization with the entire antigenic content of the virus with little or no risk of infection. Only rarely do such vaccines contain a contaminating adventitious agent or residual infectious virus that has resisted inactivation. For example, paralytic disease was produced by some of the early lots of inactivated poliovirus vaccine that contained residual infectious virus.[328,341] Contamination by an infectious adventitious agent was also detected retrospectively in some early lots of inactivated poliovirus. This was of some concern because the contaminating simian virus, SV40, was oncogenic in hamsters.[211] Fortunately, long-term follow-up of individuals who were inoculated with SV40-contaminated vaccine during early infancy failed to show evidence of a vaccine-induced oncogenic effect.[441] Another incident occurred in a research setting where live vaccinia virus was found to be present in a preparation of inactivated vaccinia-HIV recombinant virus being evaluated as a therapeutic vaccine in HIV-infected subjects. Unfortunately, an immunodeficient recipient of this vaccine developed progressive vaccinia caused by residual live virus in the inoculum.[506] Several inactivated whole virus vaccines have potentiated disease rather than prevented it.[156,235] This finding was first observed with formalin-inactivated measles virus vaccine.[156] Initially, this vaccine prevented measles, but after several years, vaccinees lost their resistance to infection. When subsequently infected with naturally circulating measles virus, the vaccinees developed an atypical illness with accentuated systemic symptoms and pneumonia.[156,327] Retrospective analysis showed that formalin-inactivation destroyed the ability of the measles fusion (F) protein to induce hemolysis-inhibiting Abs, but it did not destroy the ability of the H (hemagglutinin or attachment) protein to induce neutralizing Abs.[336,337] When the H-specific Ab had waned sufficiently to permit extensive infection with measles virus, an altered and sometimes more severe disease was seen at the sites of measles virus replication.[58] This atypical disease is believed to be mediated in part by an altered cell-mediated immune response in which Th2 cells[376] or a delayed-type hypersensitivity reaction[264] were induced preferentially leading to heightened disease manifestations at the sites of viral replication. Immune-complex deposition also plays a role in the pathogenesis of atypical measles.[377]

Potentiation of disease also was observed after parenteral administration of an experimental formalin-inactivated RSV (FI-RSV) vaccine.[235] In clinical trials conducted in the mid-1960s, an FI-RSV vaccine induced a measurable serum neutralizing Ab response but did not protect the youngest vaccinees. Unexpectedly, upon subsequent natural infection with RSV, the FI-RSV vaccinees developed severe RSV lower respiratory tract disease significantly more often than did infants and young children who had received an inactivated parainfluenza virus vaccine.[235] Speculation on the mechanism of disease potentiation by the inactivated RSV vaccine has centered on several possible aberrations of the immune response to vaccine that involve an imbalance between or within various compartments of the immune system. Most likely, the protective antigenic sites on the F protein were altered by fixation, and the altered Ag induced an aberrant T-cell and cytokine response leading to enhanced disease.[171] The major lesson learned from the FI-RSV vaccine–enhanced illness is that the chemical treatment and physical purification procedures used for the preparation of each new inactivated vaccine should be evaluated not only for their effect on the magnitude of immune responses but also on the functional characteristics of the response. Typically, the Ab induced should have neutralizing activity, and the T-cell responses should mediate efficient virus clearance.

Potentiation of disease by an inactivated virus vaccine is not limited to vaccines containing measles virus or RSV and has occurred with both human and veterinary vaccines. For example, administration of an inactivated caprine lentivirus vaccine has also been associated with an accelerated, more severe disease in animals subsequently challenged with virus.[291] Vaccine-enhanced pathology is also not limited to inactivated virus vaccines. Immunization with a subunit vaccine of another lentivirus, equine infectious anemia virus (EIAV), enhanced disease caused by subsequent challenge with a heterologous EIAV strain.[217] A similar phenomenon occurred during the development of a vaccine for feline infectious peritonitis virus (FIPV). FIPV is a coronavirus (CoV) that developed more notoriety after the emergence of the SARS-CoV in 2003. Attempts to develop a vaccine against FIPV have been largely unsuccessful and have been associated with a vaccine-enhanced illness. A major problem is that Abs are not protective even when given passively for prophylaxis and can facilitate virus entry through Fc receptors. Whole virus,[360] recombinant vaccinia expressing the major surface S (spike) glycoprotein,[467] or DNA immunization with IL-12[163] all have led to enhanced disease syndromes. Immunization of ferrets with a recombinant MVA expressing the S glycoprotein has also caused an enhanced disease with hepatitis after SARS-CoV immunization. The immunologic mechanisms responsible for these examples of enhanced disease have not been identified. When SARS-CoV-2 emerged as a pandemic virus, rapid decisions had to be made about the potential for vaccines or antibodies to cause antibody-dependent enhancement (ADE) of disease. Natural infection and vaccination with immunogenic vaccines protected against disease in humans, without detectable enhancement of infection, virus replication, or disease. A thoughtful systematic review of research on ADE was published during the COVID-19 pandemic.[15]

Another disadvantage of inactivated virus particle vaccines is that they typically must be given parenterally because without replication or gene expression, it is difficult for mucosally delivered Ag to induce strong responses. Parenteral induction of systemic immunity may not fully protect against viruses that infect and cause disease primarily at mucosal surfaces if the gradient of Ab between serum and mucosa is too large or the kinetics of viral entry are too rapid. Therefore, resistance to viral challenge in the upper respiratory tract or in the intestines usually is less robust than that conferred by local immunization or infection. This may be the reason inactivated influenza vaccines are only partially protective, and why the IPV can prevent paralytic polio but cannot prevent poliovirus infection and intestinal carriage. There are clear exceptions to this principle, best exemplified by the success of parenterally administered HPV vaccine. Although HPV is a purely mucosal pathogen, entry into basal epithelial cells is a two-step process that may take several hours.[238] Virus neutralization can be accomplished with much less Ab when given longer access to the viral antigenic sites.

Inactivated virus vaccines are clearly at a disadvantage compared to either live attenuated virus vaccines or vector-based gene delivery with respect to induction of a CTL response. CD8 CTL responses require Ags to be processed through the proteasome so that peptides can be transported into the endoplasmic reticulum and associate with MHC class I molecules. This is best achieved when proteins are synthesized in the host cell cytoplasm and is rarely achieved in primates when Ags enter the APC through the endocytic pathway. For example, inactivated influenza virus is considerably less effective than virus infection in stimulating a primary CTL response in mice. However, inactivated influenza A virus or purified surface glycoproteins derived from it can sometimes stimulate a secondary CTL response in sensitized mice or humans.[1,135] There are new adjuvants and delivery vehicles that have the capacity for moving purified proteins into the MHC class I presentation pathway, and these may be considerations for future vaccine development.

The Guillain-Barré syndrome (GBS) was associated with widespread use of inactivated influenza A H1N1 (swine) virus vaccine during 1976 and 1977.[258] GBS does occur rarely in the population, but the attributable risk was estimated at one additional case of GBS for every 100 000 doses administered. This finding suggested that unanticipated, delayed, or untoward side effects can be induced by inactivated virus vaccines. This syndrome has been associated only rarely with subsequent influenza virus vaccines. Most studies show no association. But two studies since 1976 reporting positive findings suggested a risk estimate of about one additional GBS case per 1 million persons vaccinated, and this risk has been stated by the Advisory Committee on Immunization Practices recommendations. The occurrence after use of vaccines against the 2009 H1N1 pandemic strain also is negligible, even though these products were prepared in the same manner as the 1976 vaccine.[258] The basis for the idiosyncratic syndrome associated with the 1976 influenza vaccine is still not defined.

Future Considerations for Inactivated Virus Vaccine Development

Formaldehyde, heat, and oxidation have been shown to produce reactive carbonyl groups on protein Ags that promote CD4 T-cell responses with Th2 differentiation.[302] Chemical inactivation of poliovirus during vaccine manufacturing can result in modification of a major neutralization epitope. Therefore, inactivating infectivity of nonenveloped as well as enveloped viruses can adversely affect the antigenicity of the vaccine.[140] It has also been recognized that antigenic changes can occur during selection and amplification of influenza viruses in the allantoic cavity of embryonated eggs, the substrate used to produce virus for the inactivated vaccine.[392] The genetic basis for these mutations involves host cell selection of mutants that replicate more efficiently in eggs. These variants acquire a mutation in or near the receptor-binding pocket of the HA that increases their efficiency of replication in eggs but also alters antigenicity and immunogenicity. Nevertheless, influenza viruses used to prepare inactivated vaccine for humans are often grown in eggs, and such vaccines have been repeatedly shown to be protective. While this would not be a problem for influenza vaccines produced in mammalian cell culture, vaccine Ags may be modified or processed in ways that compromise antigenicity even in mammalian cell substrates. For example, poliovirus grown in tissue culture contains an uncleaved outer capsid protein VP1, which is usually cleaved in a natural infection by intestinal proteases. Although tissue culture grown poliovirus has limited ability to induce Abs that neutralize viruses containing a cleaved VP1,[393] both cleaved and uncleaved VP1 can induce protection from replication of subsequently administered live attenuated poliovirus vaccine.[366] Nevertheless, careful assessment of the substrate-dependent antigenicity and consequences of inactivation is warranted in the development of inactivated virus vaccines.

Viruslike Particle Vaccines

There are licensed VLP vaccines for two viral pathogens in the United States (HBV and HPV) and a vaccine for hepatitis E approved in China in 2017 (HEV 239). VLPs are produced as self-assembling capsid proteins in yeast or insect cells. The term VLP was coined in 1955 after studies of reconstitution of active tobacco mosaic virus.[150] For the purposes of this section, we will define VLP as self-assembling viral proteins that can mimic the particle structure of virions and present the quaternary structures of oligomeric viral surface proteins but do not package the virus genome. There are other self-assembling nonviral proteins that can be used to display vaccine Ags that are mentioned with nanoparticles under Delivery Vehicles section.

The initial version of the HBV vaccine was based on surface Ag purified from the blood of persons persistently infected with HBV. The Australian antigen was associated with the disease caused by HBV, and later the Dane particle was found to represent the Australia antigen. Interestingly,

electron microscopy revealed not only the Dane particle, which is a 42-nm structure representing the complete infectious virion, but also smaller particles and filaments. The 22-nm particle was found to be composed of just the hepatitis B surface antigen (HBsAg) and is noninfectious because it does not contain nucleic acid. This small particle, purified from human plasma, was the first licensed HBV vaccine. An effective second-generation HBsAg vaccine was developed using a recombinant plasmid to express the gene for HBsAg in yeast. Yeast-produced HBsAg self-assembles into uniform 22-nm particles. Although the 22-nm noninfectious particle is smaller in size and technically a defective genomeless subvirion particle, it is considered a VLP because it is made of the same capsid protein (HBsAg) as the full particle. Licensed HBV VLPs are formulated with alum and are now part of the routine pediatric vaccine schedule. This vaccine often is protective against HBV infection and hepatitis even in the absence of detectable Ab response. Immunization against HBV also significantly reduces the frequency of hepatoma and is regarded as the first anticancer vaccine.[72] The immunogenicity of HBV VLP in patients with renal failure, HIV-1 infection, or other immunocompromising conditions is diminished. New adjuvant approaches such as formulation with CpG (TLR9 agonist), MPL+alum, or MPL+QS21 are being explored to improve vaccine-induced immunity in those settings.[35,36,100] HBV VLP are now produced for human used in nine countries using yeast, bacteria, or mammalian cells for manufacturing, and other substrates including transgenic plants are being explored.[395]

HPV particles were first identified by electron microscopy in 1949. In 1983, the association between HPV infection and cervical dysplasia and malignancy was proven.[129] In 1991, it was shown that VLPs lacking genomes could be produced by expression of the L1 and L2[509] or just the L1[239] capsid proteins of papillomaviruses. L1 self-assembles into pentamers and each VLP is composed of 72 pentameric capsomeres. If present, one L2 protein is associated with the center of each L1 pentamer on the inner surface of the capsid. These key discoveries led to the development of candidate VLP vaccines. Importantly, the end points for the efficacy trial were chosen carefully. While prevention of cervical carcinoma was the goal, this target was not an acceptable end point because ablative treatment would be performed if premalignant lesions were detected. Therefore, cervical intraepithelial neoplasia (CIN) grade 2 or higher was used as the end point for vaccine efficacy trials, as a surrogate for cervical carcinoma. Prevention of persistent serotype-specific HPV infection was also a primary end point. Yeast-produced HPV 16 VLP formulated in alum and delivered parenterally was 100% effective in preventing CIN.[249] A three-dose regimen of a tetravalent L1-based VLP vaccine based on HPV 16 and 18 (most common cause of CIN) and HPV 6 and 11 (most common cause of anogenital warts) is also highly effective.[469] Subsequent studies have shown that HPV VLP immunization can prevent HPV-induced cervical lesions in women[382] and anogenital lesions in both women and men.[159,162] Three doses containing 30 μg of each of the four VLPs formulated with aluminum hydroxyphosphate sulfate (Gardasil) or 20 μg of each of two VLPs formulated with a mixture of aluminum hydroxide and 3-deacylated MPL (AS04) (Cervarix) are sufficient to achieve protective immunity that is durable for >5 years.[396] The protection has been correlated with type-specific neutralizing Ab. First-generation bivalent or quadrivalent vaccines immunized against two or four HPV types, but women were still exposed to additional high-risk HPVs that cause 30% of cervical cancer. The FDA approved a second-generation nonavalent HPV vaccine (Gardasil 9) that protects against an additional five high-risk HPVs (HPV types 31/33/45/52/58). The vaccine is highly immunogenic and may prevent ~20% more cervical cancers than the original vaccines.[415]

Advantages of Viruslike Particle Vaccines

Capsid proteins from many nonenveloped viruses and the nucleocapsid or matrix proteins together with surface proteins from some enveloped viruses can self-assemble into VLPs and provide a platform technology that may be applicable as vaccines for multiple virus families. VLPs offer several advantages as immunogens. First, the viral nucleic acid is not present in VLPs, so there is no concern that viral oncogenes or other pathogenic features of the live virus are present. Second, VLPs present conformational epitopes to the immune system in the same way as native infectious particles so that neutralizing Abs and other protective immune responses are induced efficiently. Some of these epitopes are formed by the juxtaposition of parts of two different capsid proteins. Third, many of the nonenveloped viruses from which immunogenic VLPs have been developed replicate poorly or not at all in tissue culture (eg, B19 parvovirus, papillomaviruses, and hepatitis E virus), thus precluding use of purified virus as immunogen. Fourth, because VLPs are noninfectious, chemical inactivation is not required. For this reason, VLPs might prove to be better immunogens than formalin-inactivated whole virus vaccines because the deleterious effects of formalin on structure and immunogenicity can be avoided. Fifth, the immune system responds better to a viral Ag presented as an assembled multimeric particle rather than as an individual monomeric protein. Sixth, the stability of VLPs from nonenveloped viruses may simplify vaccine storage and distribution and make successful oral delivery feasible in some cases.[332]

Disadvantages of Viruslike Particle Vaccines

The major disadvantage of VLP vaccines is related to the cost and complexity of manufacture, although costs should become lower with advances and expansion of the options for cell substrates. The biological disadvantage of VLPs compared to replication-competent viruses or vectors is that there is not ongoing production of Ag following vaccination. However, these particles tend to be highly antigenic and stable, and immunogenicity can be enhanced with adjuvants.

Future Considerations for Viruslike Particle Vaccine Development

VLPs have been engineered successfully for viruses belonging to a wide range of virus families, including both nonenveloped and enveloped viruses. Because of the advantages listed above and track record of success, they should be considered as a vaccine platform technology for other virus families when possible. VLPs have been synthesized in many expression systems as diverse as bacteria, yeast, plants, insect cells, and mammalian cells.[335] VLP-based vaccine candidates are being developed for prevention of many viruses,[450] including hepatitis B,[436] Ebola virus,[460] SARS-CoV-2,[500] the flaviviruses dengue and Zika, enterovirus A71, HIV, and influenza, among others.[20]

Nonenveloped Viruslike Particles

The first characterization of synthetic VLPs followed the observation that picornavirus capsid proteins could self-assemble during the *in vitro* translation of viral RNA to yield 75S to 85S particles.[351] Later studies indicated that VLPs could form *in vitro* following translation of picornavirus viral RNA lacking most of the 5′ noncoding region.[87] Next, it was observed that expression of the open reading frames of capsid proteins of nonenveloped viruses by a baculovirus or vaccinia vector in appropriate eukaryotic cells resulted in generation of VLPs.[88,239,509] For picornaviruses, particle assembly requires expression of the entire open reading frame to permit the proteolytic processing of the structural proteins by nonstructural viral-encoded proteases. There are current vaccine development approaches being used for enterovirus 71 that involve

VLP technology.[85]

Human parvovirus B19 causes erythema infectiosum, acute and chronic red cell aplasia, and other illnesses. A vaccine candidate consisting of the human parvovirus B19 VP1 and VP2 capsid proteins that form VLPs is being developed.[24] Immunization of humans with this vaccine induces neutralizing Abs that achieve levels that are equivalent in magnitude and neutralizing activity to those seen following natural infection.[46] Antigenic VLPs can be readily produced for other human (bocavirus)[71] and veterinary parvoviruses,[395] suggesting that VLP-based vaccines may be an appropriate approach for pathogens for this viral family.

Norovirus, the prototypic member of the calicivirus family, also may be a good candidate target for a VLP vaccine. The virus is a 28- to 37-nm nonenveloped particle that is formed by a single major capsid protein (VP1). VP1 is a protein with two domains connected by a short linker. The P domain forms the outer surface of the particle, and the S domain forms an inner shell. The P portion of VP1 can self-assemble 24 protomers to form a 20-nm particle that is immunogenic.[447]

Enveloped Viruslike Particles

Expression of the nucleoprotein or matrix proteins of some enveloped viruses has also resulted in the production of VLP or virus pseudoparticles. This finding was noted first for the Gag protein of HIV when it was expressed in recombinant vaccinia-infected cells.[192] Production of purified HIV pseudovirions is being developed as a vaccine strategy,[137] and the construction of vectors that are competent to produce pseudovirions *in vivo* may improve immunogenicity beyond that of the simple expression of the isolated gene products.[77,197] VLPs have now been produced for several respiratory viral pathogens. Expression of M1, M2, NA, and HA can form influenza VLPs,[259] but HA is sufficient in the presence of NA.[76] These are potent immunogens that can be constructed to express Ags that can confer broad cross-reactivity[434] or TLR agonists that can provide adjuvant properties.[473] SARS-CoV pseudoparticles are formed by transfection of 293 cells with the M (membrane) and N (nucleocapsid) genes.[213] The M protein of Newcastle disease virus (NDV) is sufficient to produce VLPs[353] that can support the incorporation and display of RSV F and G and is immunogenic and protective in animal models.[290] The NDV VLPs appear to be a stable platform for presentation of viral glycoproteins from other viruses as well.[307] Alphaviruses and flaviviruses are also potential viral targets for VLP vaccines. For example, West Nile virus pseudoparticles are formed by coexpression of prM and E.[199] Chikungunya virus VLPs were produced that protected rhesus macaques from lethal challenge.[3]

Novel chimeric particles in which viral Ags are built onto the hepatitis B core VLP[45] are immunogenic in mice. Relatively large structures can be mounted on the recombinant VLPs if inserted covalently into the outer loops or attached through chemical conjugation in the right place and orientation to allow access to the vaccine Ag being displayed. Other chimeric VLPs can be constructed by inserting candidate vaccine Ags into the variable loops that face outward including norovirus P particles,[446] chikungunya virus,[3] or others and could be selected based on the desired particle size and Ag valency (Fig. 15.5).

FIGURE 15.5 **Variations on VLP particle size and structure**. VLPs assume a wide range of sizes and are shown here as images derived from cryogenic electron microscopy. Hepatitis B (HBV),[126] hepatitis E (HEV),[497] bovine papillomavirus (PV) representative of other PVs,[488] and chikungunya (CHIKV)[3] are shown by order of increasing size.

Other Vaccine Approaches

Molecular biology has been an important stimulus for new approaches to make live attenuated virus vaccines and has also provided avenues for production of subunit vaccines and gene delivery vehicles that express viral Ags, especially mRNA (e-Fig. 15.6). MAb and recombinant DNA and mRNA technology are now used routinely to produce large quantities of purified viral Ags for use in immunoprophylaxis. MAb immunoaffinity chromatography or lectin chromatography facilitates purification of viral Ags from infected cells, while recombinant DNA technology makes it possible to express viral proteins in eukaryotic cells of yeast, fungal, insect, or mammalian origin. The use of these techniques has yielded candidate vaccines encompassing a large array of viral proteins that can induce protective Abs in experimental animals. Immunization by gene delivery is emerging as an important way to mimic certain aspects of live virus infection and can be accomplished by a growing list of delivery methods.

Vaccination With Proteins or Peptides

There are several theoretical advantages to immunizing with selected viral Ags instead of using whole virus particles. Production of recombinant viral proteins or synthetic peptides diminishes the risk of contamination by unrecognized pathogens. In addition, the preparation of vaccines free of nucleic acid eliminates theoretical concerns about recombination or integration of viral nucleic acid. Immunizing with individual Ags or epitopes from the virus might also reduce antigenic competition and focus the response on the most relevant protective antigenic sites.

Production of Viral Proteins in Eukaryotic Cells

Before expression of viral proteins in eukaryotic cells can be used as a method for vaccine production, several obstacles must be overcome. First, it is essential to identify the correct immunogen. Second, it is necessary to produce protein in a highly efficient manner to make this approach economically feasible. Mechanisms to enhance expression of viral proteins that have been pursued focus primarily on identification of strong promoters of gene expression and development of techniques for efficient gene amplification. Third, viral proteins must be separated effectively from host cell protein, DNA, and endogenous adventitious agents. Lastly, the proteins must be produced with the desired structure and activity. This latter requirement is of special concern since immortalized mammalian cell lines are ideal for producing viral proteins because posttranslational modifications are more likely to be authentic than when these proteins are produced from prokaryotic hosts. Host cell DNA must be greatly reduced in the final vaccine (FDA guidance is <10 ng per dose) to reduce the theoretical potential for oncogenic events. Additionally, removal and inactivation of endogenous viruses must be performed for products made from continuous rodent and other mammalian cell lines. Recombinant DNA techniques to promote secretion of viral glycoproteins into the medium have been developed to facilitate effective separation of viral proteins from host cell proteins. Fourth, the procedures used to produce and purify viral protein must be gentle enough to maintain the protein in its native state thereby preserving conformationally dependent neutralization epitopes needed to induce protective Abs. Finally, because purified monomeric proteins are typically weak immunogens, they need to be formulated with adjuvants

or produced as oligomers or particles to enhance their immunogenicity. The following discussion of these approaches is not intended to be exhaustive in scope but illustrative of current strategies in use or in development.

Recombinant DNA techniques are commonly used to express viral proteins in yeast, insect, or mammalian cells. The usefulness of yeast expression to produce the HBV vaccine has been described above, and yeast is also used to produce HPV VLPs.[271] Some viral proteins such as the rabies G glycoprotein are more difficult to produce in yeast.[408]

A major advance in viral Ag production has been the development of baculovirus vectors to express foreign genes to high levels in insect cells under control of a strong baculovirus promoter such as the polyhedrin promoter.[274] Protein can be produced in large quantity (1 mg/10^6 cells) using this system. Viral glycoproteins also can be produced in this system. For example, baculovirus-produced influenza hemagglutinins can be produced efficiently and have equivalent or superior immunogenicity to the traditional trivalent split product in adults.[30] Influenza HA–based protein vaccines produced in insect cell culture have been approved in the United States since 2013 (Flublok or Flublok Quadrivalent). The baculovirus system also can be used to express more complicated viral immunogens that require polyprotein processing to generate native immunogenic surface proteins. An example of this is expression of the entire structural protein region (C-E3-E2-6K-E1) of an alphavirus to generate authentic, processed viral proteins capable of inducing an efficient neutralizing Ab response in experimental animals.[209]

Mammalian cells also have been used to produce viral proteins that can be incorporated in a subunit vaccine. Mammalian cell cultures represent an optimal system to produce viral proteins because protein folding, transport, and processing closely approximate those that occur in the infected host. Initial approaches were to purify viral proteins from infected cells or from cells transduced with a recombinant virus expression system engineered for high level of expression of the foreign viral Ag[153,154] or by transient transfection with DNA. Cell lines have been developed that can stably produce recombinant proteins or Abs, can be modified for large-scale production, and have achieved regulatory approval for clinical products.

Chinese hamster ovary (CHO) cells have long been a preferred cell line to produce protein-based therapeutics.[459] These cells have been used to produce viral glycoproteins from HIV and HSV that have been advanced to efficacy trials[147,388,438] and can be modified to improve the manufacturing efficiency and capacity even further. Immortalized human cell lines derived from healthy human embryonic material have also emerged as producer cell lines for protein production such as 293 and PER.C6. Both lines have been used extensively to produce gene delivery vectors, have fully documented passage histories, and have had no adventitious agents or oncogenic or teratogenic potential identified to date. PER.C6 was derived from embryonic retina cells and immortalized with the adenovirus E1 gene. 293-ORF6 has a similar development history and contains the adenovirus open reading frame 6 from E4 as well as the E1 gene.[59] These fully human cell lines may provide advantages for producing virus glycoproteins that authentically replicate the structures present in human infection, can be adapted to different growth conditions, and can stably produce high levels of recombinant protein without gene amplification.[223] In general, identifying immortalized human cell line platforms to produce proteins, VLPs, whole virus, or vaccine vectors will be preferable to using primary cell lines that have to be revalidated repeatedly or using less efficient production methods that require transient infection or transfection.

Production of Viral Proteins in Prokaryotic Cells

Production of immunogenic viral proteins in prokaryotic cells is difficult and requires extensive re-engineering of the gene to achieve immunogenic structures because of differences in protein processing and in microenvironment. However, there have been some notable successes, particularly in the production of VLPs. A portion of the structural protein from hepatitis E ORF2 produced in *Escherichia coli* self-assembles into particles and was shown to be efficacious in a 100 000-person study.[511]

Production of viral proteins in plant cells

Plants have been modified genetically to express virus proteins[68,444] and VLPs[110] some of which have advanced to clinical trials. Plants can be engineered with selected mammalian glycosidases to provide more authentic posttranslational modifications.[440] The major advantage of this approach is the potential for inexpensive and widely distributed manufacturing capacity.

Protein Purification

Immunoaffinity chromatography, lectin chromatography, and physical separation techniques have been used to purify a variety of viral glycoproteins that have induced partial to complete protection in animals. When directly compared in animals, protection induced by immunization is greatest when the purified viral glycoprotein is in its native conformation.[463] In the case of RSV and EBV, purified glycoprotein vaccines induced Abs that were able to bind to glycoprotein in enzyme-linked immunosorbent assays (ELISA), but these Abs had a very low level of neutralizing activity.[323,487] In contrast to purified protein immunogens, RSV glycoproteins expressed by a vaccinia virus RSV F or G recombinant induced a titer of neutralizing Abs comparable to that developed by animals infected with the virus.[96] Observations of this type underscore the potential importance of quaternary structures and presentation of proteins in the context of membranes and organized on particles to achieve functional Ab responses.

Synthetic Peptides as Immunogens

During the early 1970s, the use of synthetic peptides as immunogens was studied using a synthetic icosapeptide representing the immunodominant domain of the outer coat protein of bacteriophage MS-2.[257] A 56 aa peptide from the stem region of the influenza hemagglutinin can induce Abs to a conserved epitope that has some cross-neutralizing activity.[477] However, the immunity induced by peptides is usually less than that achieved when full-length protein, inactivated whole virus, or live virus was used as immunogen.

The fact that CD8 T-cell epitopes are short peptides of 8-10 amino acids in length presented in the context of the MHC class I heterodimer suggested that it might be possible to produce peptide vaccines to induce CTL-mediated immunity.[132] CTL induction by peptide vaccines has been achieved in several experimental systems. For example, a peptide, in adjuvant, induced CTLs and protected mice against Sendai virus infection.[232] An epitope-based vaccine candidate termed Multimeric-001 (M-001) is a single recombinant protein that consists of three repetitions of nine conserved linear epitopes from HA (four B-cell and one CD4 T-cell epitopes), NP (two CD8 T-cell and one CD4 T-cell

epitopes), and M1 (one peptide containing both B-cell and CD8 T-cell epitopes), which were derived from influenza A and B strains expressed in *E coli*.[34] Preclinical studies in animals showed protection, but a phase 3 clinical trial completed in October 2020 failed to meet the trial's primary and secondary efficacy end points. Thus far, peptide vaccines have not achieved significant immunogenicity when used in immunologically naive humans unless formulated in preparations with strong adjuvants that are associated with unacceptable reactogenicity. Also, in general, the reductionist approach to vaccine Ags has not been successful when tested in humans. In general, it is better to use a larger antigenic content in vaccines for viruses, so each individual host can select the most relevant and effective epitopes for themselves. This principle is also consistent with the concept that vaccination has its largest impact on public health at the population level. Developing tailored, personalized vaccination approaches may be in the distant future for preventive antiviral vaccines, and this type of approach is currently being explored for therapeutic vaccines against neoplasms and some chronic virus infections. Indeed, immunization with mixtures of long peptides derived from HPV E6 and E7 oncoproteins formulated in IFA has led to remission of HPV16-induced vulvar intraepithelial neoplasia.[233]

Vaccination by Gene Delivery

The age of molecular biology has made it possible to build expression vectors that can serve as a vehicle for gene delivery of vaccine Ags. The development of this technology is attractive because it combines the immunogenicity advantages of live vaccines and the safety advantages of nonliving vaccines. Genes can be modified to be nonfunctional and harmless to the host, improve expression, and yet retain the antigenicity of the expressed protein. Using the host cell for transient protein production provides the opportunity for expression of more native structures than are possible with *in vitro* protein production including glycosylation patterns that may influence antigenicity. Genes can be produced synthetically so that no component of the original virus pathogen is needed in the manufacturing process to avoid the potential complications of infection with live viruses or adventitious agents. Selected immunogenic components of the pathogens can be expressed and combined with molecular adjuvants that enhance and guide the composition of immune responses. In addition, the mechanisms that viruses use to evade or alter immune responses can be removed, or genes can be modified (eg, by adding ubiquitination sites) to improve processing and Ag presentation.[433] Therefore, it may be possible to improve on the immunity afforded by natural infection by using vector-based expression of viral Ags. New delivery approaches, including vector technology, provide the opportunity to combine Ags from multiple strains or different pathogens to potentially allow broadening of vaccine-induced immunity while simplifying vaccination regimens. They can be categorized by their functional properties (e-Fig. 15.7) and other features that may influence vaccine strategies for a particular virus (e-Table 15.2).

e-FIGURE 15.7 **Functional characteristics of vectors used for gene expression.** Vectors used for gene delivery have several different properties that may have advantages or disadvantages for a given vaccine development project. For example, replication competent vectors may have advantages if the major goal is direct induction of mucosal immunity. If the vaccine Ag being expressed is large or has a complicated secondary RNA structure, some vectors may be preferred based on insert capacity or whether nuclear or cytoplasmic transcription utilized.

e-TABLE 15.2 Considerations for vaccine vector selection

Nucleic Acid Vaccines

The concept of using mRNA or DNA to deliver vaccine Ags has many attractive features, including ease and flexibility of construction, scalable manufacturing capacity, stability, production of vaccine Ag in host cells, transient expression, no induction of antivector immunity, and induction of a balanced CD4 and CD8 T-cell response in addition to an Ab response. Gene-based immunization promotes host cell synthesis and expression of the vaccine Ag and physiologic posttranslational processing and folding in the cell cytoplasm. Immunization with mRNA or DNA has some theoretical advantages over immunization with purified viral Ags. The most important advantage is that vaccine Ags such as viral glycoproteins can be expressed on the surface of transfected cells and are presented to the immune system in a native state. During the processes of purification of viral proteins, purification and assembly of VLPs, or inactivation of viruses with chemicals, epitopes on viral proteins can be altered compromising immunogenicity. Gene-based immunization, which circumvents these problems, more closely resembles immunization with a live virus vaccine than with an inactivated viral Ag. Viral Ags encoded by nucleic acids, whether entire proteins or minimal CTL epitopes, are presented efficiently in the context of MHC class I molecules and are able to induce CD4 T cells and CTLs.[70,261,282,504] In this way, it is possible to induce a balanced immune response more like immunity induced by natural infection than to immunity induced by administration of preformed viral Ags. A second advantage of immunization with nucleic acids is their ability to transfect cells without interference by antiviral or antivector Abs. Live attenuated vaccine virus, such as that present in the measles virus vaccine, is effectively rendered noninfectious by Abs. Likewise, Abs to gene delivery vectors, such as adenovirus serotype 5 (Ad5), can diminish the immunogenicity of this approach, while mRNA or DNA immunization is not affected by preexisting Abs.

mRNA Vaccines

Lipid nanoparticle (LNP)-encapsulated nucleoside-modified mRNAs have recently deployed as a robust vaccine platform, exhibiting exceptional potency and rapid developability. The development of mRNA vaccines during COVID-19 was astoundingly rapid but was based on decades of fundamental research. RNA was used for synthetic gene expression as early as the 1970s, but typically induced cell programs that inhibited expression after triggering of TLRs. Karikó and Weissman determined that the use of modified RNA (such as substituting uridine with the analogue pseudouridine) reduced cellular recognition of the foreign RNA and enhanced protein expression. Delivery systems also needed to be developed to protect RNA (which is susceptible to rapid degradation in biological matrices) and to deliver the RNA into target cells. Investigators discovered various combinations of lipids that could cover synthetic mRNAs forming lipid nanoparticles. Particular lipids in these mixes also have adjuvanting effects, which allowed development of prototype viral vaccines starting with influenza, and later Ebola and other viruses. By early 2020, the company Moderna had advanced nine mRNA candidates for infectious diseases into the clinic. Soon thereafter, the COVID-19 pandemic occurred and SARS-CoV-2 vaccines to prevent COVID-19 were rapidly developed by Moderna and Pfizer-BioNTech using nucleoside-modified mRNAs encoding prefusion stabilized spike protein and incorporated into LNP vaccines (Fig. 15.6). The vaccines are highly effective and were rapidly approved by U.S. and European regulatory bodies in 2021. These vaccines are remarkably immunogenic, protective, and safe,[18,378] although the durability of the antibody response is short, requiring multiple boosters to sustain maximal serum antibody levels. Many other LNP-mRNA vaccine candidates are now being studied, and some have already been shown to be effective against diverse pathogens in preclinical studies. Several clinical studies are underway to prevent viral diseases including studies of mRNA vaccines for human CMV (ClinicalTrials.gov identifier NCT04232280) or human RSV (ClinicalTrials.gov identifier NCT04528719). Interestingly, antibodies for viruses also can be delivered by mRNA LNP preparations; the first soluble protein delivered to humans by mRNA was a human mAb to chikungunya virus tested in a phase 1 trial in 2019.[17]

FIGURE 15.6 **Prototype of a COVID-19 mRNA lipid nanoparticle vaccine**. The figure represents the constituents of the Moderna Spikevax vaccine. The mRNA is a nucleoside-modified mRNA encoding the spike of SARS-CoV-2. All uridines are substituted since modified nucleosides in the mRNA make it less inflammatory and more translatable. The mRNA is encapsulated in lipid nanoparticles comprising an optimized lipid mix containing polyethylene glycol, 2000 dimyristoyl glycerol, 1,2-distearoyl-sn-glycero-3-phosphocholine, cholesterol, and SM-102 (proprietary) that stabilize the mRNA and facilitate its entry into cells.

DNA Vaccines

It was originally found to be possible to express transgenes by direct intramuscular or intradermal inoculation of plasmid DNA in the early 1990s.[448,489] The first demonstration of DNA vaccine protection against a virus was in mice challenged with influenza.[305] Subsequently, immunization with DNA that encoded viral Ags, including Ags that can form VLPs, from a wide range of viruses has induced functional (ie, neutralizing or syncytium-inhibiting) Abs and/or resistance to viral infection.[122] For these reasons, DNA vaccination can elicit both CD4 and $CD8^+$ T lymphocyte responses with a variety of immunogens in animal models. DNA immunization in humans has induced significant neutralizing Ab[261,282] and T-cell responses.[176] The delivery process is partially improved by using newer delivery devices and new approaches incorporating sonoporation with sound waves or electroporation, which offer the potential for improved potency of DNA vaccines.[416] DNA vaccines have not been approved, however, for human use. One veterinary DNA vaccine was licensed in 2005 by the USDA, an equine vaccine for West Nile virus. The major factor limiting the immunogenicity of DNA vaccines is inefficient transfection of cells in a way that achieves transport of genes into the cell nucleus. DNA is a large, charged molecule that is only active in the cell nucleus.

Replication-Competent Vectors

The molecular technologies that have made gene delivery possible in general have been applied to the development of stable attenuated virus vaccines, some of which have been used to construct viable recombinants that express the surface proteins of other viruses, thus blurring the distinction between live attenuated viruses and vaccine vectors. Chimeric or live recombinant virus vectors can be designed to deliver the foreign gene from a virulent pathogen in the context of a nonpathogenic expression system, thereby improving safety. The vector design can also consider manufacturing issues to improve overall production efficiency. The use of a viral vector for immunization has the advantage that the foreign viral Ags are expressed naturally in the context of an infected cell thereby inducing cellular as well as humoral immune responses. Vector selection and design can focus vaccine Ag expression to a particular target cell or immunological compartment to tailor the organization of an immune response to a particular pathogen. Delivering the vaccine Ag in a complex structure has the benefit of broadly engaging both the innate and adaptive immune responses to better simulate the immunity to natural infection. Replication-competent vectors have additional immunogenicity advantages over replication-defective vectors because more prolonged Ag expression and more diverse stimulation of TLR pathways often translates into better Ab production and more durable immune responses.

Chimeric live virus reassortant and recombinant vaccines

Two major platforms have emerged to create chimeric viruses. One is based on reassortment of genes that occurs in segmented RNA viruses and is used in two currently licensed vaccines. The other utilizes reverse genetic systems developed to make molecular clones of viruses with nonsegmented RNA genomes. Live attenuated chimeric virus vaccines are distinguished from live viral vectors because the viral vaccine Ag being expressed is derived from the same virus family and replaces the homologous protein from the virus that supplies the coding and noncoding regions constituting the replication competent particle.

The rhesus and bovine rotavirus vaccines are examples of live attenuated chimeric viruses produced by reassortment. The chimeric viruses contain the attenuating background of the rhesus or bovine rotavirus plus the gene for a human rotavirus VP7 surface protein. Similarly, the live attenuated influenza virus vaccines are chimeric viruses, which can be antigenically updated by replacement of the HA and NA genes of the attenuated donor virus with those of a new epidemic or pandemic virus. This process was utilized in the response to the 2009 H1N1 pandemic. While the replication of A/California/7/2009 H1N1-like isolates in eggs was relatively low, the chimeric live virus produced as FluMist had outstanding growth properties that facilitated production.

Construction of recombinant live attenuated chimeric virus vaccines by gene replacement in molecular clones has mostly used flaviviruses or paramyxovirus backgrounds. For flaviviruses, a live attenuated virus vaccine candidate for JEV has been made by the replacement of genes encoding the membrane precursor (prM) and envelope (E) proteins of the attenuated yellow fever vaccine virus (YFV) with those from an attenuated strain of JEV. The resulting JEV-YFV antigenic chimeric recombinant vaccine candidate was attenuated and immunogenic *in vivo*.[185] Both components of this chimeric virus came from attenuated viruses. It has now been evaluated in advanced clinical trials[303] and is being submitted for registration.[188] Chimeric recombinant candidate vaccines have been made between a naturally attenuated tick-borne flavivirus (Langat virus) and a wild-type mosquito-borne dengue type 4 virus (DENV-4), and the resulting recombinant was found to be significantly more attenuated than its tick-borne parent virus for mice.[371] This is an example of an attenuating effect that stems from partial incompatibility between the two components of the chimeric virus. A third strategy is being pursued to produce a tetravalent dengue virus vaccine in which a DENV-4 background containing an attenuating deletion mutation in the 3′ noncoding region is used to construct antigenic chimeric viruses containing the surface proteins of other dengue serotypes.[294] Alternatively, the 3′ attenuating mutation is reproduced in the other serotypes. Chimeric flavivirus constructs appear to be a stable and effective vaccine platform for these types of viruses. A tetravalent, live attenuated dengue vaccine based on the attenuated DENV-4 background is immunogenic in humans and has been evaluated in advanced clinical trials.[188,324] A dengue vaccine containing a chimeric YFV 17D strain expressing prM and E from each of the four dengue serotypes (designated CYD-TDV; Dengvaxia) has been approved for use in persons previously infected with dengue. This vaccine is only intended for use in previously infected individuals and is partially effective in preventing infection. Inadvertent vaccination of dengue-naive individuals, however, may lead to a higher risk of severe disease during subsequent natural infection.

A chimeric virus containing the HN and F surface proteins of parainfluenza virus type 1 substituted for those of an attenuated PIV3 virus has been constructed and shown to be attenuated and protective in experimental animals.[449] Both bovine and human PIV3 chimeras are being pursued to make vaccines against several other paramyxoviruses including PIV1, -2, and -3; RSV; metapneumovirus; and measles virus. Both human and bovine PIV3 are very amenable to use as a background for chimeric paramyxovirus vaccines, but other paramyxoviruses are also being developed as vaccine vectors including Sendai virus, Newcastle disease virus, canine distemper virus, and measles virus.[214] Paramyxoviruses have also been constructed as vectors to deliver vaccine Ags from unrelated viruses such as HIV or Ebola.[118]

Poxvirus vectors

Vaccinia virus is the most used recombinant vector to date.[311] Poxviruses have large genomes into which a variety of foreign viral genes can be inserted and expressed without seriously compromising the capacity of vaccinia virus to replicate. Recombinant vaccinia viruses expressing the surface protein(s) of many viruses have been constructed and shown to be protective in experimental animals. Polyvalent live vaccinia virus recombinants have been used to successfully immunize experimental animals, even in the presence of immunity to one of the foreign viral Ags,[144] and vaccinia-rabies virus recombinants are being used to control rabies in foxes[358] (e-Table 15.3). Recombinant vaccinia has been evaluated in clinical trials,[172-174] but they are not sufficiently attenuated for use in immunocompromised hosts[139,184,386] and are complicated by other idiosyncratic side effects like myopericarditis.[14] However, new versions of attenuated replication-competent poxvirus vectors like the Tiantan strain of vaccinia have been constructed as candidate HIV vaccines and are currently being evaluated in clinical trials in China.[113]

e-Table 15.3 Licensed veterinary viral vaccines

Herpesvirus vectors

Herpesvirus vectors have been developed using herpes simplex virus type 1 (HSV-1), EBV, CMV, and some animal alphaherpesviruses. The primary advantages of this vector system are the capacity to package up to 100 kb of foreign DNA and the potential for long-term gene expression from latent episomal DNA that can be present in both neuronal and nonneuronal cells.[57] Herpesviruses have tropism for a wide variety of cells and are efficient at cell binding and attachment even at low particle to cell ratios. Vectors can also be pseudotyped to help target delivery into selected host cells. They can be given mucosally as well as parenterally and can be engineered to eliminate immune evasion genes like the HSV-1 ICP47 that interferes with the TAP to diminish MHC class I presentation. Live herpesvirus vectors can be attenuated to avoid vector-mediated disease and can also be made replication defective (see below). Because HSV is ubiquitous, a potential disadvantage for this approach is that preexisting Ab to the vector may diminish immune responses to the transgene product. In a murine model, it was shown that preexisting HSV immunity did not alter the Ab or proliferative responses to recombinant protein encoded by the HSV vector.[51] Using animal herpesvirus vectors may be an alternative approach to circumvent the potential problem of preexisting immunity to the vector, although replication is severely restricted when species barriers are crossed.[457] There is a licensed veterinary vaccine for Marek disease in chickens based on this technology (e-Table 15.3), and this technology has also been applied in HIV vaccine development. Initially, it was shown that replication-competent HSV vectors expressing Env and Nef showed partial protection against challenge with SIVmac239.[325] Subsequently, rhesus CMV vectors were constructed expressing Env, Gag, Pol, and Rev/Nef/Tat. A clinical trial is in progress using a human CMV vector to express HIV T-cell epitopes (Clinicaltrials.gov NCT04725877). Animals immunized with either recombinant CMV vectors alone or primed with CMV and boosted with recombinant adenovirus vectors had significant protection from an SIVmac239 mucosal challenge. The correlate of protection is thought to be persistence of tissue-resident effector memory CD8 T cells, sustained by the persistence of the vector.[200]

Rhabdovirus vectors

Vesicular stomatitis virus (VSV) has been engineered to serve as a vector for recombinant gene delivery. Recombinant VSV can be produced at high titer, is relatively stable, has broad tropism, and can be given mucosally.[236] VSV is a rhabdovirus and is known to have neurovirulence. Therefore, extensive work has been done to attenuate the parent vector by altering the gene order and by truncating the cytoplasmic tail of the major surface glycoprotein.[380] Gene delivery and subsequent immune responses to the recombinant gene product are potent.[193] A vaccine based on VSV that was genetically modified to express the surface glycoprotein of Zaire Ebola virus (designated VSV-EBOV or rVSV-ZEBOV) was approved in the European Union and in the United States in 2019. Rhesus macaques immunized by a VSV vector expressing envelope and gag have been protected from SHIV challenge.[398] Replication-defective VSV vectors have also been developed (see below).

Live adenovirus vectors

The live adenovirus vaccine for serotypes 4 and 7 is a licensed and highly effective vaccine that is administered mucosally. Therefore, it has ideal properties for a gene-delivery vehicle and has been developed as a candidate HIV-1 vaccine.[273,362] The advantages are the track record of the vector for both safety and efficacy, and the potential for delivery in capsules to the lower intestinal tract.[186,445]

Picornavirus vectors

Poliovirus vectors have been developed that can express recombinant foreign proteins that are excised by the virus-encoded protease after translation of the recombinant polyprotein.[11] The major advantages of this approach are the long history of successful vaccination with the vector, and the capacity for oral delivery and induction of mucosal immunity. The major disadvantage of this system is the relatively small packaging capacity (~200 aa) that requires a library of recombinant viruses in the vaccine to deliver large Ags. Enteroviruses and rhinovirus vectors have been developed using similar technology and to target different mucosal inductive sites, and new innovations like removing part of the capsid gene and can provide a larger coding region for the vaccine Ag.[120,315]

Bacterial vectors

Bacterial vectors have also been used to deliver viral Ags. Recombinant BCG has received the most attention. Some advantages of BCG as a vector include the following: (1) its safety record after administration to millions of persons especially in low- and middle-income countries (although BCG can cause local or lymph node complications [BCGitis] or disseminated infection [BCGosis] in immunocompromised recipients); (2) its persistence, and therefore prolonged Ag production that may provide a more durable immune response; (3) its potential for mucosal administration; (4) its innate chemical composition that provides an adjuvant effect through TLR-1, TLR-3, TLR-4, and possibly other pattern recognition receptors; and (5) immunity against tuberculosis could be a by-product of immune responses to the vector. Advances in mycobacterial genetics have made construction of recombinant vectors feasible,[412] and because the large capacity for accepting foreign genes, coexpression of cytokines and other immunomodulators is possible.[6,326] In addition, discoveries about how mycobacteria inhibit apoptosis of macrophages to delay immune-mediated clearance have led to the development of attenuated mycobacteria for vaccination against tuberculosis. New promoters, other vector design modifications, and combining with other modalities may further enhance immune responses to the foreign

gene products.[397] Other bacterial vectors that have been considered for delivering viral Ags include lactobacilli, *Salmonella*, *Shigella*, and *Listeria*. The *Salmonella* and *Shigella* vectors have also been designed to deliver the gene-based vaccine Ag by plasmid and thereby combine mucosal delivery and adjuvanticity with authentic glycosylation of the gene-product.[148] This concept has been tested in early phase clinical trials to express an HIV-1 envelope protein, but there was poor immunogenicity.

Replication-Defective Vectors

Replication-defective virus vectors have had genes deleted that are essential for replication *in vitro* or *in vivo*. Replication-defective viruses can replicate to high titer in cell lines engineered to express the missing protein that would be encoded by the deleted gene. The viruses produced in such complementing cells can attach and deliver their genetic payload to cells *in vivo* but are unable to replicate. Such vectors undergo an abortive infection *in vivo* but express the foreign protein during this abortive infection and can thereby induce both the humoral and cellular arms of the immune response. Nonreplicating vectors do not retain the virulence of the original agent from which they were derived and would be expected to be safe even in hosts with compromised immune systems, should they encounter the vector. Many vectors do retain the antigenicity of structural proteins from the original agent. This raises two issues. The first is reactogenicity. Many vectors can trigger innate immune responses that cause local and systemic reactions in the vaccinee. This is an advantage from the perspective of adjuvanticity but can be limiting at higher doses of the vector. The second is preexisting immunity to the vector. If the vector is derived from an agent to which the host has had prior exposure, the preexisting Ab can dampen the immunogenicity of the delivered vaccine Ag. Vector-based vaccines are of value when the vaccine target is a virus for which live attenuated or whole-inactivated virus vaccines are not considered for safety or other reasons. Vectors have added value when the vaccine strategy is focused on inducing CD8+ T-cell responses because they deliver the vaccine Ag to the cytoplasm allowing access to the MHC class I processing pathway for Ag presentation. Because this characterizes the current strategies for HIV vaccine development, most vector-based vaccine strategies have been evaluated for the induction of protective immunity against lentiviral infection. Therefore, antiviral vaccine vectors will be discussed primarily in the context of HIV vaccine development, even though they are also being developed for many other antiviral vaccine programs.

The regulatory approval pathway for vector-based gene delivery has involved scrutiny around issues such as integration, recombination, reversion to replication competence, and reactogenicity. The origins of many vaccine vectors are from the field of gene therapy, and some of the clinical events associated gene therapy trials greatly affected the evaluation of vaccine vectors. For example, the 1999, death of a teenager in a gene therapy trial at the University of Pennsylvania prompted extensive reviews of safety data from both human and animal studies of vector-based gene delivery.[16] This incident compels a cautious approach to dose and route evaluation of any antigenic substance, but particularly vector-based products. Another gene therapy incident involved a retrovirus vector used to successfully treat children with X-linked Severe Combined Immunodeficiency. After 3 years, some of the children developed leukemia associated with the integration of vector DNA into the LMO-2 protooncogene locus.[190,191]

Adenovirus vectors

Replication-defective recombinant adenoviruses (rAd) exhibit characteristics that make them ideal vaccine vector candidates. Adenovirus serotype 26 (Ad26) is a low-prevalence naturally occurring human adenovirus known to cause common cold–like symptoms, which was manipulated by gene deletion to develop a replication-defective vector. Johnson & Johnson (J&J) Janssen has used this vector to develop two approved viral vaccines. A two-dose regimen of this vector expressing Zaire Ebola virus glycoprotein (Ad26.ZEBOV) followed by a nonreplicating, recombinant, MVA vector–based vaccine, encoding glycoproteins from Zaire Ebola virus, Sudan virus, and Marburg virus, and nucleoprotein from the Tai Forest virus was approved for medical use in the European Union in July 2020. The company also developed a vector that encodes a full-length and stabilized SARS-CoV-2 spike protein that obtained EUA from the U.S. FDA in 2021. Substantial resources are being invested to develop safe and immunogenic rAd vaccines for other infectious agents including HIV, plague, anthrax, influenza, tuberculosis, and malaria.[27] These vectors possess desirable qualities for use in vaccination strategies, including efficient transduction of host cells, limited duration of gene expression, vector nonpersistence, the ability to rapidly induce both humoral and cell-mediated immunity, induction of innate immune responses that may provide an adjuvant effect, relatively high stability, and ability to scale up production for manufacturing purposes.[27] Most rAd vaccine candidates are replication-defective due to a deletion of the E1 region. Some vectors have additional deletions of E3 and E4 to increase capacity for gene insertion and to further reduce the chance of recombination in the packaging cell line to form replication-competent adenovirus. Deletion of E4 also prevents transcription of adenoviral genes encoding structural proteins to reduce antigenic competition with the vaccine Ag. Complementary human embryonic cell lines such as PER.C6[275] or 293-ORF6[52] are used to package the deficient rAd *in vitro* and allow large-scale production. Preexisting immunity to a given adenovirus serotype has been shown in animal models and in human clinic trials to diminish the immunogenicity of the vaccine Ag. Ad5 immunity has a high prevalence, particularly in developing countries.[245] Although Ad5 has been commonly used in the initial studies, there are 51 human Ad serotypes, and many have now been engineered to express foreign genes. In addition, new vectors have been constructed from adenoviruses derived from chimpanzees and macaques that have favorable properties and will provide options to avoid preexisting vector-specific immunity. An alternative to using a rare serotype recombinant adenovirus vector is to construct chimeric vectors. For example, adenovirus vectors have been developed in which the shaft and knob portions of the fiber proteins are exchanged.[496] Another novel approach involved making hexon loop chimeras in which the neutralizing targets in hexon are exchanged for those of an uncommon adenovirus serotype.[443] A mucosal route of administration is another potential option for overcoming preexisting vector immunity, with the added advantage of better induction of immunity in the mucosal compartment. This may be particularly important for inducing immunity against viruses that primarily enter the host through a mucosal surface like HIV and influenza. Replication-defective rAd has been successfully given mucosally without adverse reactions,[464] even though one study in mice showed that intranasal administration could result in Ag expression in the olfactory bulb.[263] The effects of preexisting immunity to the vector can also be partially overcome by increasing the dose or by priming with a heterologous vector expressing the vaccine Ag of interest. Finally, one can avoid preexisting immunity by carefully selecting the target population. For example, children between 6 months and 2 years of age are Ad5 seronegative, which makes rAd5 vectors a viable choice for immunization of that age group.

The Step study was a phase IIb trial that evaluated E1-deleted rAd5 vectors expressing HIV-1 Gag, Pol, and Nef in individuals at high risk of HIV infection. It was stopped prematurely in 2007 because there was a higher frequency of HIV-1 infections among vaccinees than placebo recipients.[53] The increased rate of infection was associated with being uncircumcised and with preexisting Ad5 Ab. The biological basis for this outcome is not known. HIV-1 vaccine clinical trials utilizing rare serotype rAd vectors and rAd5 vectors (E1, E3, E4-deleted expressing HIV-1 Env, Gag, and Pol) in heterologous prime-boost combinations with DNA vaccines are still in progress.

Adeno-associated virus vectors

Adeno-associated virus (AAV) vectors are unique because the wild-type virus itself is replication-defective and requires the presence of wild-type adenovirus as a helper virus to propagate. The vector is very simple and contains the promoter, foreign gene, and polyadenylation sequence surrounded by two short noncoding inverted terminal repeats from AAV. No genes from the wild-type AAV are included in the vector. Particles are produced in a packaging cell line that provides the AAV structural proteins. The AAV capsid induces an immune response, and like other vectors, anti-AAV Ab can diminish immune responses to the foreign gene product expressed by recombinant AAV vectors. Using alternative capsid serotypes and incorporating immune modulators may overcome any limitations posed by preexisting AAV immunity or allow heterologous boosting and further amplification of immunogenicity induced by primary vaccination. Transduction of muscle cells and Ag-presenting cells is efficient, and expression can be prolonged. A single dose of recombinant AAV has been shown to induce both humoral and cellular immunity sufficient to control SIV infection in macaques.[222] AAV-transduced cells achieve persistent gene expression by delivering concatemeric circular episomes that remain transcriptionally active and there is no evidence for integration.[421] Long-term episomal gene expression has been uniquely demonstrated by delivering neutralizing Ab genes to muscle cells in rhesus macaques and achieving sufficient titers in serum to protect against SIV challenge.[221] It should be noted that dozens of AAV-based gene therapies are in late-stage clinical development to treat genetic diseases, and several have been approved starting in 2012.

Alphavirus vectors

Alphaviruses like Venezuelan equine encephalitis virus (VEE), Sindbis virus, and Semliki Forest virus (SFV) have been modified to produce three distinct types of immunogens. All take advantage of the alphavirus replicon that is a minimal genome with replication origins and packaging signals. The vectors include the alphavirus nonstructural genes including the replicase and the subgenomic promoter upstream of a foreign gene that replaces the genes encoding alphavirus structural proteins. The replicon itself can be injected as either plasmid DNA or as naked RNA. Alternatively, helper cell lines can be constructed that provide the structural gene products needed for packaging of replicons and particle assembly of nonpropagating vectors.[153] These replication-defective viral particles are extremely efficient in targeting Ag-presenting cells, particularly DCs, and because of the amplification of the RNA, achieve high-level expression of the foreign protein. They have induced significant humoral and cellular immune responses to a variety of viral proteins in animal models,[208,222,381] and a VEE vector expressing HIV Ags has advanced into clinical trials.[486] The immunogenicity of the VEE vector is in part due to its tropism for DCs. When minor changes are made in the envelope protein to diminish DC entry, the induction of immune response is compromised.[276] One unique property of VEE vector–induced immunity is that parenteral immunization has been shown to induce mucosal IgA responses.[202] The mechanism underlying this phenomenon relates to the rapid and dramatic effect the VEE particles and replicons have on the systemic innate immune response,[244] an effect that occurs in the first 24 hours after inoculation.[453] Because the stimulation of the innate immune system by VEE replicons also appears to enhance adaptive immune responses, replicons that do not express a vaccine Ag can be used as an adjuvant to enhance the protective response to subunit vaccines.[66] One of the hurdles to using alphavirus vectors is demonstrating that recombinant replication-competent viruses do not reconstitute by recombination at the extremely high inoculation concentrations requested by regulators (which exceed concentrations used in manufacturing protocols).

Herpesvirus vectors

Replication-defective HSVs have been produced in a manner analogous to that of the E1A-deficient adenoviruses, that is, they have had one or more genes deleted that are essential for replication, but replication *in vitro* is supported in a cell line that constitutively expresses the essential protein needed for replication.[109,306] In contrast to the E1-deficient adenoviruses, the replication-defective HSVs are being developed as vaccines to protect against disease caused by HSV itself, as well as a vector to deliver foreign viral proteins. Another approach to vector construction is to package replication-defective HSV amplicons in HSV particles using bacterial artificial chromosomes (BAC)-encoded helper viruses with deleted packaging sequences resulting in foreign gene expression without the influence of any residual HSV genes.[168]

Poxvirus vectors

Attenuated replication-defective poxvirus vectors have been developed to address the known complications of vaccinia virus in immunocompromised persons. The most developed vectors include modified vaccinia virus Ankara (MVA), avipox (canarypox and fowlpox), and NYVAC (deliberate deletion of 18 genes associated with virulence).[354] MVA was derived by more than 500 passages in chick embryo cells[284,296] and has been evaluated as a vaccine vector for a variety of viral Ags. MVA is a highly attenuated host-range mutant that replicates well in avian cells, has limited replication in BSC-40 and baby hamster kidney (BHK) cells, but does not propagate in most mammalian cells.[41,65,125] MVA is nonpathogenic in immunocompromised hosts and has been administered to large numbers of humans without incident.[285,439,483] Attenuation of the MVA recombinant resulted from the loss of nearly 30 kb of genome including genes for immune evasion and host range during its many passages in embryonated eggs.[12] Use of avian poxviruses, referred to as avipox viruses, as vectors represents a second type of host-range–restricted poxvirus vector. Avipox viruses are naturally occurring host-range–restricted viruses that are replication-deficient in mammalian cells and mammal hosts.[354] Each of these poxvirus vectors has the property of efficient replication *in vitro* in avian cell culture but restricted replication in primates. Avipox vectors have an added advantage because preexisting immunity to vaccinia does not impact vector delivery. Poxvirus vectors have the following advantages: (1) thermostability, (2) the history of being associated with the extraordinary success of the smallpox eradication campaign, (3) large packaging capacity for foreign genes, and (4) lack of persistence or genomic integration. The major disadvantages are (1) attenuated vectors are grown in primary cell lines (chicken embryo fibroblasts), and production is difficult to scale up; (2) the foreign gene insert is sometimes unstable; and (3) poxviruses are antigenically complex, and there may be competition between the vector and the inserted gene products for Ag processing and presentation.

After extensive phase I and phase II evaluation,[166,369] a recombinant canarypox vaccine was evaluated in a controversial phase III efficacy study, RV144.[56] This landmark study provides a benchmark as the first demonstration of efficacy for an HIV vaccine.[388] A general population cohort of 16 402 people in Thailand was enrolled in the study and randomized 1:1 vaccine to placebo recipient. Vaccinees received intramuscular injections of a recombinant canarypox vector expressing envelope, Gag, and parts of Pol and Nef given at 0, 1, 3, and 6 months and rgp120 formulated in alum given at months 3 and 6. At 18 months, 74 infections had occurred in placebo recipients and 51 infections had occurred in vaccinees, which was statistically significant. A similar rgp120 did not protect men who have sex with men[161] or intravenous drug

users,[368] populations with much higher incidence. The immune correlate of protection is not yet defined, but protection appears to be temporally associated with serum Ab titers, even though vaccinee sera do not neutralize commonly transmitted strains using traditional assays.

Limitations of Gene-Based Vectors

It is beyond the scope of this chapter to cover the growing list of potential vectors to deliver genes encoding viral Ags that may be considered for future vaccine development. For example, arenavirus[142] and lentivirus[112] vectors have not been discussed here and reverse genetic systems have been developed for other virus families[240] that will make recombinant vector development feasible. Each system has a unique set of properties that should be considered when devising a strategy for a particular pathogen. One of the primary considerations is seroprevalence for the vector in the target population. Preexisting vector-specific immunity can affect both safety and potency of the vaccine. This interaction may be a problem if there is natural immunity to the vector or if competing vaccine programs for other important pathogens converge on the same vector platforms. There are several factors involving safety, Ag selection, immunogenicity, manufacturing, and stability that are important to consider when developing a vector-based vaccine strategy that are pathogen and target population specific (e-Table 15.2).

Viral Vectors as Vaccines Against the Virus From Which the Vector Was Derived

A practical by-product of the development of gene-based replication-defective viral vaccine vectors is that the vector itself may serve as a novel vaccine platform for the virus from which the vector was derived. The most advanced examples of this are the poxvirus vectors such as MVA or NYVAC. These have been evaluated as candidate smallpox vaccines in clinical trials using replication-competent vaccinia (Dryvax) as a surrogate challenge.[152,357] This type of approach has also been proposed for herpesviruses[128] and adenoviruses. Using the viral vector creates the opportunity to express additional viral antigens[4] or immunomodulatory proteins like cytokines[75] that could provide adjuvant effects and increase immunogenicity compared to the live attenuated virus platform. Another advantage of this approach is that the vector delivers the antigenic complexity of a live attenuated virus vaccine with a more favorable risk profile because of lack of replication. In addition, the vector provides more options for achieving robust manufacturing capacity, while this is often a challenge for live attenuated viral vaccines.

Vaccine Formulation and Delivery

Adjuvants

Adaptive immune responses are controlled by the amount, duration, and formulation of the Ag in conjunction with innate immunity. The Ag sequence and structure determines specificity, but the adjuvant and context of delivery and Ag presentation determine the composition, location, kinetics, and magnitude of vaccine-induced immune responses (e-Fig. 15.8). While specificity is a property of the adaptive immune response, many adjuvant effects are mediated by the innate immune system. The most potent and broad-based adaptive immune responses are induced by replication-competent virus vaccines and gene-based viral vectors. These vectors provide efficient Ag presentation and inherently stimulate innate immunity through a variety of signaling pathways thus limiting a requirement for exogenous adjuvants. By contrast, inactivated virus vaccines, purified viral proteins, or peptide Ags by themselves have relatively weak immunogenicity in a I host. There are several reasons that replication-competent viral vaccines and gene-based vectors are inherently more immunogenic than inactivated virus or subunit vaccines. First, gene expression provides an ongoing source of the relevant protective Ag that is amplified through replication beyond the dose contained in the original inoculum. Second, Ags produced during transcription in the host cells have native quaternary and multimeric particulate structures and authentic posttranslational modifications. Third, replication-competent viruses and gene-based vectors can broadly engage multiple distinct innate immune and Ag presentation pathways. Indeed, a major advantage of live or attenuated viral vaccines is that expressed antigenic epitopes are processed efficiently through both MHC class I and II pathways. This mechanism contrasts with that of inactivated vaccines where Ag processing is mostly limited to MHC class II presentation, which elicits CD4 T-cell responses but is limited for generating CD8 immunity. Finally, PAMP recognition receptors are engaged on the cell surface, in endocytic vesicles, and in the cytoplasm with live vaccines (e-Fig. 15.9). Therefore, adjuvants are needed to compensate for the diminished immunogenicity of vaccines that are not transcriptionally active in host cells by recruiting additional signaling pathways to activate innate immunity, promoting Ag-presenting cell maturation and costimulation, and prolonging Ag persistence.

e-FIGURE 15.8 **Vaccine formulation and delivery is critical for the pattern and function of vaccine-induced immune responses.** Significant attention is given to Ag selection and design during vaccine development. While the Ag determines the specificity of the vaccine-induced immune response, many other qualities important for protective immunity depend on the formulation and delivery of the product. Formulation also is the major determinant of vaccine stability, which is a key factor in overall vaccine success.

e-FIGURE 15.9 **Adjuvant effects are mediated through pathways that recognize PAMPs.** Many of the events leading to activation of innate and adaptive immune responses begin with signaling pathways triggered by the recognition of PAMPs. Cell surface and endosomal Toll-like receptors and intracytoplasmic helicases play major roles in the recognition of virus-associated PAMPs and mediate many vaccine adjuvant effects.

Traditionally, adjuvants have been derived from natural products empirically found to have immunostimulating properties. Adjuvants can improve immunogenicity by optimizing the duration of Ag presentation through a “depot” effect and/or through enhancing certain innate stimulatory pathways. It was first discovered that bacterial toxins were more protective when mixed with other substances.[383] A prototypic adjuvant used exclusively in laboratory research is Freund adjuvant prepared from mycobacterial cell walls. A modern version of incomplete Freund adjuvant (IFA) (Montanide ISA-51) is a water-in-oil emulsion composed of mineral oil mixed with the surfactant mannose mono-oleate in a 1:1 ratio with the aqueous phase. Although vaccines formulated with mineral oil have been administered to more than 1 million people since 1945, with the emergence of aluminum-based adjuvants, they fell out of favor because of the reactogenicity profile and potential for causing sterile abscesses.[177] They are still frequently used in the context of therapeutic vaccines.

There are five currently licensed adjuvants in the United States for human use in preventive viral vaccines, (1) alum, (2) AS04—a combination of alum + monophosphoryl lipid A (MPL), (3) MF59, (4) AS01B, and (5) CpG 1018. In addition, the oil-in-water emulsion adjuvant AS03, made of vitamin E and squalene, is included in an H5N1 avian influenza vaccine in the U.S. Strategic National Stockpile.

Alum is derived from aluminum hydroxide or aluminum phosphate and is formulated as a gel or used to precipitate protein Ags to create aggregates. It functions as a short-term Ag depot in which Ag that is electrostatically bound to alum is slowly released at the site of inoculation.

Some of the adjuvant activity conferred by alum is through activation of the "inflammasome" innate signaling pathway.[131] Alum has been the standard adjuvant used in licensed vaccines for several decades. All the currently licensed inactivated viral vaccines and hepatitis B VLPs are formulated with alum. Gardasil, the Merck HPV VLP vaccine, is also formulated with alum.

Ab responses can be improved by combining additional immune stimulatory molecules to alum. Indeed, AS04 (Adjuvant System 04) is a combination of alum and a modified synthetic form of MPL, a key component of LPS that is the ligand for TLR4. Cervarix, the HPV VLP from GlaxoSmithKline, is formulated with AS04 and is the first adjuvant containing a TLR ligand to be approved for use in humans. The MPL-based adjuvants when combined either with alum (AS04) or with QS21 (AS02) have been shown to have a significant dose-sparing effect and may have additional advantages in terms of the speed and durability of the humoral responses. Formulations that include MPL also stimulate IFN-γ–producing CD4 T-cell responses, which may have additional benefit.[330]

After alum, the other most widely used adjuvant in humans is MF59. MF59 is a squalene oil-in-water emulsion that is licensed for human use in Europe. MF59 was designed originally to provide an Ag depot from which Ag would be slowly released as the biodegradable oil was metabolized or removed by macrophages and as a vehicle for the immunostimulant MTP-PE (muramyl tripeptide-phosphatidylethanolamine), a derivative of muramyl dipeptide, the active component of the mycobacterium cell wall fraction in Freund complete adjuvant. However, clinical studies in humans indicated that MF59 itself was as immunostimulatory as MF59/MTP-PE with less toxicity.[175] Its adjuvant effect is not TLR dependent, but there is evidence that MF59 has some innate immune stimulatory capacity. More than 45 million doses have now been given to humans formulated with seasonal influenza vaccines. MF59 is dose-sparing, and clinical studies with H5N1, H1N1, or seasonal trivalent influenza vaccines show that protective levels of immunity can be achieved with as little as 3.75 μg of vaccine Ag.[86] A similar squalene oil-in-water emulsion (AS03) has achieved similar dose-sparing effects when formulated with influenza Ags.[331] MF59-formulated influenza vaccines also result in antibodies with greater cross-reactivity and greater avidity to conformational epitopes than alum-formulated vaccines in head-to-head comparisons.[234] MF59 is now approved as a component of a standard-dose, inactivated quadrivalent influenza vaccine for people aged 65 years and older.

$AS01_B$ is an adjuvant system that is used to adjuvant the recombinant zoster vaccine Shingrix. $AS01_B$ uses 3-deoxy monophosphoryl lipid A (MPL) and QS21 with cholesterol included in liposomes. Cholesterol bind and detoxifies ("quenches") the toxicity of QS21 which, like other saponins, binds to cholesterol and damages cell lipid bilayer membranes. Incorporation into liposomes also eliminates the toxicity of MPL. QS21 was discovered in the bark of *Quillaja saponaria*, Molina (soap bark tree). It was named for the tree's scientific name and for being the 21st peak on the HPLC analysis of the bark extract. The basis for its adjuvant properties is incompletely understood.

The CpG 1018 adjuvant is cytosine phosphoguanine (CpG), a synthetic form of single-stranded DNA that mimics bacterial and viral genetic material and is included in a recombinant hepatitis B vaccine (Heplisav-B). Specifically, CpG is a PAMP that is recognized by the pattern recognition receptor Toll-like receptor 9 (TLR9), which is expressed only in B cells and plasmacytoid DCs.[399]

Delivery Vehicles

Delivery of vaccine Ag can determine the immunological compartment that is stimulated and influence the types of Ag-presenting cells that process the vaccine Ag. Many delivery vehicles are formulated with adjuvants or have innate adjuvant properties, but in this section, the term will refer to approaches for transporting Ag to a particular location. A delivery vehicle may allow the mucosal delivery of an Ag that could otherwise only be given parenterally. Alternatively, a delivery vehicle could function as a way of co-delivering a mixture of Ags and adjuvant, produce a depot effect, or otherwise control the timing of release of Ag. Vaccine delivery vehicles have been designed to carry Ag into subcellular compartments with the intent of stimulating specific immune responses by accessing distinct Ag-processing pathways.

Lipid-Based Carriers

Many virus surface proteins are spatially oriented in lipid envelopes and that is one rationale to use lipids in the formulation of virus vaccines. Another is that the Ag may be protected by the lipid and allow delivery through harsh environments like the gastric mucosa or blood or promote a depot effect when injected. Liposomal vaccine formulations may facilitate mRNA or DNA transport into target cells and have been used extensively for transfection of cells *in vitro*. Liposomes are vesicles with a roughly spherical lipid bilayer surrounding an aqueous center.[138] If virus-derived proteins are inserted into the membranes (proteoliposomes), they are often referred to as virosomes. Liposomes have been used to deliver peptides, proteins, whole virus, and mRNA or DNA with and without adjuvants and can be designed to target or costimulate selected APCs. The intent is to produce an inert particle that concentrates in the target organ of interest and then releases its payload. Typically, when used for purposes of gene delivery, cationic lipids are used in the liposome formulation to improve the interaction with the negatively charged nucleic acid. The lipid composition of the liposome can be modified to affect charge, pH sensitivity, thermal stability, and fusogenicity to control release of the products. Licensed mRNA vaccines for COVID-19 use lipid nanoparticle formulations, and these unique delivery systems likely form the basis for much of the immunogenicity of those vaccines. The Moderna mRNA vaccine uses a PEGylated lipid nanoparticle containing 1,2-distearoyl-sn-glycero-3-phosphocholine, cholesterol, and a proprietary synthetic lipid SM-102. The Pfizer mRNA vaccine similarly uses another unique set of four lipids to form lipid nanoparticles to protect and deliver mRNA. Virosomes are used in licensed products (non–United States) to deliver vaccine Ags for influenza and hepatitis A.[309] More elaborate virosomes in which the proteoliposome is built around a polystyrene bead are being developed as a candidate HIV-1 vaccine, using the scaffolding of the particle to produce more stable conformations of the envelope glycoprotein.[183] Exosomes are natural source of liposomes. Exosomes are 50- to 90-nm vesicles produced by an endosomal process in which vesicles bud into endosomes (multivesicular bodies) and are then secreted from APCs. Interestingly, these exocytic vesicles contain many of the proteins involved in Ag presentation including MHC and costimulatory molecules.[256] In addition, they have lipid content like many enveloped viruses and lipid rafts with high-cholesterol content.[170] ISCOMs (immune-stimulating complexes) are another lipid-based vehicle for delivering vaccine Ag. They are 40-nm cagelike structures formed by a complex mixture of lipids and saponins that can be formulated with viral Ags.[2] They can deliver proteins or peptides to the cytoplasmic compartment where they can be processed to activate CD8+ T cells, and this has also been demonstrated in clinical trials of HPV and HCV vaccine candidates.[413] ISCOMs also have adjuvant properties derived primarily from the saponin component, QS21, described above.

Synthetic Particles

Synthetic polymers have been used in creative ways to contain or hold vaccine Ags for presentation to the immune system. Microparticles are

made from biodegradable polymers complexed with viral Ags.[103] The primary polymer used is poly lactic co-glycolic acid (PLGA), which can encapsulate DNA by itself or with multiple proteins, adjuvants, or other immunomodulators. PLGA has an extensive history of safety in humans because it is the polymer used in absorbable sutures. Some other advantages of microparticles (1-10 μm) include the following: (1) preferential uptake through the phagocytic pathway of DCs, (2) protection of the vaccine product from the environment resulting in a slow-release depot effect,[342] and (3) the potential payload capacity is higher than for liposomes or viral vectors. PLGA microparticles coated with cationic surfactants have also been used as a vehicle for DNA delivery by absorption of plasmid DNA to its charged surface.[342] In general, these approaches have not produced the robust gene expression and immunogenicity needed for gene-based vaccination, and the formulations are being empirically modified. One approach has been to produce a hybrid polymer by combining PLGA with other substances like poly-β amino ester to improve the sensitivity to pH change and more rapidly liberate the DNA.[269] Another approach for DNA delivery has been to use alternative polymers such as poly (ortho esters) (POEs), which had been developed for drug and peptide delivery.[474]

Nanoparticles have been used to deliver mRNA vaccines, as discussed above, and have been explored as vehicles to deliver DNA vaccines. Generally, sizes of <200 nm (close to the size of many viruses) have been used, which are less likely to be forced into the phagolysosome pathway than microparticles. One approach has involved polylysine cationic polymers with imidazole side chains to facilitate escape from endosomes.[270] Another utilizes an oil-in-water microemulsion to produce wax cationic nanoparticles[107] that can be modified to encapsulate DNA.[318] Finally, nonionic block co-polymers have been used to deliver DNA vaccines with promising results in animal models but not in human trials.[428]

Synthetic self-assembling polypeptides can be used to display vaccine Ags on particles to achieve multivalency like the use of VLPs as Ag scaffolds.[367] Novavax developed a vaccine for COVID-19 based on baculovirus/insect cell–expressed SARS-CoV-2 spike protein incorporated into nanoparticles formed by mixing the recombinant protein in a nonionic surfactant (polysorbate 80 or Tween 80). That vaccine candidate obtained conditional marketing authorization in December 2021 from the European Commission, and it has been approved in eight countries as of April 2022 and by the FDA in July 2022. A protein nanoparticle decorated with 60 copies of the SARS-CoV-2 spike protein receptor–binding domain[471] was licensed in Korea in 2022, paving the way for increased use of nanoparticle vaccine approaches in humans. Another nanoparticle approach is to use self-assembling proteins from other (nonviral) biological sources such as the yeast protein Ty,[262] although evaluation of these structures in human trials did not induce significant immune responses.[480]

Cell-Based Carriers

Dendritic cells (DCs) are important for Ag presentation, for initiating the innate responses, and bridging the innate and adaptive immune systems to coordinate a comprehensive response to a virus infection. Therefore, they have been central to several vaccine development efforts. Not surprisingly, DCs themselves have been used as the vehicle for Ag delivery. Autologous DCs have been sorted, expanded *in vitro* with selected cytokines, pulsed with peptide, inactivated whole virus, or vectors and then reinfused into subjects.[272,281,344] Another cell-based vaccine approach utilizes transgenic plants. Potatoes, lettuce, tomatoes, carrots, bananas, and corn have all been engineered to produce vaccine Ags that have been evaluated in clinical trials.[444] This technology is also in early stages but has partially overcome some of the initial theoretical concerns that delivery of edible vaccines would result in oral tolerance or possibly result in food allergies to the carrier. A major advantage of transgenic plants is that production does not require an extensive physical infrastructure, and therefore, manufacturing is inexpensive and easily distributed.

Conjugates

Vaccines derived by conjugating protein to carbohydrate have been extraordinarily successful for the control of encapsulated bacteria. The protein in this setting helps to redirect the Ag presentation so that alternative Ab isotypes are produced to control the bacteria. Since the carbohydrate structures of viruses are made by the host cell, they are not antigenic targets and often protect the virus from host immune defenses, as exemplified by the “glycan shield” of the HIV-1 gp120. Conjugates for viral Ags have typically been designed to carry the viral Ag into the cytoplasmic compartment of the APC so that processing and MHC class I presentation and CD8+ T-cell activation can occur. This objective has been accomplished by using heat shock proteins (HSP70),[69] alpha-2 macroglobulin,[268] and leader sequences that promote membrane translocation to help the protein directly enter the cytoplasm.[205,394] Protein conjugate vaccines with Ab Fc receptors, CpG motifs, TLR 7/8 agonists[78,485] also have been used to improve the efficiency of uptake of viral Ags to DCs. An additional approach is to target Ag directly to DCs through incorporating the viral Ag into an Ab such as the DEC205 Ab conjugate that delivers Ag directly to DCs.[145,329] This provides an efficient *in vivo* approach for targeting DCs instead of the *ex vivo* approach mentioned above, which may be limited to therapeutic vaccines for chronic virus infection and cancer.

Mechanical Devices

Currently, licensed vaccines are given orally or by needle and syringe, aerosol, or bifurcated needle in the case of vaccinia. Future vaccines and adjuvants or immunomodulators may utilize more technically sophisticated devices like microneedles[237] or micromechanical abrasion.[299] Other delivery devices have been adapted or developed in large part to address the need for improving the efficacy of DNA vaccines in humans. Needle-free injection systems like Biojector or Powderject have been used to deliver DNA vaccines in clinical trials,[176,401,475] and in both animal models and humans, electroporation has been shown to improve Ag expression and immunogenicity of DNA vaccination.[416,465] In addition, there continue to be new designs for delivery by traditional aerosol or needle and syringe devices that have been designed to improve effectiveness or safety. There are rapid advances in microneedle (<1 μm) technology in which arrays of needles made from a wide variety of materials (ranging from stainless steel to dissolving crystalline sugars) can effectively deliver vaccines.

Combination Approaches

Co-delivery or Multivalent Vaccines

Co-delivery of vaccines has become a matter of practicality with more than 13 pathogens being targeted during the childhood immunization series alone. Therefore, combined vaccine formulations like MMR (measles, mumps, rubella), the tetravalent product that includes varicella vaccine with the MMR combination, IPV (polio serotypes 1, 2, and 3), and quadrivalent influenza (B and A H3N2 and H1N1) are commonly

used. Factors such as antigenic competition, interference, and unanticipated adverse reactions need to be considered during the development of combination products.

Co-delivery of different vaccines against the same pathogen can sometimes augment immunogenicity. Simultaneous administration of two different influenza virus vaccines to elderly subjects, namely, an intranasally administered live attenuated[444] influenza A virus candidate vaccine and a parenterally administered licensed inactivated virus vaccine, induced greater resistance to illness than did administration of the inactivated virus vaccine alone.[458] In this situation, the greater immunogenicity of the live virus vaccine in the respiratory tract coupled with the greater efficiency of the inactivated virus vaccine in stimulating systemic immunity appear to act in concert to optimize efficacy. A replication-defective HSV vaccine was found to be most immunogenic when administered by both parenteral and mucosal routes, indicating that the same vaccine preparation can also be given by a combination of routes to augment protection.[306]

Sequential Combination of Vaccines

Sequential combination of different vaccine modalities that focus on inducing immune responses to the same pathogen is referred to as "prime-boost" strategies.[384] This concept takes advantage of the memory inherent in the adaptive immune response by sequentially amplifying the response to selected Ags. This can be done with combinations of replication-competent or gene-based vectors with inactivated or subunit vaccine approaches or by heterologous vector combinations. Combining vaccine approaches has the potential for eliciting new components of the immune response and for broadening the response to new specificities and immunological compartments. Combining heterologous vectors has the added value of the boost avoiding preexisting antivector immunity, while amplifying the response to the expressed vaccine Ag.

Combination approaches can be used both for improving the safety of the booster vaccine and for improving immunogenicity beyond either approach alone. Polio vaccination is an example where using combined modalities improved both safety and immunogenicity. It is now recommended that only IPV be used for polio vaccination in the United States Prior to this, sequential immunization with inactivated poliovirus vaccine followed by live attenuated virus vaccine was used as a safer alternative to the three-dose live virus vaccine, OPV. The combination approach provided immunity against the rare cases of vaccine-associated polio caused by the live virus vaccine and primed for a booster effect from OPV, which expanded the immune response to the mucosal compartment. Thus, immunogenicity was optimized in the individual, and herd immunity was provided to the population by inducing sufficient mucosal immunity in the gastrointestinal tract to prevent the spread of imported strains of poliovirus.[301,366] Sequential immunization with a live attenuated alphavirus vaccine candidate followed with a boost with an inactivated virus vaccine induced higher levels of Ab than live virus alone.[370] In the field of HIV vaccine development, a variety of prime-boost strategies have been evaluated. In some cases, priming has been done with a DNA or gene-based vector followed by subunit protein boost.[91,99,174] This approach led to the first demonstration of efficacy against HIV acquisition using a recombinant canarypox vector expressing Env, Gag, and Pol boosted with recombinant gp120 protein.[388] Other approaches have utilized heterologous vector combinations or DNA priming followed by gene-based vector boosting.[9,198,247,423] These studies have shown DNA priming followed by rAd5 boosting can protect against SIV infection in macaques and reduce viral load in vaccinated animals that experience breakthrough infections.[265] This concept is currently being evaluated in a phase IIb efficacy trial (HVTN 505).

Universal or Broadly Protective Vaccines

Some viruses exhibit such antigenic diversity and drift that a single vaccine antigen is unlikely to induce broadly protective immune responses that protect against all circulating or future variants (eg, influenza viruses and coronaviruses). Recent efforts to develop more "universal" vaccines that induce protective responses against diverse variants, clades, subtypes, or even families of viruses have focused on two strategies. One is identifying and using immunogens comprising only the most conserved residues for the protective antigens (eg, influenza HA stem epitopes or coronavirus spike protein receptor–binding residues). A second strategy is to incorporate antigens from diverse antigenic variants into single immunogen preparations, such as mixtures of variant VLPs or even individual nanoparticles displaying diverse antigens. Two-component influenza nanoparticle immunogens that co-display the four hemagglutinins of licensed quadrivalent influenza vaccines have been shown to induce broad responses.[49] Co-display of hemagglutinin RBDs from multiple strains across time using adjacent RBDs that are heterotypic induces more broadly protective responses than mixtures of the same antigens on separate nanoparticles.[228]

Modernization of Vaccine Manufacturing

The process of manufacturing a vaccine is complex yet, the primary cornerstone in overall production is the substrate used for vaccine growth. Early generation vaccines were often grown in animal organ cells, including adenovirus vaccine in monkey kidney cells and JEV vaccine in mouse brains. Such tissue cultures have the potential to carry adventitious agents. In the late 1950s, a polio vaccine developed by Hilary Koprowski, was used in trials in Africa, after first being tested in the United States. A vaccine virus was given to about a million people in Burundi, Rwanda, and Democratic Republic of the Congo that had been produced in tissue cultures obtained from macaque monkey kidneys. Journalists later raised the concern that HIV was transmitted to the human population during the vaccination. Residual stocks of that vaccine were tested by independent laboratories and were confirmed to have been made using monkey (not chimpanzee) cells and no contaminations with SIV or HIV was found, so this theory has been refuted.[491] Nevertheless, high vigilance about adventitious agents is warranted when using cultures of cells.

During the second half of the 20th century, modernization of vaccine production included the progression to use of cell lines as substrates, including current JEV vaccine in Vero cells and hepatitis B vaccine in yeast. Influenza vaccine researchers continue to develop U.S.-marketed vaccines using chicken eggs as the substrate but have developed cell culture-based substrates that are used effectively in some European countries and the United States. The transition to cell-based substrates offers a more efficient, more reliable, and more stable manufacturing process. In 2009 (European Medicines Agency) or 2012 (U.S. FDA), regulatory officials approved the first mammalian cell–based influenza vaccines, quadrivalent vaccines produced in the Madin-Darby canine kidney cell line. Production of influenza antigens in mammalian cells has the advantage of better mimicking virus replicating in human cells and avoiding egg-adaptation mutations that occur in egg propagation and reduce the immunogenicity for certain protective epitopes.

Impact of Advances in High-Throughput Sequencing Technology on Quality Control

The human genome project simulated major investments in sequencing technology, resulting in breakthroughs that have increased throughput

by orders of magnitude. As a result, it is now feasible to sequence all nucleic acids in samples of interest, such as vaccine preparations. Not surprisingly, such experiments have identified previously unidentified agents or nucleic acids in licensed vaccines, such as porcine circovirus-1 (PCV-1) in the commercial rotavirus vaccine Rotarix.[468] The FDA suspended use of the vaccine in 2010; however, experts agreed this highly prevalent nonpathogenic pig virus does not infect humans, and the use of vaccine was reinstituted. Porcine circovirus–free formulations of human rotavirus vaccine have now been prepared and large multicountry clinical studies have shown that these formulations had similar reactogenicity and safety profiles.[260,410]

Some vaccines are produced in avian or primate cell lines, and thus, it was not surprising that RNAs from avian leukosis virus, which is noninfectious for humans, or genetically defective DNAs from simian retrovirus (SRV), were present in products of such cell lines. Another interesting finding of such sequencing efforts is that the vaccine virus populations contain minority variants with polymorphisms or mutations (compared to the known sequence of the vaccine strains). Such variants have been observed for OPV, mumps virus, and varicella-zoster viruses, but they are not known to affect attenuation. First-generation smallpox vaccines were derived from uncloned viruses propagated in calf-lymph, including Dryvax, Aventis Pasteur Smallpox Vaccine (APVS), Lister, and Lancy-Vaxina. The smallpox vaccine Dryvax, first licensed by the FDA in 1931, contained clones with heterogeneous sequences, sometimes resulted in shedding of mouse-neurovirulent clones, and is no longer manufactured. ACAM2000 is a second-generation smallpox vaccine based on a clone isolated from Dryvax, which is purified and produced using modern cell culture. ACAM2000 differs from the Dryvax consensus sequence by single nucleotide polymorphisms and insertions-deletions of varied size.[346]

The emergency status declared during the COVID-19 pandemic starting in 2020 spurred the most rapid pace of vaccine development for an agent in history. The emerging technology of mRNA and rAd-vectored vaccines facilitated design of some vaccine candidates within hours of the public release of an SARS-CoV-2 spike protein gene sequence in January 2020. The first clinical trial of an mRNA vaccine for COVID-19 was initiated by March 16, 2020, only weeks later. This rapidity of development required new technologies, rapid manufacturing processes, expedited regulatory review, and many other innovations, and ultimately led to rapid approval for several COVID-19 vaccines. Whether lessons learned in these successful ultrarapid campaigns can be translated to time saved in future nonpandemic efforts remains to be seen.

Maintaining Vaccine Availability

Vaccine efficacy, need, utilization, and safety (or perceived safety) all have a significant impact on the success of licensure and sustained availability of a vaccine. Production of the adenovirus vaccine for serotypes 4 and 7 that is selectively given to new military recruits entering basic training was stopped by the sole manufacturer in 1995 for economic reasons, and an outbreak of acute respiratory disease hospitalizations occurred in basic training soldiers almost immediately when vaccination was ceased.[29] Morbidity from adenovirus infections increased among military recruits, and epidemics occurred in training centers.[180] By 2011, the government reinstituted immunization with newly licensed oral vaccine from a new manufacturer. In addition to economic concerns, safety concerns have also prompted an abrupt end to the use of vaccines. Specifically, Rotashield, a live tetravalent rhesus rotavirus reassortant vaccine against the four major prevalent serotypes (based on VP7, a major outer capsid glycoprotein) was effective but was later withdrawn from market. A postmarketing analysis revealed that the vaccine was associated with an excess rate of intussusception of up to 1 per 2500 vaccinees that occurred in the immediate postvaccination period, predominantly following the first dose of vaccine.[320] Following withdrawal of Rotashield, subsequent studies led to a significant downward revision of these estimates and have suggested that the early period of increase in intussusception seen after the first dose was followed by a period of compensatory decrease such that there was no net overall increase in the number of cases in vaccinees <1 year of age.[320] Furthermore, the excess cases of intussusception occurred mostly when the vaccine was used in children 3 months of age or older to “catch up” rather than in vaccinees who received the ideally recommended schedule of 2, 4, and 6 months of age.[229,432] This case highlights the importance of the analysis of postmarketing data, which needs to be especially thorough and comprehensive because it can dramatically impact the availability of a vaccine that may otherwise have a favorable risk/benefit ratio. Despite the initial conclusions and withdrawal of Rotashield from the market, two newer versions of a rotavirus vaccine were developed. Pentavalent RotaTeq has been licensed in the United States for infants <3 months of age. It consists of a mixture of live attenuated, bovine/human reassortant viruses that express a single VP4 (P1A) as well as VP7 (G) Ag from G1-G4 strains of rotavirus [8]. The second vaccine, Rotarix, is a monovalent VP7 G1:P1A [8] attenuated human rotavirus strain that was first licensed in Mexico and the Dominican Republic,[165] and later in 2008 in the United States. These two vaccines protect against severe gastroenteritis due to rotavirus. Large-scale postlicensure evaluations were conducted to more clearly elucidate the overall risks associated with rotavirus vaccines in the general population. In these studies, cases of intussusception were observed in temporal association within 21 (RotaTeq) or 31 (Rotarix) days following the first dose, with clustering of cases in the first 7 days. These findings translate to potentially 0-4 additional cases of intussusception hospitalizations per 100 000 vaccinated infants within 31 days after the first dose in the United States.

Influences on Vaccine Uptake

Government policies and the recommendations of professional societies greatly affect the use of vaccines. The U.S. Food and Drug Administration (FDA) and the European Medicines Agency (EMA) are some of the principal agencies that license (allow or authorize) vaccines for human use but then additional bodies of experts provide recommendations for use. In the United States, for example, the Advisory Committee on Immunization Practices (ACIP) of the U.S. Centers for Disease Control and Prevention (CDC), the American Academy of Pediatrics (AAP), the American Academy of Family Physicians (AAFP), and the American College of Obstetricians and Gynecologists (ACOG) publish influential recommendations. Third-party payers (such as private insurance companies, Medicare, and Medicaid) also influence vaccine use through reimbursement policies. Even when vaccines are licensed and recommended, uptake is rarely universal without legal requirements (such as school-entry requirements). The public exhibits varying levels of interest in vaccination and trust in public health official recommendations. Many people delay their acceptance or refuse vaccination despite availability of vaccination services for themselves or their family members, a state that has been termed “vaccine hesitancy.” Vaccine hesitancy stems from a variety of concerns and operates differently in varying contexts. Some people lack sufficient knowledge about the vaccine or disease in question, some have overconfidence in their natural ability to resist severe disease, and some lack confidence in the benefits of vaccination. Practical fears arise, such as anxiety about needles or the complexity of medical settings or concerns about potential side effects, real or imagined. On top of these medical issues, misinformation campaigns propagated by individuals or groups who oppose vaccination have left many in the public with an implicit association of vaccines with potential for harm. Also, when individuals do not perceive virus infections to be a threat to them, they fail to get vaccinated due to complacency. Vaccine hesitancy may also stem from broad distrust of the general medical system, a state that may be exacerbated by legitimate concerns of historical or current racial and economic disparities in health care access or practice. Less common is total vaccine refusal (so-called anti-vax sentiments) that stem from political, social, emotional origins that are difficult to address and exacerbated by social media disinformation and even malicious foreign government disinformation campaigns intended to introduce conflict and instability in societies.

Summary

Vaccine development has occurred primarily through observation and empiricism. In some cases, the emergence of new technologies allowed advances in vaccine development, and occasionally, basic research discoveries have led to successful new vaccine approaches. The earliest observations that smallpox did not occur twice in the same individual led to the development of insufflation and variolization. Observing that a relatively innocuous cowpox infection seemed to protect against smallpox led Jenner to vaccinate. When Pasteur observed that an aged bacterial culture did not cause disease in chickens, and subsequently found that those chickens were protected from challenge with fresh cultures, an era of intentional modification and attenuation of microbes began that led to the introduction of many new vaccines. New technologies, such as cell culture, led to a series of new vaccines because viruses like measles, mumps, rubella, and polio could be cultivated and produced in large quantities. The advent of molecular biology has led to the production of subunit proteins for successful hepatitis B and HPV vaccines and the technical ability to produce reassortant and recombinant viruses. Modern immunology, driven largely by the response to the HIV/AIDS crisis, has introduced new methods for measuring T-cell function that will help define the role of T cells in vaccine-induced immunity and guide the use of molecular adjuvants. Structural biology is providing an increasingly rapid way to view the atomic structures of viruses and their antigenic determinants bound to antibodies and suggesting new approaches for vaccine design. The expanded capacity for nucleic acid sequencing has facilitated the discovery and surveillance of viral threats and has provided new insights to the biology of viruses and immune effectors. Technological advances in engineering and manufacturing have made vaccines safer and have created many new approaches for delivery that will have additional benefits on safety, stability, and ease of administration.

Vaccine development typically has required decades to accomplish and has never been a process that could occur in response to a crisis. However, a better awareness of the inevitability of new emerging infectious diseases and heightened concerns about bioterrorism has challenged traditional processes and compelled the consideration of new approaches. For example, the FDA has created the “Two Animal Rule,” which is a provision for vaccine licensure based on efficacy data in animal models combined with safety data in humans for diseases that are not conducive to efficacy trials.[442] A test case for the ability to develop vaccines rapidly for emerging infectious diseases occurred during the outbreak of the SARS coronavirus (CoV). This disease was recognized in the winter of 2003, the virus was identified in March 2003, a full-length sequence was obtained in April 2003, and vaccine development of whole inactivated, vector-based, DNA, and subunit vaccines began immediately. Phase I clinical trials of the whole-inactivated virus vaccine began in the summer of 2004 and DNA trials started in December 2004. Fortunately, by that time, the epidemic had been contained through classical public health approaches of surveillance and quarantine. In 2009, when the pandemic H1N1/A/California/2009 virus appeared, both commercial licensed approaches and some experimental vaccines were in clinical use or testing within 4 months. During the onset of the COVID-19 pandemic, rapid development of highly effective mRNA vaccines was conducted with lightning speed, with the first vaccine approved by the U.S. FDA 11 months after the first case in the United States. Just as toxoids and polysaccharide conjugates have been successful platform technologies for toxin-producing and encapsulated bacteria, respectively, patterns are emerging for vaccine approaches that have a high likelihood of success against some types of viruses. For example, using reassortment to produce live attenuated vaccines for viruses with segmented genomes, or producing VLPs with the capsid proteins of nonenveloped and some enveloped viruses appear to be viable platforms for those types of viruses. While this chapter has focused on antiviral vaccines for human pathogens, much can be learned from the development of veterinary vaccines (e-Table 15.3). This list of licensed veterinary antiviral vaccines is shown to demonstrate the enormous variety of viruses to which vaccines have been developed, the types of approaches that have had some measure of success against various virus families, and to illustrate that the introduction of gene-based vaccine approaches into veterinary practice is anticipating the evolution of new human vaccines (e-Table 15.3).

The goal for future vaccine development is to identify preventive strategies for selected pathogens that cause a large disease burden (eg, HIV-1, RSV, dengue, and HSV), that have the potential for sporadic epidemics or intentional release and high disease severity (eg, orthopoxviruses, filoviruses, flaviviruses), or emerging pathogens with the potential for causing widespread epidemics (eg, chikungunya or H5N1 influenza), and at the same time, develop platform technologies that can be deployed more rapidly when new virus diseases emerge (eg, SARS-CoV and West Nile virus). A major goal in the field is development of more broadly protective or universal vaccines for antigenically variable viruses including influenza and coronaviruses. Large-scale “prototype pathogens” research programs are being launched with the goal to develop prototype vaccines for pathogens that elucidate immunity principles for entire classes of viruses. In the case of an epidemic, such principles learned with one representative pathogen might be used to rapidly develop new vaccine for emerging or new viruses in that same class or family. The 21st century promises higher capacity for protein production, structure-based Ag design, molecular adjuvants, and delivery devices to direct immune response patterns, a better understanding of the genetics of human immune response polymorphisms and repertoire, and more complete knowledge of immune effector mechanisms. In addition, the safety and efficacy of several classes of gene-based delivery vectors will be determined. These advances will hopefully provide the knowledge and infrastructure needed to develop vaccines for new emerging viruses and for difficult viruses that have eluded vaccine solutions and continue to impact human health. The optimal implementation of new vaccine strategies and informing individuals with vaccine hesitancy will require full engagement of scientists and public health authorities with the public. Clear and consistent communication about the risks and benefits of vaccines is needed. Clarifying the central goal of most vaccine programs (protection from severe disease but not always mild disease or infection) will be important. Increasing equitable access to vaccines for all people at risk is a major goal of current public health efforts.

Acknowledgments

I acknowledge the extensive previous work done on this chapter by Drs. Julie Ledgerwood and Barney Graham, with whom I worked on the previous edition. I thank the many staff members and trainees in my laboratory at Vanderbilt who provided many thoughtful conversations about the current state of the viral vaccine field.

Introduction

Diagnostic virology continues to evolve rapidly. Viral testing is essential for the care of hospitalized patients with acute respiratory infections; transplant recipients and other immunocompromised patients; patients infected with human immunodeficiency virus (HIV), hepatitis C virus (HCV), and hepatitis B virus (HBV); and infants with possible congenital infection, and many others. Diagnostic virology also stands as the first line of defense against the emergence of new viruses in the human population. Multiple test methods can be useful, but molecular tests have emerged as the dominant diagnostic technology with rapid point-of-care antigen tests serving as an additional tool. A variety of highly automated commercial molecular assays have been approved or cleared as *in vitro* diagnostic tests by the Food and Drug Administration (FDA). This is an important development because it makes viral diagnostic testing available to more laboratories, and it improves the standardization of diagnostic testing. Furthermore, the emergence of rapid, multiplex syndromic panels has reshaped diagnostic virology. The scope of diagnostic virology has broadened, especially in the wake of the COVID-19 pandemic. General categories of viral diagnostic testing and the viruses included in those categories are shown in Table 16.1.

TABLE 16.1 Categories of testing performed in diagnostic virology

Category of Testing	Specific Viruses	Methodology
Respiratory viruses	Influenza A and B, RSV, PIV 1-4, hMPV, rhinoviruses, enteroviruses, coronaviruses, adenoviruses	Rapid antigen tests (SARS-CoV-2, influenza A and B, RSV), fluorescent antibody staining, culture, multiplex NAAT
Gastrointestinal viruses	Rotavirus, norovirus, adenovirus, astrovirus	Rapid antigen tests (rotavirus, norovirus, adenovirus), NAAT
Mucocutaneous viruses	HSV, VZV, HPV	Fluorescent antibody staining (HSV and VZV), culture (HSV and VZV), NAAT
Central nervous system viruses	HSV, VZV, CMV, EBV, HHV-6, JCV, enteroviruses, parechoviruses, West Nile virus, other arboviruses	NAAT, serology (West Nile and other arboviruses)
Opportunistic agents	CMV, EBV, BKV, HHV-6, adenoviruses	NAAT, serology
Mononucleosis syndrome in nonimmunocompromised individuals	EBV, CMV, HIV	Serology, NAAT
HIV, HCV, HBV viral loads	HIV, HCV, HBV	NAAT
Viral genotyping	HCV, HBV, HPV, HIV, CMV	Nucleotide sequencing, reverse hybridization, NAAT (cleavase reaction for HPV)
HIV, HCV, HBV diagnosis	HIV, HCV, HBV	Serology, NAAT
Systemic infections of childhood	Parvovirus B19, measles virus, rubella virus, mumps virus	NAAT, serology
Tropical and emerging infections	Dengue and other flaviviruses; chikungunya and other alphaviruses; hemorrhagic fever viruses including arenaviruses, bunyaviruses, and filoviruses; Hendra and Nipah viruses	Serology, culture, NAAT (hemorrhagic fever testing is done in BSL-4 laboratories)
Unknown virus	Any	Culture, metagenomic next-generation sequencing

BKV, BK virus; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HHV-6, human herpesvirus 6; HIV, human immunodeficiency virus; hMPV, human metapneumovirus; HPV, human papillomavirus; HSV, herpes simplex virus; JCV, JC virus; NAAT, nucleic acid amplification testing; PIV, parainfluenza virus; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.

History of Diagnostic Virology

Modern diagnostic virology dates to the first growth of human viruses in tissue culture reported by Weller and Enders in 1948.[84] This and other landmarks in the history of diagnostic virology are shown in Table 16.2.

TABLE 16.2 Landmarks in the history of diagnostic virology

Year	Landmark
1892	Intranuclear and intracytoplasmic inclusions noted at the base of smallpox lesions
1898	Discovery by Loeffler and Frosch that foot-and-mouth disease of cattle is caused by a filterable agent, referred to as a virus
1929	Complement fixation method described for detection of antibodies to smallpox, vaccinia, and varicella-zoster viruses[3]
1948	First growth of pathogenic human viruses in tissue culture[84]
1956	Detection of influenza virus in respiratory secretions using fluorescent antibody staining[45]
1975	Development of monoclonal antibodies as diagnostic reagents[42]
1985	Discovery of PCR[69]
1992	Development of real-time PCR[34]
2002	Beginning of systematic approaches to virus discovery[27,31]
2007	Description of multiplex PCR for respiratory viruses[47]
2020-2021	Widespread diagnostic testing for SARS-CoV-2 for public health purposes, including availability of at-home testing

PCR, polymerase chain reaction.

Specimens for Viral Diagnosis

The ability to make a specific viral diagnosis relies on the quality of the specimen that is received in the laboratory. Important variables include the timing of the specimen in relation to the patient's illness, the type of specimen, the quality and amount of specimen material obtained, and the time and conditions of transport to the laboratory. Optimizing the variables listed requires knowledge on the part of the care provider and close attention to logistical considerations.

For the diagnosis of acute viral infections, the best specimens are usually obtained from the site of disease. For example, in the patient with suspected viral meningitis, cerebrospinal fluid (CSF) is the best specimen. In infections involving skin or mucosal surfaces, specimens obtained from those surfaces are usually the only ones required. Viral quantities are often highest early in the course of an acute illness, so that specimens obtained within the first few days after onset are most likely to be positive.

Viral culture requires more attention to conditions of transport than specimens submitted for detection of viral antigens or nucleic acids, because the viability of the virus must be preserved. A number of clinically important viruses are labile and will not survive prolonged transport. Consultation with the laboratory performing testing is generally advised.

For serologic diagnosis, an acute phase serum specimen should be obtained within the first few days of illness and a convalescent phase specimen 2-4 weeks later. If a virus-specific immunoglobulin M (IgM) assay is available, the acute phase specimen may be sufficient by itself. For certain viral infections, serologic tests can also be performed on saliva, CSF, or urine.

Methods Used in Diagnostic Virology

Viral Culture

For almost 50 years, viral culture was the signature method of diagnostic virology laboratories, and it was the method that led to the establishment of virology laboratories as distinct entities apart from other areas of the clinical laboratory. With the advent of immunological and molecular methods, which are more rapid than viral culture and potentially detect a broader range of viruses, cell culture has been eliminated by some diagnostic virology laboratories. For this reason, the treatment of cell culture in this chapter will be brief, and the interested reader is referred to other sources such as ASM's *Manual of Clinical Microbiology* or Lennette's *Laboratory Diagnosis of Viral Infection*.

By their very nature, viruses require living systems for propagation. Initially, inoculation of animals such as suckling mice or embryonated eggs was used to grow viruses. Such methods were subsequently supplanted by cell culture in the diagnostic laboratory. To grow viruses in cell culture, a clinical sample is prepared and then inoculated onto one or more cell lines (e-Table 16.1). Typically, several cell culture types are inoculated, because no one type supports the growth of all clinically relevant viruses. Cell culture types that are commonly used are shown in Table 16.3. After inoculation, viral growth is detected in one of several ways. Traditionally, the principal method was the appearance of cytopathic effect, which refers to morphologic changes observable by microscopy that occur in virally infected cells (Fig. 16.1). Confirmation of

virus growth, suspected based on one of the indicators described previously, can be achieved by immunofluorescence or by molecular analysis. In puzzling cases, electron microscopy can be used to look for viral particles that would confirm viral infection and might provide taxonomic information based on morphologic characteristics. Other methods that have been used to enhance viral cultures are use of hemadsorption to detect viral growth, centrifugation (including shell-vial cultures, e-Fig. 16.1), mixed cell type cultures, and use of cells that have been genetically engineered to enhance viral growth and/or detection in culture.

TABLE 16.3 Cell culture types used to detect medically important viruses

Cell Culture Type	Cell Type	Viruses Detected
Primary	Monkey kidney	Influenza viruses, parainfluenza viruses, enteroviruses
	Rabbit kidney	Herpes simplex virus
	Human embryonic kidney	Adenovirus, enteroviruses
Diploid	Fibroblasts (eg, MRC-5, WI-38)	CMV, VZV, HSV, rhinovirus, enteroviruses (some), adenovirus, RSV
Continuous	HEp-2	RSV, adenovirus, HSV, parainfluenza viruses (some), enteroviruses (some)
	A549	HSV, adenovirus, enteroviruses
	MDCK	Influenza viruses
	LLC-MK2	Parainfluenza viruses, hMPV
	Rhabdosarcoma (RD)	Echoviruses
	Buffalo green monkey	Coxsackieviruses

CMV, cytomegalovirus; hMPV, human metapneumovirus; HSV, herpes simplex virus; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.

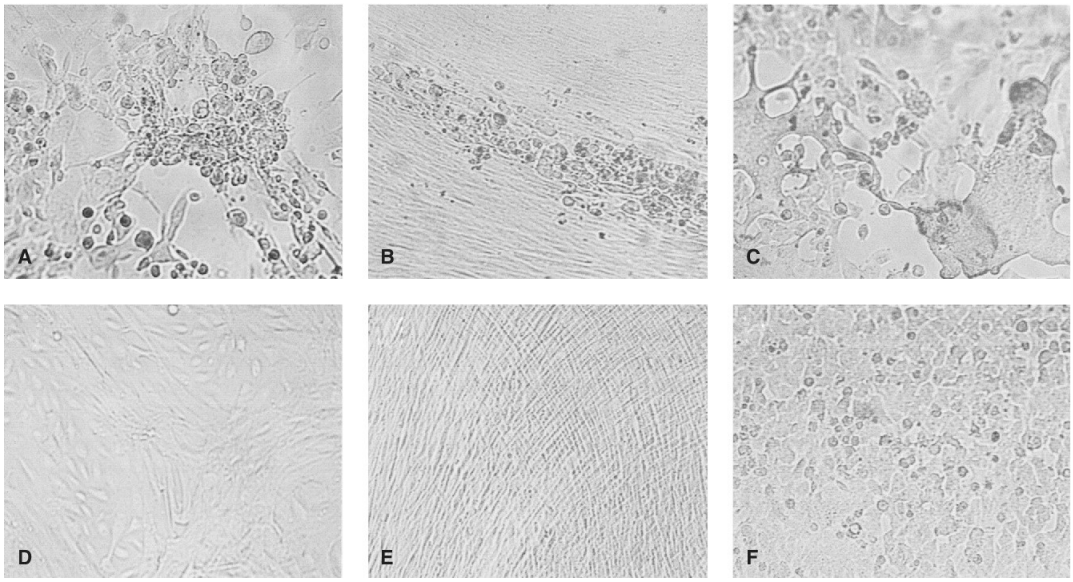

FIGURE 16.1 **Cytopathic effect caused by viruses growing in cell culture**. Herpes simplex virus growing in primary rabbit kidney cells **(A)**; uninfected primary rabbit kidney cells **(D)**. Cytomegalovirus growing in human embryonic lung fibroblast cells **(B)**; uninfected human embryonic lung fibroblast cells **(E)**. Respiratory syncytial virus growing in HEp-2 cells **(C)**; uninfected HEp-2 cells **(F)**.

e-TABLE 16.1 Instructions for obtaining and transporting specimens for viral testing[a]

Specimen	Instructions[b]
Blood	Volume requirement varies according to the specific test required. Molecular methods generally require lower blood volumes than does culture. The appropriate tube is determined by the test to be performed, the blood component on which the test is performed (whole blood, leukocytes, plasma, or serum), and the preference of the laboratory. Whole blood, leukocytes, and plasma require collection into a tube containing an anticoagulant. The most commonly used anticoagulants are ethylenediaminetetraacetic acid (EDTA) (purple top tube), heparin (green top tube), and acid-citrate-dextrose (yellow top tube). Note: Heparin is inhibitory for some polymerase chain reaction (PCR) procedures, especially those performed on plasma. Some nonculture tests performed on blood may have specific collection tube requirements that can be determined through communication with the laboratory. Most serologic procedures are performed on serum, although some tests can also be performed on plasma. Serum specimens require collection into a tube that does not contain an anticoagulant (red top tube or gold top serum separator tubes). Blood specimens do not have to be placed on ice if transport requires >1 day. Note: Prolonged transport can severely compromise the ability to recover cytomegalovirus (CMV) in culture from blood specimens.[c]
Swab	Swabs with Dacron or rayon tips are preferred. If available, swabs designed specifically for collection of viral specimens should be used. Recently, flocked swabs have been shown to be superior to standard swabs.[d,e] Swabs can also be placed in viral transport media. In this case, the shaft of the swab may have to be cut to allow the top of the transport vial to be securely closed. The swab or tube of transport media should be placed on ice if transport will require more than 1 hour.
Fluid	Place in a sterile container.
Tissue	Place in a sterile container with a small amount of viral transport media or sterile saline or phosphate-buffered saline to maintain moisture.
Stool	Obtain at least 4 g of stool. Place in a clean or sterile container.

[a]Specimens other than blood should be transported on ice if more than 1 hour is required for arrival in the laboratory. If a delay of more than 24 hours is anticipated, specimens should be frozen at −70 °C and transported on dry ice. Note: Some viruses such as respiratory syncytial virus (RSV) and varicella-zoster virus (VZV) are unlikely to retain viability with freezing. Specimens should not be frozen at −20 °C.

[b]Commercial tests may have specific recommendations for collection and transport. These should always be followed to ensure proper assay performance.[c]Roberts TC, Buller RS, Gaudreault-Keener M, et al. Electron Microscopy

Historically, electron microscopy was used for the evaluation of stool specimens from patients with suspected viral gastroenteritis. Viruses such as rotavirus, astrovirus, and adenovirus could be identified based on their characteristic morphology, but this has been replaced by rapid immunoassays and PCR assays. Electron microscopy can also be used to detect and classify viral particles in fixed tissue obtained by biopsy or at autopsy. However, viral infections are rarely diagnosed using electron microscopy for the direct visualization of viral particles in specimens due to cost and complexity of maintaining an electron microscopy, the need for a skilled operator, and limited sensitivity related to the relatively high concentration of viral particles (10^5-10^6/L) that is required for visualization.

Light Microscopy

Although viral particles, with the exception of poxviruses, cannot be directly visualized by light microscopy, indirect evidence of viral infection can be detected. The most characteristic signs of viral infection are inclusion bodies (composed of masses of virions), multinucleated cells, and syncytial cells (e-Table 16.2). These findings may be present in cytologic specimens or in tissue examined after histologic staining. Cytologic examination for evidence of viral infection can be performed on smears prepared by applying a specimen directly to a microscope slide, on slides prepared by cytocentrifugation of fluids (eg, bronchoalveolar lavage fluid), and on touch preparations prepared from pieces of unfixed tissue. Microscopy for detection of the effects of viral infections in clinical specimens is generally carried out in surgical pathology rather than diagnostic virology laboratories.

Rabies		×

Cytology and Histology

Cytologic examination for evidence of viral infection can be performed on smears prepared by applying a specimen directly to a microscope slide, on slides prepared by cytocentrifugation of fluids (eg, bronchoalveolar lavage fluid), and on touch preparations prepared from pieces of unfixed tissue. Viruses that can produce cytologic evidence of infection in respiratory specimens include HSV, CMV, adenoviruses, polyomaviruses, and measles virus. Cytologic examination is usually not a sensitive method for detection but provides strong evidence for tissue involvement. Examples of cytologic findings suggestive of viral infection are shown in Figure 16.2. The Tzanck smear is a method sometimes used to detect cytologic evidence of HSV or VZV infection. It is rarely used in diagnostic virology laboratories because techniques such as fluorescent antibody (FA) staining and PCR are more sensitive and specific. The Papanicolaou stain (Pap smear) is used to detect evidence of HPV infection in cells obtained from the uterine cervix. HPV infection produces characteristic changes in keratinocytes, including a condensed nucleus with a prominent perinuclear clear zone referred to as *koilocytosis*. Urine cytology may reveal intranuclear inclusions indicative of infection with either CMV or the polyomaviruses, JC and BK; however, PCR is both more sensitive and specific.

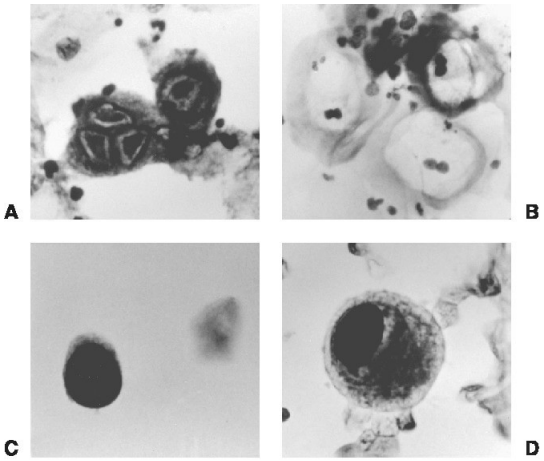

FIGURE 16.2 **Cytologic findings suggestive of viral infection**. **A**. Cervical smear showing multinucleated cells and the Cowdry type A intranuclear inclusions of herpes simplex infection. **B**. Papanicolaou smear showing binucleate squamous epithelial cells with distinct perinuclear halos. These characteristics, described as *koilocytosis*, are the cellular features associated with human papillomavirus infection. **C**. Urinary epithelial cell containing an enlarged nucleus with smudgy chromatin and a small pale *glassy* intranuclear inclusion indicative of polyomavirus infection. **D**. Cell from bronchoalveolar lavage with a large intranuclear inclusion with a perinuclear clear space (owl's eye cell) indicative of cytomegalovirus infection. (Photographs provided by Dr. Leslie Boucher, Department of Pathology, Washington University, St. Louis, Missouri.)

Antigen Detection

The detection of viral antigens directly in clinical specimens is widely used to obtain rapid evidence of viral infection. The lack of requirement for virus viability and ability to be performed at home or in a physician's office are important advantages. For most viruses, the sensitivity of antigen detection equals or exceeds that of viral culture.[64,78] Antigen detection methods can be applied when the following conditions are met: (1) viral antigen is expressed and is present in an accessible specimen, (2) an appropriate antibody (usually but not necessarily monoclonal) is available, (3) antigenic variability does not preclude recognition by immunologic reagents of different strains of the target virus, and (4) the antigen being detected is sufficiently stable that it does not degrade during transport and processing of the specimen. Methods used for viral antigen detection include FA staining, immunoperoxidase staining, and enzyme immunoassay. The latter can be subdivided into solid phase and lateral flow immunochromatographic assays.

Antigen detection can also be used to detect viral antigens in fixed tissue (immunohistochemistry [IHC]). This method can document the specific viral etiology of a nonspecific finding such as an inclusion body that could be produced by several different viruses. In some cases, IHC also enhances the sensitivity of detection of viruses in tissue compared to standard light microscopy without immunostaining. Immunoperoxidase

staining is the most common technique used for viral antigen detection in fixed tissue.

Fluorescent Antibody Staining

Fluorescent antibody staining is widely used to detect cell-associated viral antigens. In the direct format, a fluorescent label, usually fluorescein isothiocyanate (FITC), is conjugated directly to the antibody that recognizes the viral antigen. In the indirect format, the antiviral antibody is unlabeled and is detected by a second antibody that recognizes immunoglobulins from the animal species of origin of the antiviral antibody. The second antibody carries the fluorescent label. Prior to widespread molecular methods, FA staining was a common multiplexed method to detect respiratory, ocular, cutaneous, and bloodstream pathogens. Specimens are processed in the laboratory to prepare a pellet of cells, which is spotted onto one or more microscope slides. The cells are air dried, fixed in acetone, and stained with monoclonal antibodies to one or more viruses. The major limitation of FA staining is having an adequate number of cells in the specimen and low analytical sensitivity compared to molecular methods.

Enzyme Immunoassay

Enzyme immunoassay (EIA) is a versatile and widely used method that can be applied to the detection of antigens or antibodies. Because intact cells in the specimen are not required, specimen integrity is less important than for FA or IP staining. A common assay format for antigen detection is the double antibody sandwich technique, shown in Figure 16.3. In this assay, a *capture* antibody specific for the viral antigen being sought is bound to a reaction surface, for example, the wells of a plastic microtiter tray or the surface of a plastic bead. When the specimen is added, viral antigen present in the specimen binds to the capture antibody. Bound antigen is detected using a different antiviral antibody, the *detector* antibody. The detector antibody can be labeled with an enzyme or can be detected by the addition of an enzyme-labeled third antibody with specificity for immunoglobulin of the species from which the second antibody was derived. The addition of an enzyme substrate produces a color change or light emission if the enzyme is present. Thus, color change or light emission indicates that viral antigen was present in the specimen being tested. Advantages of EIA include applicability to diverse specimens and potential for automation. Laboratory instruments are now available that can perform EIA to detect either antigens or antibodies.

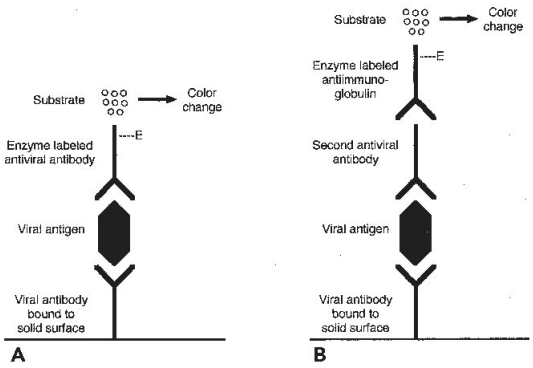

FIGURE 16.3 **Enzyme immunoassay (EIA) for antigen detection**. **A**. Direct. **B**. Indirect.

Membrane Immunoassay

The lateral flow immunochromatographic assay is a variant of EIA that was first used in home pregnancy tests. A schematic diagram of a lateral flow unit is shown in Figure 16.4. In these tests, a sample is applied directly to a membrane and is drawn across the membrane by capillary action. Antigens in the sample react first with an antibody with specificity for the antigen being detected. This antibody is conjugated to a detector label such as gold particles or fluorescein. If binding occurs, the antigen-antibody complexes sweep across the membrane until they are captured by a second antibody that is bound to the membrane. When the labeled antigen-antibody complexes are captured, a line becomes visible because of the concentration of the label into a limited physical space. Most assays also include a positive control. These assays can be configured as dipsticks or as self-contained cassettes that are amenable to highly distributed testing. Standard lateral flow immunochromatographic assays do not require an instrument and are convenient for testing single samples, with results available in 5-20 minutes. Multiple commercial versions are now available, mainly for detection of SARS-CoV-2, influenza virus, respiratory syncytial virus (RSV), and rotavirus. Many of the tests are sufficiently simple to perform that they have been assigned *waived* status under the Clinical Laboratory Improvement Amendments (CLIAs), meaning that they can be performed by individuals without specific training who can be working within or outside of a certified clinical laboratory. Sensitivity of these tests has been less than that of molecular testing. This problem was especially true for commercial influenza lateral flow tests in detecting the 2009 HIN1 pandemic. During the SARS-CoV-2 pandemic, the regulatory pathway for waived at-home antigen testing greatly eased and, as a result, tens of millions of antigen tests are now manufactured per month, opening up a new avenue for community viral diagnostics in the coming decade. These tests generally had analytical sensitivities in the tens of thousands of copies per swab, which matched that of virus culture and could help rapidly identify individuals with treatable and/or highly transmissible amounts of virus early in illness.[61] Improvements in analytical sensitivity as well as chain of custody for more regulated, diagnostic uses of these tests are expected in coming years. Addition of a detection reader may increase sensitivity of antigen tests as has been shown for RSV and influenza virus previously.[25]

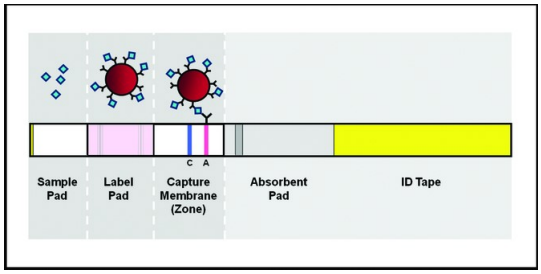

FIGURE 16.4 **Lateral flow immunochromatographic assay**. The sample is applied to the sample pad. The sample flows across the unit from left to right, drawn by the absorbent pad. Located in the label pad are one or more antibodies, each of which is conjugated to a label such as gold particles. These antibodies bind to antigen present in the sample as it moves across, forming complexes of antigen with conjugated antibody. If present, these complexes are then captured by second antibodies, located in lines in the capture membrane zone. When complexes are captured, the presence of the conjugated label causes the line to become visible. In the figure, antibodies against the target antigen are indicated by "A," and antibodies against a control antigen are indicated by "C." Presence of a colored line corresponding to A is a positive test. Presence of a line corresponding to C in the absence of a line corresponding to A indicates a negative test. Absence of both lines indicates that the test is not valid. (Figure provided by John Tamerius, Quidel Inc.)

Nucleic Acid Detection

Diagnostic virology has been revolutionized by the application of nucleic acid detection techniques, which detect specific DNA or RNA sequences, that can be applied to the detection of virtually any virus. Depending on the target sequence, the assays can be specific for a single virus species or for a group of related viruses. The latter characteristic is particularly advantageous, because it allows nucleic acid detection techniques to be applied to groups of viruses (eg, the enteroviruses/rhinoviruses) for which antigenic diversity has precluded successful application of antigen detection techniques. For example, enteroviruses, for which a rapid nonmolecular detection method had not been available, can be detected using reverse-transcription PCR assays that amplify a highly conserved sequence in the 5′ nontranslated region of the genome.[9,66] An overview of applications of nucleic acid testing in diagnostic virology is shown in e-Table 16.3.

e-TABLE 16.3 Nucleic acid detection for viral diagnosis

Target	Specimen(s)	Application(s)
HIV (DNA)	Leukocytes from infant born to HIV-infected mother	Diagnosis of perinatal infection
HIV (quantitative RNA)	Plasma	Viral load (prognosis, response to treatment)
HIV (qualitative RNA)	Plasma	Confirmation of diagnosis
HSV	CSF, ocular fluid, swabs from mucocutaneous lesions, blood	Diagnosis of encephalitis, meningitis, retinitis, mucocutaneous lesions
VZV	CSF, ocular fluid, swabs from mucocutaneous lesions, blood	Diagnosis of encephalitis, meningitis, retinitis, mucocutaneous lesions
CMV	Blood (whole blood, leukocytes, or plasma), CSF, ocular fluid, amniotic fluid	Diagnosis of systemic infection after organ transplantation, encephalitis, radiculomyelitis, retinitis, congenital infection. Quantitative assay performed on blood can be used to assess severity of infection and monitor response to therapy
EBV	CSF, blood (whole blood, leukocytes, or plasma)	Primary central nervous system lymphoma in AIDS, other EBV infection of the central nervous system, and posttransplant lymphoproliferative disorder. Quantitative assay performed on blood can be used to assess the risk of PTLD and the response to therapeutic interventions
HHV-6, -7	Blood, CSF	Diagnosis of systemic infection and of encephalitis
HHV-8 (Kaposi sarcoma virus)	Blood, pleural, or pericardial fluid	Diagnosis of body cavity lymphoma
Adenovirus	Blood, respiratory secretions, urine	Diagnosis and monitoring of disseminated infection in immunocompromised hosts, diagnosis of respiratory tract infection
Parvovirus B19	Serum, amniotic fluid	Diagnosis of acute or chronic parvovirus B19 infection, aplastic crisis, congenital infection
BK virus	Urine, plasma	Assessment of risk of transplant nephropathy in renal transplant recipients and of hemorrhagic cystitis in hematopoietic stem cell transplant recipients
Human papillomavirus	Genital secretions	Detection of viral types associated with cervical carcinoma
Enteroviruses	CSF, blood (whole blood, serum, or plasma)	Diagnosis of meningitis, encephalitis, or systemic infection
Hepatitis C	Plasma	Diagnosis of infection. Quantitative assay is used to assess response to therapy
Hepatitis B	Serum	Diagnosis of infection when serologic studies are ambiguous. Recognition of virologically active infection. Quantitative assay is used to assess response to therapy and recognize emergence of drug resistance
Rabies	Saliva, CSF	Diagnosis of rabies
Respiratory viruses	Respiratory samples	Enhanced sensitivity, including detection of noncultivable agents
Gastrointestinal viruses	Feces	Enhanced sensitivity, including detection of noncultivable agents
West Nile and other flavivirus infections	CSF, blood	Rapid diagnosis of CNS infection, especially in immunocompromised hosts, screening of blood units for presymptomatic infection
Dengue	Plasma	Diagnosis of early infection, genotyping
Arenaviruses	Serum or whole blood	Diagnosis of acute infection
Filoviruses	Serum or whole blood	Diagnosis of acute infection
Nipah and Hendra viruses	CSF, throat swabs, urine	Diagnosis of acute infection
Vaccinia and other pox virus infections	Lesion	Diagnosis of acute infection

CMV, cytomegalovirus; CNS, central nervous system; CSF, cerebrospinal fluid; EBV, Epstein-Barr virus; HHV, human herpesvirus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; PTLD, posttransplant lymphoproliferative disorder.

The earliest attempts at nucleic acid–based diagnosis involved direct hybridization of nucleic acid probes to viral nucleic acids present in clinical specimens. Direct hybridization was never widely adopted because it lacked adequate sensitivity, requiring the presence of 10^4-10^5 copies of the target nucleic acid. The development of PCR[69] and other nucleic acid amplification techniques overcame that sensitivity barrier and has led to the development of nucleic acid–based diagnostic tests for many viruses. Nucleic acid amplification tests (NAATs) were originally directed at viruses that were difficult or impossible to cultivate, viruses that grew very slowly in culture, and viruses for which antigen detection could not be applied because of antigenic diversity or because the level of viral antigen in clinical specimens was too low to permit successful detection. NAATs were also very advantageous for specimens such as CSF or ocular fluid for which sample volume could be limiting. Still another advantage of nucleic acid detection as a diagnostic method is the stability of DNA as an analyte, so that detection of viral nucleic acids can be done even when conditions of transport lead to loss of virus viability. Currently, NAATs are being applied to almost all viruses that are of interest in diagnostic virology.

Nucleic Acid Amplification Assays

Target Amplification

Polymerase chain reaction

PCR is the prototype of target amplification assays and employs short oligonucleotide primers and a thermostable DNA polymerase such as *Taq* polymerase to amplify a segment of target DNA that is typically 100-1000 base pairs (bp) in length. Classic PCR includes repetitive cycles, each

consisting of denaturation, primer annealing, and extension steps that take place at different temperatures. Progression through the steps of the cycle is controlled by a thermal cycler that controls the temperature of the reaction. After PCR amplification, the PCR product (also known as the *amplicon*) can be detected by gel electrophoresis or by one of several probe-hybridization techniques (eg, Southern blotting). The analytic sensitivity of PCR can be as low as 1-10 copies of target DNA. Because of its simplicity and broad applicability, PCR remains the most widely used NAAT.

Most PCR in diagnostic virology laboratories is carried out using real-time PCR in which reaction products are detected as they are synthesized.[24,33] Compared with conventional PCR, real-time PCR has several important advantages. Because the accumulation of PCR product is monitored in the reaction tube, no separate detection method (eg, gel electrophoresis) is required, thus shortening the effective assay time markedly and decreasing the risk of contamination of the laboratory environment by the amplified PCR product. The time from setting up the assay to completion can be <1 hour. Many systems allow the performance of multiplex reactions with simultaneous amplification and detection of more than one product. Of great importance, by following the emergence of detectable PCR amplicon vs the number of PCR cycles, real-time PCR allows estimation of the amount of viral nucleic acid within a clinical sample. Alternatively, absolute quantitation of viral nucleic acids can be performed using digital PCR techniques, which partitions the PCR reaction spatially or within emulsions into tens of thousands of separate PCR reactions.

Detection of PCR products with real-time PCR can be achieved through various methods. The simplest system uses the DNA binding dye SYBR Green, which emits fluorescence when it is bound to double-stranded DNA (dsDNA). When SYBR Green is included in a PCR reaction, the intensity of fluorescence is proportional to the amount of PCR product. Because SYBR Green binds nonspecifically to any dsDNA, signal is generated by undesired amplification products such as primer dimers, as well as by intended amplicons. Discrimination between different amplification products can be achieved through the use of dissociation curves, referred to as *melting point analysis*. Melting point analysis is performed after completion of the amplification reaction by recording fluorescence as the temperature of the reaction mix is gradually increased. When the dissociation temperature (melting point) of the dsDNA reaction product is reached, SYBR Green is released and fluorescence decreases. The melting point is affected by both length and sequence of the PCR product and thus is precisely defined for a specific PCR product. Unintended amplification products will usually have different melting points, allowing easy discrimination from the intended PCR product.

The other detection systems are based on the use of oligonucleotide probes that are labeled with fluorescent dyes that interact with one another according to principles of fluorescence resonance energy transfer (FRET). The main assay format used is the fluorogenic 5′ exonuclease assay (also referred to as the *Taqman assay*). This assay uses a probe that is complementary to a segment of the intended PCR product located between the PCR primers. This probe is labeled with two fluorescent dyes, one called the *reporter* that is linked to the 5′ end of the probe, and the other called the *quencher* that is linked to the 3′ end. When they are in close proximity (ie, bound to opposite ends of an oligonucleotide probe), the quencher prevents fluorescence by the reporter. During the extension step of PCR, the probe labeled with both dyes binds to the PCR product as it is being synthesized. During extension, the 5′ exonuclease activity of *Taq* polymerase cleaves nucleotides from the 5′ end of the bound probe, releasing the reporter dye away from the quencher, thus allowing it to emit light on excitation. The intensity of fluorescence is proportional to the amount of PCR product.

The hybridization probe assay format uses two oligonucleotide probes that are homologous to adjacent portions of one of the strands of the amplified DNA. The probes are chosen so that the 5′ end of one probe is within a few nucleotides of the 3′ end of the other probe. These adjacent ends are each labeled with a fluorescent dye. The dye on the 3′ end is termed the *donor dye* and the dye on the 5′ end is termed the *acceptor dye*. The required property of these dyes is that when they are in close proximity (within a distance of several nucleotides), excitation of the donor dye leads to emission of light by the acceptor dye. When both probes bind to their target sequences, the two dyes are within the proximity required for excitation of the acceptor dye and fluorescence occurs. The fluorescence intensity again is proportional to the amount of PCR product. Alternatively, in the molecular beacon format, a hairpin probe self-hybridizes bringing the fluorophore in proximity to a quencher due, while hybridization of probe to the target nucleic acid separates the quencher from the fluorophore allowing signal detection.

Because *Taq* polymerase uses only DNA as a template, the use of PCR to detect viral RNA sequences requires the inclusion of a reverse-transcription (RT) step before PCR (RT-PCR). Special care must be used in specimen processing because of the susceptibility of RNA to digestion by ribonucleases that may be present in clinical samples. In addition to detecting virion RNA, RT-PCR can also be applied to the detection of viral messenger RNA. This may be particularly useful in the diagnosis of infection caused by viruses that have a latent phase in their life cycle. For these viruses, detection of viral DNA might not distinguish between latent and productive infection, whereas detection of a messenger RNA (mRNA) expressed only in productive infection would be evidence of active viral infection.[70] In addition, in the case of SARS-CoV-2 diagnostics, inclusion of multiple targets for detection in RT-qPCR assays has been especially helpful for both insuring against diagnostic failure due to future viral evolution with sequence changes as well as tracking specific viral strains if and when a target does fail.

RNA amplification assays

Other approaches have been developed that are directed at amplification of RNA. *Transcription-based amplification* (Fig. 16.5) uses three enzymes, RT, ribonuclease (RNase) H, and T7 RNA polymerase, to amplify a target RNA sequence, employing a series of reactions that mimic the retrovirus replication scheme. An advantage of transcription-based amplification assays is that they are isothermal and thus do not require complicated instrumentation. The assays begin with synthesis of a DNA strand that is complementary to the RNA target, using a primer that contains a T7 polymerase binding site at its 5′ end. The resulting DNA-RNA hybrid is converted to dsDNA by the action of RNase H and a second primer that also contains a 5′ T7 polymerase binding site. The dsDNA product then serves as a template for transcription driven by T7 RNA polymerase. The newly synthesized RNA transcripts serve as templates for additional cycles of the reaction. Variants of transcription-based amplification include transcription-mediated amplification (TMA),[23] self-sustained sequence replication (3SR),[32] and nucleic acid sequence–based amplification (NASBA).[14] Currently, NASBA assays for HIV, enteroviruses, and CMV pp67 have been approved by the FDA and are marketed by bioMérieux Inc. (Durham, NC) under the trade name NucliSENS. TMA is the basis for the Panther assays for HIV, HCV, HBV, SARS-Cov-2, influenza A, and influenza B marketed by Hologic (San Diego, CA).

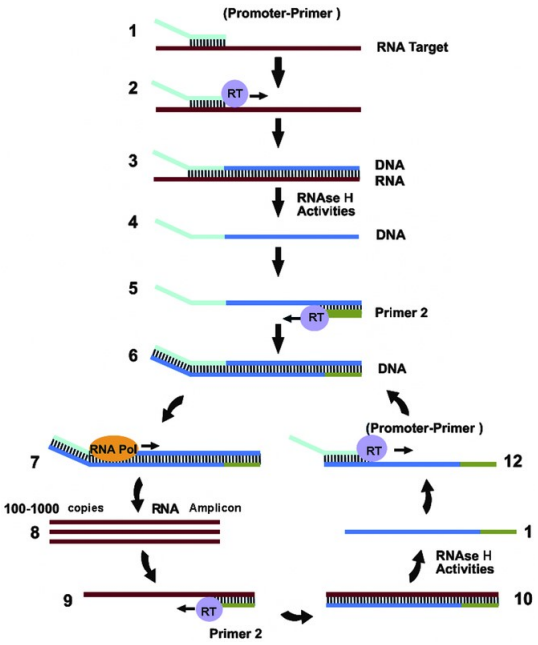

FIGURE 16.5 **Transcription-mediated assay, also called 3SR**. The 3SR reaction depends on a continuous cycle of reverse transcription and transcription reactions to replicate an RNA target by means of complementary DNA (cDNA) intermediates. Steps 1-6 depict the synthesis of a double-stranded cDNA, which is a transcription template for T7 RNA polymerase. Complete cDNA synthesis is dependent on the digestion of the RNA in the intermediate RNA-DNA hybrid (step 4) by ribonuclease (RNase) H. Transcription-competent cDNAs yield antisense RNA copies of the original target (step 7, right). These transcripts are converted to cDNA containing double-stranded promoters on both ends in an inverted repeat orientation (steps 7-12). These cDNAs can yield either sense or antisense RNA, which can re-enter the cycle.

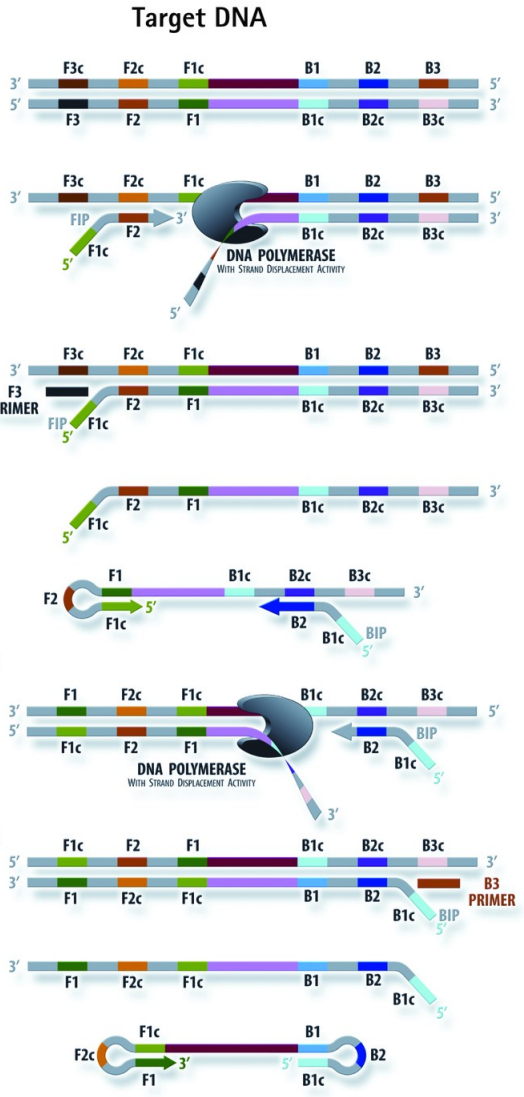
The loop-mediated isothermal amplification (LAMP) (Fig. 16.6) is an amplification reaction that employs four primers and a strand-displacing DNA polymerase.[55] The inner primers have sense and antisense sequences. When they initiate DNA synthesis, the result is a stem-loop structure, which itself serves as a target for additional amplification. The resulting reaction can produce 10^9 copies of target DNA or RNA in <1 hour under isothermal conditions. The reaction can be monitored by measuring turbidity, which results from the accumulation of magnesium pyrophosphate, a by-product of the reaction. Alternatively, the synthesis of dsDNA can be measured using an agent such as SYBR Green, which generates fluorescence when it intercalates between the strands of dsDNA. The reaction has high specificity by virtue of the inclusion of multiple primer sets. The isothermal nature of the reaction, which obviates the requirement for a thermal cycler, makes LAMP attractive for use as a point-of-care test or for use in the developing world. Addition of CRISPR-based detection to (RT-)LAMP-based amplification (or other amplification methods) allows for additional sequence-based specificity in the reaction to confirm that a given viral species was amplified.[7,38] Given the specificity of CRISPR hybridization and the numerous CRISPR-based nucleases now available, such genotyping can be performed in a highly parallel approach within a single reaction vessel. Other methods involving signal amplification are branched-chain DNA assays, hybrid capture assays, and invader assays (e-Figs. 16.2-16.4).

LAMP Process

1. Solution temperature at 60°–65° C
2. Forward Initiating Primer (FIP) anneals to Target Sequence
3. DNA Polymerase initiates synthesis that displaces single strand template DNA
4. Through polymerase activity, a strand complementary to the DNA template is formed
5. The F3 Primer anneals to the F3c Region
6. DNA Polymerase initiates synthesis and the FIP-linked complementary strand is replaced
7. This strand forms a "stem loop" at the 5' end due to complementary F1 and F1c regions
8. The BIP anneals to the 3' end of the "stem loop" strand
9. The B3 Primer anneals to the B3c target
10. From the 3' end, polymerase synthesizes a complementary DNA strand
11. DNA reverts from a Loop structure to a linear structure
12. The BIP linked complementary strand is displaced as a single strand
13. This strand forms stem-loops at either end due to the activity of the dual complementary primers
14. This is the starting structure for LAMP Cycling



A

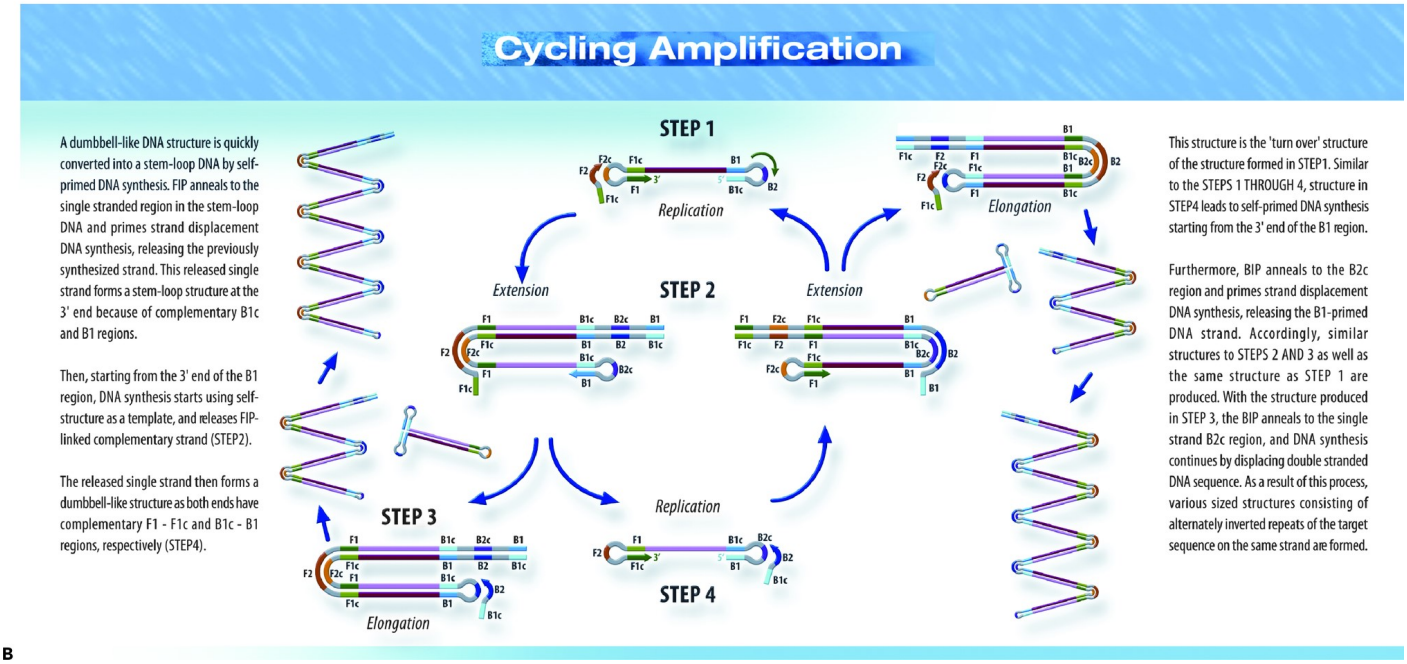


FIGURE 16.6 **Loop-mediated amplification reaction (LAMP assay)**. **A**. Steps leading up to the formation of the "dumbbell" structure. **B**. The cycling steps of the reaction, which lead to extremely rapid amplification. (Courtesy of Meridian Bioscience, Inc.)

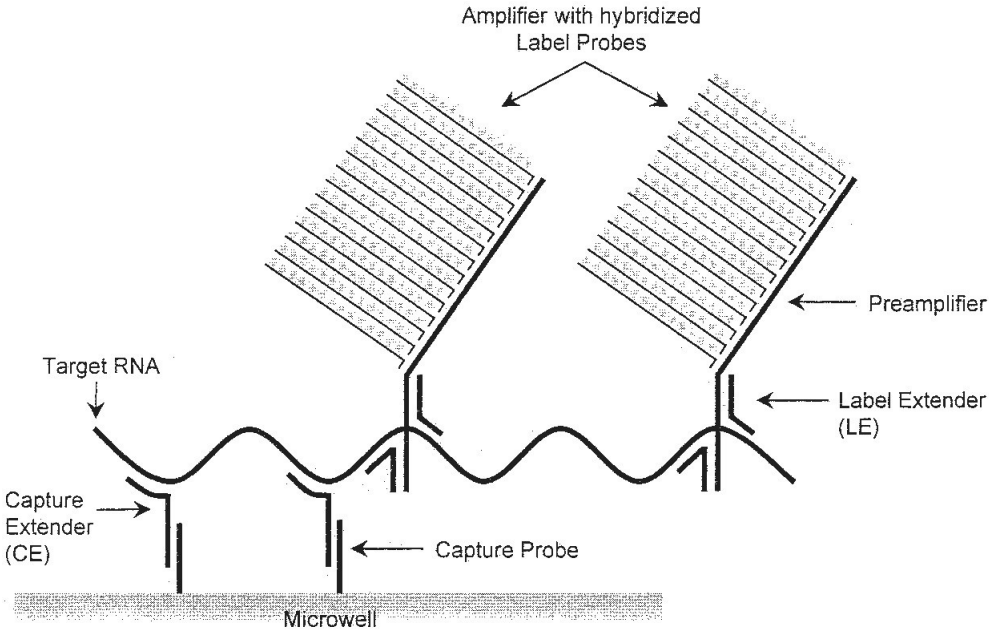
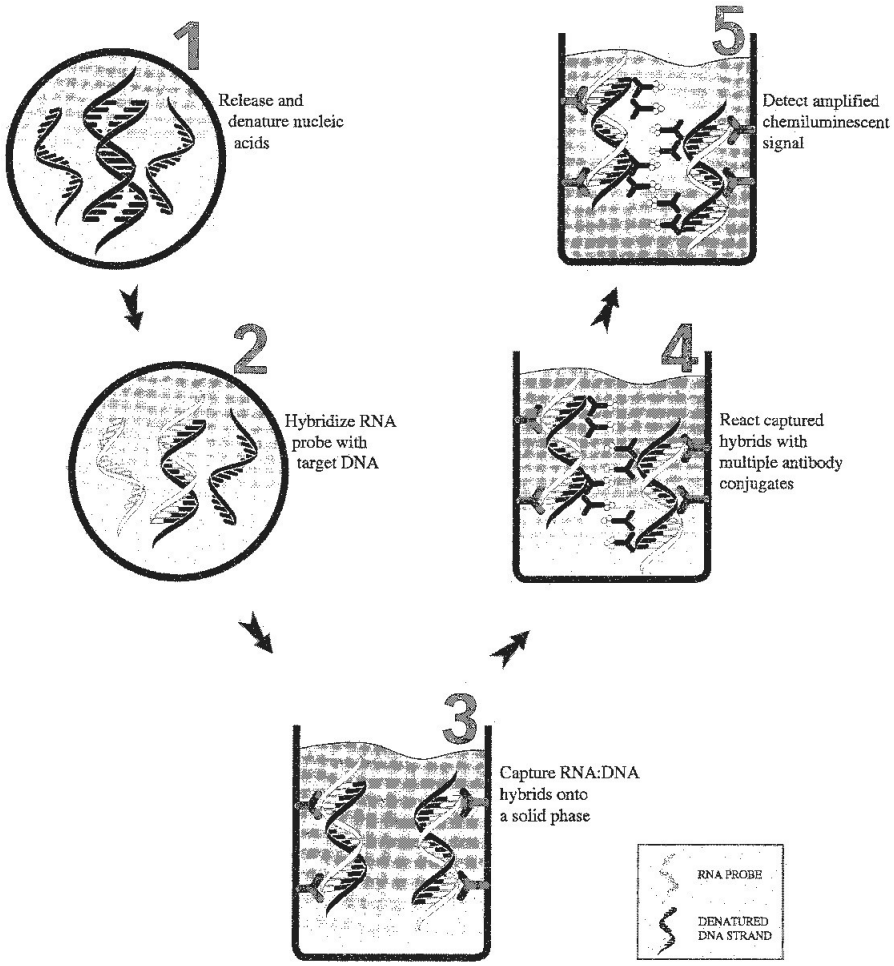
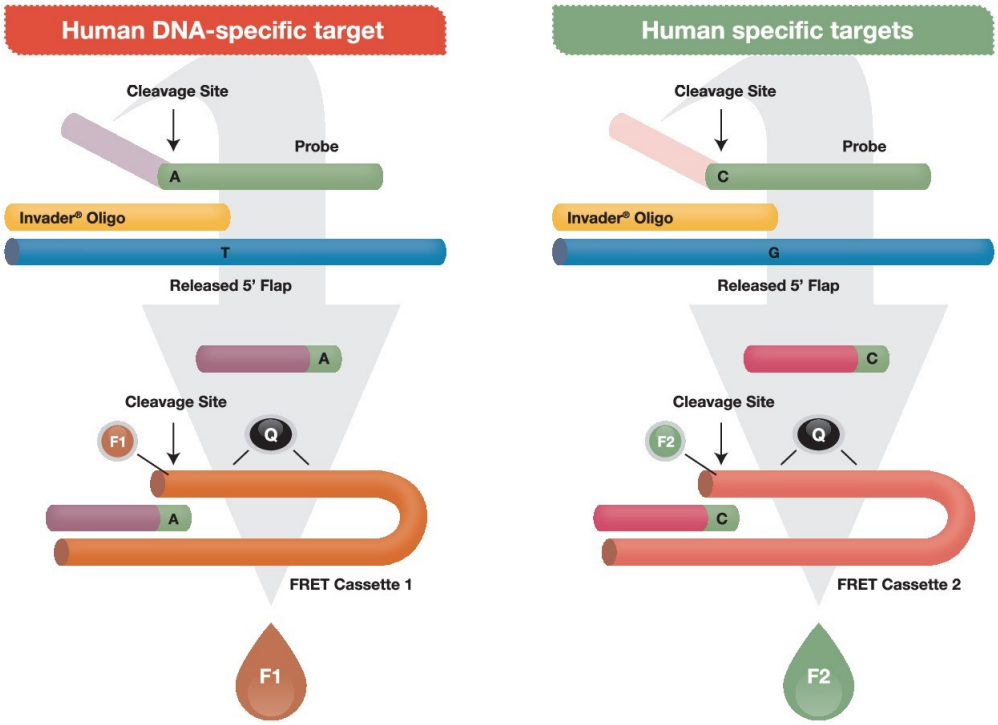


e-FIGURE 16.2 **Branched-chain DNA assay as used for ultrasensitive detection of human immunodeficiency virus (HIV).** After liberation of viral nucleic acid from the clinical specimen by a lysis buffer, viral nucleic acid is hybridized with two sets of bifunctional oligonucleotide probes, each of which contains sequences complementary to the target. One set of probes also contains a generic sequence complementary to a capture probe that is bound to the surface of a microtiter tray and serves to bind the target to the solid surface. The other set of probes contains a sequence complementary to *preamplifier* molecules. Additional specificity is achieved because two of the target-specific probes must be juxtaposed in the correct orientation to stabilize the binding of the preamplifier molecule. Each preamplifier molecule binds numerous amplifier molecules, each of which binds many subsequently added alkaline phosphatase–labeled probes. A chemiluminescent substrate is added and generated light is read by a luminometer. The cascade effect results in amplification of the signal generated from initial binding of probes to the target and allows for detection and quantification of nucleic acid present in the specimen. (Courtesy of Bayer Diagnostics, Emeryville, California.)



e-FIGURE 16.3 **Hybrid capture assay.** In step 1, target DNA is released and denatured. In step 2, RNA probe hybridizes with target DNA. In step 3, RNA-DNA hybrids are captured by an antibody to RNA-DNA hybrids that is bound to the sides of the reaction vessel. In step 4, an enzyme-conjugated antibody that recognizes RNA-DNA hybrids binds to the hybrids. In step 5, a chemiluminescent substrate is added, and light is emitted if hybrids have been formed. (Courtesy of Digene Corporation, Beltsville, Maryland.)



e-FIGURE 16.4 **Invader assay.** The **left side** of the figure shows a positive control reaction for human histone 2DNA and the **right side** shows the reaction to detect human papillomavirus (HPV). For each reaction, the probe oligo and the Invader oligo bind to the

target, with a short region of overlap occurring at a targeted single nucleotide polymorphism (SNP). This results in a structure that is cleaved by the activity of an enzyme called "cleavase," releasing the 5′ end of the probe oligo at the position of overlap. The sequence of the released portion is homologous to the 3′ end of a third oligo, which includes a fluorophore (F1 for the human DNA reaction and F2 for the HPV reaction) and a quencher (Q) and is referred to in the figure as the FRET cassette. The hairpin configuration assumed by the FRET cassette brings the quencher sufficiently close to the fluorophore to allow its fluorescence to be quenched. Binding of the released portion of the probe oligo to the FRET cassette results in a region that is another substrate for cleavase. The activity of cleavase releases the fluorophore, resulting in generation of a fluorescent signal. (Courtesy of Hologic.)

Contamination

A general concern regarding highly sensitive nucleic acid amplification assays is the occurrence of false-positive findings resulting from contamination of the reaction with exogenous nucleic acids. The source of contaminating nucleic acids can be either amplified products from previous reactions or viral nucleic acids present in a different specimen, especially one containing a high level of the intended target. Prevention of contamination requires fastidious attention to procedural detail within the laboratory. A number of specific preventive techniques are widely used to prevent carryover contamination after PCR, including the use of positive displacement pipettes or plugged pipette tips to block aerosol production, UV irradiation of reaction components (not including *Taq* polymerase and PCR primers that can be inactivated by UV irradiation), use of small working aliquots, and frequent cleaning of equipment and laboratory surfaces with 10% bleach. An important precaution is the physical separation of the laboratory into sections where (1) the specimen is prepared, (2) the PCR reaction is set up, (3) the PCR amplification reaction takes place, and (4) the detection of amplification products is carried out. After PCR has taken place, the reaction tube is opened only in the section of the laboratory devoted to product detection. Techniques such as the inclusion of uracil-N-glycosylase or psoralen and isopsoralen derivatives in the reaction mixture were developed to minimize the danger of PCR contamination. Real-time PCR is less susceptible to contamination because product detection does not require manipulating the amplified product. For any form of nucleic acid testing, an additional concern is contamination from one specimen to another, which may occur during specimen handling in the laboratory. Inclusion of negative controls in the reaction setup is important in order to detect this form of contamination.

Nucleotide Sequencing

Sequencing of PCR amplification products can be carried out using the cycle-sequencing reaction or pyrosequencing. Sequence information can be used for several purposes including precise identification of a virus, genotyping, and the presence of mutations associated with antiviral drug resistance or unusual clinical manifestations. Genotypic resistance assays are performed most commonly for HIV, HCV, CMV, HBV, and influenza A virus (see section on Antiviral Susceptibility Testing). For HBV, nucleotide sequencing of the nucleocapsid gene and its associated promoter is also used for detection of core promoter and precore mutations, which have been associated with unusually severe disease and progression to chronic infection.[56] High-throughput ("next-generation") sequencing, as described further below, has important applications in diagnostic virology, including for antiviral susceptibility testing, for identification of viruses growing in cell culture that are not identifiable by conventional means,[76] and for discovery of known[10,86] and novel viruses.[13,57] Increasingly, viral sequencing is also used for epidemiological purposes such as tracking transmission for infection prevention or monitoring effectiveness of vaccines over time.[30,59]

Microarray Technology

High-density microarrays consist of hundreds or thousands of oligonucleotide probes bound to a solid phase, such as a small silicon chip or glass slide. Amplified nucleic acid can be hybridized to the array, and binding to specific probes can be identified. Use of probes representing all possible nucleotide sequence variations within a target sequence allows rapid determination of the nucleotide sequence.[31] Sequence variants present within the specimen can also be detected. An early application in diagnostic virology has been for rapid sequencing to detect HIV mutations associated with resistance to antiretroviral drugs.[44] In another application, sequences representing all sequenced viruses have been selected to create a microarray that can be used to discover unknown viruses. This microarray was successful in categorizing the agent of severe acute respiratory syndrome (SARS) as a new coronavirus.[83] The major application of microarray technology in diagnostic virology to date has been the use of liquid arrays, which are used for the simultaneous detection of multiple respiratory viruses, as exemplified by the xTAG RVP described later. Future uses of liquid arrays and other microarray technology under development include assays to detect multiple viruses (as well as other classes of pathogens) associated with gastroenteritis, sexually transmitted diseases, sepsis, and bioterrorism.

Commercial Nucleic Acid Amplification Platforms and Tests

Government regulation

In the United States, commercially marketed diagnostic tests and test platforms are regulated by the FDA. Before marketing a test for diagnostic use, a manufacturer must receive authorization from the FDA. This authorization can take one of several forms. If there is no similar test on the market, the manufacturer must apply for premarket approval (PMA). This is a rigorous and expensive process that requires the manufacturer to provide evidence for the accuracy and utility of the proposed test. A test that is "substantially equivalent" to a test that has been previously approved or cleared by the FDA is cleared for use through a mechanism referred to as 510K, after the section of the Federal Food, Drug, and Cosmetic Act that describes the process. Some diagnostic test materials are marketed under the classification "analyte-specific reagent (ASR)." This term is used by the FDA to refer to reagents or materials, including nucleic acid primers and probes, that must meet certain specifications set by the FDA, including being produced utilizing current "good manufacturing practices." During a public health emergency, such as that seen for SARS-CoV-2, the FDA authorizes diagnostic tests using an emergency use authorization pathway, which requires fewer studies than the typical 510K pathway. For instance, over 400 EUAs were issued by the FDA during the first 2 years of the SARS-CoV-2 public health emergency.

Individual laboratories may also develop their own assays that are intended for use only in that laboratory. These tests, referred to as "laboratory-developed tests" (sometimes also referred to as "home-brew assays"), are currently not actively regulated by the FDA but instead are under the jurisdiction of CLIA passed by the U.S. Congress in 1988. Laboratory-developed tests may use ASRs as components of the test and may also use reagents obtained from diverse sources not specifically labeled as ASRs. The performance of laboratory-developed tests must be verified according to specific criteria established by CLIA. Laboratory-developed tests filled an important niche for alternative specimen types and/or analytes for which the market is too small to garner commercial interest. In addition, laboratory developed tests were critical for pandemic preparedness such as allowing for early testing in the first months of the SARS-CoV-2 pandemic.[28]

Overview of commercial assays and platforms

Since the last edition of this book, there has been a dramatic increase in molecular diagnostic tests and test platforms that have been approved or cleared by the FDA for the detection of pathogenic viruses. No single platform permits the detection of all medically important viruses, so laboratories whose mission is broad-based viral diagnosis will need to employ multiple platforms. With the high demand for high-throughput molecular SARS-CoV-2 testing combined with increased preanalytical automation and workflow advantages along with increasing regulatory requirements, testing is increasingly carried out using commercial platforms vs laboratory-developed tests. Likewise, laboratories that provide different types of service will employ different platforms. For example, hospital-based laboratories may emphasize platforms that provide rapid turnaround time, commercial laboratories may employ platforms that allow high specimen throughput, and government laboratories may employ platforms that allow for testing of viruses of public health significance. The following paragraphs describe several categories of commercial molecular diagnostic tests.

Multiplex assays

Multiplex PCR refers to PCR reactions in which more than one primer set is incorporated into the reaction mix, allowing the detection of multiple targets. Multiplex assays may be developed either as commercial tests or as laboratory-developed tests. Currently, multiplex assays are being developed for important specimen types to amplify various viral and other microbial agents that are pathogenic at the specific body site. With the increasing availability of antivirals and need to test for viral, bacterial, fungal, and eukaryotic parasite targets at the same time, multiplex testing is increasingly the norm for a given specimen type and a significant proportion of diagnostic virology assays coming onto the market today.

The FilmArray Respiratory Panel was originally cleared by the FDA in 2011 for multiplex detection in nasopharyngeal swabs. The panel has undergone several updates since and detects influenza A and B viruses; influenza A subtypes H1, H1 2009, and H3; RSV; human metapneumovirus; adenovirus; parainfluenza viruses 1 through 4; rhinovirus/enterovirus; and SARS-CoV-2 and seasonal human coronaviruses NL63, HKU1, 229E, and OC43.[63] Several bacterial species (*Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Bordetella pertussis*, and *Bordetella parapertussis*) are also included. Extraction, amplification, and detection are carried out in a self-contained unit referred to as a "pouch." Nucleic acid extraction is accomplished using magnetic beads. The nucleic acid amplification that follows is a multiplex nested PCR assay. The first amplification reaction is a multiplex reaction containing outer primers for each target virus. The reaction mix is then diluted and combined with a new primer-free master mix that contains the fluorescent dye LC Green Plus, which binds to dsDNA. This mix is then moved by microfluidic techniques into an array of individual wells, each of which contains inner primers specific for one target virus. Each target is represented in at least three wells. Production of viral amplicons is confirmed by analyzing melting curves. The entire process from inoculation of sample to availability of results takes ~1 hour, with only 2 minutes of hands-on time. The manufacturer uses a similar approach for other syndromic testing panels. Broad-based sample-to-answer multiplex testing for respiratory viruses is also available via the xTAG Respiratory Virus Panel (Diasorin/Luminex), the eSensor or ePlex (Roche/GenMarkDx), and the QIAstat-Dx systems (Qiagen).

Real-time assays for multiple seasonal respiratory viruses (eg, influenza/RSV) exemplified by the Simplexa Flu A/B & RSV Test and Verigene RV+ (Diasorin) use separate primer pairs to simultaneously amplify influenza A and B viruses and RSV plus an internal control. The Simplexa assay is run on the 3M Integrated Cycler, an innovative instrument produced by 3M/Diasorin. Multiple different specimens can be loaded on the instrument and multiple assays can be run simultaneously. The Verigene RV assay uses an innovative system to detect amplified products in which the amplicons are captured by capture probes that are bound to specific sites on a microarray. Captured amplicons are then detected by binding of silver-coated gold nanospheres that have been tagged with oligonucleotides that are specific for the amplicons and are visualized by light scatter.

Integrated platforms

The term *integrated platform* refers to test platforms in which nucleic acid extraction, amplification, and product detection are carried out within the same device or instrument. Colloquially, integrated platforms are also called "sample-to-answer" platforms. These platforms represent an important advance in diagnostic microbiology because their simplicity allows them to be performed in many laboratories that would not otherwise be able to provide viral diagnostic testing. In fact, they are so simple that they could be performed in a physician's office and some models are CLIA waived, allowing testing outside of laboratories approved for "high-complexity" testing. A widely used integrated platform is the GeneXpert Real-time PCR system, marketed by Cepheid (Sunnyvale, CA). This platform employs test cartridges into which a specimen is inoculated. The cartridge is inserted into the GeneXpert instrument, which performs nucleic acid extraction, amplification, and product detection without any intervention by the user. A similar integrated system is the Diasorin Simplexa. Tests on the small integrated platforms generally require <2 hours to result with minimal hands-on time. Other higher-throughput quantitative integrated systems include the Hologic Panther Fusion, Roche cobas, and Abbott Alinity m, which allow for up to one thousand test results per day and provide results in <4 hours, also with minimal hands-on time. These systems are generally used for high-throughput testing of HIV, HBV, HCV, HPV, and SARS-CoV-2 but also allow for testing for transplant-associated viruses such as CMV and BK virus, respiratory virus panels, and STI testing.

Serology

Measurement of antiviral antibodies was one of the first methods used for the specific diagnosis of viral infections, and it remains an important tool in the diagnostic virology laboratory. The role of serology can be for the diagnosis of acute or current infection or for the determination of past infection with specific viruses, which may be helpful in assessing virus-specific immunity. Serologic diagnosis is important for viruses that are not detected readily by molecular assays or culture. Viruses for which serology is useful in diagnosing acute infection are shown in Table 16.4. Serology is uniquely useful for defining past infection with respect to specific viruses. It is important to use sensitive assays such as EIA for this purpose, because antibody levels indicative of past infection can decline to very low levels years after the infection. The specific assay used must also be selected with care to ensure that it measures antibodies that correlate with immunity. Viruses for which serologic testing is used to determine past infection/immune status are shown in Table 16.5.

TABLE 16.4 Serology for diagnosis of acute viral infection

Epstein-Barr[a]
Cytomegalovirus (mononucleosis syndrome)[a]
Hepatitis viruses (A-E)[b]
Measles[a]
Rubella[a]
Mumps[a]
Parvovirus B19[a]
Encephalitis viruses (eg, West Nile virus)[a]
Rabies
Hemorrhagic fever viruses[a]
Dengue, zika, and chikungunya[a]
Human immunodeficiency virus (HIV)
Human T-cell lymphoma or leukemia virus types 1/2 (HTLV-1/2)

[a]Virus-specific immunoglobulin M (IgM) assays are used.

[b]Virus-specific IgM assays are used for hepatitis A, B, and E.

TABLE 16.5 Serology for diagnosis of prior viral infection

Herpes simplex virus
Cytomegalovirus
Epstein-Barr virus (immunoglobulin G antibodies to the viral capsid antigen)
Human herpesvirus type 6
Rubella
Measles
Mumps
Parvovirus B19
Hepatitis A virus (total antibodies)
Hepatitis B virus (anti-HBs)
Hepatitis E virus
SARS-CoV-2

Kinetics of the Antibody Response

Serologic diagnosis is based on the kinetics of the antibody response to viral infection. Virus-specific antibodies are absent in an individual who has never been infected with that virus, but typically become detectable several weeks after the onset of infection. Virus-specific IgM antibodies are often detectable for a short period before virus-specific IgG antibodies. The IgM response tends to decline within ~1-2 months, although low levels can persist for 1 year or more in some viral infections. IgG antibodies are much more long-lasting and can persist for the life span of the individual. Thus, the absence of virus-specific IgG and IgM antibodies signifies susceptibility to infection; the presence of virus-specific IgM antibodies, with or without virus-specific IgG antibodies, signifies current or very recent infection; and the presence of virus-specific IgG but not IgM antibodies signifies past infection. The latter pattern often, but not always, indicates immunity to subsequent infection.

An alternative serologic approach to the diagnosis of recent infection is based on the concept that the affinity of antigen-specific antibodies increases as the immune response matures.[17] Thus, antibodies produced shortly after infection have low affinity for the causative agent, and antibodies produced late after infection have high affinity. Detection of low-affinity antibodies has been used to diagnose recent infection with CMV,[16] rubella,[67] and HIV.[75]

The relationship between the onset of clinical manifestations of infection and the presence of virus-specific antibodies depends on the

incubation period of the infection. In infections with short incubation periods (eg, acute respiratory infections), antibodies are absent at the onset of symptoms. In viruses with incubation periods of 1 month or longer, however, virus-specific IgG and IgM antibodies are typically present at the onset of symptoms.

Serology in Reinfection and Reactivation

The serologic diagnoses of reinfection and reactivated infection are more complicated than that of initial infection. In both of these cases, the infection occurs in an individual with preexisting, virus-specific IgG antibodies. In reinfection, an anamnestic response may occur that results in an increase in the level of virus-specific IgG antibodies with continued absence of virus-specific IgM antibodies. Reactivation of latent infection, for example, in the case of some herpesvirus infections, may result in the appearance of virus-specific IgM as well as IgG antibodies.

Serology in Chronic Infections

The interpretation of serology is unique for viruses that typically cause chronic infection (eg, HIV) and the related retroviruses human T-cell lymphoma or leukemia virus (HTLV) types 1 and 2. For these agents, the detection of antibodies of any isotype to these viruses (in the absence of artificial immunization) virtually always signifies current infection. In the case of HCV, the confirmed presence of antibodies to the virus corresponds to active infection in ~85% of individuals. For HIV, assays that simultaneously measure HIV p24 antigen as well as HIV antibodies have proven useful because based on the early appearance of the p24 antigen, the combined test decreases the “window” during which a recently infected individual is serologically negative but capable of transmitting infection.[58]

Serologic Assays

Binding assays

The most widely used assays are those that directly measure binding of antibodies to viral antigens. Examples of binding assays include EIA and the indirect immunofluorescent antibody assay (IFA). Binding assays can be used in many different formats. In one common format, a viral antigen, which can consist of virally infected cells, a purified viral preparation, or a recombinant viral protein, is attached to a solid surface such as the inner surface of the well of a microtiter tray, a plastic bead, or a microscope slide in the case of IFA. Serum is added, allowing the binding of antiviral antibodies that might be present in the serum. After an appropriate incubation period, the serum is removed and the well is extensively washed. The next step is the addition of a second antibody (also referred to as a detector antibody) with specificity for human immunoglobulins. The second antibody is typically a mouse monoclonal or a polyclonal antibody from a nonhuman species. It is linked to an enzyme such as horseradish peroxidase. The second antibody binds to any human antibody present (ideally, because of specific binding to the viral antigen). The well is again extensively washed, and the presence of the second antibody is detected based on a colorimetric, radiometric, or fluorescent signal. An important advantage of binding assays is that they can be modified to detect IgM- or IgA-specific antiviral antibodies through the use of isotype-specific detector antibodies.

Immunobinding assays

The western blot and related recombinant immunobinding assays are assays that allow the identification of antibodies to specific viral proteins. In the western blot assay, viral antigens present in infected cells are denatured, separated by gel electrophoresis, transferred to a membrane, and allowed to react with the serum specimen. Binding of antiviral antibodies is detected through the use of labeled detector antibodies. The western blot is cumbersome but provides a very high level of specificity because of the ability to identify binding to individual viral proteins and the production of a characteristic blot fingerprint of a specific molecular weight. Thus, its main application in diagnostic laboratories is the confirmation of screening assays (eg, EIA) that are less specific. For example, for many years, the western blot was widely used to confirm a positive HIV EIA and may still be used to confirm HSV serological results. The recombinant immunobinding assay differs from the western blot in that specific viral antigens are produced in *in vitro* expression systems and artificially attached to membranes in a predetermined configuration, often in dots or in bands. The membranes are then incubated with serum, and bound antibodies are detected, as in the western blot. Because the antigens used in the immunobinding assay are not denatured as they are in routine western blots, these assays may have advantages in detection of antibodies to conformational epitopes.

Functional assays

Functional assays are based on detection of specific activities resulting from the binding of specific antibodies to viral antigens. An important example is the neutralization assay, which measures the ability of antibodies to block viral infectivity. In neutralization assays, serial dilutions of the serum to be tested are incubated with a standardized quantity of infectious virus. After a short incubation period, the serum-virus mixtures are added to cells that support the growth of the virus, in parallel with a similar inoculum of virus that has not been incubated with serum. The neutralizing antibody titer is the highest serum dilution that prevents infection of the cells. The neutralization assay correlates well with protection from infection and is sometimes considered the standard against which other serologic assays should be measured. Because it is cumbersome and expensive, the neutralization assay is rarely used in routine diagnostic laboratories, but it is commonly seen in vaccine clinical trials as a primary or secondary outcome measure. Other examples of functional assays are the hemagglutination-inhibition assay, in which the presence of antiviral antibodies is detected by their ability to block virus-induced hemagglutination, and the complement fixation assay, which measures the ability of antiviral antibodies to fix complement, preventing the complement from lysing indicator erythrocytes. These assays have been largely replaced by binding assays.

Agglutination assays

Viral antigens can be bound to a variety of particles, including fixed erythrocytes and latex particles. Agglutination assays are performed by mixing dilutions of serum with a suspension of antigen-coated particles. The agglutination titer is the highest serum dilution that results in visible agglutination of particles. The advantage of agglutination assays is simplicity; they are rapid and do not require sophisticated equipment. Therefore, they are well suited for *stat* testing and for use under field conditions. For example, a rapid latex agglutination assay for varicella antibodies can be used for rapid determination of the varicella immune status of health care personnel who are exposed to a patient with varicella.

Virus-Specific IgM Assays

Assays for virus-specific IgM antibodies are important because they often allow for diagnosis of an acute infection based on analysis of a single serum specimen obtained during the acute phase of illness. These assays are most likely to be useful in diseases with incubation periods that are sufficiently long so that virus-specific IgM levels are present at detectable levels at the onset of illness. Hepatitis A provides an excellent example; because of its incubation period of 2-6 weeks, hepatitis A IgM antibodies are virtually always detectable at the time patients seek medical care.

A number of methods are used to measure virus-specific IgM antibodies. Two older methods include (1) separating IgG and IgM fractions before performing the virus-specific antibody assay and (2) performing the virus-specific assay before and after procedures, such as treatment with β-mercaptoethanol, that selectively destroy IgM antibodies. Many modern virus-specific IgM antibody assays use IFA or EIA with a detector antibody that binds only to human IgM. The IgM capture assay is an alternative approach in which IgM antibodies present in the serum sample being tested are first *captured* using an antibody specific for human IgM. A preparation of viral antigen is added, followed by an enzyme-labeled antibody specific for the viral antigen. Binding is detected by the addition of the appropriate enzyme substrate.

Virus-specific IgM assays have several potential pitfalls and must be interpreted in conjunction with clinical findings. False-positive results can occur if the serum being tested contains rheumatoid factor (IgM antibodies to human IgG) plus virus-specific IgG antibodies that form complexes that may be falsely detected by the assay as virus-specific IgM antibodies. This problem can be avoided by pretreatment of the serum to remove either rheumatoid factor or IgG antibodies. One or the other of these pretreatments is included routinely in many commercial virus-specific IgM antibody assays. False-negative results can occur if the serum being tested contains high levels of virus-specific IgG antibodies that may compete with the virus-specific IgM antibodies. The IgM-capture assay configuration avoids this problem, as does serum pretreatment to remove IgG.

Complexities in the nature of the IgM antibody response must also be considered in interpreting virus-specific IgM antibody tests. In some patients, the IgM antibody response is transient or low level, leading to failure to detect virus-specific IgM antibodies, whereas in others, low levels of IgM antibodies may persist for 1 year or longer, decreasing the specificity of the assay as an indicator of very recent infection. In herpesvirus infections, IgM antibodies can sometimes be detected in reactivations as well as in primary infection.

Saliva and Urine Assays

Virus-specific antibodies can often be detected in saliva and urine. These body fluids are attractive for use in serologic assays because they avoid the need for phlebotomy. Assays for HIV antibodies in these fluids are commercially available and have performance characteristics similar to assays carried out on serum.[20,79]

Cerebrospinal Fluid Serology

Serologic testing can be applied to CSF for the diagnosis of central nervous system (CNS) infection. For unusual viruses (eg, rabies), the presence of any virus-specific antibodies within the CSF is diagnostic of active infection. For the diagnosis of encephalitis caused by the alphaviruses, bunyaviruses, or flaviviruses, the presence of virus-specific antibodies in CSF is highly suspicious and the presence of virus-specific IgM antibodies in CSF is diagnostic and often more clinically sensitive than CSF PCR. For more common viruses (eg, herpesviruses) or the common respiratory viruses, the mere presence of virus-specific antibodies in CSF is not diagnostic of CNS infection because antibodies produced in the blood are present in the CSF even in the absence of CNS infection. The problem is further complicated by the fact that defects in the blood-brain barrier that can occur during many neurologic diseases can increase the passage of antibodies from blood to CSF. Therefore, for the common viruses, intrathecal synthesis of specific antiviral antibodies must be demonstrated to provide evidence of CNS infection.

Intrathecal synthesis of a specific antiviral antibody is evaluated by determining the quotient of two ratios: (1) the ratio of specific antiviral antibody level in CSF to the level in serum and (2) the ratio of total IgG in CSF to total IgG in serum ($CSF_{specific\ antibody}$:$serum_{specific\ antibody}$ divided by CSF_{IgG}:$serum_{IgG}$). A quotient >1.5 is evidence of intrathecal antibody synthesis of the specific antibody. The antibody assay used to measure the specific antiviral antibody must have certain special characteristics. First, it must be very sensitive, because CSF antibody levels are usually low (~1000 times less than serum levels). Second, it must be capable of providing a quantitative result that allows calculation of the CSF-to-serum ratio of specific antibody level. EIA is usually used, but testing of a series of dilutions of CSF and serum is required to obtain linear quantitative estimates of antibody level suitable for calculating the necessary ratio. Because of the complexities involved, accurate determination of intrathecal antibody synthesis of specific antiviral antibodies is performed in only a limited number of reference laboratories.

Measurement of intrathecal antibody synthesis has been used in a variety of CNS infections. The applications for which experience is most extensive are encephalitis caused by HSV and VZV. In HSV encephalitis, the utility of determinations of intrathecal antibody synthesis is limited because intrathecal antibody synthesis may not be detectable until 7-10 days after the onset of illness. Interestingly, intrathecal antibody synthesis can persist for years after the acute infection. Therefore, the main application is in cases in which specimens were not available early in the illness to allow a definitive diagnosis based on PCR. A caveat concerning diagnosis by demonstration of intrathecal antibody synthesis is that nonspecific polyclonal intrathecal antibody synthesis can occur in some diseases (eg, multiple sclerosis).[65] This pitfall can be avoided by evaluating intrathecal synthesis of antibodies to at least one other virus other than the one of primary interest. Serologic diagnosis has been shown to be more sensitive than PCR for diagnosis of VZV vasculopathy.[52] This is explained partly by the fact that CSF samples from some patients in this study were obtained months after the onset of neurologic manifestations.

Antiviral Susceptibility Testing

In recent years, antiviral drugs have been licensed for the treatment of infections caused by HSV, VZV, CMV, influenza A and B, RSV, SARS-CoV-2, HIV, HCV, and HBV. Not surprisingly, increasing use of these drugs has been accompanied by the appearance of antiviral drug resistance. Testing for resistance may be required for optimal patient management. Antiviral drug susceptibility testing is performed in some diagnostic virology laboratories and is also available through reference laboratories.

Phenotypic Assays

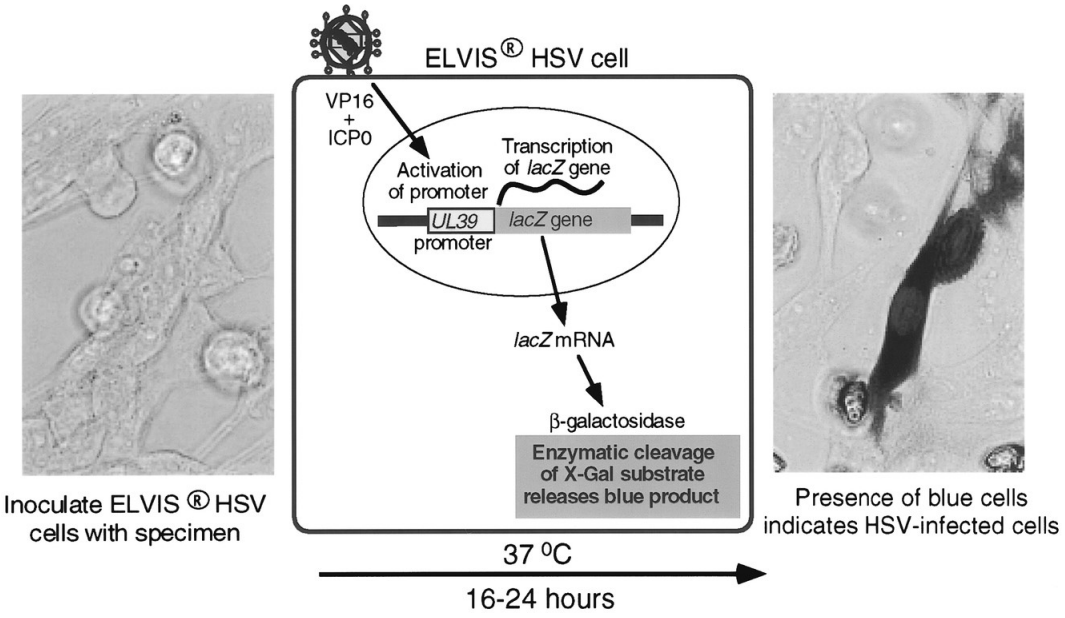
Antiviral susceptibility testing is divided into phenotypic and genotypic methods. Phenotypic methods analyze the effect of antiviral drugs on the

replication of virus, which can be measured by infectivity, viral antigen or nucleic acid production, or effect on the activity of a viral enzyme such as influenza neuraminidase. Phenotypic assays are important because they directly measure the effects of antiviral drugs on viral replication. In addition, they are more universal than genotypic assays because they can be used when the genetic basis for resistance is unknown. In the case of HIV, phenotypic assays are useful in analyzing viruses in which the presence of multiple mutations makes it difficult to predict phenotype from genotypic data. Finally, phenotypic assays must be used to determine the significance of candidate mutations found in drug-resistant isolates. However, from a practical standpoint, phenotypic assays tend to be labor-intensive, slow, and poorly standardized. In addition, there is a theoretical concern that the growth of the virus in cell culture may lead to selection of nonrepresentative viral variants, especially because antiviral resistance may in some instances be associated with decreased viral fitness. For these reasons, phenotypic assays are not performed in most diagnostic virology laboratories. Table 16.6 shows recommended *cutoffs* that define resistance to several drugs used for HSV and CMV infections.

TABLE 16.6 Cutoffs for antiviral susceptibility testing for herpes simplex virus (HSV) and cytomegalovirus (CMV) using the plaque reduction assay

		Cutoff (μM)		
Virus (Reference)	**Drug**	**Sensitive**	**Intermediate**	**Resistant**
HSV[68]	Acyclovir	<8		≥8
	Foscarnet	<330		≥330
CMV[18,85]	Ganciclovir	≤6	6-12	>12
	Foscarnet	≤400		>400
	Cidofovir	≤2		>4

The plaque assay was the traditional method for performing phenotypic susceptibility testing. However, this method is rarely used in diagnostic virology laboratories for the reasons mentioned previously and will not be discussed further here. Assays measuring viral antigen or nucleic acid production are alternatives to infectivity-based assays. A variety of assays have been used in individual laboratories, but they are not commercially available. The ELVIS assay has also been adapted for the performance of antiviral susceptibility testing (e-Fig. 16.5).[74,77] For influenza virus, resistance to neuraminidase inhibitors has been measured using neuraminidase inhibition assays based on either fluorescent or chemiluminescent signal generation.[8,53]



e-FIGURE 16.5 **ELVIS herpes simplex virus (HSV), a genetically engineered cell line for the detection of HSV clinical samples.** ELVIS cells are baby hamster kidney (BHK) cells that contain a β-galactosidase gene under the control of the HSV promoter UL39. If HSV is present in the specimen, viral particles enter the cells and the HSV proteins ICP0 and VP16 activate the UL39 promoter, leading to synthesis of β-galactosidase. The presence of β-galactosidase is detected by adding X-gal, a substrate for the enzyme. The activity of β-galactosidase on X-gal results in blue staining of ELVIS cells, visible microscopically.

Recombinant phenotypic assays have been developed and widely used for HIV. These assays involve insertion of HIV genes that are targets for antiretroviral drugs (polymerase, protease, integrase) from a patient being evaluated into a vector consisting of a rapidly replicating laboratory strain of HIV that also contains a reporter gene (eg, luciferase) that is used to measure viral growth.[60] These assays allow relatively rapid testing of the susceptibility of HIV to multiple drugs as well as to drug combinations. Commercial tests have been developed by Monogram Biosciences (San Francisco, CA) and Virco (Antwerp, Belgium) and are available in the United States through national reference laboratories. A special case is the HIV drug maraviroc, which blocks HIV entry by binding to the CCR5 receptor. Viruses that use the CXCR4 receptor rather than the CCR5 receptor are resistant to maraviroc. A commercial assay called Trofile (Monogram Biosciences)[85] is used to predict response to maraviroc by determining the receptor tropism of a patient's isolate.

Genotypic Assays

Genotypic assays test for the genetic basis for resistant phenotypes. A variety of methods are used, including detection of restriction fragment length polymorphisms, PCR assays that detect mutations by virtue of differential primer or probe binding, and nucleotide sequencing. With rapid improvements in sequencing technology, sequencing-based methods are becoming increasingly used, though it is difficult to turn around results fast enough for acute infections. Genotypic assays are informative only when the genetic basis for resistance is known and are most useful when the resistance being evaluated is accounted for by a limited number of genetic changes. During the SARS-CoV-2 pandemic, genotypic surveillance was used to inform the shipment of specific therapeutic monoclonal antibodies to different regions based on the prevalence of specific viral variants in the population.

Genotypic assays have been most widely used for CMV, HIV, HCV, HBV, SARS-CoV-2, and influenza A virus, because phenotypic assays for these viruses are slow and expensive or not widely available. Application of genotypic assays requires an extensive body of knowledge concerning the effect of specific mutations on antiviral resistance. Some single mutations may confer high-level resistance, while others may confer only partial resistance, and others are not associated with resistance at all.

For CMV, resistance to the currently FDA-approved drugs ganciclovir, foscarnet, maribavir, and cidofovir has been related to mutations in the phosphotransferase (*UL97*) and polymerase (*UL54*) genes while resistance to letermovir is associated with terminase (*UL56*) mutations.[11,46] Most laboratories now use sequencing to detect these mutations. Because ganciclovir-resistance mutations generally arise first in the *UL97* gene, some laboratories sequence this gene first, proceeding to sequencing *UL54* only if no significant mutations are detected in *UL97*, or if the patient is being treated with foscarnet or cidofovir, which exert their antiviral effect by inhibiting this gene. Different mutations within *UL97* or *UL54* are associated with different levels of antiviral resistance.[46]

For HIV, genotypic testing for resistance is commonly used by physicians in the developed world in the management of antiretroviral drug therapy. This testing involves RT-PCR amplification of regions of the polymerase and protease genes and sometimes the integrase gene, followed by nucleotide sequencing of the amplicons. Certain mutations are highly associated with phenotypic resistance and drug failure, whereas the significance of other mutations found in drug-resistant strains is less clear. Interpretation of HIV genotypic testing is most straightforward in patients who are not highly drug experienced and have relatively small numbers of mutations. Patients who have been treated more extensively may have multiple interacting mutations and may also have mutations that lie outside of the segments that are sequenced but nevertheless affect susceptibility to antiretroviral drugs.[26] High-throughput sequencing can be used to detect rare drug-resistant mutants that make up a small percentage of viral genomes.[73] The clinical significance of small minority populations of drug-resistant mutants is still under investigation.[6,12]

The presence of resistance of HBV to antiviral agents is detected by sequencing of the DNA polymerase gene. Genotypic testing for HSV has been less commonly used than phenotypic testing because of the diverse genetic loci within the HSV thymidine kinase and polymerase genes that can account for resistance, but as less and less viral isolation is performed genotyping testing is likely to increase in frequency.[21]

Selected Clinical Problems

e-Tables 16.4 through 16.9 provide information related to specific areas of diagnostic virology not covered elsewhere in the chapter.

e-TABLE 16.4 Laboratory diagnosis of human herpesvirus infections

Virus	Clinical Problem	Test(s)	Specimen
Herpes simplex	Mucocutaneous lesions	Culture, NAAT, FA stain	Swab of lesion
	Encephalitis or meningitis	NAAT	CSF
Varicella-zoster	Mucocutaneous lesions	Culture, NAAT, FA stain	Swab of lesion
	Encephalitis or meningitis	NAAT	CSF
	CNS vasculopathy	Intrathecal antibody synthesis, NAAT[a]	Serum or plasma plus CSF
Cytomegalovirus	Systemic infection in immunocompromised individual	Quantitative NAAT, pp65 antigenemia assay	Plasma or whole blood
	Mononucleosis syndrome in nonimmunocompromised individual	CMV IgM antibody assay, NAAT	Serum or plasma for antibody assay, plasma or whole blood for NAAT
	Tissue-invasive disease (eg, involving the gastrointestinal or respiratory tract)	Histology, immunohistochemistry *in situ* hybridization, culture, NAAT	Tissue from involved organ
	Encephalitis	NAAT	CSF
	Retinitis	NAAT	Vitreous or aqueous fluid
Epstein-Barr virus (EBV)	Infectious mononucleosis	Heterophile antibody assay,[b] IgM antibodies to the viral capsid antigen	Serum or plasma
	Posttransplant lymphoproliferative disorder	Quantitative NAAT	Whole blood or plasma
	Primary central nervous system lymphoma	NAAT	CSF
	Encephalitis or meningitis	NAAT[c]	CSF[c]
Human herpesviruses types 6 (HHV-6) and 7 (HHV-7)	Acute infection[d]	NAAT,[e] IgM antibody assay, IgG avidity assay[g]	Plasma (NAAT), plasma or serum for IgM antibody assay, or IgG avidity assay[g]
	Systemic infection in immunocompromised individual	NAAT[e]	Whole blood or plasma[e]
	Encephalitis	NAAT[e]	CSF
Human herpesvirus type 8 (HHV-8) (Kaposi sarcoma virus)	Systemic infection[f]	NAAT	Blood or body fluid

[a]Intrathecal antibody synthesis has been shown to be more sensitive than NAAT for diagnosis of varicella-zoster virus central nervous system vasculopathy. (Nagel MA, Cohrs RJ, Mahalingam R, et al. The varicella zoster virus vasculopathies: clinical, CSF, imaging, and virologic features. *Neurology*. 2008;70:853-860).

[b]Slide tests or other modified heterophile assays are usually used.

[c]Should be performed only in the setting of primary EBV infection. In other clinical settings, specificity and positive predictive values are low.

[d]Some but not all cases have a rash and are diagnosed as roseola.

[e]Approximately 1% of the population has chromosomal integration of HHV-6 and has very high levels of HHV-6 DNA in blood and tissue, which is not indicative of disease attributable to HHV-6. Chromosomal integration in immunocompetent patients can be excluded by testing a follow-up sample (those with chromosomal integration will have persistently high levels of HHV-6 DNA) or a pretransplant sample from the transplant recipient (those with chromosomal integration will have high levels of HHV-6 DNA in the pretransplant sample).

[f]Systemic HHV-8 infection may be associated with body cavity lymphoma or multicentric Castleman disease. CSF, cerebrospinal fluid; FA, fluorescent antibody; Ig, immunoglobulin; NAAT, nucleic acid amplification test.

[g]Ward KN, Turner DJ, Parada XC, et al. Use of immunoglobulin G antibody avidity for differentiation of primary human herpesvirus 6 and 7 infections. *J Clin Microbiol*. 2001;39:959-963.

e-TABLE 16.5 Laboratory diagnosis of viral respiratory and gastrointestinal tract infections

Virus	Test Method	Comments
Respiratory tract infections		
Influenza A, B	NAAT	Most sensitive test
	FA stain	Less sensitive than NAAT
	Culture	Less sensitive than NAAT, requires viable virus
	Antigen detection	Low sensitivity, especially for pandemic 2009 H1N1 virus
Respiratory syncytial	NAAT	Most sensitive test
	FA stain	Less sensitive than NAAT
	Culture	Requires viable virus
	Rapid tests	Less sensitive than other methods
Parainfluenza	NAAT	Most sensitive test
	FA stain	Less sensitive than NAAT
	Culture	Requires viable virus
Human metapneumovirus	NAAT	Most sensitive test
	FA stain	Less sensitive than NAAT
Rhinovirus	NAAT	Most sensitive test; primers and probes must be selected carefully to detect all serotypes/genotypes. May be difficult or impossible to distinguish from enteroviruses
	Culture	Requires viable virus; is less sensitive than NAAT. Clade C rhinoviruses have not been successfully cultured as of time of writing
Coronaviruses (OC43, 229E, NL63, HKU1)	NAAT	Most sensitive test
SARS-CoV-2	NAAT	Most sensitive test
	Antigen	Less sensitive than NAAT, ability to perform in home
Adenoviruses	NAAT	Most sensitive test
	FA stain	Less sensitive than NAAT or culture
	FA	Less sensitive than culture
Gastrointestinal tract infections		
Rotavirus	NAAT	Most sensitive test
	Antigen detection	Less sensitive than NAAT
Norovirus	NAAT	Most sensitive test
	ELISA	Less sensitive than NAAT
Adenoviruses (group F, serotypes 40 and 41)	ELISA NAAT	Specific assay for serotypes 40 and 41 Most sensitive test
Astroviruses	NAAT	Most sensitive test

ELISA, enzyme-linked immunosorbent assay; FA, fluorescent antibody; NAAT, nucleic acid amplification test.

e-TABLE 16.6 Laboratory diagnosis of central nervous system infections

Syndrome	Virus	Method[a]
Meningitis	Enterovirus	NAAT
	Herpes simplex virus	NAAT
	Varicella-zoster virus	NAAT
	Human immunodeficiency virus	NAAT on plasma
Encephalitis in nonimmunosuppressed individuals	Herpes simplex West Nile virus and other arboviruses Varicella-zoster virus Epstein-Barr virus HHV-6 Rabies Mumps Lymphocytic choriomeningitis virus	NAAT IgM antibody assay on serum and CSF[b] NAAT, intrathecal antibody synthesis[c] NAAT, IgM antibody assay on serum and plasma NAAT NAAT on CSF and saliva, rabies antibody assay on CSF and serum,[d] FA stain of skin biopsy from nape of neck NAAT on CSF and saliva, IgM antibody assay on serum IgG and IgM antibody assays on CSF and serum (acute and convalescent samples), NAAT, culture
Encephalitis in immunosuppressed individuals	Cytomegalovirus Epstein-Barr virus Varicella-zoster virus JC virus	NAAT NAAT NAAT, intrathecal antibody synthesis[c] NAAT

[a]Indicated test is performed on CSF unless otherwise indicated.

[b]Testing should be performed on CSF and serum. Testing of CSF is more specific for current infection.

[c]Detection of intrathecal antibody synthesis has been shown to be more sensitive than NAAT for the diagnosis of varicella-zoster virus central nervous system vasculopathy. (Nagel MA, Cohrs RJ, Mahalingam R, et al. The varicella zoster virus vasculopathies: clinical, CSF, imaging, and virologic features. *Neurology*. 2008;70:853-860).

[d]CSF is preferred if the individual being evaluated has previously received rabies immunization. CSF, cerebrospinal fluid; HHV-6, human herpesvirus type 6; Ig, immunoglobulin; NAAT, nucleic acid amplification test.

e-TABLE 16.7 Laboratory diagnosis of congenital and neonatal viral infections

Virus	Recommended Testing
Cytomegalovirus	NAAT or culture of urine and/or saliva during first 2 weeks of life
Herpes simplex	NAAT or culture of a vesicle, CSF, blood (plasma, serum, or whole blood). Conjunctiva, nasopharynx, oropharynx, urine, and rectum/stool may also be tested
Human immunodeficiency virus (HIV)	NAAT for HIV RNA on plasma or DNA on whole blood
Rubella	IgM antibody assay of serum or plasma, NAAT or culture of urine, oropharynx, blood, stool, CSF. Amniotic fluid and products of conception can also be tested
Parvovirus B19	IgM antibody assay of serum or plasma, NAAT of plasma or serum
Hepatitis B	Hepatitis B surface antigen test on serum or plasma
Varicella-zoster virus	NAAT, culture, or FA stain on vesicle, CSF, or blood. NAAT on amniotic fluid
Enteroviruses	NAAT on plasma or serum, CSF, nasopharyngeal or oropharyngeal swab, stool, urine
Hepatitis C	NAAT on plasma or serum on two occasions between 2 and 6 months of age or HCV antibody assay at age ≥15 months of age

CSF, cerebrospinal fluid; FA, fluorescent antibody; Ig, immunoglobulin; NAAT, nucleic acid amplification assay.

e-TABLE 16.8 Laboratory diagnosis of human immunodeficiency and other retrovirus infections

Indication	Test
Routine diagnosis	ELISA for HIV antibodies[a]
Confirmation of a positive ELISA	Samples that are reactive on the screening HIV antibody or combined HIV antigen-antibody assay should be tested with a confirmatory antibody test that differentiates HIV-1 and HIV-2 antibodies.[b] Patients who are positive with this assay should have a second sample tested for HIV RNA. Rare patients who are reactive on the screening test and the confirmatory HIV-1/HIV-2 antibody assay but negative for HIV RNA should have additional testing performed under the direction of an HIV specialist. This testing might include a repeat of the screening assay, an HIV western blot, or an HIV DNA PCR assay. Patients who are negative with the confirmatory HIV-1/HIV-2 antibody assay should have an HIV RNA assay performed. Patients who are reactive on the screening assay, negative on the confirmatory HIV-1/HIV-2 antibody assay, and positive for HIV RNA are presumed to have recent infection and should be referred immediately to an HIV specialist[c]
Blood donor screening	ELISA for antibodies to HIV-1 and -2, HIV RNA assay
Infant born to infected mother	HIV RNA or DNA assay at 14-21 days of age, 1-2 months, and 4-6 months[d]
Acute antiretroviral syndrome	HIV RNA assay
Prognosis	Quantitative HIV RNA assay
Response to therapy	Quantitative HIV RNA assay
Resistance to antiretroviral drugs	Genotypic assay based on nucleotide sequencing of the relevant genes, or phenotypic assay based on inserting relevant genes from the patient's HIV strain into a laboratory vector
Diagnosis of HIV-2 infection	ELISA for HIV-2 antibodies[e]
Monitoring of HIV-2 infection	HIV-2 RNA assay[f]
Diagnosis of HTLV-1 or -2 infection	HTLV-1 and 2 antibody ELISA assays
Confirmation of HTLV-1 or -2 infection	HTLV-1 and -2 western blot, line immunoassay, or immunofluorescent antibody assay[e]

[a]Most FDA licensed tests detect antibodies to both HIV-1 and -2. Third-generation antibody assays are preferred because they detect immunoglobulin M (IgM) as well as IgG antibodies and thus become positive earlier after infection than assays that detect only IgG antibodies. An alternative approach is to use a fourth-generation test that measures HIV p24 antigen in addition to HIV antibodies.

[b]A licensed rapid HIV antibody test approved by the Food and Drug Administration (FDA) is now available that differentiates HIV-1 and HIV-2 antibodies.

[c]Branson BM, Mermin J. Establishing the diagnosis of HIV infection: new tests and a new algorithm for the United States. *J Clin Virol*. 2011;52(Suppl 1):S3-S4.

[d]DNA PCR may be preferred while the infant is on prophylactic antiretroviral treatment because of the possibility that antiretroviral therapy may make HIV RNA undetectable.

[e]Most HIV antibody assays currently in use detect antibodies to both HIV-1 and HIV-2, but only one FDA-licensed test differentiates between HIV-1 and HIV-2 antibodies.

[f]Available only in selected reference laboratories. ELISA, enzyme-linked immunosorbent assay; HIV, human immunodeficiency virus; HTLV, human T-cell lymphoma or leukemia virus; PCR, polymerase chain reaction.

e-TABLE 16.9 Laboratory diagnosis of tropical and other geographically localized viral infections

Virus or Syndrome	Location	Preferred Tests
Sin Nombre virus	Western United States	Virus-specific IgM antibody assay, NAAT
Other hantaviruses	Asia, Europe	Virus-specific IgM antibody assay, NAAT
Colorado tick fever	Western United States	Virus-specific IgM antibody assay, NAAT
Dengue fever	Asia, Central and South America	Virus-specific IgM antibody assay, NAAT
Filoviruses (Ebola and Marburg viruses)	Central Africa	Virus-specific IgM antibody assay, NAAT
Arenaviruses (eg, Lassa, Junin, many others)	West Africa (Lassa fever), South American (Junin)	Virus-specific IgM antibody assay, NAAT, culture
Hendra and Nipah viruses	Australia, Malaysia, Bangladesh, India	Virus-specific IgM antibody assay, NAAT
Yellow fever	Central Africa, Amazon region	Virus-specific IgM antibody assay, NAAT
Crimean-Congo hemorrhagic fever and other bunyavirus infections	Asia, Africa, Europe	Virus-specific IgM antibody assay, antigen-capture ELISA, culture, NAAT
Rift Valley fever	East Africa	Virus-specific IgM antibody assay, antigen-capture ELISA, culture, NAAT, culture
Chikungunya and other alphavirus infections (O'nyong nyong, sindbis, Mayaro, Ross River)	Africa, India, Central and South America, Europe, Australia (Ross River)	Virus-specific IgM antibody assay, culture, NAAT

ELISA, enzyme-linked immunosorbent assay; IgM, immunoglobulin M; NAAT, nucleic acid amplification test.

Virus Discovery and Metagenomics

Experimental methodologies used for viral discovery have traditionally relied on classic approaches such as electron microscopy, cell culture, and antibody-based detection. Despite the success of these approaches, which have resulted in the discovery of many viruses throughout the years, each of these methods suffers from significant limitations. For example, electron microscopy requires high viral titers and may not provide the necessary resolution to unambiguously identify the type of virus even when viral particles are observed. Many viruses cannot be cultured, and those that can often require very specific cell types; crucially, there is no universal cell line capable of broadly supporting growth of all, or even a majority of, known viruses. Antibody-based methods are limited in breadth, require the development of specific reagents for a given viral group, and, most critically, require selection of specific candidates based on prior knowledge in order to be useful in identifying a virus. Due to these limitations, there have been ongoing efforts to develop additional complementary strategies for detecting and discovering novel viruses. In the last decade of the 20th century, various molecular methods were developed in efforts to circumvent limitations of these classic approaches. These molecular methods, including library immunoscreening, degenerate PCR, and representational difference analysis, led to the discovery of many clinically important viruses including HCV, Kaposi sarcoma herpesvirus (KSHV), and others.[41]

The 21st century has witnessed a revolution in the field of virus discovery as evidenced by the dramatic increase in the rate of identification of novel viruses. This increase has been driven largely by the advent of the genomic era, which has created novel sequencing technologies that in turn have geometrically increased the volume of sequencing data that can be generated. The combination of increased sequences in public databases and increased sequencing capacity has enabled the development of new, sophisticated sequence-based approaches for viral detection and discovery. Even existing methods, such as consensus PCR approaches, have benefited from the geometric growth in sequence databases. With the availability of many more viral genome sequences, improved consensus PCR primers can be designed for many viral taxa.

All of the recently developed viral discovery methods are based on detection of viral nucleic acids. Fundamentally, the major challenge in sequence-based viral discovery is identifying the relatively few copies of viral DNA or RNA in specimens that typically contain a vast excess of host genomic DNA and/or RNA. In theory, given unlimited sequencing capacity, there would be no need to be concerned with the host; exhaustive direct sequencing of a given sample should reveal the presence of any viral sequences in the sample no matter how low the abundance of the virus. However, practical limitations on sequencing, either in terms of sheer capacity or cost, have until recently required that additional methods be employed to effectively increase the relative percentage of viral sequence to host sequence. For example, propagation of a virus in cell culture is one means of increasing the relative abundance of viral sequences. Physical purification of virions, by ultracentrifugation or nuclease treatment to eliminate nonencapsidated nucleic acids, is another means of enriching for viral sequences. Subtractive hybridization strategies achieve a similar end point by physically reducing the amount of host sequences. However, we are rapidly approaching a point where sequencing capacity and costs are no longer limiting.

One potential limitation in sequence-based virus discovery is the quantity of nucleic acids available for sequencing. To circumvent this challenge, multiple experimental approaches to increase the total abundance of nucleic acids to levels amenable to further analysis have also been developed. An essential feature of all of these amplification strategies is that no prior knowledge regarding the nature of the sequences to

be amplified is required because it is unknown what type of virus may be present. Several different approaches for enriching for viral nucleic acids for viral discovery as well as library preparation strategies are illustrated in Figure 16.7.

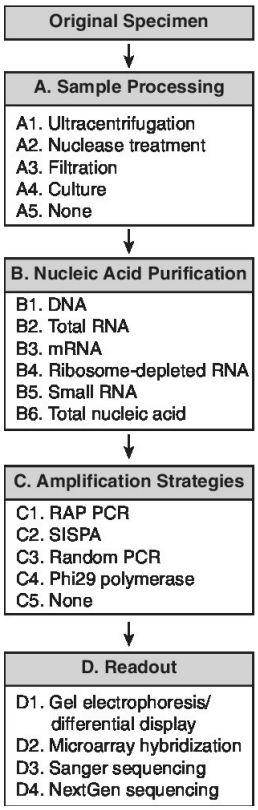


FIGURE 16.7 **Pathogen discovery methods**. Recently developed sequence-based pathogen discovery methods all fundamentally follow a similar overall scheme. A clinical specimen of interest is collected. **A**. If desired, samples can be manipulated to increase the ratio of virus to host by various methods. **B**. Nucleic acid species of interest is isolated. **C**. In cases where the quantity of purified nucleic acid is limiting, random sequencing-independent amplification is applied. **D**. A readout method is selected. For example, the identification of human bocavirus used the sequence of steps A1-A2-B1-C3-D3. The identification of Merkel polyomavirus used the sequence A5-B3-C5-D4.

For sequence-based detection technologies, a key step is the computational analysis required to identify a sequence as viral in nature. In early efforts, only a few sequences were generated and thus analysis could easily be done via commonly used web-interface software. With advances in sequencing capacity, the number of sequences generated from a sample increased initially to hundreds or thousands and now can easily surpass a million sequences or more. In order to efficiently analyze this volume of sequence data, automated high-throughput bioinformatics pipelines had to be developed. Although many variations on this theme exist, most computational pipelines utilize very similar overall strategies. Typically, sequence alignment software, such as BLAST, is used to compare the sequences generated from a sample to established public databases. Sequences with perfect or near-perfect alignments to known sequences (host, viral, bacterial, etc.) can then be categorized based on the identity of the reference sequence to which a given read aligned. Sequences derived from novel viruses are those that have only limited similarity to known viruses in the available databases. For more definitive characterization of the relatedness of these sequences to known viruses, phylogenetic methods are subsequently used.

As mentioned previously, a key driving factor in the advances in virus discovery has been the evolution of sequencing technology. For over 30 years, from its inception in the late 1970s until the late 2000s, Sanger dideoxy sequencing was the dominant sequencing technology in use, and all efforts to identify viruses using sequencing-based strategies relied on this technology. At its highest throughput, automated 96-capillary Sanger sequencing could generate up to ~100 000 bp of sequence in a single run. Starting in 2005, the first of the so-called next-generation sequencing (NGS) platforms was introduced.[49] These platforms dramatically increased the quantity of sequence that could be produced. For example, the Roche/454 platform in its initial format was capable of generating 100 000 reads of 100 bp length in a single run, or ~100-fold greater sequence than a run on the previous instrument standard, the ABI 3730. Over the next few years, this platform rapidly evolved such that by 2009, the Roche/454 platform could readily generate 1 000 000 reads that averaged 400 bp each, or 400 megabases (MB) of total sequence. Two other major NGS platforms, Solexa (Illumina) and SOLiD (ABI), also emerged during this time (reviewed in[48]), with Illumina the dominant platform for more than a decade. At the current time, top-line sequencers are capable of generating billions of reads in less than a day and terabases of sequence in a single run. It is the unprecedented growth in sequencing capacity offered by these new platforms that has transformed the process of virus discovery. In addition, metagenomic NGS is now available clinically for broad-based pathogen detection in plasma, CSF, and bronchial alveolar lavage fluids.[4,51]

Representative Novel Human Viruses Discovered

A number of new human viruses were discovered from 2000 to 2010 using these more unbiased molecular approaches. These include parvovirus 4, anelloviruses, bocaviruses, multiple polyomaviruses, astroviruses, rhinoviruses and other picornaviruses, and arenaviruses.[1,2,5,18,22,29,35,37,39,40,54,57,71,72,81,82] Among the most important discoveries were the surprisingly common rhinovirus C lineage and several novel human astroviruses associated with meningoencephalitis. More recently, these techniques in combination with cell culture

have also been critical for finding tick-borne illnesses such as severe fever and thrombocytopenia virus,[87] Heartland,[50] and Bourbon virus,[43] novel zoonotic respiratory pathogens such as MERS-CoV,[80] variegated squirrel bornavirus, and SARS-CoV-2. In addition to the minority of novel viruses that have clearly been associated with pathogenicity in humans, many newly identified human, animal, and arthropod viruses await further characterization and assessment of their zoonotic potential and/or clinical relevance.[27]

Prospects and Challenges for the Future

Advances in molecular methods have dramatically increased the rate at which viral genomes can be detected, resulting in our awareness of the existence of many more viral genomes than just a few years ago. For example, following the initial discoveries of BK and JC viruses by culture in 1971, there were no additional polyomaviruses of humans identified until 2007. Since then, a total of 12 new polyomaviruses have been identified in humans, all by molecular methods. Parallel situations exist in many viral taxa, wherein geometric increases in the number of known members have been observed. With the continued growth in sequencing capacity, there is little doubt that many more viruses will be identified in the upcoming years. Recently, specific efforts to comprehensively catalog the spectrum of viruses present in humans have begun. One objective of the international Human Microbiome Project is to define the set of viruses present in different anatomic sites in a set of "healthy" adults. These and other similar efforts to define the "viromes" of humans, animals, plants, or environmental niches will undoubtedly uncover a tremendous diversity of new viral genomes. While our ability to identify viral nucleic acids and genomes has grown at an astounding rate, our ability to define the molecular properties and the biological relevance of these new agents has unfortunately lagged behind. In order to effectively study these new viruses, commensurate new developments in traditional virology must occur. For example, novel methods of virus culture must be developed in order to keep pace with the rate of discovery of new viral sequences, as the ability to propagate a virus in culture is, in many instances, the rate-limiting step in our ability to further characterize a virus and to define its pathogenicity. Many of the viruses being discovered today by sequencing-based molecular methods are unlikely to grow in the traditional cell lines utilized by virologists. As an example, the advent of differentiated primary respiratory epithelial cultures has opened new frontiers by enabling the culture of several newly identified respiratory viruses, such as human bocavirus[15] and coronavirus HKU,[62] that have failed to grow previously in traditional respiratory tract–derived cell lines. Two- and three-dimensional organoids composed of multiple cell types that more closely mimic the complexity of tissues provide another avenue for cultivation of viruses. Another area of great importance is the development of robust animal models, including those with impaired innate immunity and/or engrafted with human cells, for these new agents, which will be a critical part of efforts to define pathogenicity and disease causality. Finally, the criteria used for defining "pathogenicity" must also be revisited. While Koch's postulates, the 100-plus-year-old gold standard for proof of disease causation, have served us well in the past, this era of molecular virus discovery necessitates an enhanced emphasis on the role of epidemiologic and seroepidemiologic approaches in defining disease associations.[19] Furthermore, more nuanced conceptions of microbially induced disease, such as disease as a consequence of imbalance or perturbation of host microbial populations, must also be considered. In summary, technology-driven advances in sequencing have led to a golden era of discovery of new viruses in the first decade of the 21st century. Hopefully, parallel advances in understanding the biology of these new agents will come to fruition in the next decades of the 21st century.

Perspective

Diagnostic virology is at a critical point in its history, especially in the wake of the COVID-19 pandemic. The field has matured considerably, with detection of a selected group of viral pathogens emerging as an important component of clinical laboratory services at major medical centers. Molecular detection of respiratory viruses; diagnosis and monitoring of viral infections, especially CMV, EBV, and BK virus in immunocompromised patients; viral load and antiviral susceptibility testing for HIV, HCV, and HBV; and testing for HPV have all become mainstream diagnostic procedures. After consolidating the conversion to molecular methods, the methodology of diagnostic virology is again evolving rapidly, with newly available distributed CLIA-waived antigen and molecular testing at home and high complexity metagenomic NGS in specialized laboratories. The development of standardized commercial molecular tests that have passed through the review processes of the FDA continues to gain momentum, while reimbursement for multiplex testing remains a challenge. Greater availability of therapeutics for viral diseases through monoclonal antibodies and small molecule antivirals will help drive continued innovation and demand for rapid and widespread viral diagnostics. While new innovations in molecular methods from CRISPR-Cas detection systems to digital PCR and NGS show promise, it is the front-end automation and dispersion of more mature diagnostic methods such as qPCR and antigen testing that has had the greatest impact over the past half decade. In addition, there is little doubt that unforeseen technological advances will drive the evolution of the field in directions that are currently impossible to predict.

Disclosures

Dr. Storch serves on the medical advisory board of Roche Molecular Systems and has served as a consultant to Idaho Technology, PrimeraDx, Abbott, and Diagnostic Hybrids. He has received an honorarium from GenProbe and Meridian. He is currently performing research funded by Luminex and Meridian. Dr. Greninger reports contract testing from Abbott, Cepheid, Novavax, Pfizer, Janssen, and Hologic and research support from Gilead and Merck, outside of the described work. Dr. Wang and Dr. Jerome have no disclosures.

Introduction and History

The discovery and characterization of giant viruses in the last decades have raised fundamental questions regarding the boundaries of the virosphere. Not only are their virions remarkably complex and gigantic, but their double-stranded DNA (dsDNA) genomes are often in the megabase range and encode proteins that were previously thought to be exclusive of cellular organisms (Fig. 17.1).[1] The term "giant virus" is quite flexible and often used interchangeably with "large virus" to refer to the same virus.[10,51,99,144] In the context of unicellular eukaryote–infecting viruses, the term "giant virus" was first used in 1999, to designate Paramecium bursaria Chlorella virus, the defining member of a group of algae-infecting viruses whose particles are 140-190 nm in diameter.[172] However, the description of Acanthamoeba polyphaga mimivirus (APMV) in 2003, an amoeba-infecting virus whose virions are ~750 nm, popularized the use of the term.[82] Although some bacteriophages with large genomes and particles have been described ("jumbo phages"), the term giant virus has been used to refer to an evolutionary lineage of viruses belonging to the phylum *Nucleocytoviricota*, mostly those infecting unicellular eukaryotes, including amoebas, flagellates, algae, and others.[77,186] Therefore, in this chapter, we discuss the main features of this group. We even discuss some nucleocytoviruses of unicellular eukaryotes with relatively small capsids (~100 nm), because they highlight structural and evolutionary features observed in their giant relatives.

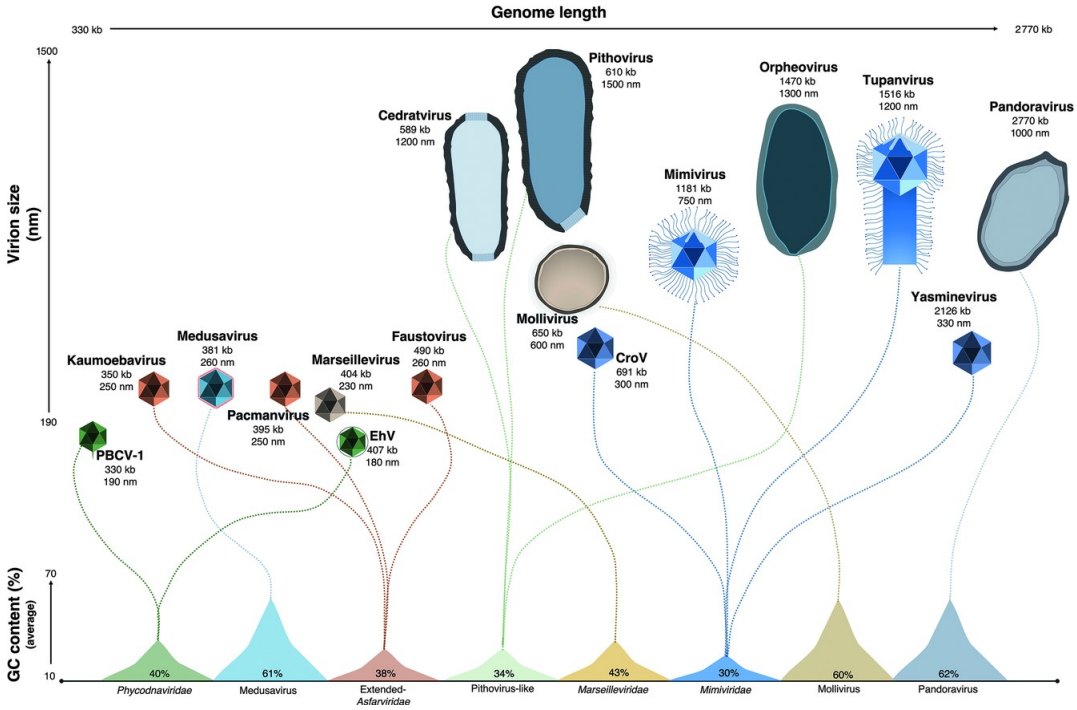

FIGURE 17.1 **Schematic illustration of genomic and structural features of giant virus representatives**. GC content and virion dimensions are shown on the y-axis. Genome length is plotted on the x-axis.

Seminal studies in the 1970s described the presence of viruslike particles (VLPs) with diameters of hundreds of nanometers in association with eukaryotic, mostly unicellular, organisms containing chloroplasts, including *Heteromastix* sp., *Oedogonium* sp., *Hymenomonas carterae*, and *Monodus* sp.[60,121,122] Some of these studies have advanced the chemical characterization of VLPs, such as those related to *Uronema gigas*, revealing particles around 400 nm, containing dsDNA and a guanine/cytosine (G/C) content of 73.5%.[60] Interestingly, about 10% of those purified VLPs had a tail measuring about 1 μm in length, which could be associated with adhesion of the virus to the algal wall and trigger the onset of infection.[46] However, due to technical difficulties related to the propagation of VLPs, most studies in the 1970s did not characterize these large VLPs further.

The propagation and characterization of large eukaryotic algae viruses started to be described systematically in the early 1980s. The so-called chloroviruses, currently belonging to the family *Phycodnaviridae*, have been described as infecting different species of the eukaryotic algal genus *Chlorella*.[97,173,174] Although these algae can be observed as free-living entities in nature, they usually live as symbionts with a variety of organisms, including the coelenterate *Hydra viridis*, the ciliate *Paramecium bursaria* and the heliozoan *Acanthocystis turfacea*. Several large DNA viruses such as Hydra viridis Chlorella virus, Paramecium bursaria Chlorella virus, and Acanthocystis turfacea Chlorella virus were isolated from these symbiotic species of *Chlorella*. Because *Chlorella* could be cultured in the laboratory, it was possible to establish innovative protocols for studying the newly discovered chloroviruses, such as an algal adaptation of the plaque assay.[168] Therefore, the description of the first chloroviruses represents a hallmark in the study of unicellular eukaryote–infecting giant viruses.

As the number of complete viral genomes in the databases increased, comprehensive analyses published in the early 2000s indicated that phycodnaviruses share a set of nine genes with viruses belonging to other dsDNA virus families, such as *Poxviridae*, *Iridoviridae*, and *Asfarviridae*. Twenty-two genes were shared by at least three of these families, which is a substantial number if we consider other distantly related viral families. Other shared features include particle sizes of a few hundred nanometers, genomes more than 200 kilobase pairs (kb) long, and a partially or completely cytoplasmic mode of replication. The term nucleocytoplasmic large DNA virus (NCLDV) was then proposed to designate this group with a hypothetically monophyletic origin.[72]

However, in 2003, the NCLDV group gained a notable member: mimivirus. The discovery of this virus dates back to 1992, when Dr. T.J. Rowbotham's team isolated an obligate intracellular parasite of amoeba from a cooling tower. This intracellular parasite stained Gram positive and was termed Bradfordcoccus. After unsuccessful attempts to identify it, a few years later, this supposed bacterial agent was sent to the Unité des Rickettsies in Marseille, France, and by electron microscopy, it was possible to observe, in the cytoplasm of amoebas, isometric capsids (500 nm) covered by long fibrils, giving the particles a total size of ~750 nm.[82] Together with these micrographs, genomic sequencing confirmed that Bradfordcoccus was in fact a gigantic virus with a ~1.2-Mb genome.[124] This new virus was named Acanthamoeba polyphaga mimivirus (mimivirus stands for *mi*micking *mi*crobe).

The discovery of mimivirus prompted further studies and the discovery of even larger viruses associated with protists.[3,12,87,119] New unicellular eukaryotic hosts have been explored, and the ubiquity of giant viruses has been revealed by comprehensive metagenomic studies in the most diverse biomes on the planet.[20,56,64,126,146] The origin of NCLDVs, now incorporated as members of the phylum *Nucleocytoviricota*, has been the subject of intense study and debate in recent years, highlighting exclusive biological characteristics of this remarkable group of viruses. Finally, the ecological role of giant viruses represents one of the frontiers of current knowledge and has revealed sophisticated mechanisms for regulating the populations of their hosts.[28,56,69,135] In this chapter, we summarize the most important aspects of the main groups of known giant viruses of unicellular eukaryotes, including information about (1) the structure and composition of their virus particles, (2) the organization and content of their complex genomes, and (3) what we currently know about their replication cycles.

Classification and Evolutionary Relationships

In 2020, the International Committee on Taxonomy of Viruses (ICTV) presented a global organization and proposed a megataxonomy of the virus world.[77] Based on gene-sharing networks and phylogenetic analyses of hallmark genes, viruses of the NCLDV clade are now classified in the realm *Varidnaviria*, kingdom *Bamfordvirae*, phylum *Nucleocytoviricota*. In addition to the families *Phycodnaviridae*, *Mimiviridae*, and *Marseilleviridae*, several other groups of dsDNA viruses infecting unicellular eukaryotes belong to the nucleocytoviruses, including pandoraviruses, pithoviruses, molliviruses, orpheoviruses, cedratviruses, medusaviruses, faustoviruses, kaumoebaviruses, pacmanviruses (Fig. 17.2).[12,13,15,21,87,89,119,126,185] Most members of the kingdom *Bamfordvirae* encode a major capsid protein containing a double jelly-roll fold (MCP-DJR), forming pseudohexameric capsomers (Fig. 17.2). Each jelly-roll domain consists of two juxtaposed four-stranded beta sheets, and the icosahedral capsid lattice is made of vertical jelly rolls.[23,77] In addition, bamfordviruses encode other structure-related proteins, such as a single jelly-roll minor capsid protein and an FtsK-HerA–like ATPase involved in virus genome packaging, and replication enzymes, such as DNA polymerases and superfamily 3 helicases.[77] Remarkably, despite these structural and/or replication hallmark genes being shared and encoded by most bamfordviruses (including those not yet officially classified), some bamfordviruses have presumably lost a few of those hallmark genes or, in some cases, the original functions of the encoded hallmark proteins have been modified. These facts may explain, in part, why some protist-infecting viruses present atypical capsid shapes—such as the oval pandoraviruses, pithoviruses, cedratviruses and orpheoviruses, and the spherical molliviruses—in contrast to the icosahedral symmetry observed in most of the known viruses of this group (Fig. 17.1).[12,87,89,119]

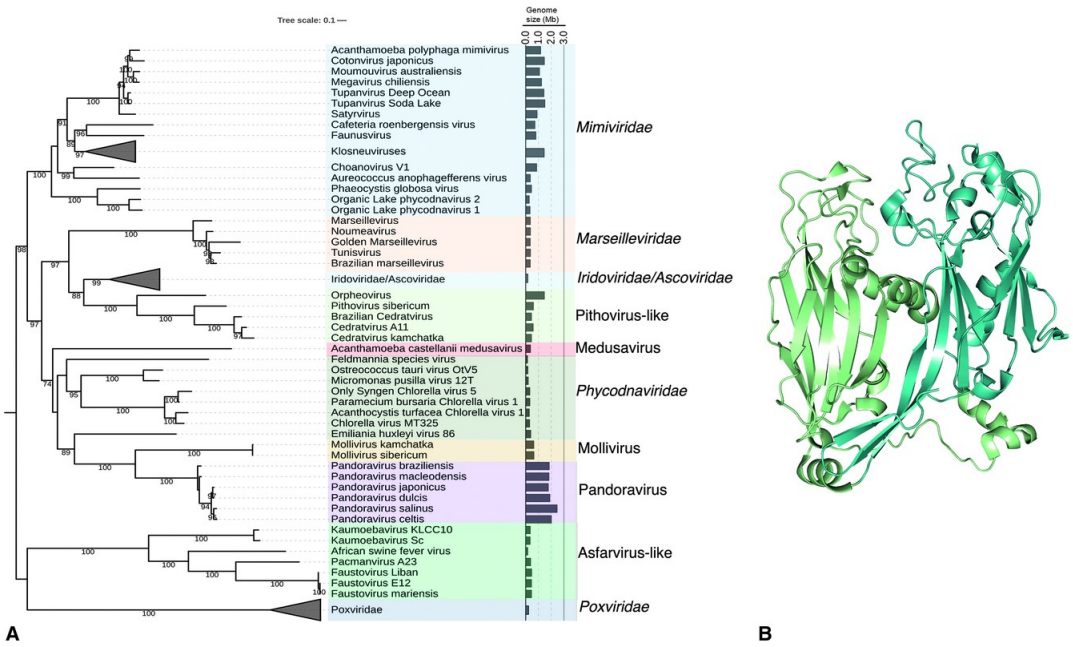

FIGURE 17.2 **Hallmark proteins of bamfordviruses**. **A**. Phylogenetic relationship within the phylum *Nucleocytoviricota* based on the polymerase B gene sequence. Representatives of all families included in the phylum were incorporated in this maximum likelihood tree. The genome size of each virus is shown in the *bar graph*. The genome size related to the collapsed clades is the mean value considering the viruses used to reconstruct the phylogenetic tree. The tree was built by using IQ-TREE with an evolutionary model LG+F+R5, selected by ModelFinder, based on the amino acid alignment of 72 viral sequences. Nodes have been labeled with bootstrap values. The scale bar represents the substitution rate. (Tree courtesy of Prof. Rodrigo Rodrigues, Universidade Federal de Minas Gerais, Brazil.) **B**. Structure of PBCV-1 MCP with the typical double jelly roll (PDB ID: 5TIP) shared by most of bamfordviruses. The N-terminal jelly-roll domain is colored in *pale green* and the C-terminal domain is colored in *light teal*. (Courtesy of Mateus Serafim, Universidade Federal de Minas Gerais, Brazil.)

The virions of nucleocytoviruses of unicellular eukaryotes are mostly nonenveloped, containing an inner lipid membrane.[1,77] The inner lipid membrane is usually related to the uncoating of the virion core into the host cell, by fusing with cellular lipid membranes, including the phagosome, endosome, or plasma membrane.[3,87,89,119] There are some notable exceptions. It seems that the faustovirus inner membrane has

been replaced by an inner protein capsid.[76] In tupanviruses, a long cylindrical tail is attached to an icosahedral capsid.[3] Moreover, in coccolithoviruses, an outer lipid envelope covers the capid.[92]

Considering the possible monophyletic origin of the viruses encoding the MCP-DJR structural module, it has been proposed that giant viruses evolved from smaller viruses, in a complex and long-term scenario[77,78]: (1) a tectiviruslike ancestor–infecting bacteria was incorporated by a proto-eukaryotic host during the endosymbiotic event that gave rise to mitochondria; (2) this tectiviruslike ancestor recombined with other mobile genetic elements, integrated into the host nucleus and evolved into the Maverick/Polinton-like elements. Most, if not all of these entities are likely more viral than transposons in their lifestyle; (3) after the acquisition of genes encoding RNA polymerase and capping apparatus, polintons escaped from the nucleus and then were able to replicate in the cytoplasm; (4) finally, after the acquisition/replacement of some genes and genome expansion, polintons gave rise to giant viruses. Interestingly, in this scenario, polintons are key players during the emergence and evolution of other viruses, including virophages, adenoviruses, and bidnaviruses.[77,78] Another theory, much more speculative and less detailed about the origin of giant viruses argues that they are descendants of a lost cellular domain and have faced reductive evolution.[33] Regardless of the giant virus origin, horizontal gene transfer, gene duplication, or even "*de novo*" gene creation have been described as evolutionary events that improve and speed up giant virus adaptation.[4,52,88]

Phycodnaviridae

As mentioned, electron microscopy observations of large VLPs in association with unicellular eukaryotic algae in the 1970s constitute some of the first potential records in the literature of the existence of giant viruses.[46,60,121,122] However, seminal studies on chloroviruses in the early 1980s represent a hallmark in the history of virology. For the first time, a large virus of a unicellular eukaryotic algae could be propagated, purified, and analyzed by classical virology methods, including the plaque assay standardized by James Van Etten and colleagues.[97,168,173,174] Since then, numerous studies on the structure, genomics, virus-host relationships, and even related to the biotechnological use of chlorovirus proteins have been carried out.[51,53,135,181]

Over the years, new eukaryotic algae viruses have been discovered, constituting what we know today as the family *Phycodnaviridae*, order *Algavirales*, class *Megaviricetes*. Metagenomic studies have revealed the diversity and ubiquity of these viruses in diverse environments.[70,146] According to the ICTV, six genera make up the family today: *Chlorovirus*, *Coccolithovirus*, *Prasinovirus*, *Prymnesiovirus*, *Raphidovirus*, and *Phaeovirus*. The last one encompasses viruses infecting multicellular brown algae. However, most phycodnaviruses infect unicellular eukaryotic algae, inhabitants of freshwater and sea, and are currently recognized as important players in aquatic communities, acting in algal bloom control, nutrient cycling, and carbon flow.[68,141] Among the hosts of phycodnaviruses are beautiful organisms, which establish complex symbiotic and ecological relationships in aquatic environments, such as *Emiliania huxleyi*, *Chlorella* spp., and *Ostreococcus* spp. However, with the discovery and phylogenetic analysis of new giant viruses of amoeba, it is increasingly evident that some genera currently classified in the family *Phycodnaviridae* must become new independent viral families.[19]

Virion Structure

Phycodnavirus virions consist of a 100- to 220-nm icosahedral outer shell and an inner bi-lipid membrane enclosing the genome and proteins in a dense core (Figs. 17.1 and 17.3).[170] An additional external membrane (envelope) was described in coccolithoviruses, a rare feature among unicellular eukaryote–infecting nucleocytovirus.[92] Among the phycodnaviruses, Paramecium bursaria Chlorella virus 1 (PBCV-1) has been the most structurally characterized. To date, a near-atomic analysis of the 190-nm capsid of PBCV-1 has been described, and it is the largest virus to be resolved at 3.5 Å resolution (Fig. 17.3). The PBCV-1 icosahedral capsid has a triangulation number of 169 (h = 8; k = 7), composed of trimeric capsomers arranged into 20 triangular and 12 pentagonal facets.[51] Three-dimensional (3D) reconstruction of cryogenic electron microscopy (cryo-EM) images revealed that one PBCV-1 vertex has a 560 Å long spike structure, of which 340 Å extend from the virus surface. This structure makes first contact with the host cell wall during infection (*see stages of replication*) (Fig. 17.3). The spike width is 35 Å at the tip and 70 Å at the base; this base is rooted inside the shell and extends 160 Å, allocated in a large pocket (a gap between the capsid and the inner membrane).[38] The PBCV-1 genome is not homogeneously distributed in the particle core due to this pocket. External fibers have also been described to extend from trisymmetron capsomers and might play a role in virus attachment to host cells. The capsid consists of 5040 major capsid protein copies, 60 copies of a penton protein and 1800 units of 13 different types of proteins. The minor capsid protein P2 acts as a tape-measure element, connecting fivefold vertices (Fig. 17.3).[51,167]

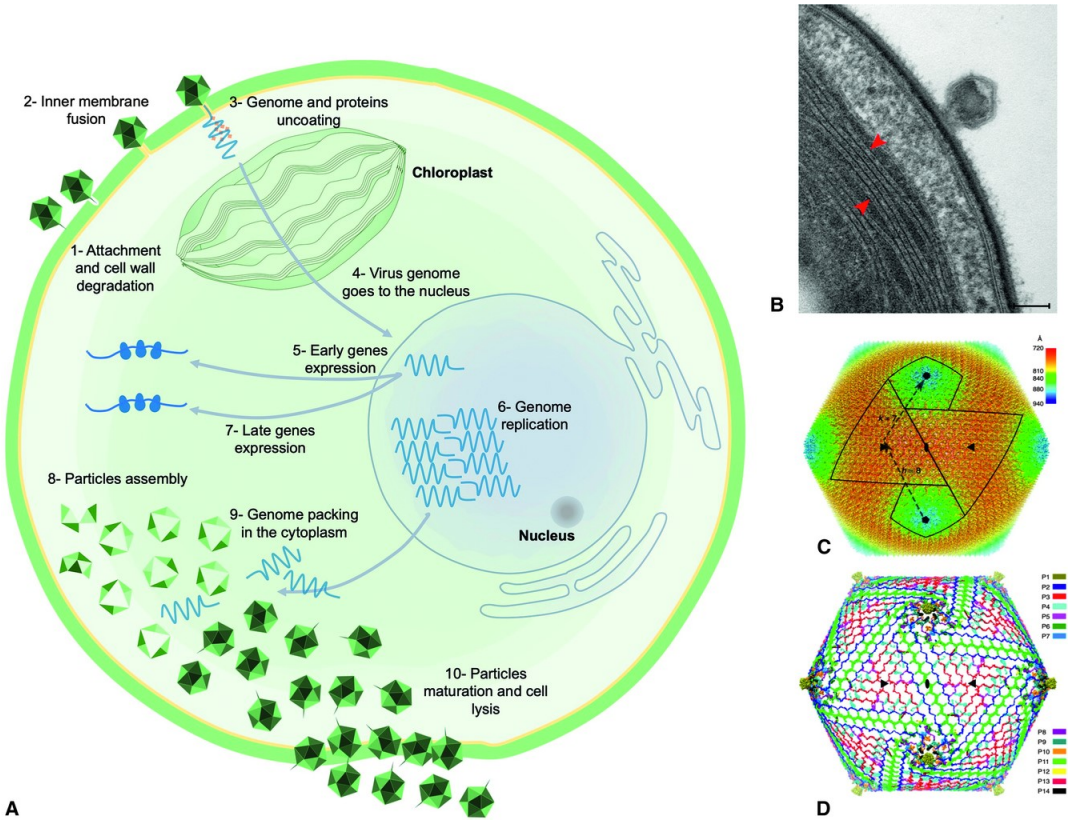

FIGURE 17.3 **Paramecium bursaria Chlorella virus 1 (PBCV-1) replication cycle and structural features**. **A**. Schematic overview of the PBCV-1 replication cycle. *1*—Infectious PBCV-1 particle attachment to the cell wall is mediated by the spike structure; wall degradation is probably promoted by the C-terminal portion of an alginate lyase–like protein present in the virion. *2*—The virion inner membrane fuses with the cell plasma membrane, forming a tunnel for uncoating. *3*—The virus genome and proteins are released into the host cytoplasm. *4*—The PBCV-1 genome moves to the algae nucleus. There is evidence that the virus promotes disruption of adjacent thylakoid membranes.[99] *5 and 6*—Early genes are expressed, including those related to genome replication, which occurs in the nucleus. *7*—Late genes are expressed, including those encoding structural proteins. *8-10*—In assembly sites, structural proteins are organized, forming empty particles. Those particles are filled with the virus genome in the cytoplasm. Particles are then released by lysis of the cell wall and plasma membrane. **B**. PBCV-1 virion attached to the cell wall. *Red arrowheads* show thylakoid membrane stacks adjacent to cell plasma membranes. There is evidence that adjacent thylakoid membrane disruption can be promoted by PBCV-1, paving the way for the virus genome to reach the nucleus. (Adapted from Milrot E, Shimoni E, Dadosh T, et al. Structural studies demonstrating a bacteriophage-like replication cycle of the eukaryote-infecting Paramecium bursaria chlorella virus-1. *PLoS Pathog*. 2017;13(8):e1006562.) **C**. Icosahedrally averaged cryogenic electron microscopy reconstruction of the PBCV-1 capsid. Colors indicate the distance from the center of the virus. The h and k vectors are indicated (used to calculate the T number). **D**. Cryogenic electronic microscopy density of PBCV-1 minor capsid proteins and the penton proteins after removing the outer capsid shell. The colors to the right indicate the several proteins present in the capsid. (**C** and **D** are adapted from Fang Q, Zhu D, Agarkova I, et al. Near-atomic structure of a giant virus. *Nat Commun*. 2019;10(1):388. http://creativecommons.org/licenses/by/4.0/.)

The proteome analysis of PBCV-1 virions indicated 148 virus-encoded proteins (from <10 to >200 kDa) and at least one host protein. A total of 106 proteins have unknown functions or homologs in databases (except for orthologs found in other phycodnaviruses).[117] PBCV-1 MCP (Vp54) seems to be totally glycosylated by virus-encoded proteins.[171] Besides the aforementioned major and minor capsid proteins, PBCV-1 virions carry signal transduction proteins, several membrane proteins, histone methylase, Cu/Zn superoxidase dismutase, and others.[117] Interestingly, a protein (A561L) containing a domain that resembles an alginate lyase was found in the virion: its C-terminal domain has *Chlorella* cell wall–degrading activity, strongly suggesting that this protein is essential during the chlorovirus entry phase.[6]

There are limited data on virion structure and composition regarding other phycodnaviruses. To date, the structure of Phaeocystis pouchetti virus, a prymnesiovirus, has also been resolved, revealing that the 220-nm icosahedral particles are composed of 2192 capsomeres arranged quasi-symmetrically with the triangulation number of 219 (h = 7; k = 10). A total of 60 fiberlike protrusions were described in association with the outer surface of the capsid; they may be important to virus attachment.[182] The proteomics of the E huxleyi virus (EhV), a coccolithovirus, revealed that its virion comprises 28 types of virus-encoded proteins, including MCP, lectin-binding proteins, thioredoxin, protein kinases, and >20 membrane proteins.[9] Additional studies on virion proteome and structure are necessary to unveil shared and exclusive features of phycodnavirus groups.

Genome Structure and Organization

Phycodnaviruses have dsDNA genomes ranging from 154 to 560 kb in size and a G/C content from 30% to 55%.[170] As mentioned previously, some representatives will probably be allocated to other viral families, especially those with the largest genomes.[19] A large number of phycodnavirus genome sequences are available, especially chloroviruses, coccolithoviruses, and prasinoviruses.

The chloroviruses have linear dsDNA genomes, 290-370 kb, encoding 330-416 predicted proteins so far.[167] As observed in other

nucleocytovirus, some chlorovirus proteins have multiple domains, expanding the functional repertoire encoded by the genome. The genome of PBCV-1 (331 kb with 416 coding DNA sequences [CDS]) has a terminal 35-nucleotide-long region covalently closed, forming hairpin loops.[191] Each hairpin is followed by a 2.2 kb inverted repeat sequence.[157] Intergenic regions are minimal and the coding regions of some genes overlap. Some core protein genes are located in clusters, named "gene gangs," which suggests selection for functionally related genes to remain in proximity.[150] In the central region of the genome, there is a polycistronic gene containing 11 transfer RNAs (tRNAs). Individual chloroviruses encode different tRNAs.[167] The intergenic regions of most of the early PBCV-1 genes contain the sequence AATGACA, preceding the start codon by ~100 nucleotides; however, there is no consensus promoter motif that has been identified for all early or late genes of PBCV-1.[59] Genome analysis of 36 chlorovirus genomes identified four distinct clades and an open pangenome, with 1345 clusters of orthologous genes, including 126 conserved in all viruses.[131] Comparison of the genomes of different chlorovirus host types revealed poor syntenic conservation.[150]

Interestingly, chloroviruses encode several remarkably small proteins well characterized, a factor that facilitated the characterization and even commercial use of some of these proteins: ATP-dependent DNA ligase, 5 mC and 6 mA DNA methyltransferase, site-specific DNA endonuclease, a type II DNA topoisomerase, and a tiny (82 amino acid) protein that forms a functional K^+ channel.[5,170] As mentioned previously, PBCV-1 encodes an extensive glycosylation machinery; some chloroviruses encode chitin synthase and enzymes involved in sugar metabolism, including UDP-glucose dehydrogenase, hyaluronan synthase, and glutamine/fructose-6-phosphate aminotransferase.[167,170,171]

The genome sequence of EhV strain 86 was announced in 2005, just a few years after its discovery in the English Channel.[177] Since then, other EhV genomes have been sequenced, revealing common features among coccolithoviruses genome.[10,107,108] Coccolithoviruses have linear 376-421 kb genomes, encoding 444-548 predicted proteins, with a G/C content of about 40%. At least four clades (A1, A2, A3, and B) have been identified among EhV strains, based on average nucleotide identity and phylogenetic analysis. Interestingly, EhV genomes are largely syntenic, even across different clades; the only exception is a region located between nucleotides 200 000 and 300 000, which presents several inversions, rearrangements, and substitutions.[108] Only ~90 EhV genes have functional predictions, including those related to a near-complete sphingolipid biosynthetic pathway that seem to be homologous to host (*E huxleyi*) genes.[177] Important EhV genes probably were acquired from eukaryotes, including those genes related to replication, repair, recombination, transcription, and nucleotide metabolism. Therefore, horizontal gene transfer seems to be an important feature in EhV evolution.[100] Three to six tRNAs were predicted in EhV genomes, including those common to all genomes: Arg, Asn, and Gln.[108]

The comparative analysis of viruses infecting the prasinophyte marine eukaryotic phytoplankton revealed that Micromonas pusilla virus genomes can harbor up to seven tRNAs, including five shared by all analyzed viral strains: The genomes of those strains are 173-205 kb, encoding 244-275 predicted proteins and a G/C content ranging from 39% to 43%. Only 80 clusters of orthologous genes are shared by all analyzed strains (core genome), including genes related to DNA replication, transcription, and structural proteins.[53] Ostreococcus tauri virus genomes also encode for tRNAs (eg, OtV-2 and OtV-5 encodes for five tRNAs), and some strains encode for cytochrome b5; DNA methyltransferase; and enzymes involved in sugar metabolism, lipid modification, and DNA methylation.[176] The comparative analysis of seven Ostreococcus lucimarinus viruses revealed ~190 kb genomes, with a G/C content of ~40%, encoding 243-269 putative proteins and five tRNAs. Some viral strains presented a 32 kb inversion in the central region of the genome.[44]

Although phaeoviruses infect multicellular algae, here, we will present some data for comparative purposes. Among the phaeoviruses, the genome of Ectocarpus siliculosus virus was announced in 2001, revealing a ~335-kb genome encoding 231 predicted genes.[43] Genes putatively involved in DNA integration were identified, which is compatible with the virus lifestyle and its latent phase. Repetitive elements, namely tandem repeats, represent 12% of the E siliculosus virus genome, and single-stranded DNA regions were described in the genome.[43] The sequence of Feldmannia virus strain 158 showed a ~154-kb genome encoding 150 predicted proteins, including those involved in DNA transposition, integration, replication, and methylation.[145] Finally, the 274-kb genome of Heterosigma akashiwo virus strain 53, a raphidovirus, encodes three tRNAs and ~240 proteins. Only 23 proteins had phycodnaviruses as best hits.[110] Therefore, the genomic data obtained in recent years have suggested that phycodnavirus consist of a genetically variable, heterogeneous, and polyphyletic group, encoding for a narrow set of shared universal genes (core) and deeply influenced by events of horizontal gene transfer with their hosts and other organisms. As aforementioned, the criteria to define the members of this family need to be revised.

Stages of Replication

Phycodnaviruses have been detected to infect a plethora of unicellular eukaryotic algae taxa as well as multicellular organisms. Most phycodnaviruses are lytic, but some can establish a latent phase after integrating the viral DNA in host genomes (eg, E siliculosus virus), being released only in the algal reproductive stage of life.[93,94,170] Furthermore, environmentally induced genetic and/or metabolic changes in host cells, including variations related to chromosomal euploidy, reproductive vs vegetative stages, and motile vs sessile forms, have been described as important factors regarding host susceptibility and permissiveness. In this regard, there are exciting data on the ecological roles of phycodnaviruses in aquatic environments.[95,101,116,165] Here, we present examples of the most studied viruses in the context of their replication cycle steps.

Virus entry in the host cell is quite variable depending on the phycodnavirus species. As mentioned previously, coccolithovirus and phaeovirus virions may have an external envelope. Therefore, EhV enters after envelope fusion with the host plasma membrane or endosomes.[92] Lipid rafts have been described as important for virus attachment and entry.[134,170] Despite the fact that EhV genomes encodes up to six RNA polymerase subunits, these proteins are not present in the virions; consequently, the transcription of virus early genes is promoted by the host machinery in the nucleus.[9] The enveloped E siliculosus virus infects wall-less host gametes via fusion of the virion envelope with the cell plasma membrane. The virus genome and associated nucleoproteins are directed to the cell nucleus within 5 minutes postinfection. Integration of virus DNA into the host genome is likely promoted by the integrase protein packaged in the virion. In the latent phase, the E siliculosus virus genome is propagated by mitosis in vegetative cells.[93,94]

The chlorovirus PBCV-1 attaches to the *Chlorella* cell wall, a process mediated by the virion spike (Fig. 17.3).[38,99] The punctiform degradation of the cell wall is probably promoted by the C-terminal portion of an alginate lyaselike protein present in the virion.[6] The inner membrane of the virion then fuses with the host membrane, forming a tunnel, where the virus genome linearly passes toward the host cytoplasm. Host plasma membrane depolarization is initiated by a virus K^+ channel present in the virion inner membrane, reducing cell turgor pressure, favoring the

release of the virus genome in the host cytoplasm, and blocking infection by other PBCV-1 virions.[5] The PBCV-1 genome, likely associated with proteins containing nuclear localization signals, moves to reach the nucleus, and there is evidence that the virus promotes disruption of adjacent thylakoid membranes.[99] In <10 minutes postinfection, there is transcription of virus early genes mediated by the host transcription–related proteins. The synthesis of the virus genome has been described to start either in the host nucleus (PBCV-1) or in the cytoplasm (EhV).[170]

Phycodnavirus virion assembly usually occurs in the host cytoplasm (Fig. 17.3). The PBCV-1 virus factories are composed of host cisternae derived from the endoplasmic reticulum. The cisternal membrane is cleaved into single bilayer membranes, which are associated with capsomers, forming empty capsids. DNA packing occurs at the periphery of viral factories.[98] Massive progeny formation has been described for most of the analyzed phycodnaviruses, filling the host cells with particles.[96] Interestingly, preceding complete cell lysis by 30-50 minutes, the partial disruption of the host cell membrane allows the release of part of the PBCV-1 progeny.[169] In contrast, the newly formed EhV particles move to the plasma membrane, and the envelope is acquired during budding of virus particles at ~4.5 hours postinfection (hpi).[92]

Mimiviridae

The aforementioned serendipitous discovery of APMV represents a scientific hallmark. For the first time in the history of virology, a 1 mega base pair (Mb) dsDNA genome had been described, encoding for proteins that were previously thought to be exclusive of cellular organisms.[124] The APMV virion has gigantic structure with icosahedral symmetry covered by long-associated fibrils, reaching up to 750 nm (Fig. 17.4); therefore, APMV particles are not filterable through 0.2-µm filters and can be visualized by optical microscopy.[82] This set of novel characteristics supported the establishment of a novel viral family named *Mimiviridae*, encompassing the genus *Mimivirus* and the species *A polyphaga mimivirus*. The family *Mimiviridae* belongs to the phylum *Nucleocytoviricota*, class *Megaviricetes*, and order *Imitervirales*. A few years later, the genus *Cafeteriavirus* was incorporated into the family, to encompass the species *Cafeteria roenbergensis virus* (CroV), a virus infecting a marine flagellate. A number of potential new species and strains have been described or reclassified as mimiviruslike entities, including klosneuvirus, tupanvirus, Bodo saltans virus, Aureococcus anophagefferens virus, Chrysochromulina ericina virus, Phaeocystis globosa virus, Tetraselmis viridis virus, and Prymnesium kappa virus, among others, revealing a considerable diversity in relation to virion structure, host spectrum, gene repertoire, and replication strategies.[3,14,22,27,36,42,74,137,140,147,148,156] The relationship of mimiviruses to smaller viruses called virophages has fueled debates on the definition of subviral agents.[58,83] In this section, we present a condensed view of the most important features regarding members of the family *Mimiviridae*.

Virion Structure

Members of the *Mimiviridae* family are variable in their size, composition, the presence of surface fibrils, and the tail (Figs. 17.1 and 17.4). Among cultivated mimiviruses, virions range from ~150 nm in diameter (*Phaeocystis globosa virus* I) to 1200 nm (tupanviruses) in length.[3,24] Since the discovery of APMV, several techniques, as thin-section electron microscopy, cryo-EM, atomic force microscopy, STEM tomography, and others, have been applied to better understand its structure, composition, and life cycle.[80,104,105,143,149,180,187] The APMV virion is composed of a 500-nm outer capsid shell covering an inner capsid shell, an inner membrane, and a core wall containing the genome and other

elements (proteins and tRNAs) related to early steps of viral replication cycle. The outer capsid shell has icosahedral symmetry and comprises MCP trimers (the L425 gene). The capsid has 20 faces and an exit portal structure in 1 of the 12 vertices, named stargate (Figs. 17.4 and 17.5).[143,180,187] This structure opens during the early steps of the virus cycle, ultimately promoting the viral core/seed transfer to the host cytoplasm (Fig. 17.5).[11] The stargate portal is sealed by a proteinaceous complex named starfish (Fig. 17.5).[143,180,187] The product of APMV gene L454 probably acts as a tape-measure, connecting fivefold vertices beneath the outer MCP layer,[178] and the APMV protein L410 is an abundant component of the viral core.[125] The APMV triangulation number was not determined due to limited resolution of structural studies, but it is estimated to be 972-1200 (h = ~19; k = ~19).[180] However, the triangulation numbers of other *Mimiviridae* members have been obtained: the A anophagefferens virus triangulation number is 169 (h = 7; k = 8),[65] and CroV has the highest triangulation number determined so far: 499 (h = 7; k = 18), with 4980 capsomers and 14 940 MCP copies (Fig. 17.4).[179]

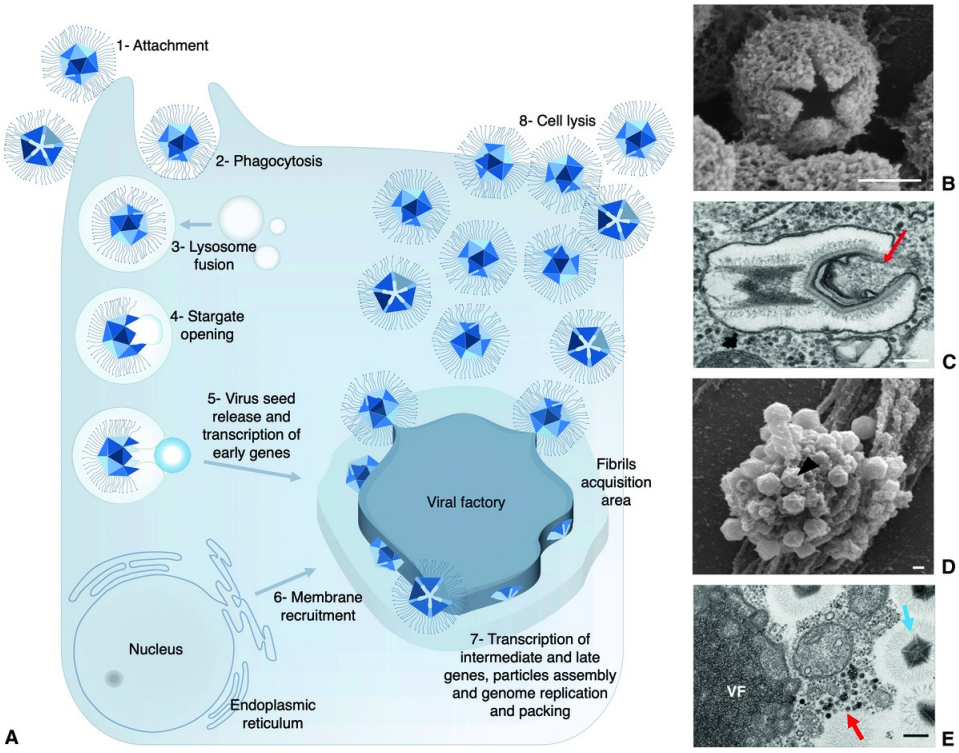

FIGURE 17.5 **Mimivirus replication cycle and structural features**. **A**. Schematic overview of the APMV replication cycle. *1 and 2*—APMV infectious particle attachment to the cell surface is mediated by viral fibrils, triggering phagocytosis. *3-5*—Lysosomal fusion with phagosome-containing APMV promotes acidification, leading to stargate opening and release of the viral seed into the amoebal cytoplasm. APMV early genes are then expressed by a transcriptional set of proteins present in the virion. *6 and 7*—The viral seed gives rise to a mature and micrometric viral factory. Membrane recruitment from the endoplasmic reticulum to the viral factory is involved in the initial steps of particle morphogenesis. Intermediate and late genes are expressed, the genome is replicated, and particle assembly occurs sequentially in the periphery of the viral factory. The virus genome is packaged into the particles at a site opposite to the stargate vertex. Fibrils are incorporated into the particle surface concomitantly with genome packaging, in a region named the fibril acquisition area. Newly formed mature particles fill the amoebal cytoplasm and are released by cell lysis. **B**. Scanning electron microscopy of a tupanvirus with an open stargate. Scale bar: 200 nm. Abrahão, Center of Microscopy, Universidade Federal de Minas Gerais, Brazil.)

The surface of the APMV outer capsid shell, except for the starfish structure, is covered with 140-nm-long fibrils, which give the virion a hairy appearance and expand its size to up to 750 nm (Fig. 17.4).[104,132] These surface fibrils are variable in size, thickness, abundance, and organization, depending on the mimivirus.[3,18,132] The fibrils consist of multiple components, including *N*-acetylated viosamine and gene products R135, L725, L829, and R856.[32,120,154] Fibrils are capped with an ellipsoidal protein head of 25 kDa.[81] Fibrils are glycosylated and have been referred to as a peptidoglycanlike containing structure, which favors the affinity of APMV particles for crystal violet during Gram staining. It has been hypothesized that fibrils are important but nonessential elements to promote virus attachment in host cells and may act as "bait" to optimize virion internalization by triggering phagocytosis in amoebas.[132] Cotonvirus japonicas fibrils are denser and shorter than those of APMV,[163] and in Megavirus chiliensis, some fiber bundles called cowlicks are longer than the rest.[18] No fibrils were observed on the surface of CroV virions[179] (Fig. 17.4).

Tupanvirus soda lake and tupanvirus deep ocean are tailed mimiviruses.[3] However, in contrast to some bacteriophages, the tupanvirus tail is not a strawlike structure that promotes the injection of the virus genome into host cell compartments during virus entry. In fact, tupanvirus has

a capsid that is structurally similar to APMV, including the stargate vertex. The 550-nm-long and 450-nm-thick cylindrical tail is attached to the capsid at the vertex opposite of the stargate vertex (Fig. 17.4). Tupanvirus capsid and tail are covered by a shorter, thicker fibril layer. Both the capsid and tail content are released in amoeba upon infection. The tupanvirus tail is variable in length, reaching up to 2300 nm.[3,152]

A total of 236 different proteins were found in APMV particles,[61] including structural proteins (eg, major capsid protein and major core proteins), several RNA polymerase subunits, mRNA capping enzymes, helicases, and other transcriptional elements; proteins involved in redox pathways that may be important in the context of the amoeboid phagosomal environment during virus entry; and DNA repair, which presumably acts on viral DNA even inside the particle. Some mRNAs have been found in APMV particles, including those related to aminoacyl tRNA-synthetases (aaRS), DNA polymerase, and TFII-like transcription factor.[41] CroV, tupanvirus, and A anophagefferens virus particle proteomics have indicated 141, 187, and 43 proteins, respectively, some of them with functions similar to those described for APMV particles.[57,65,143] Future studies targeting specifically the composition of the tupanvirus tail will be useful to understand the role of this structure in early steps of the cycle.

Genome Structure and Organization

The members of the *Mimiviridae* family have dsDNA genomes ranging from 371 kb in A anophagefferens virus to 2.12 Mb in Yasminevirus (Fig. 17.1). The genomes are mostly linear, although the genome of T viridis virus has been described as circular. The G/C content ranges from 23.3% in CroV to 41.2% in T viridis virus and is usually lower than the G/C content of their protist hosts.[55,148] Different methods have been used to predict the number of genes in each cultured mimivirus genome, but current information indicates that it ranges from 377 in A anophagefferens virus to 1541 in yasminevirus.[22,64] In APMV and other *Mimiviridae*, introns or inteins have been described in association with genes encoding the major capsid protein, DNA polymerase, DNA topoisomerase, or RNA polymerase large subunit.[30,41,109] As observed in other DNA viruses, variable and nonessential genes are more likely to be found at the termini of the genome. A Q-like topology model has been proposed to explain APMV genome replication, based on the pairing of 617 bp inverted repeats.[40] Putative promoter motifs have been described, including the AAAATTGA (early) and TCTA (late), but variations may be found in different mimiviruses.[160]

A substantial number of predicted genes with no recognizable homologs in databases, usually referred as ORFans, have been identified in mimivirus genomes; many of them are shared by several strains and encode for proteins also present in the virions.[41,61,124] As mentioned previously, *Mimiviridae* members may encode for proteins that are rare or have never been seen in the virosphere. A trademark among mimivirus genomes is the presence of translation-related genes, including aaRS, tRNAs, and translation factors (initiation, elongation, and termination).[3,22,41,55,124,147] Sequencing of the APMV genome revealed the presence of four types of aaRS-coding genes.[124] aaRS promotes the attachment of a given amino acid to cognate tRNA. Following the characterization of APMV, several mimivirus isolates have been described, including lineage A mimiviruses (including APMV), lineage B (moumouviruslike viruses), and lineage C (megaviruslike viruses), with slight variations in the number and variety of aaRS genes, including paralogous genes with distinct evolutionary histories.[18,29,124,183] However, in 2017, the metagenomic analysis of a wastewater treatment plant in Austria revealed up to 19 aaRS in the genome of klosneuviruses, a group of mimivirus relatives.[147] In the following year, a complete set of 20 aaRS and up to 70 tRNAs, corresponding to all 20 amino acid specificities, was found in tupanvirus genomes.[3] Subsequently, a similar profile was observed in minevirus.[22] Conclusions about mimivirus aaRS gene origins based on phylogenetic analyses are controversial. Tracking aaRS gene origins has been challenging because some mimivirus aaRS genes belong to deep-branching viral clades, while others seem to have been acquired more recently from cellular organisms. Those aaRS genes seem to have been obtained by mimiviruses in different scenarios and evolutionary occasions.[3,4,147] The reason why some mimivirus have conserved an extensive set of aaRS and other translation-related genes needs further investigation, but perhaps the retention of translation-related genes in viral genomes could be advantageous for exploring new hosts with different codon and amino acid usages: tupanviruses, for example, are able to infect both *Vermamoeba vermiformis* and different species belonging to the *Acanthamoeba* genus. In addition, keeping translation-related genes would be an advantage in when host translation system is shut-off as viral defense.[3,152]

Other unexpected genes have been found in different putative members of *Mimiviridae*. Tupanviruses encode a putative citrate synthase, an enzyme belonging to the tricarboxylic acid cycle, probably acquired from a sympatric bacterium by horizontal gene transfer.[129] Genes putatively encoding enzymes related to the biosynthesis of 3-deoxy-d-manno-octulosonate, involved in carbohydrate metabolism, were found in CroV.[55] Key genes related to mannitol metabolism and fermentation were found in T viridis virus, including mannitol 1-phosphate dehydrogenase, alpha-galactosidase, pyruvate formate-lyase, and pyruvate formate-lyase–activating enzyme.[148] Genes encoding rhodopsin, a protein that captures or senses sunlight, were found in the metagenome of Choanovirus, a member of the extended *Mimiviridae*.[106] Myosin, actin, and kinesin genes have been found in giant virus genomes by metagenomic and metatranscriptomic studies.[69,75] Therefore, as the knowledge on mimiviruses expands, a more sophisticated and complete repertoire of genes will be incorporated into the family pangenome.

Stages of Replication

Mimiviridae members are able to infect a broad range of heterotrophic or autotrophic eukaryotes, including amoeba such as *Acanthamoeba* sp. (eg, APMV, Tupanvirus, Cotonvirus) and *V vermiformis* (eg, Tupanvirus, Yasminevirus, Fadolivirus); the marine flagellate grazer *Cafeteria* sp. (CroV); the kinetoplastid flagellated phagotrophic protozoa *Bodo saltans* (Bodo saltans virus); the bloom-forming phytoplankton *Phaeocystis globosa* (Phaeocystis globosa virus group I); the heterokont alga *Aureococcus anophagefferens* (Aureococcus anophagefferens virus); other phytoplankton species such as *Chrysochromulina* (Chrysochromulina ericina virus) and *Tetraselmis viridis* (Tetraselmis viridis virus); and choanoflagellates (Choanovirus). Mimiviruses have been found widespread in oceans, spring water, soil, and even as members of animal microbiomes.[3,24,27,36,42,55,74,82,137,140,146,148,156,163] The association between mimiviruses and disease in vertebrates is controversial and requires further investigation.[2,84,139,190]

In contrast to other DNA viruses, such as vaccinia virus, studies on the replication of APMV and other giant viruses of amoebae are still in the descriptive phase, and the molecular mechanisms that explain virus entry, morphogenesis, and release remain unknown. The enormous number of mimivirus genes, the need for a robust gene knockout system, and the scarcity of reagents and antibodies applicable to protists cells represent some of the challenges that the giant virus scientific community will need to face to elucidate molecular mechanisms.

Fibrils may optimize the adhesion of APMV to *Acanthamoeba castellanii* cells mediated by glycans, specifically mannose and

N-acetylglucosamine. The absence of fibrils does not prevent infection, but virus adhesion to host cells seems to stimulate the formation of membrane protrusions and particle intake.[132] It is very likely that APMV-related strains, Yasminevirus, Tupanvirus, and other close relatives enter the host cells by the phagocytic pathway (Fig. 17.5). Consistently, the treatment of amoebas with cytochalasin D reduced APMV particle intake.[11] Amoebas can ingest one or several APMV particles, and there is increasing evidence that phagosome acidification is a stimulus for stargate opening.[11,143,187] Vesicles containing electron-dense content, probably lysosomes, fused with phagosomes containing APMV particles in *A castellanii* cells.[11] After acidification, the starfish seal is removed, resulting in the stargate opening[143,162,187] (Fig. 17.5). After the stargate opening, the virion inner membrane fuses with the phagolysosome membrane, forming a tunnel through which the viral core is transferred to the cytoplasm.[11,105] Tupanvirus capsid-core release is very similar to that described to APMV, but the tail content is released by an unknown process.[3] The entry and uncoating mechanisms of other family members may differ from APMV entry, for instance in cell-walled or flagellated hosts.

APMV gene transcription is temporally regulated, and early genes start to be expressed immediately after core release (Fig. 17.5).[105] The core, also known as the viral seed, expands in complexity and size in the cytoplasm, forming a >1.5-µm viral factory.[105,162] As mimivirus particles carry a complete set of transcriptional related proteins, it is believed that all steps of the replication cycle occur in the cytoplasm.[61,143] However, the role of nuclear factors in the APMV cycle needs further investigation. The virus factory is roughly oval shaped, nonmembrane bound, contains a large electron-dense center, and is surrounded by an electron-lucent fibrillar area. Ribosomes often surround the viral factory but are mostly excluded from it, raising questions regarding the regulatory signals used by APMV to recruit newly synthesized viral proteins to the factory.[11,105,162] APMV DNA replication and repair occur in the factory, promoted by an extensive set of viral proteins.[61,143] The virions are assembled in well-defined, sequential zones.[11,105,162] Endoplasmic reticulum membranes are transported to the viral factory, arranged as multivesicular bodies, and then modified to form membrane sheets. During particle assembly, these membranes associate with nascent capsid protein lamellae.[11,104,158] The incorporation of new capsomers probably occurs in a spiral fashion around a pentameric vertex.[179] Nascent capsids appear at the surface of the viral factory, with the stargate facing away from the center of the viral factory.[11,61,152] The genome is packaged at a capsid opening opposite of the stargate region. In tupanviruses, the tail is attached in the same region as genome packaging occurs, but it is unknown if and how the two processes are related.[187] Concomitantly, fibrils are attached to the capsid surface at the periphery of the viral factory, in a zone called the fibril acquisition area (Fig. 17.5).[11] After maturation at 8 hpi, particles accumulate in the amoebal cytoplasm, surrounding the viral factory and eventually filling the entire cytoplasm; they are subsequently released by cell lysis.[11] It is noteworthy that tupanvirus-infected cells often aggregate with uninfected cells, a process mediated by expressing a mannose-binding protein on the cell surface. Large aggregates of cells, named bunches, are formed and might be related to the optimization of virus dissemination.[113]

Virophages

Following the discovery of mimiviruses, the description of associated, smaller viruses called virophages added even more complexity to the protist-infecting virus universe.[58,83] Virophages are *la*rge *vi*rus-*d*ependent or -*a*ssociated *vi*ruses classified in the family *Lavidaviridae*. This family belongs to the phylum *Preplasmaviricota*, class *Maveriviricetes*, order *Priklausovirales*.[77] Virophages have 50- to 70-nm icosahedral membrane-less capsids, with a triangulation number of 27, mostly formed by MCP in association with a minor capsid protein, also known as penton protein.[58,83,161,189] In addition, virophages encode other morphogenesis proteins, such as a cysteine protease and a Fts-HerA–like ATPase. The virophage genomes are dsDNA, linear or circular, ranging from 17 to 30 kb, encoding not only the aforementioned structure-related proteins but also a DNA replication module.[49] In addition, recombinases and integrases may be found in virophage genomes, which is compatible with the fact that virophages have been found integrated in giant viruses or even in host-cell genomes (provirophages).[45] Virophage sequences have been found in several metagenomic surveys and seem to be important ecological players in natural environments, balancing the levels of giant virus populations.[136]

The virophages Sputnik and Zamilon were described in association with different mimiviruses, co-infecting *A castellanii*[45,63,83,102]; the virophage mavirus was described in association with CroV, co-infecting *C roenbergensis*.[58] Those host cells are not permissive to virophage replication by themselves. Therefore, virophages replication cycle is dependent on the presence of a compatible giant virus. Virophages are presumably dependent on the transcriptional machinery of giant viruses. This hypothesis is strongly supported by the fact that virophages have transcriptional signals very similar to those found in their associated giant viruses, including late promoter motifs.[40,58,86] Interestingly, the transcription of virophage genes starts during the late steps of the associated giant virus cycle. Newly formed virophage particles are assembled within giant virus factories (Fig. 17.5) and released after cell lysis and potentially also by exocytosis.[45,73,83]

The impact of virophage replication on the final titers of the associated giant virus varies. Mavirus, for example, reduces CroV replication by about 99%[58]; some sputniklike virophages reduce mimiviruses progeny by ~66%-90%.[83] Zamilon virophage replication, however, has no impact on lineage B and C mimivirus progeny formation.[63] It is worth noting that the deletion of 81 nucleotides at ORF 8 of Guarani (a sputniklike virophage) results in a broader virophage host range, allowing Guarani to replicate in association with not only APMV strains but also tupanviruses.[103] Remarkably, the mavirus genome can integrate in the DNA of the cellular host *C roenbergensis*, a phenomenon likely mediated by the virophage-encoded integrase. When such a cell is infected by the lytic CroV, provirophage genes are transcribed and translated, resulting in the release of virophage particles and protection of the *C roenbergensis* population.[56] On the other hand, a mimivirus lineage A defense system against Zamilon virophages called MIMIVIRE has been described. Although the mechanisms need further investigation, the gene R349 has 28 or 15 nucleotide repeats similar to regions found in the Zamilon genome, and it was hypothesized that it guides a system analogous to CRISPR-Cas to block virophage replication.[90] In addition to virophages, mimiviruses have been associated with mobile genetic elements called transpovirons.[45,73] These elements are 7 kb long, linear dsDNA, encoding 6-8 genes including a transposase and a helicase, and have been found in association with all lineages of mimivirus. The phylogenetic similarity among transpovirons subclades found in association with each mimivirus lineage suggests that these mobile genetic elements established dependence on mimiviruses before evolutionary radiation.[73]

Marseilleviridae

The discovery of mimiviruses prompted the search for other viruses of amoebae. In this context, in 2007, a new viral entity was isolated from a water sample collected in a cooling tower located in Paris, France.[34] This virus, isolated in *A polyphaga*, was named marseillevirus, referring to the city where this virus was first isolated (Aix Marseille Université, Marseille, France). Since its discovery, dozens of marseilleviruses have been

described in different continents and from a plethora of substrates, both by isolation methods and by metagenomic studies.[16,20,47,48,50,138,164] Currently, five different marseillevirus lineages have been described (A-E). The 230-nm icosahedral marseillevirus particle contains a circular dsDNA genome that is up to 404 kb in length (Fig. 17.1).[138] The marseilleviruses are classified in the class *Megaviricetes*, order *Pimascovirales*, family *Marseilleviridae*, genus *Marseillevirus*.[77] The viruses of this group highlight the sympatric lifestyle of parasites and symbionts of amoebas, which resulted in the mosaic profile of marseillevirus genomes.[34]

Virion Structure

Studies using thin-section and cryo-EM 3D reconstruction, coherent diffractive imaging, cryo-tomography, and single particle analysis of different marseillevirus isolates, especially melbournevirus (a lineage A marseillevirus), have revealed that the particles have icosahedral shape, with a diameter of ~230 nm and a 8.4-nm-thick capsid shell (Fig. 17.6).[34,91,111] The triangulation number is 309 (h = 7; k = 13), constructed by 3080 pseudo-hexagonal capsomers, which are assembled from 9240 MCP molecules. Ordered fibrous protrusions that are 7.5 nm in diameter and 12 nm in length with globular ends were described on the particles surface. A 3-nm-thick inner membrane surrounds the genome and proteins in a central region of the particle.[111] The composition of this membrane still needs further investigation, but Western blot assays of the particles indicated the presence of the endosomal protein SNX2.[17] A structure called "large and dense body" (30 nm) was consistently observed in all melbournevirus particles, close to the inner membrane; however, its function is not yet known.[111]

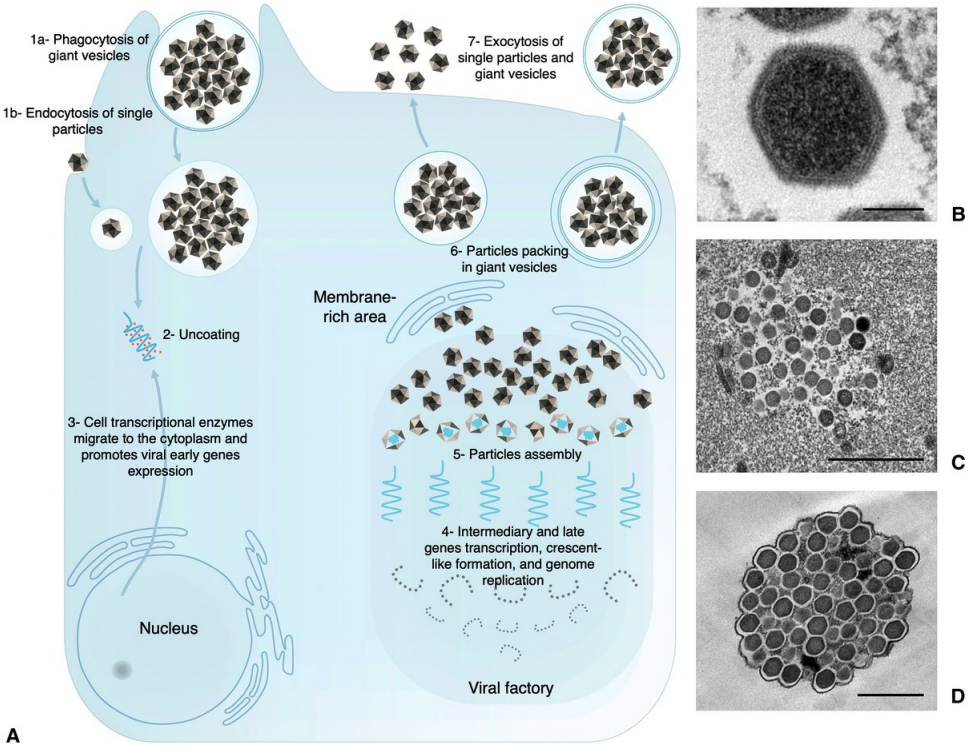

FIGURE 17.6 **Schematic overview of the marseillevirus replication cycle**. 1a—Marseillevirus particles attach to the cell membrane and likely trigger clathrin-mediated endocytic pathways. 1b—Alternatively, giant vesicles containing several marseillevirus particles trigger the phagocytic pathway. 2 and 3—Particles release the viral genome and proteins into the host cytoplasm. Virus early gene transcription is mediated by host enzymes recruited from the nucleus. 4—In the viral factory, intermediate and late genes are transcribed, followed by crescentlike formation and genome replication. *5*—Structural and genomic components are assembled concomitantly in mature particles and migrate to a membrane-rich area, at the periphery of the viral factory. 6—Part of the newly formed particles are wrapped into large and giant vesicles, containing from one to several membranes. 7—Single particles and giant vesicles containing many particles are exocytosed. Eventually, the host cell lyses, releasing more particles. **B**. Transmission electron microscopy of a marseillevirus lineage A particle. Scale bar: 100 nm. **C**. Transmission electron microscopy of a region of marseillevirus factory. Scale bar: 1000 nm. **D**. Transmission electron microscopy of marseillevirus giant vesicle after exocytosis. Proteomic analyses of different marseillevirus isolates show marked differences in relation to the number of proteins detected in the particles, from 49 to 283 proteins (including proteins incorporated from the amoebal host). This discrepancy is probably due to methodological differences, including the purification of particles, sensitivity, and analysis of the results.[34,50] Nevertheless, MCP, usually the most abundant protein in the virions of other icosahedral viruses, is ranked third and fourth in the marseillevirus isolates noumeavirus (NMV_116) and melbournevirus (MEL_305), respectively. The most abundant protein in the marseillevirus particles is a 150 amino acid hypothetical protein, which is highly conserved among all isolates. Other proteins found in high abundance in marseillevirus particles are three virus-encoded histonelike proteins.[50] The analysis of the marseillevirus fused histone pairs Hβ-Hα and Hδ-Hγ show strong structural analogy with the eukaryotic histone pairs H2B-H2A and H4-H3, being virtually identical to canonical eukaryotic nucleosomes.[166] Therefore, it is very likely that those abundant virus-encoded histonelike proteins act by condensing viral DNA during encapsidation. Host proteins associated with oxidative stress, such as peroxidases and thioredoxins, have been found in marseillevirus particles and may be important in the context of the endosome or phagosome environment during virus entry.[34,50]

Genome Structure and Organization

The amoebal intracellular environment promotes a sympatric lifestyle for many types of organisms, including viruses, bacteria and other eukaryotes. In this environment, gene transfer can occur among amoebas, their parasites and symbionts. Lateral gene transfer has been described to be important for giant virus evolution, and this feature has also been observed in marseillevirus genomes. Genes putatively acquired from bacteria, eukaryotes and other viruses seem to contribute to the marseillevirus genetic repertoire, and this feature has led to the proposal that amoebas are “melting pots” of microbial evolution.[34,138]

Marseillevirus genomes are circular dsDNA ranging from 340 to 404 kb and a G/C content of about 43%.[26,138] However, metagenomic data indicate that the genomes of marseillevirus relatives can reach up to an impressive 763 kb and a G/C content of 62.3%, suggesting that marseilleviruses might have diversified and adapted to unknown niches and hosts.[20] Considering the marseillevirus strains discovered by isolation methods only, the number of predicted ORFs range from 386 to 550.[26,138] As observed for most giant viruses, most (59%) of the predicted ORFs of marseillevirus isolates had no homologs in databases (ORFans). However, marseillevirus genomes contain NCLDV core genes and are thus part of the *Nucleocytoviricota* (Fig. 17.2).[34] Translation-related genes are absent among the isolated marseilleviruses, in contrast to the extensive arsenal found in members of the family *Mimiviridae*. However, several classes of aaRS and tRNAs were attributed to be part of marseillevirus in metagenomic sequences.[20]

Paralogous genes are abundant in marseillevirus genomes (from 18% to 31% of the predicted ORFs), especially 20 genes encoding proteins containing membrane occupation and recognition nexus (MORN) repeats, which may promote important steps during viral morphogenesis and release. Serine-threonine kinase paralogs have also been described, and their encoded proteins may act in cell signaling. Several copies of predicted proteins containing the PFAM02399 domain have been detected, and they likely participate in the replication of the viral circular genome.[34]

Comparative analysis of 12 marseillevirus isolates suggested a bias in genome sequence conservation. Considering the MCP gene as the starting point of such circular genomes, the rightmost parts of the genomes are more conserved at the nucleotide level, regardless of the marseillevirus lineage. Core genes are more frequently found in this conserved region. Genetic inversions and rearrangements are more frequently observed at the leftmost two-thirds of the genomes.[26]

The AT-rich motif AAATATT is widespread in intergenic regions of all marseillevirus lineages, in association with 55% of the predicted genes. Different single nucleotide polymorphisms (SNPs) in the AAATATT motif impact experimental gene expression.[115] However, RNA-seq analysis of marseillevirus-infected amoebas was not able to associate this motif with any class of temporally expressed genes, suggesting that other sequences and elements may control the expression of early, intermediate, and late transcripts.[130]

Stages of Replication

Although marseilleviruses were discovered after inoculating environmental samples into cultures of *A polyphaga*, these viruses are also capable of infecting *A castellanii*.[17,34] In both cells, marseilleviruses induce cytopathic effects, including rounding, cell detachment, and lysis. Some lineage B marseilleviruses can induce cell aggregation, forming “bunches,” similarly to those described for tupanviruses, but in this case, cell interaction seems to be mediated by galactose.[16,113]

Marseilleviruses have multiple entry pathways in *A castellanii* (Fig. 17.6). Individual virus particles trigger an endosomal acidification-dependent pathway, possibly via clathrin-coated endosomes.[17] Pretreatment of amoebas with chloroquine negatively impacts virus replication. In addition, marseilleviruses can enter amoebas as collective infectious units, called giant vesicles. Such vesicles are formed at the end of the replication cycle and are then released to the extracellular environment by lysis or exocytosis. The giant vesicles can reach >1000 nm in diameter, containing from a few to thousands of marseillevirus particles. Most of those vesicles present two membrane layers surrounding the particles, although vesicles with one, three, or even more membrane layers have also been described. Giant vesicles seem to trigger the phagocytic entry pathway, because virus entry and replication are negatively impacted after pretreating *A castellanii* with cytochalasin D but not with 5-(*N*-ethyl-*N*-isopropyl) amiloride (EIPA) or chloroquine.[17] However, due to the poorly characterized activity of pharmacological inhibitors in amoeba, more studies are needed to confirm whether the aforementioned pathways are indeed activated by marseillevirus particles and giant vesicles. Clusters of aggregated marseillevirus particles (not wrapped by membranes) also seem to trigger the formation of pseudopods.[17]

The mechanisms related to uncoating giant vesicles containing marseillevirus particles after being phagocytized by amoebas are unknown. However, based on transmission electron microscopy and biological assays, purified giant vesicles are indeed infectious.[17] Single (isolated) particles can be found inside amoebal endosomes 10 minutes after inoculation.[50] Twenty minutes postinfection, a progressive alteration in particle appearance is observed, including degradation of the protein shell. The virion core is then transferred to the cytoplasm through an opening in the endosome membrane after interaction with the inner membrane of the virus particle (Fig. 17.6).[50]

Immunofluorescence and protein-labeled assays revealed that marseillevirus induces the migration of nucleolar and nuclear proteins to the cytoplasm at very early times of infection (30-60 minutes).[50] Because proteomic analysis of marseillevirus particles demonstrated the lack of transcriptional machinery elements in the virion, it was hypothesized that such nuclear elements are recruited to the cytoplasm to promote the expression of marseillevirus immediately early genes. Interestingly, between 2 and 4 hpi, nuclear and nucleolar proteins return to the nucleus (Fig. 17.6).[50]

The electron-lucent viral factory occupies one-third to one-half of the amoebal cytoplasm. The morphogenesis of particles usually starts in the central region of the virus factory, from crescentlike 50-nm structures.[17,34] Dense fibrillar elements are incorporated by forming particles, suggesting that capsid shell synthesis and core element (genome/proteins) incorporation occur simultaneously. However, this point of the cycle requires further investigation. From 5 hpi, the viral progeny can be detected inside infected cells.[34]

After morphogenesis, mature particles migrate to the periphery of the viral factory. Adjacent to this region, a membrane-rich area is observed, where a large portion of the particles are wrapped, forming the aforementioned giant vesicles.[17] When those vesicles present only one membrane layer, they migrate to the cell periphery and fuse with the plasma membrane, releasing free particles to the outside environment. When they present two or more membranes, they fuse the outer one with the cell plasma membrane, releasing to the outside environment giant vesicles containing from a few to thousands of marseillevirus particles. Treating cells with brefeldin A affects both particle and giant vesicle

formation, indicating that membrane traffic is important to the marseillevirus replication cycle. Although the endoplasmic reticulum protein GRP78 has been found in purified vesicles, additional studies are necessary to reveal the origin of membranes present in those giant vesicles. After cell lysis (starting at 6 hpi), particles and giant vesicles are released (Fig. 17.6).[17]

Pandoraviruses

The first pandoraviruses described in 2013 were isolated from the Tunquen River at the central coast of Chile (*Pandoravirus dulcis*) and from a freshwater pond near Melbourne, Australia (*Pandoravirus salinus*).[119] Interestingly, in 2008, biological entities with morphological properties similar to pandoraviruses had been described, but they were defined as amoebal endocytobionts.[142] Inside their oval virions measuring 1 μm in length, pandoraviruses package linear dsDNA genomes that reach up to 2.77 Mb and represent the largest virus genomes described so far (*P salinus*) (Fig. 17.1).[119] In subsequent years, many pandoraviruses have been described, isolated from different substrates and continents, including *P massiliensis*, *P braziliensis*, *P kadiweu*, *P neocaledonia*, *P japonicus*, and others.[7,71,85,88,118] Comprehensive genomic, transcriptome, and proteomic studies have substantially accelerated the understanding of the biology of this fascinating group of viruses.

Virion Structure

Pandoravirus particles are oval and measure about 1 μm in length and 0.5 μm in width, with a predicted volume of 7.5×10^7 nm^3 [119] (Figs. 17.1 and 17.7). The particle has a 70-nm-thick tegument, composed of three layers (20, 25, and 25 nm, from inside to outside), with the middle layer being the most electron dense. There is an internal lipid membrane juxtaposed to the tegument, which in turn surrounds an electron-lucent region containing the genome and proteins. A spherical structure, about 50 nm, has been described at varying positions in the particle's core. At one end of the particle, the tegument opens into an ostiole (~90 nm in diameter). The genome is released from this ostiole in the uncoating phase.

Diversity and evolution of the emerging Pandoraviridae family. *Nat Commun*. 2018;9(1):2285. http://creativecommons.org/licenses/by/4.0/.)

P massiliensis particles may have a membrane potential (proton gradient).[8] This result has been observed for purified virions and particles in the context of the replication cycle. About 20% of the observed particles were concomitantly labeled by anti-pandoravirus antibodies (FITC conjugated) and by MitoTracker. In addition, purified particles were also stained with tetramethylrhodamine methyl ester, a molecule acknowledged as a marker to assess mitochondrial membrane potential, further supporting the membrane potential of these particles. Treatment of *P massiliensis* virions with the depolarizing agent carbonyl cyanide chlorophenylhydrazone abolished the potential membrane of

the particles. The role of this possible proton gradient in energy generation during the pandoravirus cycle remains to be investigated.[8]

The treatment of *P massiliensis* with calcofluor indicated that cellulose might be present in the viral tegument wall. Incubation of the particles with cellulase caused degradation of the tegument. However, *P massiliensis* lacks genes clearly associated with cellulose synthesis. It has been hypothesized that the cellulose present in the viral tegument is synthesized by the amoebal machinery, because the amoebal cellulose synthetase gene appears to be expressed during the phase of viral morphogenesis.[35]

An in-depth study of virus particle proteomics, using high-sensitivity methods, revealed wide variation in the number of proteins detected in different pandoravirus isolates: 424 for *P salinus*, 357 for *P quercus*, 387 for *P dulcis*, and 337 for *P neocaledonia*. However, it was assumed that most of the detected proteins could be contamination from host proteins, randomly incorporated or externally associated with the particles.[88] A more stringent analysis revealed that a total of 102 protein clusters are shared by all four pandoravirus strain particles analyzed (core proteome). Interestingly, the genes encoding the core proteome present the strongest purifying selection among all pandoravirus genes.[88] Only 19 out of 102 clusters of the core proteome could be associated with identifiable functional and structural motifs. Four of these 19 proteins exhibit generic motifs, including two with a collagenlike domain, one with a Pan-APPLE–like domain, and 1 with a terminlike domain.[88]

Some proteins involved in redox processes were detected in particle proteomics, including an ER-like thiol oxidoreductase, a protein with slight similarity to a thioredoxin reductase, a putative NAD-dependent amine oxidase, and a FAD-coupled dehydrogenase. Ser/Thr kinase and phosphatase, a DNA-binding protein (probably related to genome packing) and endoribonuclease domain proteins were also detected. An MCP-like protein was detected not in pandoravirus particles, nor were other nucleocytoviricota hallmark proteins, such as DNA-packing ATPase and DNA-binding core protein.[88] Multiple sequence alignments and remote homology searches indicated that the second most abundant protein present in the pandoravirus proteome evolved from an inactivated derivative of a bacterial glycoside hydrolase of family 16 (GH16).[79] RNA polymerase was not found in the particle proteomes, suggesting that the early stages of the pandoravirus cycle require the host's transcription machinery located in the nucleus.[88] Similar results were described for the *P massiliensis* particle proteome, although 162 proteins were found in the virion, including 99 hypothetical proteins.[8] Therefore, pandoravirus particles are mainly made up of proteins with no known homologues.

Genome Structure and Organization

Pandoravirus genomes are linear dsDNA molecules with a GC content of about 61%. A wide variation in the size of the genomes of different viral isolates has been observed, ranging from 1.6 Mb in *P massiliensis* to 2.5 Mb in *P salinus*.[7,88] There is evidence that the *P salinus* genome can reach up to 2.77 Mb due to variations in terminal tandem repeats.[119] Therefore, pandoravirus genomes are the largest described in the known virosphere (Fig. 17.1). Initial predictions of the number of genes present in the genomes of *P dulcis* and *P salinus* revealed 1502 and 2556 putative CDS, respectively, corresponding to about 90% of ORFans.[119] However, a combined genomic and RNA-seq analysis of a set of pandoravirus isolates revealed that these initial numbers of CDS had been overestimated, especially with regard to ORFs < 300 nucleotides. In light of this analysis, a total of 1430 ORFs were predicted for *P salinus*.[88] This impressive reduction in the number of predicted ORFs seems to be the result of the combination of a high GC content and a large number of ORFans. Hence, a combined genomic and RNA-seq approach is necessary to obtain greater accuracy in predicting bona fine ORFs. Even with these more stringent parameters, up to 73% of pandoravirus ORFs are ORFans.[88]

In addition to conventional transcripts, a number of long noncoding transcripts (lncRNAs) were detected: up to 268 in *P dulcis*. These lncRNAs have a poly(A) tail, and 4% of them have spliceosomal introns and probably regulate pandoravirus gene expression. Overall, up to 87% of the pandoravirus genome appears to be transcribed, but only 68% appears to be translated into proteins.[88]

As observed for most nucleocytovirus families, the analysis of the genomes of several pandoravirus isolates has revealed an open pangenome; therefore, the discovery of new isolates continues to increase knowledge of new groups of orthologous genes.[8,88] Analysis of the organization of pandoravirus genomes has shown a collinearity of homologous blocks of about 80%. Interestingly, one-half of the genome is more conserved, carrying a good part of the genes of the core genome, thus suggesting that they are essential genes. The other half of the genome is highly variable, with more insertions and inversions of syntenic blocks.[88] Researchers have observed abundant tandem gene duplication.[88] In addition, based on G + C content, ORF length, and CAI analyses of clade-specific or core genes, it has been proposed the eukaryoticlike *de novo* gene creation hypothesis for pandoraviruses genomes.[88]

A large proportion of the few ORFs with detectable homologs in databases putatively encode proteins containing motifs and domains like ankyrin, MORN, and F-box; this limited homology does not allow reliable speculations about their biological functions. However, the identification of 14 genes commonly shared by other large and giant DNA viruses reinforces the classification of pandoraviruses among members of the phylum *Nucleocytoviricota* (Fig. 17.1). Among the identified genes, a DNA polymerase, a virion-packing adenosine-triphosphatase, an mRNA-capping enzyme, and subunits of the DNA-dependent RNA polymerase are noteworthy.[7,71,88,119] A substantial number of genes involved in DNA processing and transcription have also been identified in the pandoravirus genome, in addition to several components of the ubiquitin-dependent protein degradation pathway. Translation-associated factors have also been found, although in a smaller number than those observed for *Mimiviridae*: two aaRS (Tyr and Trp), three tRNAs, and one translation initiation factor (eIF4E). Genes encoding DNA ligases, topoisomerases, and a DJR-like major capsid protein have not been identified in pandoravirus genomes.[119]

Stages of Replication

Several studies have described *A castellanii* as a known host of pandoraviruses.[7,71,118,119] Transmission and scanning electron microscopy have shown that pandoravirus particles can induce pseudopod formation in host cells.[118] The particles are internalized, one by one, probably by phagocytosis (Fig. 17.7). Several particles can be internalized by a single cell. Such particle-containing phagosomes appear to fuse with lysosomelike structures, and it is speculated that acidification of the phagosome results in uncoating.[118] During this process, in the ostiole region, the inner membrane of the particle fuses with the membrane of the phagosome, releasing the genome and viral proteins into the cytoplasm.[118,119] Between 2 and 4 hpi, the cell nucleus begins to show morphological changes by losing its rounded shape. The nucleolus gradually becomes electron-lucent in electron microscopy images, until it is no longer visible.[118,119] Although such modifications have been observed for most pandoraviruses, some isolates show temporal differences in relation to the induction of the described sequence of events.[119]

The pandoravirus factory is visualized by electron microscopy as a large >2-μm electron-lucent structure (Fig. 17.7). This factory can occupy about one-third of the host cell. Recruitment of mitochondria and membranous structures into the viral factory is observed from the beginning of factory formation until the morphogenesis of the first particles.[118,119] Due to the absence of the transcription machinery in pandoravirus virions, it is very likely that elements of the cell nucleus participate in the transcription of viral immediately early genes. However, studies are still needed to confirm whether these elements are recruited to the cytoplasm, as described for the marseilleviruses.[50,88]

The morphogenesis of pandoravirus particles seems to start with the formation of semicircular electron-dense structures, measuring about 190 nm, in the center of the viral factory. Such structures become thicker and electron-dense with the incorporation of more structural layers, assuming a crescentlike appearance. The tegument development and the filling of the particle with genomic material, replicated in the cytoplasm, occur concomitantly, mainly starting from the ostiole region. The formation of the first mature particles occurs, on average, from 6 hpi onward.[118,119] Cytopathic effects such as rounding, circular movements, and formation of intercellular bridges have been described for cells infected with pandoravirus.[62]

As mature particles are formed, long membranous structures become evident in the viral factory. Such membranes wrap particles on the periphery of the factory, forming vesicles of varying sizes, containing from one to nearly a dozen particles. The vesicles can be seen from 6 to 8 hpi, depending on the pandoravirus isolate, and probably correspond to exosomes. From this moment on, it is possible to observe many of these structures in the periphery of host cells, and an increasing accumulation of virus particles in the extracellular environment, without cell lysis occurring so far (Fig. 17.7). This observation suggests that the release of particles occurs by exocytosis.[118,119] The treatment of infected amoebas with brefeldin A negatively impacts the transport of virus particles to the extracellular environment.[118] In the later stages of the replication cycle, virus particles are visualized in different regions of the cell, and the nucleus is completely degraded, as observed for most known pandoravirus isolates. Cell lysis eventually takes place, releasing the rest of the virus particles.[118,119]

"Extended *Asfarviridae*": Faustovirus, Kaumoebavirus, and Pacmanvirus

Virus isolation studies using *V vermiformis* as a host resulted in the discovery of faustovirus in 2016 and of kaumoebavirus in 2018.[21,126] This new group of viruses, also known as "extended *Asfarviridae*" phylogenetically clusters with the animal-infecting African swine fever virus (family *Asfarviridae*), and also comprises pacmanvirus, isolated from *A castellanii*.[14] The members of "extended *Asfarviridae*" of protists are dsDNA, linear or circular, ranging from ~350 kb (kaumoebavirus) to ~490 kb (faustovirus), with genomes substantially larger than those found in some strains of African swine fever viruses (~170 kb) (Fig. 17.1). Although the studies on "extended *Asfarviridae*" are still in the initial phase, recent information has revealed that some members possess unique structural and genomic characteristics.

Virion Structure

Among the "extended *Asfarviridae*," the faustovirus virions have been studied the most, by using MCP crystallization methods and cryo-EM. Faustovirus particles have an outer and an inner protein capsid shell, which is rare among large icosahedral dsDNA viruses.[76] The faustovirus MCP (645 amino acids) forms a homotrimer with each monomer consisting of two sequential jelly-rolls. MCP capsomers in the particle are arranged in an icosahedral fashion with a triangulation number of 277 (h = 7; k = 12). The inner shell has T = 16 (h = 4; k = 0) quasi-icosahedral symmetry and varies in diameter from 160 nm (without DNA) to 190 nm (filled with DNA). The whole particle, including the inner and outer shells, can reach up to 260 nm in diameter (Fig. 17.8). Cement proteins are observed under the capsid protein and presumably serve to maintain the stability of the outer shell.[76] Fifty angstroms-long, thick fibers decorate the particle surface, especially at the fivefold vertices. Although small amounts of lipids have been detected in faustovirus particles, it was hypothesized that the inner membrane has been replaced by the inner protein shell. Further analysis could confirm whether such detected residual lipids represent sample contamination. Faustovirus particle proteomics revealed 162 proteins, 76 of which had homologs in GenBank including MCP and A32-like packing ATPase.[76,126]

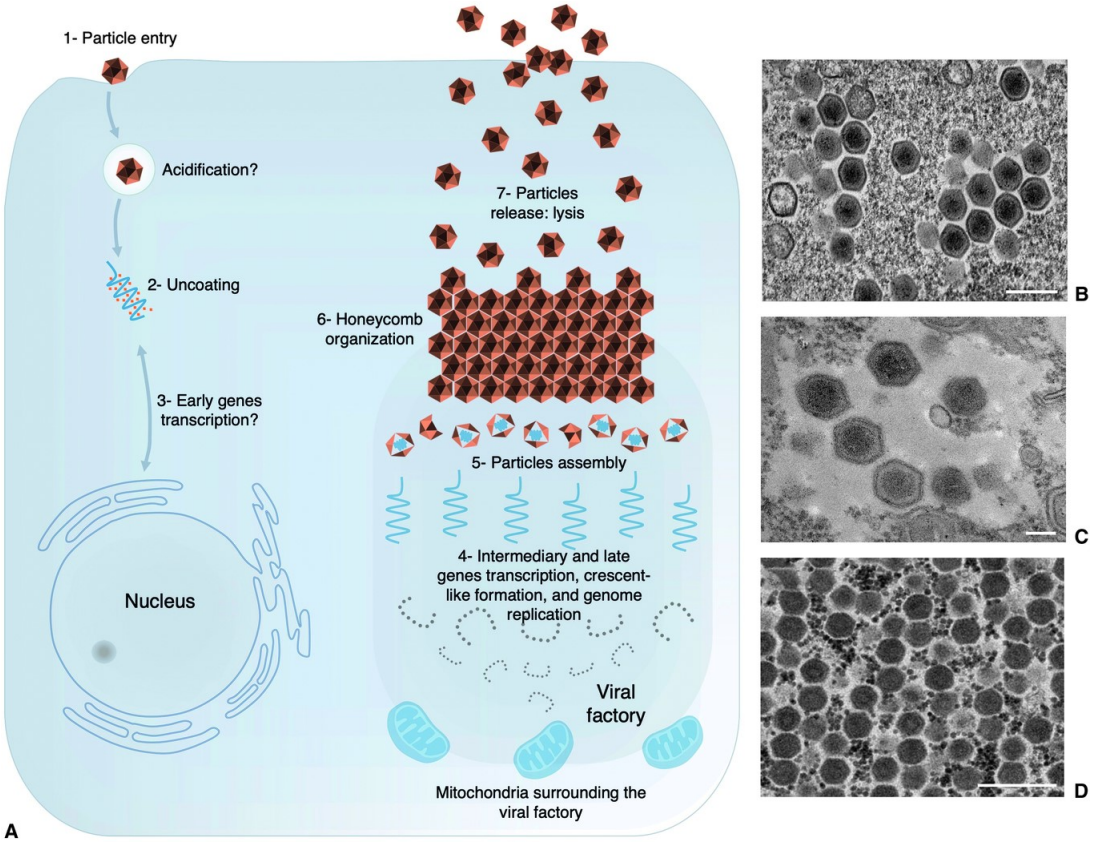

FIGURE 17.8 **Replication cycle and structural features of viruses of the extended *Asfarviridae***. **A**. Schematic overview of the faustovirus replication cycle. 1-3—Particles enter the amoeba by unknown mechanisms. The virus genome and proteins are released into the host cytoplasm, and it is believed that transcription of early genes is promoted by nuclear machinery. 4 and 5—Intermediate and late genes are expressed, and a large viral factory is formed in the cytoplasm. The virus genome is replicated, and particle morphogenesis starts from crescentlike structures. The genome is incorporated into particles. 6 and 7—Newly formed particles are organized in a honeycomb fashion and eventually are released after cell lysis. **B**. (Courtesy of Julien Andréani and Bernard La Scola, Aix-Marseille Université, France.)

For pacmanvirus, cryo-EM analyses showed icosahedral particles with a spiky outer surface and an inner membrane. Unlike faustovirus, no inner protein shell was observed.[14] Pacmanvirus particles are about 250 nm, with a triangulation number of 309 (h = 7; k = 13). Its MCP has a typical double jelly-roll fold. The protein PACV_341 was identified at the icosahedral fivefold axis as the putative minor capsid protein.[14] For kaumoebavirus, future structural and proteomics studies of its 250-nm-wide virions may elucidate whether this virus share characteristics with other members of the group.

Genome Structure and Organization

More than a dozen faustovirus strains have been isolated from samples collected in France, Senegal, Lebanon, and Brazil.[25,31,126] Sequencing the genomes of some of these strains has enabled comparative analyses on their evolution, gene conservation, synteny, and specific features. On average, the faustovirus genomes are ~470 kb long, with a G/C content of about 37%. At least four faustovirus lineages have been identified based on core-gene analysis.[25] Regarding faustovirus E12, the first to be described, a total of 457 genes were predicted, including more than 300 ORFans. Paralogs represent about one-fifth of the genes.[126] A number of genes shared by other protist-infecting viruses have been predicted in faustovirus, kaumoebavirus, and/or pacmanvirus, including some related to DNA replication, recombination, and repair; transcription; and RNA processing.[14,21,25,126] However, translation-related elements are rare in this group (a single tRNA, for Ile, was predicted in pacmanvirus).[14] The motifs TATTT and TATA are abundant in intergenic regions of faustoviruses and kaumoebavirus—as has been described for asfarvirus—suggesting that those motifs may act as gene promoters.[114]

It is noteworthy that the MCP-encoding gene has an atypical arrangement in faustovirus genomes, stretching over 17 000 bp with up to 18 introns (including group I and spliceosomelike introns). Splicing results in a 1939 bp transcript that encodes a 645 amino acid protein.[25,37,126] Similarly, the kaumoebavirus MCP gene spans a 5000 bp region (nucleotides 180 327-185 966), including at least three distinct exons.[22,66] Although faustovirus genomes exhibit a highly conserved synteny, their terminal regions and the central region containing the MCP gene have evolved at faster rates compared with other genomic regions, containing more indels and rearrangements.[67] On the other hand, the ~395 kb pacmanvirus encodes a single MCP ORF—as has been described for asfarvirus—indicating that the colonization of faustovirus and kaumoebavirus MCP genes by introns occurred after diversification of this group.[14] Pacmanvirus has three copies of genes encoding proteins containing PAN/apple domains and a tRNA His guanylyltransferase, which is not found in asfarvirus, kaumoebavirus, and faustovirus.[14]

Stages of Replication

Vermamoeba vermiformis is the only known host for faustovirus and kaumoebavirus.[21,126] In contrast, pacmanvirus infects *A castellanii*.[14] Faustovirus and kaumoebavirus cause trophozoite lysis around 18-20 hpi.[21,126] On the other hand, the pacmanvirus cycle is remarkably rapid, causing cell lysis starting at 6 hpi.[14] A common feature among faustovirus, kaumoebavirus, and pacmanvirus is that internalization of the particles takes place between 30 minutes and 3 hours, individually or in particulate clumps, by a still unidentified endocytic or phagocytic routes hpi.[14,21,126] In early stages, transmission electron microscopy revealed particles in regions adjacent to mitochondria (pacmanvirus) or even within the cell nucleus (faustovirus).[14,31] However, most virions are observed in free endosomes/phagosomes in the cytoplasm in the early stages of the cycle, indicating that virion uncoating occurs at this site. In the early stages of faustovirus infection, the cell nucleus undergoes morphological modifications, becoming more elongated and with the nucleolus in a more peripheral position.[31,126] From 3 to 6 hpi, signal transduction regulation transcripts are highly expressed by faustovirus, indicating a possible modulation of cell pathways that precedes viral factory formation.[37]

The viral factories of faustovirus are electron-lucent structures of more than 3.5 μm in diameter. A large number of mitochondria migrate to the periphery of faustovirus factories, suggesting virus-induced energy optimization during viral morphogenesis (Fig. 17.8).[31,126] From 6 hpi onward, expression of transcripts related to structural proteins increases.[37] The morphogenesis of faustovirus starts from 50 nm crescentlike structures, which gain in complexity until they form empty immature particles with a small opening. The particle is then filled by the virus genome and proteins. Then, particle closure occurs, presenting an electron-dense core.[31] As the mature virions are formed, they are organized in a honeycomblike fashion as geometrically arranged clusters (Fig. 17.8).[14,31,126]

Virus particle release occurs individually after plasma membrane rupture, or in large clusters of particles,[14,31,126] or alternatively for kaumoebavirus, release by exocytosis has been suggested.[21]

It is noteworthy that a unique antiviral mechanism has been described in *V vermiformis* upon faustovirus infection. Once infected by this virus, some *V vermiformis* trophozoites release a soluble factor, possibly containing Mg^{2+}. This soluble factor induces neighboring cells to turn into cysts. If these cells are infected, the virus cycle is aborted and virus particles are stably imprisoned in nonviable cysts, reducing the amount of viral progeny in the supernatant and impacting the overall infection rate of the amoeba's population. Noninfected cells also encyst upon contact with this soluble factor, and eventually excyst and survive.[31] This mechanism illustrates how the discovery and study of new giant viruses can reveal novel biological processes.

Pithovirus, Cedratvirus, and Orpheovirus

The search for new giant amoeba viruses has inspired research into diverse geographical locations. Pithovirus sibericum was described in 2014, isolated from samples collected from Siberian permafrost in Russia (Kolyma lowland region).[87] Radiocarbon dating indicated that this substrate corresponded to the late Pleistocene, ~30 000 years old. This virus was isolated after inoculation of the aforementioned substrate in cultures of *A castellanii*, causing cytopathic effects similar to those observed for other giant viruses. Pithovirus sibericum particles resemble pandoraviruses in their oval appearance; however, further analysis showed that pithovirus virions are ~1.5 μm long, being, on average, the largest virus particles described so far, although their genome is only 600 kb (Fig. 17.1).[87,119] In subsequent years, other pithoviruslike viruses have been discovered, including a new group called cedratvirus,[12] also isolated in *A castellanii*, as well as orpheoviruses, capable of infecting *V vermiformis*.[13]

Virion Structure

Pithovirus particles are oval and have a mean length of 1.530 ± 230 nm and a mean diameter of 810 ± 60 nm (Fig. 17.9)[87,112]; however, some can reach up to 2.5 μm in length and 0.9 μm in diameter.[112] Cryo-EM analyses also revealed that the particles have a wall ~60 nm wide formed by a structure called the tegument, which is organized in parallel bands. The tegument contains a poorly characterized structure called the low-density out-layer, and it was speculated that such a layer is composed of materials such as polysaccharides.[87,112] Below the tegument is an inner membrane surrounding the so-called nucleoid, a region of the virion that houses the genome and other elements (early-stage proteins). At one end of the virion is an apical pore sealed by a cork, 80 nm thick and 160 nm wide.[87,112] The cork appears to be composed of 15-nm-wide parallel stripes that resemble a honeycomb when viewed from above. Energy-filtered cryo-EM at 200 kV revealed an additional horizontal Moiré pattern on the stripes in the side view.[112] Although most pithovirus virions contain only one cork, particles containing two corks, nonaligned at both ends of the particle, similar to cedratviruses, have also been observed less frequently.[112] The mean volume of pithovirus particles is 26.2 ± 5.1 × 10^7 nm^3. The density of the nucleoid region of pithovirus sibericum particles is 0.77 times less than that observed in mimiviruses.[112]

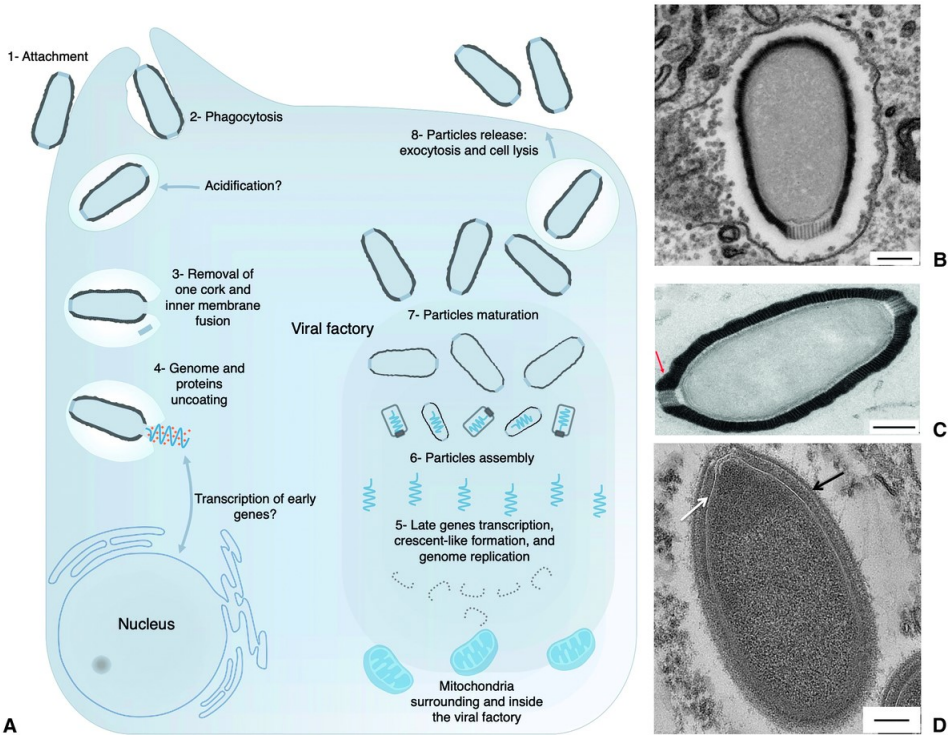

FIGURE 17.9 **Replication cycle and structural features of pithoviruses**. **A**. Schematic overview of the cedratvirus replication cycle. 1 and 2—Cedratvirus particle attachment to the cell membrane induces pseudopod formation and phagocytosis. 3—It is not known whether phagosome acidification is required for the removal of one cork and viral inner membrane fusion with the phagosome. 4—The virus genome and proteins are released into the host cytoplasm. 5 and 6—In the viral factory, genome replication, transcription of late genes, and particle morphogenesis occur. The assembly of particles is complex and sequential, involving intermediates with diverse shapes. 7 and 8—The particles undergo maturation, including tegument thickening. Then, particles are released by exocytosis and cell lysis. **B**. Transmission electron microscopy of a pithovirus (*P sibericum*) particle. Scale bar: 200 nm. Proteomic analysis of pithovirus particles identified 159 different gene products, two-thirds of which correspond to proteins with unknown functions.[87] Pithovirus particles have all the transcription machinery proteins encoded by their genome. Proteins such as an adenylosuccinate synthetase (pv90), an ADP-ribosyl glycohydrolase, protein kinases (pv156, pv405, and pv438), hydrolases (pv212 and pv289), oxidoreductases (pv342 and pv467), and a dehydratase (apv385) were also found. No proteins with clear homology to MCP or major core protein were detected and, therefore, the elements that compose the tegument remain to be investigated. The four most abundant proteins detected by proteomics do not correspond to proteins with known homologs (pv449, pv461, pv93, and pv106). Finally, 37 proteins from *A castellanii* were detected in low abundance in pithovirus particles.[87]

Characterization of the first cedratviruses in 2016 revealed 1.2-µm-long virions with a shape very similar to those of pithoviruses, including regions such as the tegument, gap, inner membrane, and nucleoid region.[12] However, the most striking feature of cedratviruses is the presence of two cork-covered ostioles in most particles (Fig. 17.9). Different cedratvirus isolates show variations in their particle sizes, as highlighted for the Brazilian cedratvirus strain, whose particles have an average size of 910 nm in length and 510 nm in width.[128]

Orpheoviruses—despite being phylogenetically related to pithoviruses and cedratviruses—present particles with substantial structural differences in relation to the rest of the known pithoviruslike viruses.[13,155] Orpheovirus particles are oval, with average dimensions of up to 1300 nm along its longer axis (Fig. 17.9). Externally, 30-nm-long fibril-like structures cover a tegument formed by two layers each about 5-10 nm wide. Unlike pithovirus and cedratvirus teguments, the orpheovirus tegument appears electron-lucent when viewed with transmission electron microscopy.[13,155] A membrane inside the two tegument layers encloses the genome and proteins (nucleoid).[13,155] A lateral flattening of the mature particles has been described.[155] Corks covering the ostiole have not been observed in orpheoviruses, and the elements that protect this opening have not yet been characterized.[13,155] Future proteomic studies for cedratviruses and orpheoviruses may reveal shared similarities among members of the pithoviruslike group.

Genome Structure and Organization

Despite having gigantic virus particles (on average, 1.5 µm long), the genome of pithovirus sibericum is a 610 033 bp dsDNA molecule, considerably smaller than that observed for other giant viruses, such as mimiviruses and pandoraviruses (Fig. 17.1).[87,119,124] The genome is either circular or a terminally redundant circularly permutated linear DNA molecule, with a high repeat content, and is predicted to encode 467 proteins. At the time of its genome description, 32.5% (152/467) of the proteins had recognizable homologs. Of these proteins with recognizable

homology, the best matches are distributed similarly between eukaryotes, bacteria, and viruses.[87] The low percentage of similarity between pithovirus genes and their best matches suggests that Pithovirus sibericum is the first representative of a new virus family. Of the 152 proteins predicted with homologs in databases, only 125 have functional attributes, including genes related to DNA transcription, DNA repair, nucleotide synthesis, DNA replication, carbohydrate processing, RNA processing, hydrolases, and oxidoreductases.[87]

Unlike other giant amoeba viruses such as mimiviruses, no component of the protein translation machinery has been found in the genome of pithovirus.[87] The gene encoding the DNA-dependent RNA polymerase large subunit has a group I self-splicing intron. Interestingly, a low similarity (21% of identical residues, e-value = 0.002) was observed between the predicted protein product for the pv460 gene and the divergent MCP of iridoviruses (megalocytiviruses). Bioinformatic analyses suggested that pv460 assumes the jelly-roll type structure, common among viruses belonging to the phylum *Bamfordvirae* (Fig. 17.2). However, pv460 was not detected in virus particle proteomics.[87] Although the 589 068 bp genome of cedratvirus A11 presents great similarity with the main aspects described for the pithovirus, 30.8% of its predicted proteins (177/574) did not present matches with the databases, therefore being considered ORFans.[12]

With a dsDNA genome of 1 473 573 bp, orpheovirus IHUMI-LLC2 has the largest genome described so far among the pithoviruslike viruses (Fig. 17.1).[13] A total of 1199 genes were predicted, with 690 (~57.5%) being considered ORFans. The best hit profile observed for orpheovirus predicted genes follows a similar distribution described for other pithoviruslike viruses, matching with eukaryotes, prokaryotes, and viruses. However, similarly to mimiviruses, orpheovirus has an extensive arsenal of genes associated with protein translation, including eight aaRS and four translation factors (three initiation factors and one release factor).[3,15,22]

Stages of Replication

Current data indicate that pithoviruses and cedratviruses replicate in *A castellanii*, whereas orpheoviruses are capable of infecting *V vermiformis*.[12,13,87,153,155] The pre-entry stages are still poorly characterized, but it was demonstrated that virus particles for the isolate Cedratvirus getuliensis are able to adhere to the surface of *A castellanii* cells, suggesting the involvement of possible adhesion factors (Fig. 17.9).[153] Because the virions of pithovirus, orpheovirus, and cedratvirus are >500 nm, it is assumed that they are able to trigger phagocytosis in amoebas.[175] In fact, considering all these viruses, there is an abundance of evidence to support this hypothesis. The induction of pseudopod formation has been described after inoculation of *V vermiformis* with orpheovirus.[155] Assays using inhibitors of endocytic and phagocytic pathways have shown that the treatment of amoebas with cytochalasin affects the uptake of cedratvirus particles, while treatment with EIPA or chloroquine does not have such a reducing effect, reinforcing that phagocytosis might be important to orpheovirus entry.[153] After phagocytosis, pithoviruslike virions undergo structural changes that induce the exposure of the internal membrane of the particles. In the case of pithoviruses, the cork is detached from the virion, and then the inner membrane fuses with the membrane of the phagosome, forming a channel that projects the internal content of the particle into the cytoplasm of the host amoeba.[87] The cedratviruses, as mentioned previously, have two corks, but electron microscopy analysis indicates that only one of the corks is removed preceding the genome uncoating (Fig. 17.9).[12,153] In the case of the cork-less virions of orpheovirus, the inner membrane is projected from the ostiole localized at the apex of the particle, also fusing with the phagosome membrane, and then releasing the genome and proteins into the host cytoplasm.[13,155]

The formation of the pithovirus, cedratvirus, and orpheovirus factories occurs in a region close to the cell nucleus, which in turn, remains morphologically intact throughout the replication cycle (Fig. 17.9).[12,13,87,155] The recruitment of mitochondria to the periphery of the viral factory has been described for cedratvirus and orpheovirus, indicating a possible energy optimization related to the formation of new particles.[153,155] The pithovirus, cedratvirus, and orpheovirus factories occupy a large portion of the amoeba's cytoplasm, comparable to the volume occupied by the cell nucleus. These factories show an electron-lucent appearance on electron microscopy, very different from the electron-dense factories of mimiviruses.[11–13,87,155,162]

The morphogenesis of pithovirus, cedratvirus, and orpheovirus virions involves a complex and sequential organization of immature viral structures, starting at the center and moving to the periphery of the viral factories. This process has been characterized extensively for infection with viruses corresponding to the isolate Cedratvirus getuliensis (Fig. 17.9), but it appears to be very similar to pithoviruses.[87,153] The first discernible structures during particle assembly are the crescent-shaped precursors (~100 nm), very similar to the crescents described for other nucleocytoviruses.[127,153] These crescents appear to grow lengthwise, reaching about 600 nm, assuming a staplelike shape. The cross section of these structures reveals a horseshoe-like shape, and at this stage, only one cork is visible (cedratvirus) in the longitudinal section, probably at the pole where the morphogenesis starts.[153] The immature particles appear as open cylinders: in the longitudinal section, they appear as rectangles, and in the cross section, they appear as circles. Then, a progressive filling of the capsid is observed, followed by its closure and then the addition of the second cork (in the case of cedratviruses).[153] After closing the structure, the particle undergoes differentiation processes in a region very close to the periphery of the viral factory, resulting in thickening of the tegument.[87,153] At this stage, the tegument does not have the same thickness as the cork, but during maturation, the tegument thickens, giving rise to mature particles (Fig. 17.9). Between 6 and 12 hpi, immature and already formed particles coexist in abundance in the amoebal cytoplasm.[153]

The morphogenesis of the orpheoviruses has many similarities to that described for the other pithoviruslike viruses. Electron-dense semicircular crescents develop, extend, and then are filled with material present in the factory, including the genome and proteins needed for early phase.[13,155] At this stage, lamellar structures are recruited that possibly associate externally with the tegument of the particles in formation. Finally, the particles are closed and assume their beanlike appearance, with a lateral flattening.[13,155] Amoebas infected by orpheovirus present increased motility, mainly at 12 hpi. The detection of infectious orpheovirus particles occurs from 12 hpi and reaches a plateau after 48 hpi.[155]

Concomitantly with the formation of mature particles, there is intense trafficking of intracellular membranes, resulting in packing one or more particles in exosomes. These filled vesicles migrate to the periphery of the amoebas, releasing the virions to the outside environment. This phenomenon has been described for pithovirus, cedratvirus, and orpheovirus (Fig. 17.9).[12,13,87,153,155] The exocytosis of pithoviruslike virus particles has also been demonstrated by quantifying the accumulation of virus particles in the supernatant of infected cell cultures, a phenomenon that precedes cell lysis. Immunofluorescence microscopy analysis suggests the polarization of exosomes containing orpheovirus particles at one end of elongated amoebas.[155] Treatment of infected cells with brefeldin A negatively affects the formation of such particle-containing exosomes. Some particles are also released after cell lysis, which occurs from 24 hpi and continues up to 48 hpi.[155]

Mollivirus

Following the search for new giant amoeba viruses, a new type of giant virus was isolated from the same permafrost sample from which the first pithovirus strain (Pithovirus sibericum) had been obtained.[87,89] The so-called mollivirus (Putative species Mollivirus sibericum) has almost spherical 600-nm virions and a linear dsDNA 650 kb genome (Figs. 17.1 and 17.10). Metagenomic analysis of the mentioned permafrost sample revealed the presence of reads of mollivirus, pithovirus, and *Acanthamoeba*, reinforcing that such biological entities were in fact present in this frozen soil dated at an age of 30 000 years.[89]

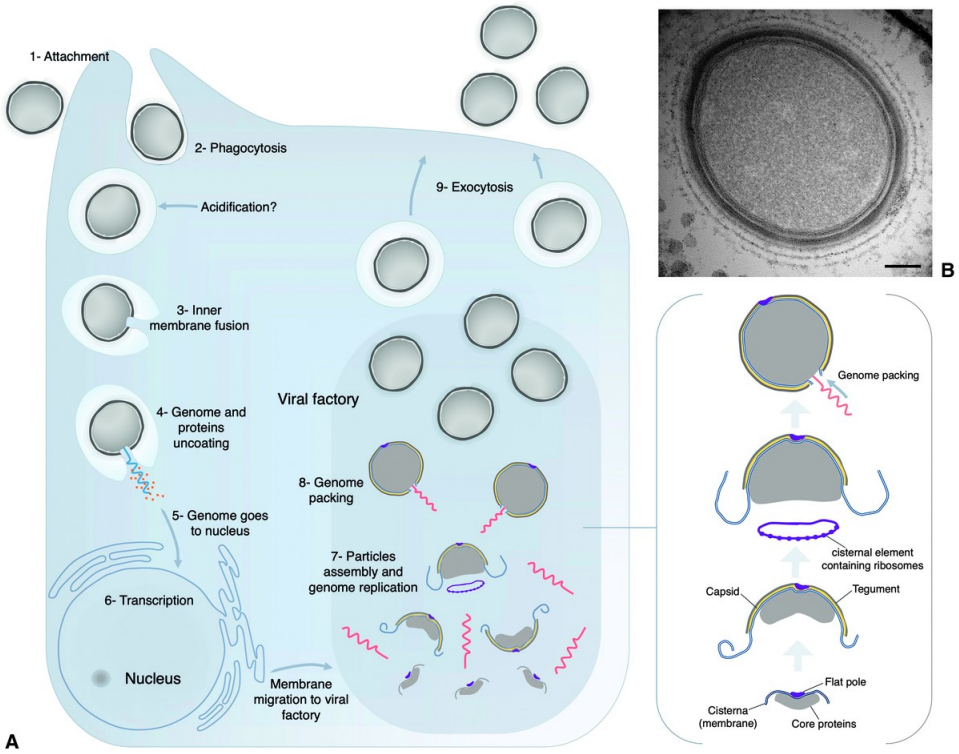

FIGURE 17.10 **Mollivirus replication cycle and structural features**. **A**. Schematic overview of the mollivirus replication cycle. 1 and 2—Mollivirus particles enter amoebas after attachment and phagocytosis. 3 and 4—The phagosome environment (likely acidified) induces mollivirus inner membrane fusion with the phagosome membrane, triggering the uncoating of virus genome and proteins into host cytoplasm. 5 and 6—The virus genome goes to the host nucleus, where its genes are transcribed. 7 and 8—Cellular membranes migrate to the newly formed viral factory and participate in particle morphogenesis. The sequential assembly and maturation of mollivirus particles are highlighted in the *bottom right panel*. Cisternalike membranes are associated with a flat pole and core proteins. Tegument and capsid layers are then incorporated into that structure, which expands with the addition of more membrane and core proteins. A cisternal element containing ribosomes contributes to the development of this structural complex. A mollivirus particle is then almost formed, keeping an open ostiole where the genome is incorporated. Finally, the ostiole is closed. **B**. Transmission electron microscopy of a mollivirus (*M sibericum*) particle. Scale bar: 100 nm. (Courtesy of Chantal Abergel, CNRS, Aix-Marseille Université, Information génomique & structurale (IGS), UMR 7256, Institut de microbiologie de la Méditerranée (IMM), France.)

Virion Structure

The ~600-nm-diameter mollivirus virions are almost spherical, surrounded by two to four ~25-nm spaced fibril rings (Fig. 17.10).[89,123] The outer fibril layers appear to be associated with the adjacent internal fibril layer. Alternatively, such a visual effect may be the result of the association of fibrils of different sizes relative to the tegument. In addition to fibril layers, the particles appear to be formed by two additional capsid layers and a tegument composed of two layers of fibrillar components, made of 30- to 40-nm interspaced parallel strips.[89,123] Inside the capsid layers, a membrane encloses the genome.[89,123] A circular fiber-free depression of about 200 nm is observed in the tegument. This region corresponds to the apex of the particle.[89]

Particle proteomics revealed 230 proteins, including 136 (59%) virus-encoded proteins and 94 (41%) corresponding to *Acanthamoeba*.[89] Among the proteins encoded by mollivirus, 74 (54.4%) are ORFans and only 35 (25.7%) of the viral proteins could be associated with functional or domain predictions. The three most abundant proteins in the particle are ORFans. A homologous protein of the MCP of other nucleocytoviruses, ML_347, was also detected in the virion, but despite its high abundance, it was not detected on the surface of the particle. In analogy to poxviruses, this protein could serve as a scaffold for the development of the tegument followed by proteolytic processing during the assembly, giving rise to nonicosahedral capsid.[89] Six of eight oxidoreductases predicted in the genome of mollivirus were detected in the virion. It has been speculated that such proteins may be important for particle resistance to the intraphagosomal environment of *Acanthamoeba*. None of the seven components of the predicted transcription machinery found in the genome of mollivirus was detected in the particle, which reinforces the dependence of the virus in relation to the *Acanthamoeba* nucleus at the beginning of the cycle (Fig. 17.10).[89]

The variety of amoebal proteins present in the virions of mollivirus is worth noting. Interestingly, several ribosomal proteins were consistently detected (S4, S7, S8, S9, S15, S23, L5, L6, L18, L30, and L35).[89] A total of five helicases, a translation initiation factor 4A, three enzymes involved in nuclear RNA processing and transportation, three histones, and HMG-like chromatin-associated proteins were also detected,

comprising a total of 13 different nuclear proteins carried in the virion. In addition, 11 proteins possibly involved in the transport of the virion to the nucleus and reorganization of the cytoskeleton were detected, including actin, propilins, and fascin.[89] Membrane prediction software analysis identified a total of 27 proteins containing at least one transmembrane domain, corresponding to about 20% of the proteome of the virions, including those involved in cell adhesion (ML_499), membrane fusion (ML_417), and lysosome-associated proteins (ML_309 and ML_331).[89,123]

Genome Structure and Organization

The genome of the Siberian mollivirus isolate consists of linear dsDNA of 651 523 bp, including long inverted repeats at each extremity (10 kb).[89] The G/C content is 60%, one of the highest among the known giant viruses (Fig. 17.1). Gene prediction was performed in association to transcriptome sequencing, revealing 523 protein-coding genes and 3 tRNAs (Leu, Met, and Tyr). Spliceosomal introns were detected in 21 (4%) genes, mostly a single intron per gene.[89]

When mollivirus was discovered, 337 (64.4%) ORFans were detected in its genome.[89] Among the proteins with identifiable homologues, 93 (17.8%) are more similar to viruses, 50 (9.6%) to *A castellanii*, 22 (4.2%) to other eukaryotes, and 18 (3.4%) to prokaryotes.[89] Eighty-three predicted proteins have pandoravirus sequences as their best match, although they are only about 40% similar, including B-type DNA polymerase, a primase, helicases, and exonucleases. It is notable that the protein ml_347 (*Mollivirus sibericum*) is distantly similar (62.6% identical) to the MCP encoded by *A castellanii*. Other proteins predicted in the mollivirus genome are DNA-processing enzymes (polymerase, nuclease, helicase, etc.), deoxycytidylate deaminase, guanylate kinase, and ribonucleotide reductase. In conclusion, genomic analysis of the molliviruses indicates a new group of giant viruses related to pandoraviruses.[39,89]

Stages of Replication

Due to the dimensions of the virus particle, entry is likely to occur by phagocytosis in individual vacuoles, with the estimate of incorporation of up to 10 particles per *A castellanii* cell.[89,123] As described for other nucleocytoviruses, the internal membrane of the virion fuses with the membrane of the phagosome, and the interior of the particle is invaded by cytoplasm content (Fig. 17.10).[89,123] As mentioned, the ML_417 protein, present in the particle, has a fusion domain and might therefore be involved with uncoating.[89] There is migration of viral DNA to the nucleus of the amoeba, a phenomenon that is compatible with the absence of detection of transcriptional machinery in the virion.[89] Remarkably, the amoebas infected by mollivirus sibericum remain adhered and with typical morphology throughout the replication cycle. Analysis of *M sibericum* transcriptome revealed that, unlike what had been described for other dsDNA viruses, there is no temporally regulated gene expression over the cycle, because most genes are constantly expressed in early, intermediate, and late phases of the cycle.[89]

Although few mollivirus isolates have been described, there have been remarkable advances in characterizing the particle morphogenesis (Fig. 17.10).[39,89,123] At 8 hpi, the cell nucleus appears absent or disorganized, reduced in size, and loses its spherical aspect. A >3-µm viral factory is observed in the cytoplasm, occupying most of the cell. Most cellular organelles are displaced toward the cell periphery, and the mitochondria appear smaller and more elongated. Particles at different assembly phases are observed concomitantly.[89,123] Mollivirus particle assembly starts by a unique membrane precursor resembling a cisterna associated with a central flat pole (Fig. 17.10).[123] The assembly starts from this pole and extends toward symmetrical, open curling ends. The layers of capsid and tegument are gradually deposited starting from the flat pole. The development of the internal membrane appears to be associated with the recruitment of vesicles, which open upon contacting the ends of the membrane. As the internal membrane develops, viral core proteins are incorporated by the particle. At this stage, there is a cisternal element containing segregated ribosomes near the developing particle. The particle then develops, acquiring a spherical symmetry, but maintains an opening in an antipodal position to the flat pole.[123] Fibrillar material, possibly the genome, is then incorporated in the particle through this opening. Finally, the particle is closed. Virus particles are released in the supernatant of infected cells from 6 hpi onward. Although lysis of the infected cells was not described, it was hypothesized that the viral progeny is released by exocytosis—on average 250 particles per cell.[89,123]

Medusavirus

The first medusavirus described was discovered from a muddy freshwater sample collected from a hot spring in Japan.[185] This virus was isolated in *A castellanii*, and even though the virus causes cell lysis, part of the trophozoites turn into cystlike cells. This encystmentlike phenomenon has inspired authors to name the virus Acanthamoeba castellanii medusavirus, after Medusa, the character in ancient Greek mythology who turns onlookers to stone.[185] Recently, a new related virus has been described, named clandestinovirus.[133] This virus was isolated on *V vermiformis* from a wastewater sample collected in France, and despite differences in relation to the gene content, it was proposed that clandestinovirus is a member of the putative family "*Medusaviridae*."[133] Medusavirus and clandestinovirus present striking similarities, including an extensive set of histones in their virions, an intense gene exchange with amoebas, and the exploitation of the host nucleus, especially during the early and intermediate phases of infection.[133,185]

Virion Structure

Single-particle cryo-EM revealed that the medusavirus virion is a T = 277 icosahedron (h = 7; k = 12) and is ~260 nm in diameter (Fig. 17.11). The capsid is 8 nm thick and associated with surface spherical-headed spikes of ~14 nm in length. Each capsomers has a protruding spike. An inner membrane (6 nm thick) is observed in association with the capsid. The membrane wraps the 381-kb genome and core proteins of medusavirus (Fig. 17.1).[185]

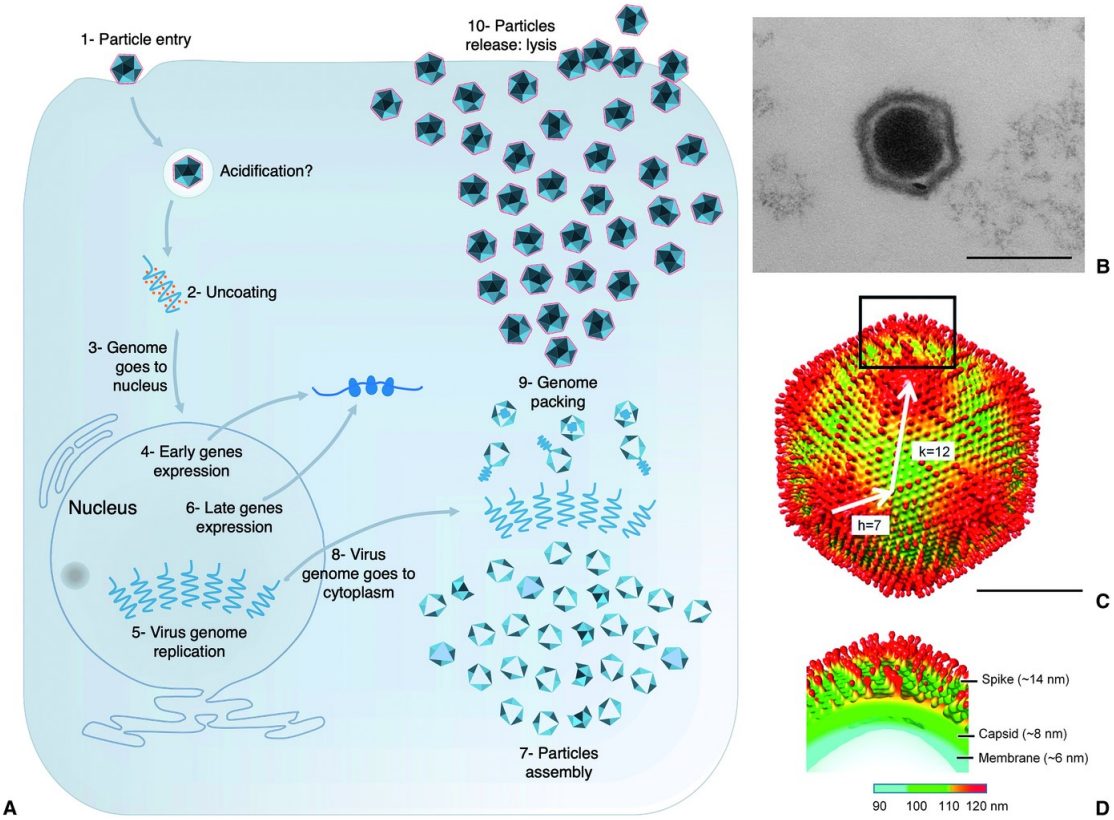

FIGURE 17.11 **Medusavirus replication cycle and structural features**. **A**. Schematic overview of the medusavirus replication cycle. 1-3—Medusavirus particles enter amoebas by an unknown mechanism. Virus genome and proteins are released into the host cytoplasm and go to the nucleus. 4-6—In the nucleus, virus early genes are transcribed by the cellular machinery, followed by genome replication and expression of late genes. 7-9—The assembly of virus particles occurs in the cytoplasm. Particles under different stages of assembly are usually observed in the cytoplasm. Concomitantly with the virus assembly, the mollivirus genome copies migrate from the nucleus to the cytoplasm and are then packed into the particles. 10—Newly formed medusavirus particles are released after cell lysis. **B**. Transmission electron microscopy of a medusavirus particle. Scale bar: 200 nm. (Courtesy of Dr. Masaharu Takemura, Tokyo University of Science, Japan.) **C**. Three-dimensional reconstruction of a medusavirus particle. The k and h values (used to calculate the T number) are indicated in the figure. The *black square* region is highlighted in panel **D**. Scale bar: 100 nm. **D**. Periphery of the medusavirus fivefold axis, highlighting the length of the spike, capsid, and membrane regions. For images in panels **C** and **D**, the *colors* indicate the distance from the center of the particle (scale at the bottom of panel **D**). (Images in panels **C** and **D** were adapted from Yoshikawa G, Blanc-Mathieu R, Song C, et al. Medusavirus, a novel large DNA virus discovered from hot spring water. *J Virol*. 2019;93(8):e02130-18. http://creativecommons.org/licenses/by/4.0/.)

The proteomic analysis of *A castellanii* medusavirus particles revealed 80 proteins, including >50 with unknown functions. Among the identified proteins, an MCP homolog is the most abundant.[185] In addition, DNA-packing ATPases, Rho transcription termination factors, and redox-active proteins were described in the particle. As a hallmark of medusaviruses, a set of viral-encoded core histones (H2A, H2B, H3, H4) are present in dissimilar abundances in the virion.[185] Transcription-related proteins were not found, explaining the medusavirus dependence on the host nucleus, especially during early phases of the cycle.

Clandestinovirus particles analyzed by transmission electron microscopy are 180-nm-wide icosahedrons. Future studies on particle proteomics and structure need to be performed to address its possible resemblance to medusavirus.[133]

Genome Structure and Organization

The *A castellanii* medusavirus genome is a linear 381 277 bp dsDNA molecule with a G/C content of 61.7% (Fig. 17.1).[185] 461 predicted protein-coding genes were identified, seven of which harbor spliceosomal introns. In addition, three tRNA-like sequences were found. The genome has a theoretical coding density of 89.5%. 279 (61%) predicted genes have no identified homologs (ORFans). Among the 182 (39%) genes with homologs, 115 presented eukaryotes as best matches, with 86 having their closest homologs in *A castellanii*. Interestingly, 57 genes were identified as candidates involved in horizontal gene transfer between medusavirus and *A castellanii*, including the MCP gene, which seems to have been transferred from the viral to amoeba genome.[185]

Identifiable motifs and functional domains were found in only 105 (23%) ORFs. Among the predicted proteins are enzymes related to DNA metabolism (including a family B DNA polymerase), transcription-related proteins, translation initial factor elF1, MCP, and A32-like DNA-packing ATPase. As mentioned, *A castellanii* medusavirus encodes homologs of all four core histones (H2A, H2B, H3, and H4) and the linker histone H1.[185] Medusavirus stheno, a strain described in 2021, has H3 and H4 fused into a single CDS.[184] Finally, the *A castellanii* medusavirus genome contains a putative cyclin B homolog, a putative metacaspase, and a homolog of the mitochondrial chaperone BCS1.[185]

The clandestinovirus genome is 581 987 bp with a G/C content of 43.5%[133] and encodes 617 predicted proteins and two tRNAs. 403 ORFs (65.3%) presented no identified homologs (ORFans). An extensive set of histones coding genes was also observed in clandestinovirus, including

H2B/H2A, H3, H4, and the linker H1/H5.[133]

Stages of Replication

As mentioned previously, medusavirus was described to replicate in *A castellanii*, while clandestinovirus was described to replicate in *V vermiformis*.[133,185] The entry pathways and genome uncoating mechanisms associated with medusavirus and clandestinovirus particles are unclear (Fig. 17.11). However, fluorescence *in situ* hybridization assays indicated that the genome of medusavirus migrates to the nucleus of the host in <1 hpi.[185] Medusavirus does not encode a DNA-dependent RNA polymerase or mRNA capping enzyme, which explains the need to access the host transcription machinery.[185] Temporal analysis of the medusavirus transcriptome revealed that 42 genes are expressed immediately early, including 35 genes with unknown functions, a linker H1 histone gene, and a poly-A polymerase regulatory subunit gene.[188]

From 2 hpi, the genome of medusavirus begins to be replicated in the host nucleus, in a region near the nucleolus (Fig. 17.11).[185] Early genes are expressed at this stage, including those related to nucleotide metabolism, DNA replication, recombination, and repair.[188] The amount of viral DNA in the nucleus increases considerably at 8 hpi.[185] After 8 hpi, intermediate and late viral genes are expressed, including the four core histones (H2A, H2B, H3, and H4), transcription factors, structural genes (such as MCP), and some translation factors.[188] Large amounts of virus particles are then assembled in the cytoplasm; at 8-10 hpi, they are empty or contain electron-lucent material. At this stage, the cellular nucleus remains morphologically intact but is filled with copies of virus genomes. From 14 hpi onward, copies of the virus genome migrate to the cytoplasm where they are packaged in particles.[185]

Similarly, clandestinovirus particles migrate to the nucleus of *V vermiformis* cells from 4 hpi, and by an unknown mechanism, the particles penetrate the nucleus.[133] The clandestinovirus induces the formation of a nuclear viral factory. Particles appear to be assembled and filled on the periphery of the viral factory, followed by particle migration to the cytoplasm.[133]

Medusavirus particles are released from 14 hpi onward, likely after host cell lysis.[185] Clandestinovirus particles are released by exocytosis from 16 hpi. Interestingly, infected cells become rounded, lose adhesion, but do not suffer lysis for at least 7 days.[133]

Perspectives

Research on giant viruses is expanding and experts from different disciplines unravel details about infection cycles, structures, host-virus relationships, evolution, metagenomics, and ecological aspects.[54] Nearly two decades after the serendipitous discovery of APMV, we know that giant viruses are ubiquitous and diverse pathogens of natural protist communities and that they interact with a variety of other microorganisms and mobile genetic elements. Yet, the majority of giant viruses still await discovery, requiring us to improve methods for their isolation and culture-independent characterization. Novel entities, such as yaravirus, mininucleoviruses, and meelsvirus, as well as thousands of novel viruses discovered by metagenomic give us a first taste of the richness and diversity of viruses within the kingdom *Bamfordvirae*.[20,28,146,151,159]

Acknowledgments

I would like to thank all the colleagues from the giant virus community for their efforts in the last decades and for providing images and information for this chapter. A special thanks to Dr. Matthias Fischer (MPI for Medical Research, Heidelberg, Germany) for his comments and suggestions on this chapter. I also thank CNPq, CAPES, FAPEMIG, and UFMG. I dedicate this chapter to Getúlio (*in memoriam*).

Interactions of VSRs with host pathways

Surveillance pathways of cellular mRNA metabolism and plant virus infection

Autophagy and plant virus infection

Ubiquitin proteasome system, SUMOlylation, and plant virus infection

Effector-triggered immunity and cross-talk with other cellular pathways

Pathogen-associated molecular pattern triggered immunity

Unfolded protein response in regulation of virus infection

Plant viruses and insect vectors

Insect vectors that benefit from feeding on virus-infected plants

Viruses modify plant metabolism to enhance transmission by vectors

Other virus-induced metabolic modifications that benefit the vector

Beneficial plant viruses

Plant viruses that benefit their hosts

Plant viruses as delivery vehicles for siRNAs and proteins

Plant viruses and biotechnology

Epilogue

Acknowledgments

Plant viruses are exceptional model systems with which to address universal concepts in virus replication, translation, intracellular movement, and other common aspects of virus infection cycles. Plant virus investigators uncovered the vascular super highway as a conduit for long distance intercellular movement of RNAs and unveiled the existence of RNA silencing, which controls gene expression, development, intercellular communication, and pathogen targeting. Plant viruses are also critical concerns for global food security, responsible for over 30 billion US dollars in annual losses.[119] Current viral epidemics threaten the world's rice production and supply of cacao, coffee, and other commodities of critical importance to the countries that cultivate them (and the consumers that require them), making the study of plant viruses and the development of therapeutics increasingly important as there are currently no treatments available for any virus-infected plant.

Recent reports have revealed that plant viruses are much more than just pathogens. Viruses can exist in mutualistic relationships with their insect vectors and host plants and virus capsids are emerging as important components of nanotechnology with boundless applications for human and animal health. Virus VIGS (virus-induced gene silencing) vectors are effective tools for genetic research by quickly and efficiently suppressing gene expression and may also be the long-sought silver bullets for controlling pathogens that are decimating entire industries by serving as delivery vehicles for siRNAs in both annual crops and long-lived trees and vines. This chapter cannot hope to cover even a small fraction of the exciting research being conducted on plant viruses in labs throughout the world, and we regret the many outstanding omissions. Rather, we have tried to give an overview of the current state of the field and point to some of the recent developments in plant-virus-vector interactions that are revolutionizing our understanding of these important pathogens. We refer readers to the excellent chapter from W. Allen Miller and Steven Whitham on Plant Viruses in the previous edition of Field's Virology for a history of the field and basic information on plant virus genome organization and material introductory to some of the information presented here.

Ecology of Plant Viruses

Viruses and plants are major occupants of our ecosystem. Identified plant viruses comprise only a small sampling of Earth's plant virome, since known viruses are mainly those that attract attention due to diseases that they cause on cultivated plants, leaving a large number of viruses that exist in noncultivated plants without causing phenotypic symptoms waiting to be recognized (Fig. 18.1). Traditional detection and diagnostic methods such as host range and indicator host responses, ELISA, electron microscopy (EM), and PCR/RT-PCR remain useful tools for diagnosing known viruses that are suspected of causing diseases, but these methods have shortcomings for discovery of novel viruses. Recent combinations of advanced techniques including viral nucleic acid enrichment methods, purification of viral-like particles from host samples, total RNA or total DNA extractions with sequence-independent amplification, analysis of virus-derived small interference RNAs (vsiRNA) combined with next generation sequencing (NGS), metagenomics or large-scale metatranscriptomic sequencing, and associated bioinformatics methods have resulted in the identification of many novel viruses and viroids (small, circular noncoding RNAs) from samples of all living organisms in land and sea.[247,261,274,320] These novel viruses are filling evolutionary gaps and have greatly expanded our basic knowledge of virology.

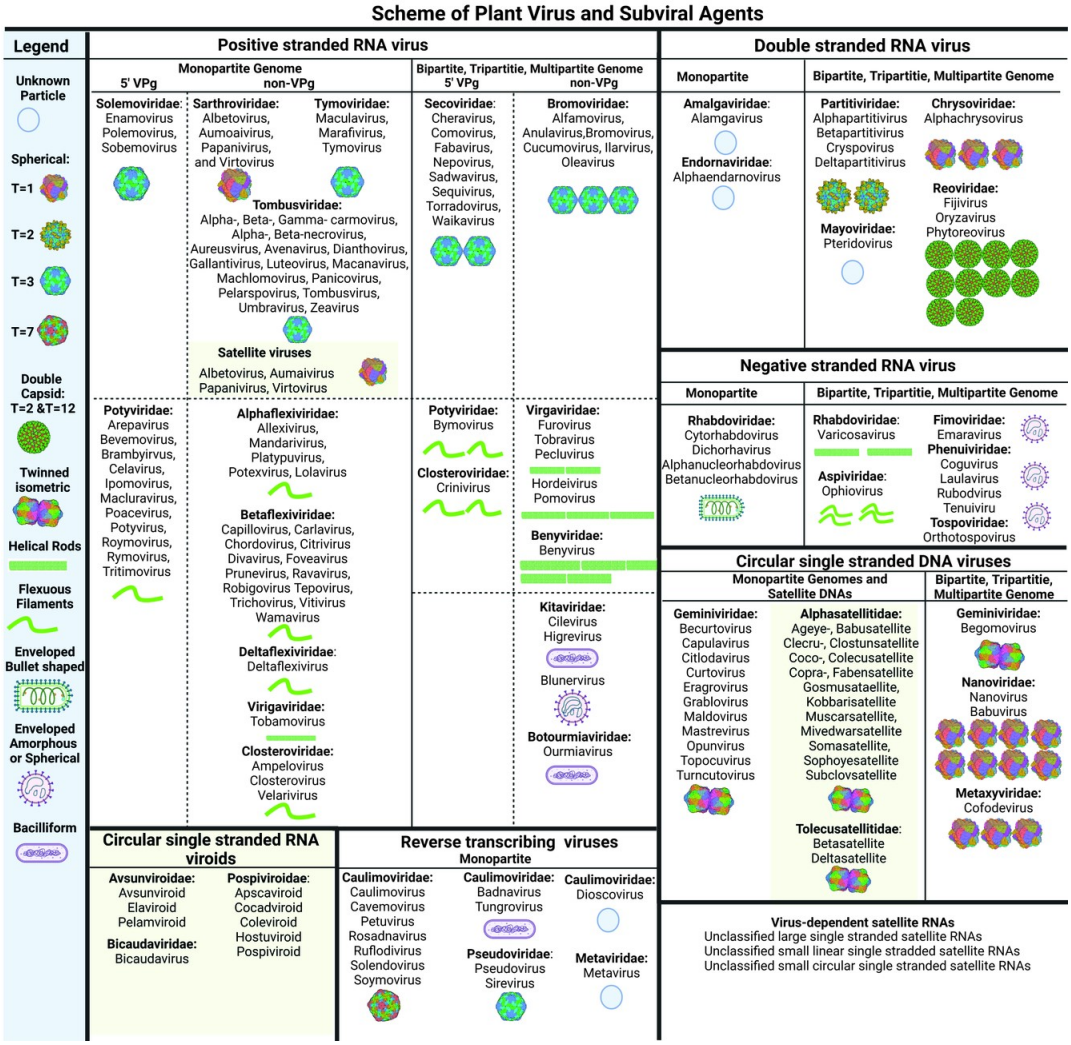

FIGURE 18.1 **Representation of the taxonomic scheme of plant viruses**. The first hierarchy of the scheme identifies RNA or DNA viruses as well as viroids and virus-associated satellites. Positive-strand (+)RNA viruses are separated into columns representing ones that have 5′ VPg and those without VPg. The next hierarchy identifies virus families and genera within those families. The conserved virion structure for each family is represented.

To detect novel plant viruses, plant viral metagenomic approaches have focused on four classes of nucleic acids as targets for virus discovery: (1) total host plant RNA or DNA; (2) virion-associated nucleic acids (VANA); (3) dsRNA replication intermediates or by-products; and (4) vsiRNAs. NGS of total RNA or DNA from a plant sample is the simplest method to explore viral sequences, but viruses represent a very small percentage of total reads. VANA combined with NGS is more laborious, but much more selective and effective, while isolation of dsRNA for metagenomic studies of plant viruses provides an in-depth analysis of virus-specific sequences.[246,247] Infections of both viruses and viroids produce abundant siRNAs covering their entire genome in the plant, with a reduced amount in their insect vectors, making this a very sensitive method of detection.[304] siRNAs are the products of RNA silencing, the host adaptive antiviral response (see section on Host-Virus Interactions) that produces small RNAs from replicating viral RNA genomes or resident stem-loop structures.[321] This method can also detect transcriptionally active integrated endogenous viral elements (EVFs).[247] While these methods have led to the discovery of new viruses and viral nucleic acids, the viruses must be convincingly demonstrated to infect the suspected host plant before a new host-virus combination is confirmed.[321]

Past and present human activities, including expansion of agricultural cultivation and world trading either by companies or individuals receiving uninspected plant materials by post, have affected virus short- and long-distance spread in the environment, host selection and host range, host response and adaptations, and ultimately virus-plant coevolution and codivergence. Studies on the distribution of different isolates of turnip mosaic virus (TuMV; family *Potyviridae*), which mainly infects crops and ornamental plants of the family *Brassicaceae*, illustrates this point. Phylogeographic and molecular clock analyses of over 700 TuMV isolates revealed subgroups with different host ranges spread from the center of emergence to the rest of Eurasia in relation to the host plants grown in each country. Interestingly, the migration pathways of TuMV retraced some of the major historical trade arteries in Eurasia, a network that formed the Silk Road.[126,218,224] Fifteen years of evolutionary analysis also allowed the origin tracing of hop stunt disease, caused by hop stunt viroid (HSVd), which is currently responsible for hop stunt epidemics in commercial hops in Japan, China, and the United States. Over 70% of grapevines were found to be symptomless reservoirs for the viroid, which require few if any mutations to spread and adapt to hops.[113,125,253] Grapevine as a viroid reservoir is illustrated by a very old ungrafted grapevine named “Munage” (King of Grapevine) that has lived in the Xinjiang autonomous region in Northwestern China for more than 150 years (Fig. 18.2). At least three species of viroids coexist in Munage, but still it flourishes.

FIGURE 18.2 **Munage, King of the Grapevine**. The 150-year-old Munage, located in Xinjiang, China, is infected with viroids HSVd, GYSVd-1 (grapeHSVdvine yellow speckle -1), and GYSVd-2 with no visible symptoms. (Reprinted from Jiang DM, Sano T, Tsuji M, et al. Comprehensive diversity analysis of viroids infecting grapevine in China and Japan. *Virus Res*. 2012;169(1):237-245. Current Plant Virus Epidemics

World-wide demand for vegetable and seed markets is expanding with the growth in global populations and the desire of consumers for greater access to food choices. As climate change intensifies, new cropping systems are changing existing farm landscapes and converting natural land into cultivated land, both of which introduce new crops into a shifting geographical environment. Without the benefit of long-term coevolution of crops and pathogens, opportunities are created for disease outbreaks including many caused by viruses.[119] Climate change is also driving the emergence of new virus diseases in wild plant populations that have spilled over into major food crops.[284] The dynamics of global trade and the influence of climate change on temperature and rainfall have impacted the distribution of insects that vector plant viruses, which further threatens food production. Localized and sporadic epidemics are causing hunger in food-insecure regions, while some plant viruses endanger food security on a worldwide scale. Viruses that once existed in distinct landscapes are now sharing hosts with emerging viruses, creating the opportunity for enhanced accumulation and spread, along with altered tissue tropism, expanded host range, vector behavior, and other synergistic interactions that result in devastating diseases.[76,186,199]

Single and complex virus infections are causing major epidemics and pandemics among staple food crops worldwide (Table 18.1). One example is tomato brown rugose fruit tobamovirus (ToBRFV; family *Virgaviridae*), a recently identified virus infecting tomato and pepper that is causing regional outbreaks around the globe. ToBRFV is vectored mechanically by people and equipment and is unaffected by the many known sources of tobamovirus genetic resistance bred into domestic tomato plants.[91] Discovered in Israel in 2014,[177] ToBRFV is a major threat to tomato and pepper production globally, and international phytosanitary standards have been imposed by the International Plant Protection Convention (IPPC) and other trade organizations to ensure safe trade of products between countries.

TABLE 18.1 Examples of current most important epidemic or pandemic plant viruses

Name of Virus or Synergistic Viral Disease	Known or Potential Vectors	Disease Symptoms	Locations and Control Methods
Viruses of cereal crops (reducing crop yield and symptoms affect marketability)			
Maize lethal necrosis disease caused by coinfection of maize with maize chlorotic mottle virus (MCMV; family *Tombusviridae*) and one of several viruses from *Potyviridae* including sugarcane mosaic virus (SCMV), maize dwarf mosaic virus (MDMV), and wheat streak mosaic virus (WSMV)	Thrips (*Frankliniella williamsi*) and beetles transmit MCMV; several aphid species transmit potyviruses	Negligible yield or plant death	Located in Asia, Africa, and the Americas. Chemical control in fields and/or certified seeds that have been tested for known viruses
Maize dwarf mosaic disease caused by maize dwarf mosaic virus (MDMV: family *Potyviridae*)	Several aphid species	Mottling or mosaic leaf symptoms and dwarfing	
Maize streak disease caused by maize streak virus (MSV; family *Geminiviridae*)	Leafhoppers	Yellow or white streak disease on youngest leaves and yield loss	
Maize rough dwarf disease caused by one or a complex of four figiviruses: maize rough dwarf virus (MRDV), Mal de Rio Cuarto virus (MRCV), rice black–streaked dwarf virus (RBSDV), and southern rice black–streaked dwarf virus (SRBSDV)	Planthoppers	Leaves are distorted, panicle discoloration, dwarfing	
Rice tungro disease caused by a complex of rice tungro bacilliform virus (RTBV; genus *Tungrovirus*) and rice tungro spherical virus (RTSV; family *Caulimoviridae*)	Leafhoppers and planthoppers	Leaf discoloration, stunted growth, reduced tillers, sterile or partly filled grains	Tungro disease is located on all continents except Australia, RYMV is specific to Africa, and all the common dwarf diseases are found on all continents. Control by cultural practices and using virus or insect resistant plant varieties
Rice yellow mottle virus (RYMV; family *Solemoviridae*)	Beetles, grasshoppers, and leafhoppers	Leaf streaking and malformation, death of young plants	
Common causes of dwarf or stunted growth diseases in rice are caused by viruses of *Bunyaviridae*, *Rhabdoviridae*, and *Reoviridae*: rice black–streaked dwarf virus (RBSDV), rice dwarf virus (RDV), rice gall dwarf virus (RGDV), rice grassy stunt virus (RGSV), rice stripe mosaic virus (RSMV), rice ragged stunt virus (RBSV), rice stripe virus (RSV), and southern rice black–streaked dwarf virus (SRBSDV)	Leafhoppers and planthoppers	Extreme stunting, leaf discoloration, deformed panicles	
Yellow dwarf and yellow mosaic disease caused by viruses of *Tombusviridae and Potyviridae*: barley yellow dwarf virus (BYDV), cereal yellow dwarf virus (CYDV), and wheat yellow mosaic virus (WYMV)	Several aphid species	Severe yellowing and dwarfing	Located on all continents. Control by cultural practices and chemical control of aphids
Soilborne mosaic diseases in wheat caused by viruses of the family *Virgaviridae*: Chinese wheat mosaic (CWMV) and soilborne wheat mosaic virus (SBWMV)	*Polymyxa graminis*	Mosaic pattern on foliage	Located on all continents. Control by cultural practices
Viruses of horticultural crops (reducing crop yield/marketability and causing tree death)			

Mosaic and necrotic diseases caused by members of the family *Potyviridae*: papaya ringspot virus (PRSV), plum pox virus (PPV), potato virus Y (PVY), zucchini yellow mosaic virus (ZYMV), and turnip mosaic virus	Several aphid species	Mosaic, mottling, ringspot, chlorosis, necrosis patterns on leaves as well as the fruits, tubers, and vegetables reducing or eliminating marketability	Located on all continents with some exceptions. Pepper, lettuce, and tomato infecting viruses are not found in Australia, and CGMMV is not found in South America. Controlled by one or more of the following methods: using insect- or virus-resistant plant varieties, seed certification, cross-protection, and chemical control of insects
Potato leafroll virus (PLRV; family *Solemoviridae*)			
Pepper vein yellows virus (PeVYV; family *Luteoviridae*)			
Pepino mosaic virus (PepMV; family *Flexiviridae*), tobacco mosaic virus (TMV; family *Virgaviridae*), and tomato brown rugose fruit virus (ToBRFV: family *Virgaviridae*)	Unassisted mechanical transmission		
Hot pepper endornavirus (HPEV; family *Endornaviridae*)	Horizontally transmitted		
Tomato yellows diseases caused by members of the genus *Crinivirus*: lettuce chlorosis virus (LCV) and tomato chlorosis virus (ToCV)	Several whitefly species		
Tomato yellow leaf curl virus (TYLCV; family *Geminiviridae*)			
Tomato spotted wilt virus (TSWV; family *Bunyaviridae*)	Western flower thrips (*Frankliniella occidentalis*)		
Beet severe curly top virus (BSCTV; family *Geminiviridae*)	Leafhoppers		
Cucumber green mosaic mottle virus (CGMMV; family *Virgaviridae*)	Unassisted mechanical and seed transmission		
Turnip yellows virus (TuYV; syn beet western yellows virus; family *Luteoviridae*)	Several aphid species		
Cucumber mosaic virus (CMV; family *Bromoviridae*)			
Grapevine leafroll disease caused by several members of the family Closteroviridae: grapevine leafroll–associated virus 1 through 13 (GLRaV) with GLRaV-3 being the most important	Several species of mealybugs and scale insects, grafting of infected grapevine material	Leaf discoloration and downward curling or cupping, delayed and uneven fruit ripening, reduced fruit quality and yield, affects wood causing graft incompatibilities	Located on all continents. Controlled by one or more of the following methods: chemical control of insects, cross protection, culture methods, production of clean propagative wood for planting or grafting, use of certified planting stocks that have been tested for known viruses
Grapevine fanleaf degeneration disease is caused by grapevine fanleaf virus (GFLV: family *Secoviridae*)	Soilborne nematodes	Plants show reduced growth, leaf distortions and unusual chlorosis including yellow mosaic and yellow veins	
Grapevine degenerative decline disease is caused by members of the family *Secoviridae*: tobacco ringspot virus (TRV) and tomato ringspot virus (ToRSV)	Soilborne nematodes	Leaf symptoms include yellow lines and flecks as well as ringspots, vines are unproductive, small grape clusters	
Hop latent stunt viroid (HLVd; family *Pospiviroidae*)	Vegetative propagation	Reduced growth, shorter internodes, stunting	Located on all continents
Cacao swollen shoot virus (CSSV: family *Caulimoviridae*)	Mealybugs	Leaf discoloration, stem/root swelling, die-back, kills trees within a few years	Primarily located in West Africa. Controlled by eradicating trees

Virus species belonging to genera *Begomovirus*,[216] *Tospovirus*,[167,225] *Potyvirus*,[330] *Reovirus*, and *Tenuivirus*[336,341,349,350] represent only a portion of the viruses currently causing devastating diseases. To ensure food safety, new technologies and novel solutions are needed including (1) improved diagnostic testing such as NGS and small RNA (sRNA) sequencing to rapidly identify emerging diseases and improved sanitary certifications[290]; (2) advanced breeding methods including genome editing, which has been successfully used to engineer resistance by targeting viral sequences[6,13] or the plant genome[30,236]; (3) novel sRNA delivery systems (sprays, injections, VIGS) that do not require modification of the plant genome; (4) drone technology in field monitoring; and (5) active communication between growers and researchers and phytosanitary officials who can offer solutions and preventative or eradication measures.

RECOMBINATION IN PLANT VIRUS EVOLUTION

Viruses evolve when genetic and environmental factors lead to increased virus fitness for amplification within a host or transmission between hosts or in acquisition of new hosts. RNA virus evolution is the product of many factors, but most important is the encoded RNA-dependent RNA polymerase (RdRp), which is error-prone and poorly processive. Due to lack of repair functions associated with most RdRp, missense mutations are generated during each replication cycle, generating a population of viral genomes with varying degrees of fitness relative to the

cellular environment. In addition, premature termination by RdRp can lead to RNA recombination, where the RdRp continues synthesis in *cis* elsewhere on the same RNA genome or in *trans* by using host mRNAs or RNA from the same virus species (intraspecies recombination) or different virus species (interspecies recombination), both of which require coinfection of the same cell. Interspecies recombination generates a chimeric, recombinant virus that may have increased fitness due to new combinations of translated products and/or RNA controlling elements.[1,137,197] High mutation rates and low template processivity of RdRp may go hand in hand as generation of deleterious mutations are counterbalanced by high levels of RNA recombination, which rids the viral population of poorly fit variants while enriching viruses containing beneficial mutations to speed adaptation to selective pressure from environmental variations.[325] Recombination can also generate replication-competent subviral RNAs, such as defective interfering RNAs and satellite RNAs, whose properties can be beneficial for viral infection.[266] Along with polymerase-driven recombination, nonreplicative recombination also occurs, but at a much lower frequency using poorly understood processes that require one or more internal RNA lesion and subsequent ligation of RNA segments.[137] Other viral-encoded proteins can also affect recombination, as evidenced by mutations generated in CP-binding RNA motifs significantly reducing recombination in brome mosaic virus (BMV; family *Bromoviridae*).[275] Host factors can also play a role in recombination, with different BMV recombination "hot-spots" found in different hosts,[138] and at different times in the infection of a host by turnip crinkle virus (TCV: family *Tombusviridae*).[27] Forty host proteins affecting tombusvirus recombination were identified using a yeast temperature-sensitive library that included several actin network proteins that reduced recombination and a cellular DEAD-box helicase that enhanced recombination.[234] In addition, generation of replication-competent recombinants between insect and plant viruses in yeast and plants was positively affected by reduction of the cellular SERCA-like Pmr1 ATPase-driven Ca^{2+}/Mn^{2+} pump, which regulates intracellular Ca^{2+} and Mn^{2+} levels in the Golgi apparatus.[146]

Recombination in the *Potyviridae*

Potyviridae, the largest family of plant viruses, has members that contain a single stranded positive sense (+)RNA genome with a 5′ VpG and a 3′ polyA tail. Potyvirids encode a single polyprotein that is proteolytically processed into 10 mature proteins and two additional extension products. Although potyvirids only infect plants, they contain polyphyletic genomes with three proteins showing significant similarities to proteins from three unrelated viruses: (1) the DEAD helicase-helicase C region of the C1 protein, which is related to that of classical swine fever and hog cholera pestiviruses; (2) the CP, with its core domain rich in alpha helices, is structurally similar to that of orthomyxoviruses and bunyavirids; and (3) the RdRp, which shares significant similarity with those of animal and avian astroviruses.[78] Since no other sequence relationships are discernable between potyvirids and these or any other virus, recombination in a common ancestral host was likely an important factor in the evolution of the modern *Potyviridae*.

Phylogenic studies to identify common ancestors among the 12 *Potyviridae* genera identified discrete lineages based on the assumption that divergence results from accumulating mutations from common progenitor viruses. Evidence indicates that hosts (monocot or dicot) and vector niches are important contributors to their evolutionary divergence.[135] The central role of recombination in the diversification of potyviruses has also been well established,[22,180,277] with intraspecies recombination being common and interspecies recombination appearing to be quite rare.[78,229] Using viruses with different markers in their genomes to identify recombinants, and assuming that trans recombination only occurs in coinfected cells, Tromas et al.[285] estimated a very high rate of recombination, 3.3×10^{5} recombination events per nucleotide site per generation, which is similar to the potyvirid rate for individual mutations. However, this exceptionally high value was based on reports suggesting very low levels of cellular coinfection by potyvirus strains.[47] This view was recently challenged by a report examining epidermal cells in two different hosts, where many cells were found to be coinfected by two distinct potato virus Y (PVY) strains, with the amount of colocalization changing over the course of the infection.[198] The exceptionally high level of potyvirus recombination that likely results from prevalent cell coinfection, along with other factors, has contributed to the emergence of numerous recombinant strains in the United States and Europe that are transmitted more effectively by their aphid vectors compared with the single dominant strain that was present in the last century, causing significant problems currently for the potato industry.[81]

Recombination in the *Tombusviridae*: Umbraviruslike RNAs

Umbraviruses (family *Tombusviridae*) are positive sense (+)RNA viruses that lack an encoded CP and thus depend on a coinfecting virus member of the family *Solemoviridae* for encapsidation. As with all members of the *Tombusviridae*, umbraviruses encode a replication-required protein and an extended version of this protein that is generated by -1 ribosomal frameshifting, which is the viral RdRp (Fig. 18.3A). In addition, umbraviruses code for two proteins that allow for cell-to-cell and long-distance vascular movement, and the assisting virus benefits from the umbravirus cell-to-cell movement protein to escape from vascular cells.[276] Recently, subviral (+)RNAs that encode an RdRp with significant similarity to umbraviruses also generated through a −1 ribosomal frameshifting were identified by NGS performed across several monocot and dicot plants.[170,306] These umbravirus-like RNAs (ulaRNAs), which contain umbravirus-related 3′ terminal sequences and structures as well as umbravirus-like transcription start sites, were divided into three classes based on maximum likelihood phylogenetic analyses (Fig. 18.3C) and additional secondary structure similarities.[170] Class 1 ulaRNAs only encode the two replication-required proteins and are found in papaya and babaco (mountain papaya) in Central and South America. All class 2 ulaRNA (with one exception) have at least one additional ORF (ORF5) that overlaps with the end of the RdRp ORF in the −1 frame, and class 2 infecting monocots have an additional ORF (ORF6) in the −2 frame that is nearly completely imbedded within ORF5 (Fig. 18.3B). The function of the ORF5/ORF6 products are not known, but the ORF5 amino acid sequence contains motifs found in the 30 kDa superfamily of plant virus movement proteins.[170,207] Class 2 ulaRNA citrus yellow vein–associated virus (CYVaV-citrus) has no additional ORFs due to (1) mutations near the presumptive subgenomic RNA transcription start site; (2) mutations at the translation start site; and (3) two extensive deletions within the analogous ORF5 region (Fig. 18.3D and E). Class 3 ulaRNAs have one of two different ORFs of unknown function that are not related to ORFs 5 or 6 and the RdRp overlap region is different (Fig. 18.3B).

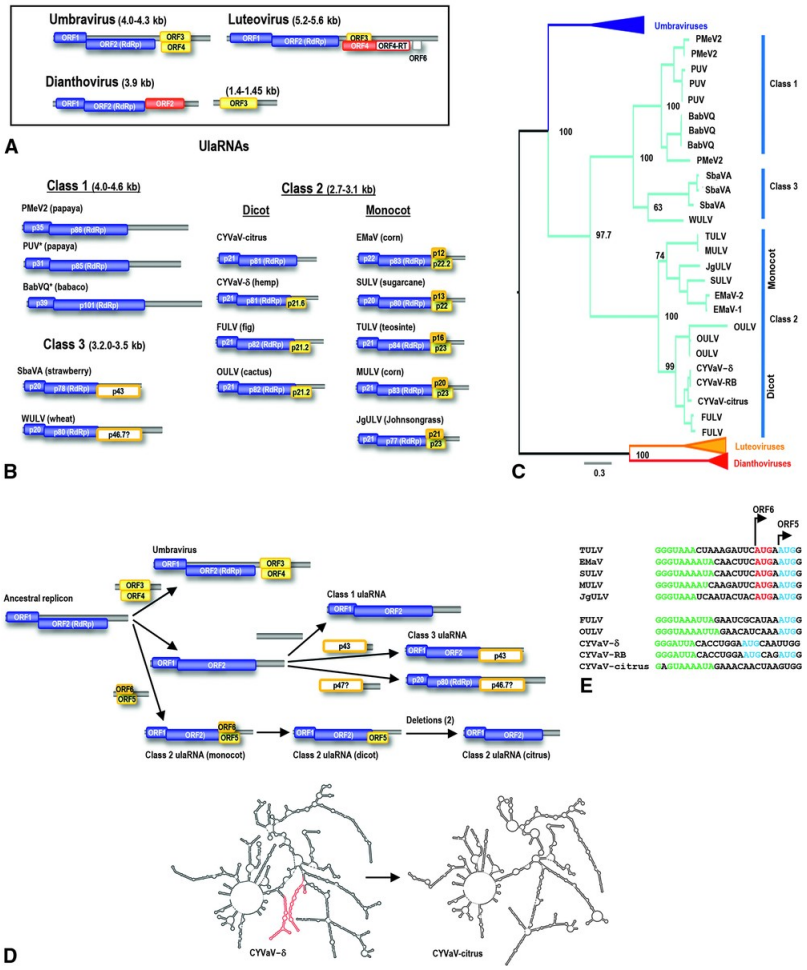

FIGURE 18.3 **Recombination in the evolution of umbraviruslike (ula)RNAs**. **A**. Gene organization of umbraviruses and two other genera of umbraviruses and viruses from two other genera of family Tombusviridae that generate their RdRp through ribosome -1 frameshifting. Replication-required proteins (ORFs 1 and 2) are in *blue*, MPs are in *yellow*, and CPs are in *orange*. **B**. The three classes of ulaRNAs. Class 1 have extensive 3′ UTRs; class 2 ulaRNAs (with the exception of CYVaV-citrus) have an additional ORF (ORF5) with motifs characteristic of the 30 kDa class of MPs. Monocot-infecting class 2 ulaRNAs have an embedded ORF (ORF6) of unknown function. CYVaV-citrus has two large deletions (see **D**, *bottom*) and other changes (see **E**) that eliminate ORF5. Class 3 ulaRNAs form a monophyletic group based on the RdRp sequence but contain additional ORFs of different origin. **C**. Phylogenetic tree based on RdRp amino acid sequences show ulaRNAs and umbraviruses share a common ancestor. Tree was midpoint rooted. **D**. Model for the origin of ulaRNAs. The model suggests that multiple recombination events led to the different classes of ulaRNAs. (*Lower*) The secondary structure of CYVaV-citrus and the proposed secondary structure of CYVaV-δ are shown. Sequence missing in CYVaV-citrus is in *red*. **E**. Sequence at the initiation sites of ORF5 and ORF6. An umbravirus-like sgRNA promoter is just upstream of this sequence, which begins with a sequence (in *green*) that is commonly found at the 5′ ends of gRNAs and sgRNAs in umbraviruses and carmoviruses. ORF6 initiation codon is in *red*, and ORF5 initiation codon is in *blue*. (Phylogenetic tree courtesy of Sayanta Bera.)

Based on related RdRp and conserved 5′ and 3′ sequences and structures, a model was proposed suggesting that the progenitor for both umbraviruses and ulaRNAs was a class 1-type ulaRNA, with different recombination events introducing different putative MP-encoding genes or noncoding sequences into the viral genomes (Fig. 18.3D).[170] The recombination event that introduced ORF5/6 also included an efficient 3′ cap-independent translation enhancer (3′CITE)[171] (see section on (+)RNA Virus Translation below) not found in class 1 and class 3 ulaRNAs. Unexpectedly, several class 1 and class 2 ulaRNAs were reported in infected plants in the absence of any detectable helper virus.[151,170,306] One of these was CYVaV- citrus, the class 2 member without ORF5. CYVaV has only been found once, in four southern California limequat trees with yellow vein symptoms in the 1950s.[307] When trees containing the original grafted materials were examined many years later by NGS, no helper virus was found.[151] This suggest that at least some ulaRNAs may be capable of an independent existence in plants, even in the absence of any additional ORFs, which was confirmed for CYVaV-citrus, CYVaV-δ, and opuntia umbralike virus (OULV) (Simon, unpublished). What advantage CYVaV-citrus might have acquired by losing ORF5 is not known.

Geminivirus, Potyvirus, and Negative-Strand Virus Infection Cycles

Plant viruses initiate infections following assisted or unassisted entry into the first cell(s). Assisted transmission requires vectoring by mites, insects, parasitic plants, humans, protists, or nematodes, whereas unassisted transmission includes pollen and seed transmission, contacts between foliage, roots, other plant parts, as well as via water, exudates, and soil. Unlike animal viruses, cell entry is never through interaction with cell surface receptors but rather requires processes that either disrupt the cellulose wall surrounding cells or seed/pollen transmission. The cues for virion disassembly are largely unknown but can be coupled to translation of the exposing genome for (+)RNA viruses. The genomes of (−)RNA viruses need to be transcribed to (+)RNA by the encapsidated viral RdRp prior to protein synthesis. In the presence of RdRp and other virus-encoded replication proteins, modifications of host endomembranes occur leading to the formation of clustered replication organelles (see

section on (+)RNA replication). The genomes of double-stranded (ds)RNA viruses cannot be uncoated to avoid activation of antiviral RNA silencing, which targets dsRNA. Instead, the dsRNA genome segments become transcribed within the particle, after which the capped transcripts are transported into the cytoplasm. The genomes of single-stranded (ss)DNA and dsDNA viruses replicate and become transcribed in the nucleus and must modify nuclear processes to ensure successful multiplication.

Plant viruses employ various genome expression strategies to provide temporal and quantitative control over expression of viral proteins needed for replication, encapsidation, cell-to-cell and systemic movement, and vector transmission. Common strategies are division of ORFs on separate genomic (g)RNAs, synthesis of polyproteins, ribosome recoding, and/or the production of subgenomic RNAs (sgRNAs). sgRNAs are frequently the templates for expression of proteins needed for genome encapsidation, as expression is delayed in comparison to gene expression for the gRNA, which ensures that replication is not interrupted by premature particle assembly. Cellular defense measures elicit viral counter measures that include suppression of RNA silencing and nonsense-mediated decay (NMD) (see section on virus-host interactions) and ensures translation of sufficient proteins for encapsidation and transmission to the next plant.

Plant viruses transit out of infected cells through structures called plasmodesmata (PD). PDs provide cytoplasmic continuity between adjacent cells, facilitating diffusion as well as active transport of molecules, proteins, and all types of cellular RNAs. Plant viruses evolved specialized movement proteins (MPs) and several strategies for cell-to-cell movement through PD (see section on virus movement). Systemic spread of the infection to the entire plant requires delivery of viral genomes into the phloem (part of the plant's vascular system) and from the phloem to cells in systemic leaves and roots. Viral genomes require protection during movement, which unlike animal viruses can involve (depending on the virus) virions or complexes composed of gRNA, MP, and additional proteins (vRNPs).

Until recently, replication, translation, and the spread of viruses in plants were considered relatively simple processes. However, with the development of more sophisticated research tools, the astonishing complexity of these processes has become apparent, including the involvement of hundreds of host proteins that both assist and counter viral infections. Here, we summarize some characteristics of the infection cycles of gemini- [ssDNA]), poty- [(+)RNA], and tospo- [(−)RNA] viruses to exemplify recent advances, followed by sections where we delve more deeply into current knowledge on selected host-virus interactions associated with replication, translation, movement, and host defense.

Geminiviruses

Family *Geminiviridae* currently consists of 14 genera and 520 species. Geminiviruses comprise a major part of the plant virome[246] and have either mono- or bipartite circular ssDNA genomes that total 2.5-5.2 kb. Depending on the genus to which they belong, geminiviruses are vectored by phloem-feeding whiteflies, leafhoppers, or treehoppers, and virus infection is often limited to the phloem. Although active nuclear DNA synthesis is required for geminivirus replication, these viruses typically infect terminally differentiated cells that lack active DNA synthesis machinery. Geminiviruses encode proteins that activate the cell cycle so that cells enter S-phase, while also interfering with host transcription, cellular homeostasis, and developmental processes to create a cellular environment that favors virus infection.[3,92] Monopartite begomoviruses are frequently associated with β-satellites that have ssDNA genomes unrelated to the helper geminivirus genome and encode a protein with an important role in symptom induction, suppression of transcriptional and post-transcriptional gene silencing, and regulation of MAP kinase pathways.[100,353]

Upon entry of the ssDNA genome into the plant cell nucleus, the viral ssDNA genome is replicated by host DNA polymerase α and δ through a dsDNA intermediate by rolling circle replication. Recombination-dependent replication is facilitated by the multifunctional viral-encoded Rep initiator protein, which cleaves the geminiviral genome at a conserved sequence within an intergenic region to initiate replication[141,319] (Fig. 18.4). The replication ancillary protein C3 of curto- and begomoviruses enhances replication by fine-tuning the recruitment of DNA polymerase subunit δ (in preference to subunit ε), to synthesize ssDNA molecules.[295] Rep restores the circular ssDNA genome structure and releases the nascent ssDNA molecules. Partially replicated ssDNA can recombine with viral dsDNA to ensure reliable replication. Newly formed ssDNA molecules are packaged into geminate particles via their interaction with CPs after which the virus is transmissible by the biological vector.

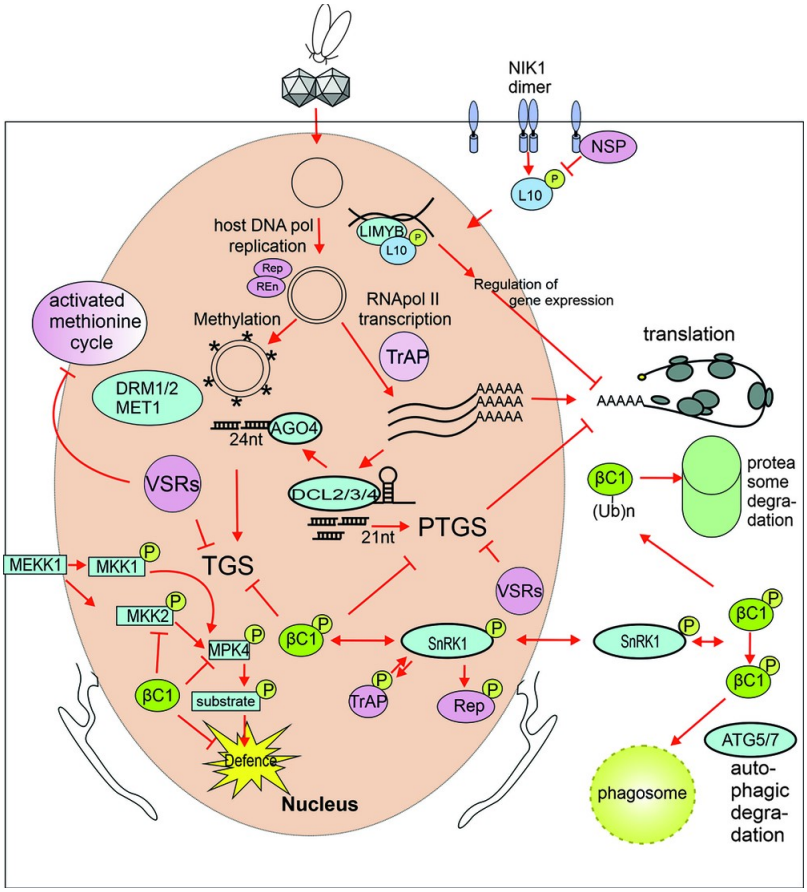

FIGURE 18.4 **Geminivirus infection cycle and interactions with the host cell**. Geminiviruses enter the cell via vector-assisted transmission. The uncoated ssDNA genome is transported to the nucleus of the cell, where it is amplified by host DNA polymerase via a dsDNA intermediate. Geminivirus bidirectional dsDNA transcription that is catalyzed by host RNA pol II produces viral mRNAs that are translated into viral proteins on host ribosomes. The replication initiator protein Rep initiates rolling circle replication by creating a nick into a viral dsDNA molecule to generate a primer for ssDNA synthesis. Replication enhancer protein REn contributes to efficient genome amplification. The host cell fights the infection with different responses. RNA silencing pathways, both transcriptional gene silencing (TGS) that operates with 24 nt sRNAs and transcriptional gene silencing (TGS) with 21 nt sRNAs, are activated upon geminivirus infection. Geminiviral suppressors of RNA silencing (VSRs) inhibit the antiviral activity of TGS and PTGS by (1) interfering with host cell metabolic pathways and key enzymes and (2) interactions with activated methionine cycle enzymes, which are essential for methylation of geminiviral dsDNA by DRM1/2 and MET1 methyltransferases during TGS. Many geminiviral proteins are substrates of kinase complex SnRK1 that regulates energy homeostasis of the host cell. Both proteasomal and autophagic degradation machineries contribute to the outcome of geminivirus infection, thereby degrading post-translationally modified βC1 protein derived from ssDNA βsatellite that associates with diverse geminiviruses. The βC1 protein is involved in the inhibition of the defense response activated by the MAPK pathway. Geminivirus infection detected by PM receptorlike kinases triggers an immune response that, in the case of the NIK1 receptor, results in translation inhibition. Details of the geminivirus infection cycle including its cell-to-cell and long-distance transport and cellular responses that are triggered are presented in the corresponding parts of the text. Viral proteins are shown in *pink*, βsatellite is in *green*, and host proteins that either promote or prevent infection on a *blue-gray* background. (Modified from Gupta N, Reddy K, Bhattacharyya D, et al. Plant responses to geminivirus infection: guardians of the plant immunity. *Virol J*. 2021;18:143. http://creativecommons.org/licenses/by/4.0/.)

Host RNA polymerase II transcribes the geminivirus dsDNA, enabling the translation of C1/Rep and other viral proteins. The geminiviral AC2/C2, also called TrAP, serves as the transcriptional regulator for late gene expression and contributes to the suppression of host defenses.[82] AC2 stimulates transcription of the late gene encoding nuclear shuttle protein BV1 through an abscisic acid (ABA) responsive promoter element.[272] To counter antiviral defenses on an epigenetic level, TrAP serves as a H3K9me2 histone methyltransferase activity inhibitor, preventing the H3K9me2 factor from acting on the viral mini-chromosomes to block gene expression through methylation-dependent restriction.[29]

Potyviruses

Family *Potyviridae* consists of twelve genera, with members containing (+)RNA genomes of 8.2-11.5 kb and flexible nonenveloped filamentous particles with modal lengths of 650-950 nm and widths of 11-20 nm. Potyvirus is the largest genus with 190 current member species. Potyviruses infect cultivated plants worldwide and are abundantly present in wild plants.[246] The infection cycle of potyviruses was recently reviewed[330] and is schematically depicted in Figure 18.5. As described above, VPg is covalently linked to the 5′-terminal nucleotide of the genomic RNA, and the 3′ end is polyadenylated. The genome encodes a major polyprotein that is co- and post-translationally processed by three viral-encoded proteinases into 10 mature proteins, and an 11th trans-frame protein P3N-PIPO, which is produced from two ORFs fused together due to transcriptional slippage that occurs on a fraction of gRNAs.[64,195] The genome organization of potyviruses has similarities to animal picornaviruses including VPg-linked gRNA and similar order of cistrons encoding for the replication proteins in the polyprotein

encoding ORF. The potyvirus core replicase proteins are named as follows: the viral RNA helicase is cylindrical inclusion protein CI, the membrane spanning protein is 6K2, VPg, a chymotrypsin-like cysteine protease related to the picornavirus 3C protease is nuclear inclusion protein a–protease (NIa-Pro), and nuclear inclusion protein b (NIb) is the RdRp.

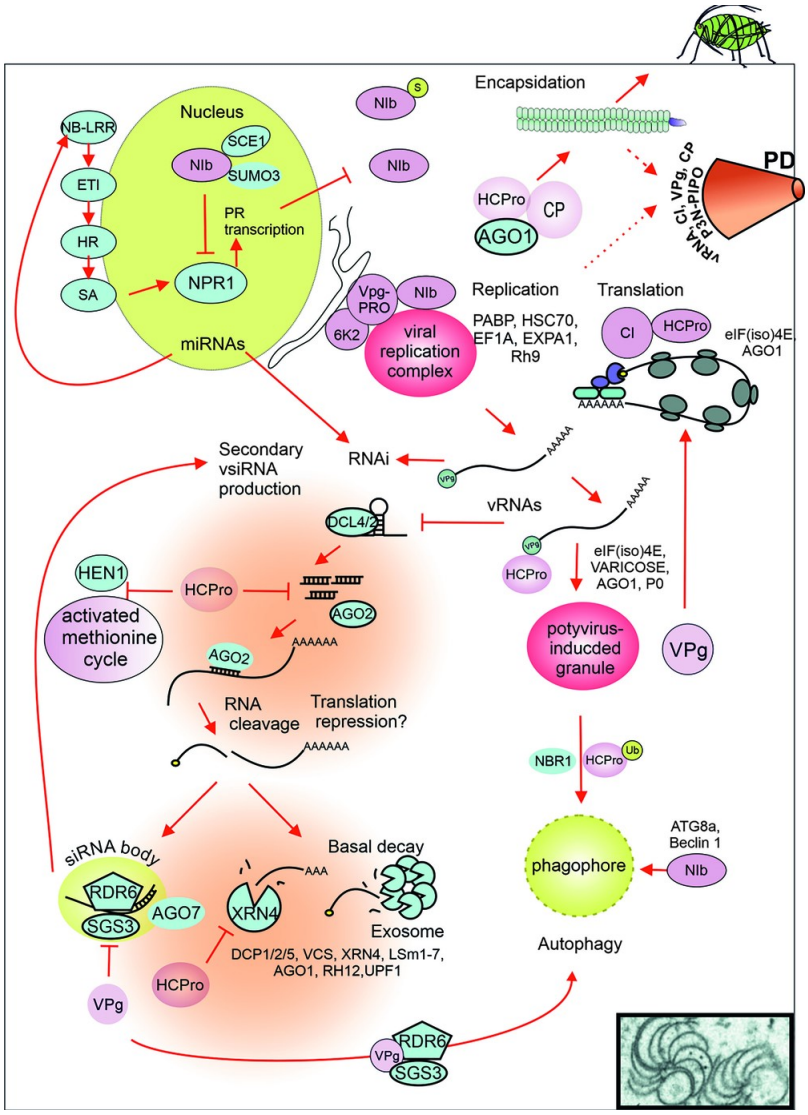

FIGURE 18.5 **Potyvirus infection cycle and interaction with the host cell**. After entering the cell with the help of an aphid vector and uncoating, the potyviral ssRNA genome initiates synthesis of viral proteins and formation of the viral replication complex in association with the ER. Potyvirus infection activates RNA silencing (RNAi), during which host proteins DCL4/2 and AGO2 are key enzymes. When RNA silencing suppression fails, viral RNAs are cleaved and intact viral RNAs serve as the templates for formation of secondary vsiRNAs to amplify RNA silencing responses and interfere with host cell gene expression. The RNA silencing pathway and 5′-3′ decay pathway of mRNAs interact during potyvirus infection. Potyviral VSRs, HC-Pro, and VPg serve in diverse functions in RNAi suppression to promote infection by interfering with accumulation of both siRNAs and secondary vsiRNAs. These proteins escort the replicated viral RNA to ribosomes for viral protein synthesis together with several host proteins through a pathway that includes formation of potyvirus-induced granules. Silencing suppression-associated granules are targeted by autophagy as a second layer of defense, which also includes the RDR6/SGS3/VPg protein complex required for vsiRNA production. Recognition of potyvirus infection by an R-gene activates an NPR1-mediated immune response, whereas potyviral RNA polymerase NIb suppresses this response via its interactions with the host SUMOlylation pathway. Host miRNAs interfere with potyvirus immune responses. The intracellular trafficking pathway to complete potyviral RNA amplification, cell-to-cell and long-distance RNA transport, and many details of immune responses are described in the corresponding parts of the text. Encapsidation of potyvirus genome into stabile particles require both viral and host proteins, such as AGO1. Potyvirus cell-to-cell movement via plasmodesmata (PD) requires the conical structures formed by CI protein and several viral and host proteins. Later in the course of infection, the conical structures detach from the PD and can be detected as hallmark structures of potyviruses (**inset**) by electron microscopy. Host proteins are in *blue*; viral proteins are in *pink* and *orange*.

Viral RNA translation initiates on rough ER, and potyviral 6K2 or 6K2-VPg-NIa-Pro precursor proteins assist COPI- and COPII-dependent virus replication complex formation at ER exit sites.[115,309] Most potyviral proteins, excluding P1, P3N-PIPO, and likely CP, and many host proteins like GADPH, eEF1A, HSPs 70 and 90 are present in the potato virus A (PVA) replication complex.[172] During TuMV infection, 6K2 is essential for release of motile replication vesicles from the ER. 6K2 engages host RHD3, an ER fusogen, and NIb recruits NbEXPA1, a host α-expansin, to promote TuMV replication and cell-to-cell movement.[202,227] Together with prevacuolar SNARE protein VTI11, 6K2 directs TuMV replication vesicles to an unconventional Golgi apparatus bypass pathway.[24] Dynaminlike proteins AtDRP1A and AtDRP2 required for endosomal trafficking promote TuMV infection and interact with several TuMV replication and cell-to-cell movement proteins, indicating that potyviruses may also recruit late endosomes for replication.[316,322] The SNARE protein Syp71 mediates the chloroplast fusion of TuMV replication vesicles

to ensure robust replication.[310] In the PVA replication complex, 25% of the proteins are derived from chloroplasts.

The close association of replication and translation is demonstrated by the specific presence of most ribosomal proteins in the PVA replication structures.[172] Current data indicate that production of potyviral proteins is highly dependent on VPg, especially interaction of VPg with eukaryotic initiation factor 4E (eIF4E) and eIF(iso)4E, but also many other viral and host proteins.[88] Potyviral HC-Pro has an important postreplication role in assisting the VPg-linked viral RNA to the RNA silencing suppression pathway, which includes formation of potyvirus-induced granules (PGs; Fig. 18.5). Many of those host proteins that enhance potyviral translation in association with VPg, such as ribosomal P0 protein, VARICOSE, and AGO1, also localize to the microscopically visible PGs.[43,88,232]

Spread of infection to adjacent healthy cells and systemically to other parts of the plant requires the coordinated action of many potyviral proteins including HC-Pro, P3N-PIPO, CI, 6K2, VPg, and CP.[241] CI forms a conical structure that anchors to PD to assist potyviral RNA transport through the channel (Fig. 18.5). Later, this cylindrical inclusion structure detaches from the PD and exists as a pinwheel-like structure in the cytoplasm, which is an indicator of potyvirus infection. Interactions between the potyviral P3N-PIPO and the host PCaP1 protein enable localization of the movement complex to the PD.[298] A developmentally regulated plasma membrane (PM) protein of *Nicotiana benthamiana* (NbDREPP) interacts with P3N and CI and influences cell-to-cell movement.[72] The majority of amplified (+)RNAs are encapsidated, and studies show that viral replication and particle formation are tightly linked.[68,288]

Negative-Strand RNA Viruses

The phylum *Negarnaviricota* was established in 2019 by the International Committee on Taxonomy of viruses (ICTV) to encompass all negative-sense (−)RNA viruses. The monopartite viruses of the order *Mononegavirales* include six genera, a few of which infect plants and are naturally transmitted by arthropods (or plasmodiophorid protists in the case of lettuce big-vein associated varicosavirus). The enveloped virions contain the gRNA encapsidated by nucleocapsid (N) protein and the RdRp. The order *Serpentovirales* are segmented filamentous viruses and the genus *Ophiovirus* includes plant-infecting members that are also transmitted by plasmodiophorid protists. Additional enveloped plant viruses with three or more genome segments are assigned to the order *Bunyavirales* and the family *Fimoviridae*, genus *Emaravirus*; the family *Tospoviridae*, genus Orthotospovirus; and the family *Phenuiviridae*, genus *Tenuivirus* and genus *Coguvirus*.[23,142] These virions also contain the viral RdRp and nucleocapsid surrounding the RNA genome. Fundamental research on these plant viruses has been recently accelerated with the development of reverse genetic systems for sonchus yellow net nucleorhabdovirus (family *Rhabdoviridae*), tomato spotted wilt tospovirus (TSWV; family *Tospoviridae*), rice stripe tenuivirus (RSV; family *Phenuiviridae*), and rose rosette emaravirus (RRV; family *Fimoviridae*).[57,58,111,295] A yeast replicon system for TSWV has also been reported.[108] The plant infecting members of *Bunyavirales* has been extensively reviewed.[143] The oldest and most well-known member is TSWV, which has become one of the most important and devastating plant viruses worldwide. TSWV is vectored by *Frankliniella occidentalis*, the Western flower thrips.[143]

Within the order *Bunyavirales*, all viruses appear to have gRNA with complementary 3′ and 5′ ends of the genome that form a dsRNA panhandle to create a pseudo-circular appearance during replication. Studies in yeast showed that the terminal 15-17 nt at the 5′ and 3′ ends are essential for activation of the RdRp[108] and likely act as promoters for replication through a viral complementary (vc)RNA. The tospoviruses have three genome segments denoted as large (L, 9 kb), medium (M, 4.8 kb), and small (S, 2.9 kb). The (−)RNA serves as a template for mRNA transcription and viral mRNAs are produced by cap-snatching, whereby the 5′ 12-8 nt of a host mRNA, including the methylated guanosine cap, are cleaved by viral endonuclease activity and used to prime transcription on the viral RNA template. Thus, viral mRNAs differ from the antigenomic RNA molecules that are required for replication due to the presence of a heterogeneous nonviral sequence at the 5′ end. The mRNAs encode (in the positive polarity) the RdRp from the L segment, the envelope glycoprotein (G) from the M segment, and the nucleocapsid (N) protein from the S segment. In opposite orientation, the M segment also encodes the nonstructural NSm protein, which is the viral MP, and S segment encodes NSs, which is a silencing suppressor protein. NSm produces tubular structures that extend between cells for movement of the viral nucleoprotein complex involving the N protein.

The functional domains of the bunyavirus RdRp are also well conserved across families of viruses infecting a wide range of hosts.[9,62,278] For TSWV, the N-terminal endonuclease domain is preceded by an N-terminal extension of unknown function. Following the endonuclease region are eight conserved motifs (A-H), which provide viral RNA binding and polymerase activities. The crystal structure of the TSWV N protein shows that it has structural homology with other orthobunyaviruses and some phleboviruses and forms a trimer subunit surrounding the viral RNA.[84] The replication cycle for (−)RNA viruses is poorly understood. However, given the extensive conservation of RdRp and N proteins, (−)RNA likely enters the cytoplasm as ribonucleoprotein segments that are transcribed by virion-associated RdRp activity. The positive-sense mRNAs derive in part from scavenged host cell mRNAs (via cap snatching) and may be devoid of mRNA at their 3′ ends. Following translation, the viral RdRp is available for further rounds of mRNA synthesis as well as for genome replication through the synthesis of full length complementary RNAs. Virions form by budding through the Golgi apparatus.

Arabidopsis mutant lines with defects in the RNA decay machinery were inoculated with TSWV to identify host genes that can influence virus infection. TSWV infection in plants with mutations in either decapping 2 (DCP2) and exoribonuclease 4 (XRN4), which are engaged in decapping and degrading mRNAs via NMD, or mutations in the Dicer-like proteins (DCL) that are essential for RNA silencing and can attack viral RNAs, revealed that DCP2 and XRN4 played greater roles in TSWV RNA degradation than DCL proteins. This points to the importance of the decapping of cellular RNAs and the availability of caps for TSWV infection.[179] Other host factors critical for virus amplification include the eukaryotic translation elongation factor 1a (eEF1A) and ribosomal protein S6. It is likely that these proteins have features beyond their roles in global mRNA translation that can be hijacked by TSWV, although their direct mechanistic contributions to virus replication are not known.[95,96,139]

(+)RNA Virus Translation

Because of space limitations, this section is confined to a discussion of recent advancements in cap-independent translation of (+)RNA viruses, which are the most thoroughly investigated.

Cap-Independent Translation: Internal Ribosome Entry Sites

Translation of (+)RNA viruses begins shortly after virions enter a new cell and release of the encapsidated (+)RNA genome, or upon entry of a vRNP complex. Like animal viruses, plant (+)RNA viruses have a variety of 5′ and 3′ ends that dictate the mode of translation. Viral genomes that contain the canonical 5′m7GpppG cap attract translation factors and ribosomes similar to host mRNAs, whereas genomes with covalently linked 5′ VPgs or free 5′ phosphates attract ribosomes using alternative sequences and/or structures. The expansive internal ribosome entry sites (IRES) associated with noncanonical translation of 5′ terminal or internal ORFs of animal viruses are largely missing from plant viruses. Known or putative IRES, when they exist, are mainly unstructured sequences of 50-150 nt that can be pyrimidine- or purine-rich[73,196,267] (see Fig. 18.6C). For example, internal translation initiation of the capsid protein ORF in TCV (family *Tombusviridae*), which is likely required early in the infection of the cell for its RNA silencing suppressor function, requires an A-rich sequence that can be functionally replaced with the reverse or reverse complement, and translation is stimulated *in vitro* by addition of eukaryotic translation initiation factor 4G (eIF4G). In addition, mutations outside of the IRES that allow downstream sequences to pair with IRES sequences to form a hairpin structure strongly reduced activity.[189] Weakly structured IRES were reported at the 5′ ends of several VPg-containing potyviruses,[196] with the best studied being the AU-rich pseudoknot in the tobacco etch virus 5′ UTR that binds to eIF4G[239,340] and is frequently used to drive internal translation in virus vectors. Nepoviruses blackcurrent revision virus (BRV) and tomato ringspot virus (ToRSV; family *Secoviridae*) also contain a 5′ VPg but have more structured 5′ IRES elements with multiple poly-pyrimidine stretches in unpaired loops and require uncharacterized 3′ CITEs (see section Cap-independent translation enhancers) for function.[122,123,228] Unlike other potyviruses, the triticum mosaic virus (TriMV) IRES contained within an expansive 739 nt 5′ UTR is more similar to picornavirus IRES and directs translation to the 13th AUG.[244] As with picornavirus IRES, the TriMV IRES binds to eIF4G[243] and contains a 16 nt polypyrimidine segment 11 nt upstream from the translation start site.[112] Another potyvirid with an unusual 5′ IRES is the bipartite wheat yellow mosaic virus (WYMV).[74] Two weak hairpins in the 5′ UTR of RNA1 each contain two residues that interact with identical bases in the sequence between the two hairpins, suggesting that dynamic exchanges of base-pairing are necessary for efficient IRES activity. Sequences within the WYMV IRES interact with eukaryotic translation initiation factor 4E (eIF4E) and connect with the 3′ UTR through long-distance base-pairing.

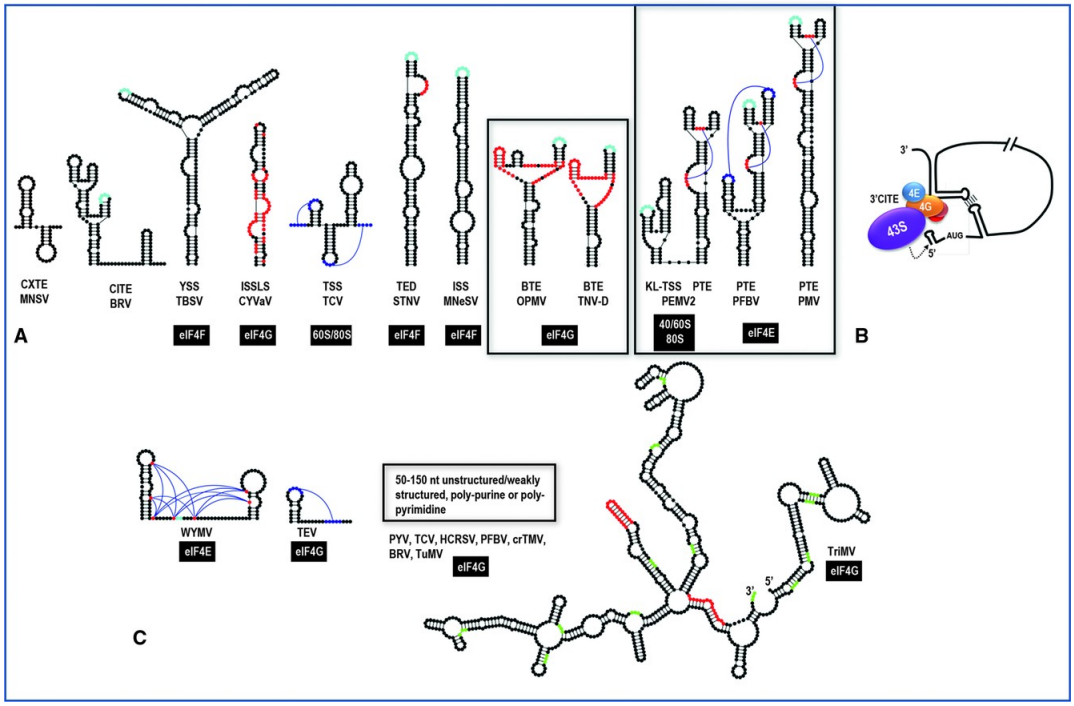

FIGURE 18.6 **Structures involved in cap-independent translation**. **A**.3′ end proximal cap-independent translation enhancers (3′ CITEs). Names of the CITEs are shown above the virus names. Bases in *red* are highly conserved among related viruses. Bases in *light blue* are involved in long-distance interactions with the 5′ end. Bases in *dark blue* and/or *dark blue lines* represent known local tertiary interactions. Translation factors that directly bind the elements (if known) are boxed in *black*. Multiple versions of the same element are boxed. **B**. Schematic representation of the long-distance interactions connecting the 5′ end with 3′ CITEs and assembled translation initiation complex. **C**. Plant virus IRES. Coloring is as in **(A)** except for the TriMV IRES, where AUG sequences are in *green* and *red* sequences denote critical elements required for IRES function.

Cap-Independent Translation Enhancers

The best studied translation elements in plant viruses are the 3′ proximal CITEs (Fig. 18.6A). Viruses can contain one or multiple 3′CITEs, with the three 3′CITEs of PEMV2 used differentially for translation of the gRNA and the sgRNA.[69] Previous reviews of 3′CITEs identified about 7 types that are grouped according to their secondary structures and abilities to bind to particular translation components, usually eukaryotic translation initiation factor 4F (eIF4F) through either its eIF4E or eIF4G subunits, or directly to ribosomal subunits.[196,265,286] However, it is now recognized that many viruses harbor 3′CITEs with structures and features outside of these groupings,[170,228] most of which remain to be characterized. In addition, not all 3′CITEs of a certain type share conserved features, as demonstrated by panicum mosaic virus (family *Tombusviridae*) translation enhancers (PTEs), some of which contain an additional hairpin and kissing-loop interaction,[118] and barley yellow dwarf virus (BYDV; family *Solemoviridae*) translation enhancers (BTEs), which contain at least three different sub-types that share signature features but also contain their own distinctive conserved sequences[106] (Fig. 18.6A). Interestingly, virus members of the same genus can share highly conserved structures at their 3′ termini and have different 3′CITEs just upstream, suggesting that recombination has played an important role in the addition of 3′CITEs to plant virus genomes.[265]

Several 3′CITEs have been shown to assemble translation complexes, including 40S subunits, in the 3′ region of viral genomes,[41,51,347] which are then transferred to the 5′ end through long-distance base-pairing between 3′CITE-associated sequences and unstructured sequences within ~100 nt of the 5′ end, followed by ribosome scanning in from or near the 5′ terminus[267] (Fig. 18.6B). Transfer of the 40S subunit from the BYDV BTE to the 5′ end requires both the long-distance RNA:RNA interaction and eIF3, which bridges the BTE and 5′ UTR sequences and increases 40S recruitment by 25-fold.[18] While it was generally accepted that long-distance interactions circularizing viral templates would enhance the translation initiation rate leading to an increase in the number of ribosomes occupying the template, disruption of the long-distance interaction in umbravirus pea enation mosaic virus 2 (PEMV2; family *Tombusviridae*) had no effect on ribosome occupancy but significantly reduced the overall number of translated templates.[51] The presence of key translation elements near the 3′ end of the viral genome ensures that both viral and subviral RNAs have access to the elements, and the close proximity or overlapping of translation elements with structures required for RdRp-mediated transcription from the 3′ end of the genome allows for conformational rearrangements that remove translation factors that could interfere with replication.[155,338]

(+)RNA Virus Replication

Significant advances have recently been made in understanding the replication of plant (+)RNA viruses. As with animal RNA viruses, plant (+)RNA viruses replicate in the cytoplasm and encode only a tiny fraction of the components needed for replication. An expansive number of host factors have been already identified that are co-opted by viruses to reorganize cellular membranes, hijack transport systems, and rewire energy generating pathways to create a cellular environment conducive to rapid and efficient synthesis of progeny while simultaneously avoiding antiviral defenses.[103,209,212] As described in reference[209] the co-opting of host factors to assist in virus replication has led the host to respond with similar proteins to suppress progeny generation, creating an “arms race” that might be exploitable for developing antiviral reagents to protect vulnerable plants. Additional details on plant virus replication can be found in earlier sections on geminivirus, potyvirus, and (−)RNA virus infection cycles.

Most plant and animal (+)RNA viruses construct large, nucleus-sized, single or double membrane-bound protective microenvironments known as virus replication organelles (VRO) that contain the viral replication complexes (VRCs), which for many viruses consist of spherules (single membrane vesicles) and cylindrical channels where replication of individual viral genomes take place.[219,223] Viruses can induce the rearrangement of virtually every type of membrane for VRO and VRC formation, with the virus-specific selection necessitating a massive proliferation and modification of membrane lipids that requires the substantial rewiring of cellular lipid metabolism. Plant virus VROs are located proximal to PD for coupling replication with progeny intercellular movement, and also distal to PD, where progeny are encapsidated for future vector acquisition.[94,157] Viruses establish these membrane environments, which include modification of both phospholipids and sterols,[7,103] by hijacking membrane contact sites (MCS), which are locations where membranes of two different organelles come into close (tethered) apposition. MCS are naturally involved in the nonvesicular, bidirectional shuttling of lipids, Ca^{2+}, amino acids and metals,[254] and a substantial number of ER/PM MCS are located at the entrance of PDs. These MCS are closely associated with VRCs, and SYTA/1, a synaptotagmin involved in generating MCS, is also necessary for formation of normal turnip vein clearing tobamovirus VRCs, with SYTA/1 localizing inside the structures. SYTA/1 binds to MP of many different plant viruses, which likely is key for the spatial coupling of replication and viral progeny movement through associated PDs.[157,169] These recent findings may explain why specific binding of MP to their cognate viral genomes is not required for MP to selectively transport vRNP through PD into adjacent cells.[157,282]

Deciphering the surprising complexity of virus replication has benefited enormously from the ability to replicate components of model (+)RNA viruses BMV (family *Bromoviridae*) (tripartite) and tomato bushy stunt virus (TBSV; family *Tombusviridae*) (monopartite) in yeast to take advantage of the extensive availability of genetic and proteomic resources.[208,213] TBSV encodes five ORFs, two of which are replication-required proteins: a smaller, highly expressed protein encoded by the 5′ proximal ORF (p33) and a ribosome readthrough extension product (p92), which is the RdRp. Genomic and proteomic-based screening of yeast programmed with p33, p92, and a well-studied TBSV defective interfering RNA, revealed that around 500 yeast gene products either support or suppress TBSV replication. In addition to a structural role lining the interior of the VRC peroxisomal membrane spherules, p33 plays an expansive role in assembling VRCs by interacting with about 100 host proteins that participate in VRO and VRC formation and re-direction of host resources[59,209-211] (Fig. 18.7). Some highlights of recent work on TBSV (that is likely applicable to many (+)RNA viruses) include p33 and p92 replication proteins binding to sterols through cholesterol recognition/interaction amino acid consensus (CRAC) and CARC-like binding motifs that are located within the two transmembrane domains of p33.[327] Binding of the two viral proteins to sterols and lipid transfer proteins is thought to aid in the transfer of sterols from ER membranes to the assembling VRO through MCS. p33 also was recently found to retarget small GTPase Rab7 and its cofactors to VRO that results in the co-opting of endosomal vesicles containing proviral components with lipid modifying properties to the sites of replication.[59]

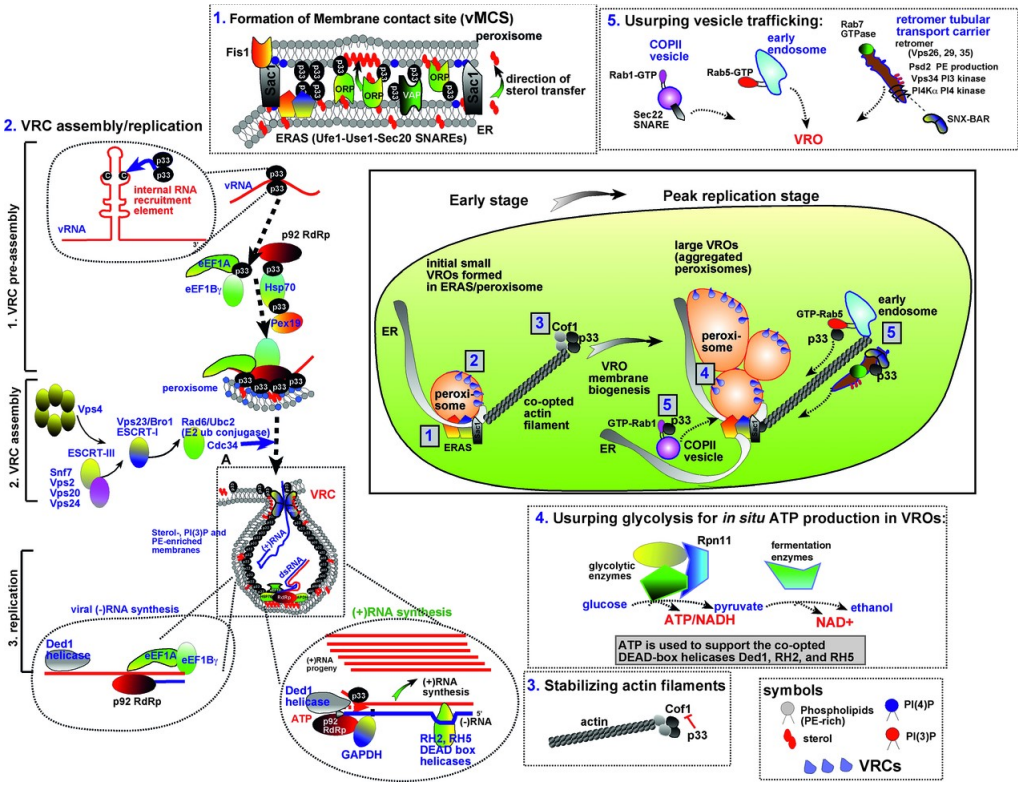

FIGURE 18.7 **Rewiring host pathways and co-opting host factors and membranes during TBSV replication**. Main scheme in the center: TBSV replication is divided into early and peak stages. Note that all the processes described below occur in both stages of replication, but more robustly and with higher intensity in the peak stage. TBSV gRNA is translated resulting in two replication proteins, the more abundant p33, which is the master regulator (*black circle*) of VRO biogenesis, and the p92 RdRp. Process no. 1: Virus-induced formation of viral (v)MCS. The ERAS (ER arrival site of COPI vesicles) subdomain of the ER containing ER SNARE proteins, the Sac1 PI4P lipid phosphatase, and VAP scaffold proteins are targeted by p33 to initiate the biogenesis of VROs. Peroxisomes containing Fis1 mitochondrial/peroxisomal fission protein are also co-opted by p33. By hijacking the cytosolic oxysterol binding proteins (ORPs in plants, called ORBP in mammals) through interaction with p33, vMCSs are formed (as shown in box no.1 on *top*). vMCS serve to enrich sterols, phospholipids, and phosphoinositides within the ER-tethered peroxisomal boundary membranes to optimize lipid composition for TBSV replication. Process no. 2: VRC assembly. During the VRC preassembly process, p33 selectively binds to the TBSV (+)RNA by recognizing a unique internal RNA recruitment element. The p33-viral RNA complex also recruits eukaryotic translation elongation factor 1A (eEF1A) and eEF1Bγ and the p92 RdRp, Hsp70, DDX3-like Ded1/RH20 helicase and with the help of Pex19 chaperone, the complexes are targeted to peroxisomes. During VRC assembly, mono/biubiquitinated p33 recruits the endosomal ESCRTI/III factors and Vps4 AAA ATPase to bend the membranes inward with the VRC preassembly complex inside. This results in a vesiclelike structure with a narrow opening toward the cytosol (as shown schematically). Viral RNA replication starts after Hsp70-driven activation of the p92 RdRp and with the assistance of the RNA chaperone activities of co-opted eEF1A and eEF1Bγ. The synthesis of TBSV (−)RNA leads to double-stranded dsRNA replication intermediates. Then, the dsRNA is partially opened at the 3′ end by co-opted DEAD-box helicases, followed by loading of the p92 RdRp, and (+)-strand RNA synthesis proceeds by strand displacement. The newly synthesized TBSV (+)RNA and sgRNAs are exported out of the spherules to engage in new rounds of translation. Process no. 3: Enhanced recruitment into VROs via stabilization of actin filaments. p33 sequesters Cof1/Adf1 actin depolymerization factor, which leads to stabilization of actin filaments. The actin filaments are then used to deliver co-opted host factors and vesicles into the growing VROs. Process no. 4. Usurping glycolytic and fermentation enzymes for *in situ* ATP production within VROs. Several co-opted enzymes, such as DEAD-box helicases, Hsp70 and AAA ATPases, require plentiful ATP for their functions within VROs. To supply ATP, p33 hijacks the cytosolic glycolytic and fermentation enzymes with the assistance of the proteasomal Rpn11 central interaction hub protein and stabilized actin filaments, which transport into VROs. Process no. 5: Rewiring vesicle trafficking pathways. At the peak stage of replication, the continuously growing VROs require new membrane surfaces to produce many new VRCs/spherules. This is partly accomplished via p33-driven rewiring of the host endomembrane system. The hijacked Rab1-positive COPII vesicles, Rab5-positive early endosomes and the retromer tubular transport carriers all contribute to extra membrane proliferation and delivery of host factors into VROs. Host factors, such as the membrane curvature-sensing endosomal sorting Nexin-BAR proteins and PI(3)P, are proposed to facilitate VRCs/spherules formation. Other co-opted host factors contribute to phospholipid and phosphoinositide production to optimize lipid composition in VROs, which are needed to provide protection of the viral RNAs from cellular nucleases. Altogether, the VROs organize spatiotemporally the replication process leading to the production of hundred thousands of TBSV progeny (+)RNAs per infected plant cells. In the *bottom left box* are symbols of host lipid components subverted by tombusviruses for VRO biogenesis. Note that only a select number of known proviral host factors are presented to simplify the figure. (Figure and figure legend courtesy of Peter Nagy.)

p33 and p92 also bind to the glycolytic ATP generating enzymes phosphoglycerate kinase (PGK1) and pyruvate kinase (PK), redirecting cellular ATP production to the interior of the VROs to support the energy heavy requirements of RNA virus replication.[211] These requirements include activation of chaperone heat-shock protein (HSP)70 by PGK1, which is required along with cochaperones for recruitment and stabilization of p33 and p92 in the VRC membranes, and formation and activation of the replicase complex. PK is necessary for the proviral activity of RNA chaperone DEAD-box helicases, which become permanent residents of VRCs to unwind the 3′ end of the (−)strand portion of dsRNA replication intermediates to allow access to the p92 RdRp for (+)-strand synthesis. Since glycolysis is dependent on regeneration of NAD^+, TBSV also induces expression of fermentation enzymes that reduce pyruvate to ethanol and oxidize NADH. TBSV additionally co-opts translation elongation factors, the actin and ubiquitin networks and the ESCRT machinery for replication, and many more proteins identified in yeast

screens remain to be analyzed. Additional details on TBSV replication can be found in Figure 18.7 and the accompanying figure legend.

The co-opting of host cellular components such as the machinery that generates reactive oxygen species (ROS) in response to various biotic and abiotic stresses[134] into a proviral component for a number of virus-required processes including replication is becoming a familiar scenario in plant-virus interactions.[103,105,209] The p27 replication protein of red clover necrotic mosaic virus (RCNMV; family *Tombusviridae*) associates with the host ROS-generating machinery, relocating the NADPH oxidase enzyme and its regulators from the PM to the perinuclear ER and triggering rapid intracellular ROS bursts that are required for robust viral RNA replication.[104] BMV, which similarly requires ROS bursts for replication, encodes replication protein 1a that functions as a viroporin, generating pores in the ER membrane that release oxidizing power from the ER lumen. This is proposed to form di-sulfide bonds linking 1a proteins together to form a crown on the neck of replication spherules, which is necessary for late functions in replication.[104,223]

Plant Virus Movement

Plant viruses establish replicative infection in leaf epidermal, mesophyll, phloem, or root cells, following introduction by a vector or through mechanical damage. Viral genomes spread between neighboring epidermal and mesophyll cells through PD that connect the cytoplasm between cells. PD nanochannels are lined by the cell wall and PM of adjoining cells. The central channel, known as the desmotubule, is derived from the ER stretching through the PD. This symplastic continuity has been referred to as the "supracellular nature" of plant cells and enables passive diffusion of low molecular weight signals, nucleic acids, and proteins between neighboring cells.[175] Transfer of larger proteins (>60 kDa) across PD occurs via the noncell-autonomous pathway (NCAPP) whereby the large protein or its chaperoning partner actively expands the size exclusion limit (SEL) of the PD, dilating the central channel to enable cell-to-cell transfer.[156] PD proteomic studies have identified more than 1300 PD-associated proteins, some of which are likely involved in movement of endogenous RNAs or viruses between cells.[61] Calcium signaling and callose deposition are highly regulated at PD by proteins such as Ca^{2+} calmodulinlike binding protein (CML41), calreticulin, and β-1,3-glucanase, which modulate callose deposition at the cell wall. Noncell autonomous MP-like cellular proteins have also been identified, including cucumber PHLOEM PROTEIN 2 (PP2) and PHLOEM PROTEIN 16 (PP16), maize KNOTTED1(KN1) transcription factor, and Arabidopsis FT.[21,33,127,175,188,240]

Linkage Between Virus Replication and Intracellular Movement to the PD

The first virus MP characterized was the 30K MP of tobacco mosaic virus (TMV; family *Virgaviridae*).[45] 30K binds nonspecifically to viral RNAs like beads on a string and is responsible for increasing the PD SEL and transporting linear nucleic acids into neighboring cells. The only identified PD localization signal (PLS) on viral MPs or RNAs is in the N-terminal 50 amino acids of the TMV MP, which contains two amino acids (Val-4 and Phe-14) critical for PLS function.[337] The TMV PLS sequence interacts with Arabidopsis SYTA/1, which promotes its association with PD. The Arabidopsis SYTA/1 is a Ca^{2+} sensor that regulates endocytosis. As described in the section on replication, SYTA/1 also associates with ER-PM MCS and is recruited by MPs encoded by TMV, turnip vein clearing virus (TVCV; family *Virgaviridae*), cabbage leaf curl virus (CaLCuV; family *Geminiviridae*), and TuMV (family *Potyviridae*).[157,158,287]

TMV is emblematic of a wide range of viruses whose replicating genomes are found within VRCs. These factories also include actin and microtubules that affect the mobility of VRCs and drive interactions with other viral proteins.[94,221] Microtubules act as a scaffold for anchoring VRCs as they grow and mature into X-bodies or inclusions. The ER is associated with actin filaments that along with myosin motors enable lateral movement of proteins. The TMV MP, which binds to a microtubule-associated protein that plays a regulatory role in virus cell-to-cell movement,[249] accumulates in the vicinity of VRCs and directs some to the vicinity of PD where either newly synthesized viral genomes or intact VRCs migrate across PD into neighboring cells[50,221] (Fig. 18.8).

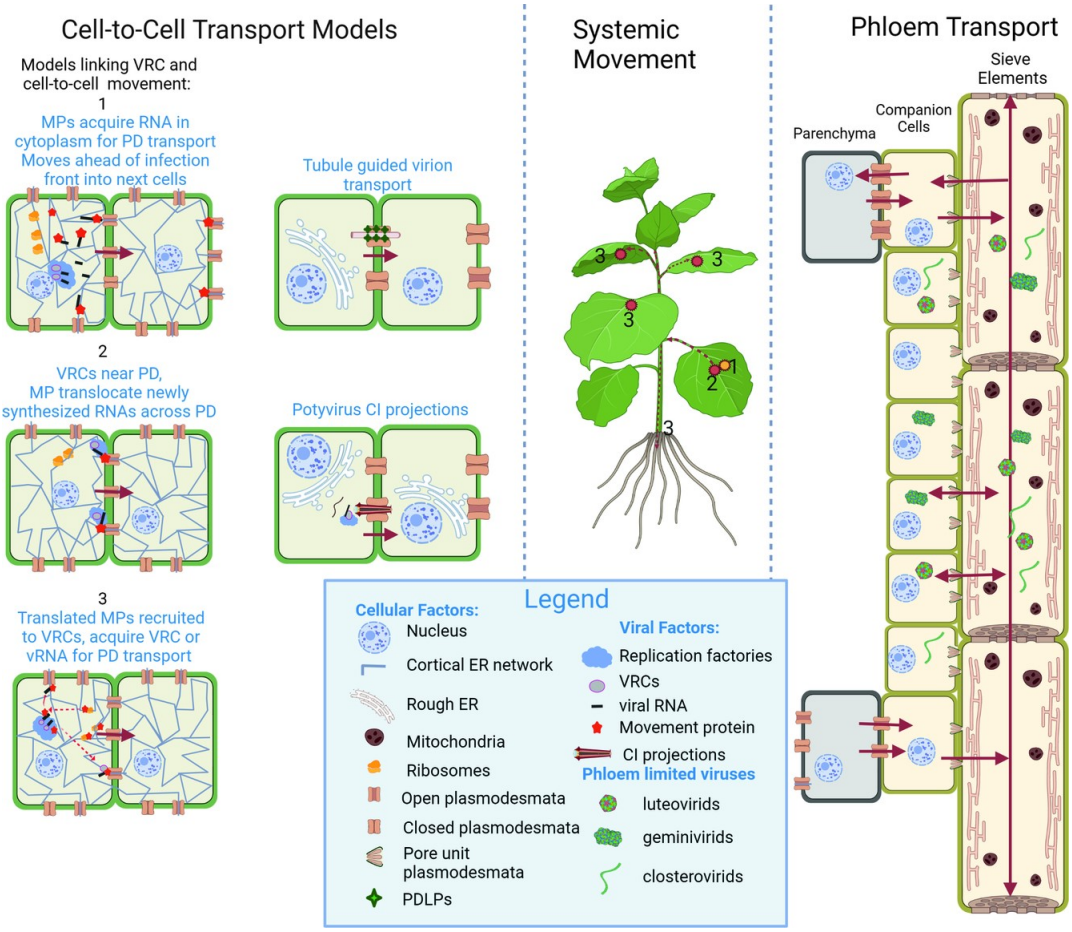

FIGURE 18.8 **Virus movement mechanisms from the cellular to whole plant levels**. The legend identifies cellular and viral factors in each diagram. For viruses that closely integrate VRCs and PD transport, there are three models that depict how viral MPs engage with newly synthesized genomes or VRCs to drive infection into neighboring cells. Two other models are for viruses that produce tubules and for potyviruses that require CI projections. Regarding systemic movement, infection starting in the *orange circle* (1) is primary movement from cell-to-cell in the inoculated leaf followed by (2) entry into the vasculature for movement to the upper leaves. Step (3) is unloading in upper leaves. *Arrows* indicate direction of movement in the plant. Regarding phloem transport, there are three genera of viruses that are examples of phloem limited viruses that are restricted to infection of the phloem parenchyma, companion cells, and sieve elements (listed at *top* of diagram). *Red arrows* show source to sink direction of movement as well as the exchange between neighboring cell types.

Other taxonomic groups of plant viruses encode several MPs that act together to move viral genomes from cell-to-cell. Some viruses encode small membrane binding proteins in conserved gene modules known as the binary movement block (BMB) and triple gene block (TGB), which typically include an RNA binding protein and one or more membrane proteins.[201] A representative BMB virus is melon necrotic spot virus (MNSV; family *Tombusviridae*) whose membrane-associated MPs traffic viral RNA via the Golgi apparatus to PD.[75,153,215] The TGB of potato virus X (PVX; family *Alphaflexiviridae*) has an N-terminal RNA binding domain and C-terminal RNA helicase domain. TGB1 functions as both the viral silencing suppressor and the cell-to-cell MP and has the capacity to destabilize virions to promote translation of viral RNAs.[205,280] BMB2 as well as TGB2 and TGB3 are membrane-binding proteins that associate with the ER, ER-derived granular vesicles, and ER-derived bodies near PD.[120,147,153,280] TGB2 has RNA-binding activity, and the vesicles may scaffold ER-anchored replication complexes for transport toward PD. The viral CP is also essential for cell-to-cell movement. The PVX X-body is an organized inclusion structure of remodeled actin, ER, and Golgi membranes that is arranged around large aggregates of the TGB1 protein. These structures compartmentalize viral gene products, granular vesicles, ribosomes, virions, and VRCs.[14,169,281,297]

Replication and trafficking of alphaflexivirids are closely linked and TGB-associated VRCs remain active in virus replication at the entrance of PD.[157] As described in the section on (+)RNA virus replication, separate viral factories appear to produce VRCs for movement of newly synthesized genomes[94,280] and for packaging and vector acquisition. However, other reports suggest that all active VRCs accumulate near PD, and X-bodies that form at late stages of infection are for removal of aggregated and overexpressed proteins.[94] Interestingly, the PVX TGB1 interacts with remorin (REM), which associates with lipid rafts and locates in microdomains along the PM and PD. Studies show that REM interferes with PVX cell-to-cell movement by binding directly to the TGB1 protein.[231,238] Bamboo mosaic virus (BaMV; family *Alphaflexiviridae*), a close relative of PVX, can be associated with a satellite virus (satBaMV) whose encoded p20 protein interacts with fibrillarin in the nucleolus and with PDs and enables independent satBaMV movement.[31] *N benthamiana* high mobility group (HMG) 1/2a protein, a nonhistone protein associated with chromatin, Rap-GAP1, and thioredoxin h protein, serves as a positive and negative regulator of BaMV cell-to-cell and systemic movement.[4,34,101] The protein kinase CK2 also regulates virus cell-to-cell movement through phosphorylation of the CP in a manner that regulates RNA binding.[102]

The dynamic cellular interactions involving TGB proteins of the multipartite *Virgiaviridae* differ from the monopartite viruses (ie, PVX, BaMV). For these viruses, TGB1 does not increase PD SEL, lacks silencing suppressor activity, and accumulates in the nucleolus in association with

fibrillin or coilin.[176,255,256,314] Potato mop-top virus (PMTV) TGB1 shuttles into the nucleus mediated by importin-α, and defects in nuclear import restrict virus systemic movement. For many of these viruses, fibrillarin is transported out of the nucleus and joins the ribonucleoprotein complex that is trafficked long distances. TGB1 complexes with TGB2 or TGB3 in the cytoplasm for cell-to-cell movement.

As described earlier in this chapter, potyvirus movement is via replication vesicles that appear to be transported to healthy surrounding cells via PD.[80] In addition to P3N-PIPO and CI, viral CP is essential for TuMV movement.[40] Both CP and CI are abundantly present in the PD proteome of TuMV-infected plants[227] and the specific nature of the molecular complex that moves viral genomes between adjacent cells is not entirely understood. Current data suggest that replication vesicles move between mesophyll cells and enter into the vasculature, but PD transport also requires the viral CP and possibly viruslike structures. Furthermore, HC-Pro and AGO1 of PVA and TuMV are required for virion stability.[232] While partially formed virions can move cell-to-cell, they weakly support long-distance movement and mature virions are essential for phloem transport. In addition, TuMV replication vesicles and virions are visible by microscopy in xylem tissues.[299] These seemingly contradictory data suggest the possibility that VRCs as well as virions have essential roles in the spread of infection.

The 70 kDa cylindrical inclusion protein (CI) contains two helicase domains that are required for replication and movement. P3N-PIPO, generated from ribosome recoding, recruits CI, cellular Ca^{2+} binding protein PCaP, and α-expansin EXPA1 creating a complex associating with PD. CI oligomers form conical projections that aggregate near PD and either act as a funnel or beacon for cell-to-cell movement.[38,195,202,203,311] VPg and CP participate in cell-to-cell movement either by acting to remodel PDLPs or by directing virions toward PDs.[301] Alternative models suggest that either virions or viral (v)RNA/CP complexes are guided to the CI conical structures for transport to neighboring cells, or that VRCs themselves are transported across PD, since the 6K2 protein induces motile ER-derived vesicles containing vRNA.[80,301]

Other RNA and DNA icosahedral viruses such as cowpea mosaic virus (CPMV; family *Secoviridae*), grapevine fanleaf virus (GFLV; family *Secoviridae*), tomato spotted wilt virus (TSWV; family *Tospoviridae*), and cauliflower mosaic virus (CaMV; family *Caulimoviridae*) produce MPs that form tubules, which extend between neighboring cells for transport of mature virions.[8,124,233,271] These hollow tubules displace the desmotubule within the PD lumen and become the conduit for virions that march through the tubule into the neighboring cells.[44] Notably, PDLP isoforms interact with the CPMV, GLFV, and CaMV MP and appear to act as host receptors mediating PD targeting, although their functions in virus movement are not fully established.[8,44] Myosin XI-K and myosin XI-2 motors drive anterograde transport from the ER-to-Golgi-to-PM. The proposed model for GFLV is that the MP reaches PD either by diffusion or microtubule mediated transport. The PDLPs traffic along the secretory system to PD in a manner that is dependent upon myosin XI-K and myosin XI-2.[8] At the PD, the PDLP promotes assembly of the GFLP MPs into tubules, which then conduct virions into neighboring cells.[8]

Geminiviruses encode nuclear shuttle proteins (NSP/CP) and MP to facilitate the transport of nascent viral DNA from the nucleus to the cytoplasm and through PD to adjoining cells.[185] CP acetylation promotes viral (v)DNA-NSP complex formation and vDNA transport to the cytosol, where the infectious genomes move to neighboring cells and then systemically throughout the plant. The exact composition of the movement-competent complex is unclear. The NSP and MP interact together and with the vDNA and host proteins.[185] A complex composed of histone H3, NSP, MP, and vDNA was identified from bean dwarf mosaic virus (BDMV; family *Geminiviridae*)-infected leaves. H3 colocalizes with NSP in the nucleolus and MP at punctate bodies at the cell wall. The interaction between NSP and MP may mediate the export of the H3-associated movement complex from the nucleus via nuclear pores to the PD. NIG, an NSP-interacting GTPase that shares transport properties with the human Rev-Interacting Protein may be involved in release of the NSP-vDNA complex from the nuclear periphery to the cytoplasm. NSP-interacting proteins that display proviral functions and suppress host antiviral defenses are reviewed in Ref.[185]

Long-Distance Movement Into and Out of the Phloem

Viruses move in the direction of the vasculature, entering bundle sheath cells and then into the vascular bundles that include xylem, phloem, and parenchyma. The bundle sheath is a primary barrier for virus entry and exit to the vasculature and requires compatible interactions between viral MPs and host proteins to transit across this barrier. Once past bundle sheath cells, viruses enter phloem companion and vascular parenchyma cells. Specialized PD pore units (PPUs) provide another selective barrier for virus transfer into phloem sieve elements.[65] Sieve elements are enucleated cells that stack end to end, comprising the phloem that conducts a wide range of molecules throughout the plant. Virus movement through the phloem is passive, with transport following along with the upward or downward flow of photoassimilates and other molecules. Unlike cellular proteins and smaller molecules, viruses do not move freely across the PPU but require the activities of MPs. Many (+)RNA viruses whose genomes contain 3′ tRNA-like structures require these elements for phloem loading and transport.[159]

As described above, many viruses rely on two modes of long-distance transport, as virions or vRNPs, and the choices between these modes may be host selective. Other viruses may exclusively require viral particles only for long-distance movement.[98] For cucumoviruses, potyviruses, and tombusviruses, the surface-exposed domains of the CP allow direct interactions with host factors that facilitate phloem mobility. Viral MPs with their capacity to modify PD SEL can also be required for entry into and out of the phloem. Potyviruses require VPg linked to the 5′ end of the viral RNA, as well as the CP and 6K2 membrane binding protein.[300]

A few cellular proteins that aid viral transport in the phloem have been identified. For example, umbraviruses do not encode a CP and thus cannot produce virions. Instead, the umbravirus ORF3 protein enters the nucleus and relocalizes nuclear fibrillarin to the cytoplasm to integrate into vRNP complexes,[132] which then move systemically. Fibrillarin is also adopted by other viruses and subviral entities for long-distance movement, including rice stripe tenuivirus, potato mop top pomovirus, and satRNA of BaMV (family *alphaflexiviridae*).[65,98,121]

Species belonging to *Closteroviridae* and the family previously known as the *Luteoviridae* are delivered by phloem-feeding hemipteran insects and are limited to infecting phloem parenchyma, companion cells, and sieve elements.[270] Closteroviruses form long flexuous filamentous virions and their movement is associated with virion assembly. Particles have unique tail structures composed of the viral MP Hsp70h proteins and a p20 protein at the tip of the tail, which docks with host receptors at PD. Lettuce infectious yellow virus is a member of the genus Crinivirus, within the *Closteroviridae*, and also produces conical structures at PD that are functionally reminiscent of the CI structures produced by potyviruses.[237] In addition, the leader protein (L-Pro) is necessary for long-distance transport but is not associated with virions.[98]

Members of family *Reoviridae* that infect plants include genera Fijivirus, Oryzavirus, and Phytoreovirus, and many (but not all) are phloem

limited. These viruses infect primarily monocot plants and have nonmembrane-bound icosahedral virions. Their genomes are multipartite, (ds)RNAs with up to twelve genome segments and induce galls, tumors, or vein swellings. Reoviridae viruses create cellular hyperplasia in the phloem and modify the arrangement of phloem sieve element-companion cell complexes in the vasculature of maize and rice leaves and stems. Within tumors, these viruses create unique structures known as “flexible gateways” at the interface between sieve elements.[178,258,326]

Viruses have also been detected in the xylem, the nonliving cellular tubes that transport water. For example, wheat soilborne mosaic virus (WSBMV; family *Virgaviridae*) is transmitted by a plasmodiophorid vector into growing root cells and establishes infection in immature xylem parenchyma. As roots grow and xylem matures, virions and virus inclusion bodies are seen in xylem vessels and guttation fluid.[294] Other viruses detected in the xylem include icosahedral and filamentous viruses such as rice yellow mottle virus (RYMV family Solemoviridae), TBSV (family *Tombusviridae*), cucumber green mottle mosaic virus (CGMMV family *Virgaviridae*), PVX (family *Alphaflexiviridae*), zucchini yellow mosaic virus (ZYMV; family *Potyviridae*), BMV (family *Bromoviridae*), TMV (family *Virgaviridae*), pepper mild mottle virus (PMMV; family *Virgaviridae*), citrus tristeza virus (CTV; family *Closteroviridae*), and TuMV (family *Potyviridae*).[17,48,182,200,226,273,300]

Viroids are small single-stranded circular RNAs that replicate in host cells but do not encode proteins. They are the smallest noncoding RNA infectious agent in plants ranging in size from 250 to 400 nt. While a few examples such as potato spindle tuber viroid (PSTVd; family *Pospiviroidae*) spread systemically throughout the plant, many viroids are phloem limited. All viroids use components of the host for replication and transport. Investigations of PSTVd identified many unique three-dimensional loop structures and 12 loops were identified as involved in systemic trafficking. In particular, Loop19 is flanked by *cis*-Watson-Crick base pairs, categorized as an A/C loop and mutations impede cell-to-cell movement but not replication.[114] Distinctive motifs control trafficking from the epidermis to the mesophyll and parenchyma, across bundle sheath cells into companion cells, and then into sieve elements.[303] The tomato Virp1 was shown to bind to the TR hairpin of PSTVd and is associated with phloem transport.

PP2 is an RNA-binding protein with viral MP properties that is associated with phloem transport of HSVd (family *Pospiviroidae*).[292] Surprisingly, PP2 is also implicated as a MP for ulaRNA CYVaV-citrus (Simon, unpublished). PP2 binds specifically to CYVaV, conferring partial protection from RNases and allowing the replicon to transit through the vascular system of a large number of unrelated plants including citrus, cucumber, tomato, papaya, and grapevine. Specific binding to PP2 correlates with the appearance of virion-sized “bundles” that aggregate both *in vitro* and in phloem sap.

Host Responses in Defense and Immunity

The major forms of plant antiviral immune responses are (1) RNA silencing (RNA interference [RNAi]) and other associated pathways; (2) resistance (*R*) gene-mediated responses triggered by intracellular recognition of pathogen effectors (effector-triggered immunity [ETI]); (3) pattern-triggered immunity (PTI) based on recognition of pathogen-associated molecular patterns (PAMPs), which lead to a nonspecific systemic response (systemic acquired resistance or SAR); and (4) the unfolded protein response (UPR).

RNA Silencing and Associated Pathways

Vector-assisted entry of plant viruses injures the plant, which rapidly triggers Ca^{2+} influxes,[329] a prerequisite for activation of the calmodulin-binding transcription activator CAMTA3. Activated CAMTA3 relieves suppression of the salicylic acid (SA) defense pathway,[133] thus improving biotic and abiotic stress tolerance[107] that is linked to RNAi through direct activation of RNA-dependent RNA polymerase 6 (RDR6) and bifunctional nuclease-2 (BN2).[305] BN2 stabilizes the key RNAi components AGONAUTE1/2 (AGO1/2) and DICER-LIKE1 (DCL1) by degrading the microRNAs (miRNAs) that normally target their transcripts.[305] Virus infection also induces miRNAs that regulate plant’s defense responses, as demonstrated by potyvirus soybean mosaic virus (SMV; family *Potyviridae*) infection of soybean, where upregulated miRNAs control expression of many key silencing components and the NBS-LRR family of resistance genes.[15]

Antiviral RNAi in Plant Virus Infection

Once triggered, antiviral RNA silencing begins with endonucleolytic cleavages of double-stranded regions of the gRNA by DCLs with assistance of dsRNA-binding proteins (DRBs), leading to the biogenesis of 21-24 bp viral small interfering RNA (vsiRNA) that are stabilized by 3′ end methylation catalyzed by Hua Enhancer 1 (HEN1). The guide strand of the vsiRNA duplex that is complementary to the gRNA target assembles with AGO proteins to form the RNA-induced silencing complex (RISC) or RNA-induced transcriptional silencing complex (RITS). RISC, which targets RNA genomes and transcripts of DNA viruses for posttranscriptional gene silencing (PTGS), limits virus infection via the 21 and 22 bp vsiRNAs produced by DCL4 and DCL2. Silencing of target viral RNAs occurs by the slicing activity of the RNase H endonuclease fold within AGO or by RISC-mediated translational repression. Although most AGO proteins target nonprotected viral RNAs, only a subset (AGOs 1/2/3/4 /5/7/10 in Arabidopsis and AGOs 1/18 in rice) appear active in antiviral defense.[264]

While defense by AGO-mediated slicing is well studied, less is known about RISC-mediated viral RNA translational repression.[56] Translational repression requires the association of ribosomes with sRNAs, their viral RNA targets, and AGO1/AGO2. AGO1 was shown to repress translation of nepovirus RNA2[77] and translation of a reporter mRNA carrying the 5′ UTR of a potyvirus was inhibited by a vsiRNA complementary to the UTR.[110] Translation repression was thought to occur by steric hindrance of ribosome movement by RISC binding either at the initiation or elongation phase. AGO1 associates with polysomes during potyvirus infection,[109] but it remains to be shown if it has a role in translational repression.

Replication in membranous compartments protects viral RNAs from RNA silencing, while progeny extruded into the cytoplasm must be protected by virus-encoded suppressors of RNA silencing (VSRs). Maintaining silencing suppression and viral gene expression during PVA (family *Potyviridae*) infection requires assembly of a high molecular weight protein complex consisting of the potyvirus VSR (the HC-Pro protein), host protein VARICOSE, and other viral and host proteins[43] (Fig. 18.5). AGO 1 is co-opted by PVA to play a positive role during potyvirus infection by interacting with HC-Pro within a large protein complex to stabilize PVA particles, providing an additional example of the evolutionary arms race between viruses and their hosts.[232] This leaves AGO2 as the main antiviral effector in potyvirus infection.[70]

Antiviral defense against DNA geminivirus genomes occurs by transcriptional gene silencing (TGS)[87] when viral dsRNAs formed by highly

structured or overlapping bidirectional transcripts are cleaved by DCL3 into 24 nt siRNAs and loaded into AGO4 to form RITS. RITS includes the RNA-directed DNA methylation apparatus to methylate cytosines in targeted viral DNA sequences to suppress viral minichromosomes. Geminivirus infection also induces the biogenesis of repeat-associated (ra)siRNAs from Pol VI or Pol V transcripts that associate with AGO4 and mediate plant DNA methylation, which contribute to host defense along with histone post-transcriptional modifications, chromatin remodeling, and nucleosome repositioning. As a counter defense strategy, geminivirus proteins interact with components of the methylation pathway to help the virus escape host defense (Fig. 18.4).[339]

Antiviral defense against (ds)RNA and (−)RNA viruses is not identical in monocotyledonous and dicotyledonous plants: for example, R-genes such as NLRs do not appear to play a major role in rice antiviral defense.[348] Phytohormone jasmonic acid (JA) accumulates in response to viral infection and induces AGO18 transcription through the previously established JAMYB transcriptional regulation pathway.[332,333] AGO18 sequesters the two miRNAs, miR168 and miR528, which normally negatively regulate AGO1 and l-ascorbate oxidase (AO).[317,318] AGO18 acts as a decoy, whereby miR168 and miR528 are loaded into AGO18, thus preventing binding to their targets, AGO1 and AO. AGO1 binds vsiRNAs to cleave viral gRNAs through RISC, while AO elevates the base ROS levels to restrict viral infection.

Secondary sRNA Production in Antiviral RNAi

Host RDRs together with SUPPRESSOR OF GENE SILENCING 3 (SGS3) use primary vsiRNAs as primers for conversion of viral RNA into dsRNA for biogenesis of secondary vsiRNA. This RNAi amplification step allows for production of trans-active sRNAs (tasiRNAs) that target viral RNA sequences external to the original RISC target site, a phenomenon known as transitive silencing. Transitive silencing allows for cell-to-cell and systemic spread of silencing to distal tissues via the phloem. Noncell-autonomous mobile silencing requires a DCL2-dependent genetic network and 22 nt siRNAs as mobile signals,[345] which play a role in tissue recovery during viral infection.[145] Plasma membrane-localized receptorlike kinases BAM1 and BAM2 play redundant roles in cell-to-cell spread of the mobile silencing signal[248] and are targeted by the geminivirus C4 protein and tombusvirus p19,[79,248] suggesting that both VSRs may halt cell-to-cell spread of RNA silencing.

Using an *in vitro* system for generating secondary siRNAs, RDR6 recruitment to viral RNA templates required SGS3 (a putative nuclear RNA export factor), SILENCING DEFECTIVE5, primary siRNAs, and AGO.[252] Essential components for biogenesis of secondary vsiRNAs also includes AMINOPHOSPHOLIPID TRANSPORTING ATPase 2 (ALA2), the related ALA1,[85] and ANTIVIRAL RNAI-DEFECTIVE2 (AVI2).[86] ALA2/1 and AVI2 are also important for production of host siRNAs induced during virus infection (vasiRNAs), which guide AGO2-mediated RNAi of hundreds of host genes correlating with broad-spectrum antiviral activity.[25] ALA1 and ALA2 are cellular flippases, which aid cross-membrane movement of phospholipids between the two leaflets of the PM, suggesting that biogenesis of secondary vsiRNA and vasiRNA molecules may require a membranous environment.

Interactions of VSRs With Host Pathways

Plant viruses encode VSRs to suppress the host's silencing machinery, interfering with sRNA biogenesis, RISC assembly/function, and systemic silencing.[332] VSRs are multifunctional, also interacting with other cellular pathways involved in immune responses. For example, cucumber mosaic virus (CMV; family *Bromoviridae*) 2b, potyviral P1/HC-Pro, geminiviral C2, and satellite βC1 inhibit antiviral signaling mediated by phytohormones SA and JA.[28,349] SA normally leads to suppression of RDR1-mediated regulation of basal virus resistance, restriction of meristem invasion by viruses, and symptom amelioration and recovery. In addition, SA is involved in mitochondrial ROS accumulation and redox signaling and their regulation by alternative oxidase and glutathione, a pathway that serves to limit virus accumulation and spread and aids in host plant recovery.[206] SA-mediated induction of autophagy during CMV infection promotes VSR 2b degradation and RNA silencing and negatively impacts SA-immunity driven disease development.[262] This complex interplay between SA, 2b, RNA silencing, and autophagy is thought to balance virus accumulation and plant fitness using these two parallel pathways.

The multifaceted interactions of geminiviral VSR induce activation of endogenous VSRs that suppress PTGS, downregulate a histone methyltransferase to suppress TGS and direct inhibition of host methionine cycle enzymes S-adenosyl homocysteine hydrolase (SAHH), adenosine kinase (ADK), and S-adenosylmethionine decarboxylase (SAMDC) to suppress both PTGS and TGS[87,291] (Fig. 18.4). Due to inactivation of ADK, cellular cytokinin levels increase, which affect cell cycle regulation and positively impact viral replication.[12] Cellular energy metabolism and stress-related SUCROSE NONFERMENTING-related protein kinase (SnRK1) are activated upon geminivirus infection,[260] with SnRK1 phosphorylating βC1, which negatively affects its RNA silencing suppression activity and results in reduced infection[351] (Fig. 18.4). The βC1 satellite also suppresses the antiviral activity of the mitogen-activated protein MAPK pathway that is activated during geminivirus infection[100] (Fig. 18.4).

Like geminiviral VSRs, the activities of potyviral HC-Pro in silencing suppression and other antiviral responses are versatile[289] (Fig. 18.5). HC-Pro is responsible for formation of RNA silencing suppression-related granules that contain gRNA.[88] These proviral RNA granules are subjected to NEIGHBOR OF BRCA1 (NBR1)-dependent selective autophagy, suggesting autophagy is a second layer of antiviral response after RNAi.[90]

Surveillance Pathways of Cellular mRNA Metabolism and Plant Virus Infection

RNAi and RNAi suppression networks interact with the cytoplasmic RNA regulatory network of the infected host cell.[181] Interaction between PTGS and the 5′-3′ decay pathway of mRNAs during potyvirus infection suggests that RNA fragments partially cleaved by exonuclease XRN4 following mRNA decapping may serve as templates for RDR6 in dsRNA synthesis.[160] In potyvirus infection, HC-Pro interacts directly with and inhibits XRN4 activity, whereas VPg interacts with decapping factor DCP2 and sequesters it to nucleus reducing mRNA decay.[160] In addition, VPg directs RDR6 and SGS3 to ubiquitination-dependent autophagy degradation[36] (Fig. 18.5).

NMD, which detects and eliminates mRNAs with premature termination codons (PTC) or mRNAs with naturally long 3′ UTRs (over 200 nt in plants), is another cellular mRNA surveillance pathway that targets viral RNAs encoding multiple ORFs whose stop codons are recognized as PTCs.[129] Viruses have evolved mechanisms to escape decay through the action of *cis*- or *trans*-acting viral factors.[191] For example, p26, the long-distance movement protein of PEMV2 (family *Tombusviridae*) binds to viral and cellular mRNA 3′ UTRs, restricting the binding of NMD

factors.[190] TCV (family *Tombusviridae*) counters NMD with unstructured sequences just downstream from the CP termination codon.[192] N6-methyladenosine (m6A) abundance, which is a nucleotide modification known to regulate life cycle of animal viruses, appears to co-operate with the NMD in antiviral regulation of alfalfa mosaic virus (AMV; family *Bromoviridae*) gRNA.[184]

Autophagy and Plant Virus Infection

Autophagy is an evolutionarily conserved degradation mechanism that regenerates cells by eliminating unnecessary and/or harmful cell organelles and macromolecules. Autophagy is activated in response to cellular stress conditions and appears to play a central role in antiviral defense.[150] Interactions of plant viruses with autophagic processes are as complex and diverse as those of animal viruses and vary between antiviral and proviral processes.[99,323] Delivery of VSRs and other viral proteins to autophagic degradation limits infection of both plant DNA and RNA viruses. CaMV (family *Caulimoviridae*), a pararetrovirus with a dsDNA genome, accumulates in the cytoplasm, where NBR1 cargo receptor delivers them to autophagy and vacuolar destruction unless they are protected in cytoplasmic inclusion bodies comprised of CaMV P6 protein and particles.[89] VSRs HC-Pro and 2b are subjected to autophagy in association with a calmodulinlike protein (rgs-CaM)[214] and the βC1 suppressor of cotton leaf curl multan virus (CLCuMuV; family *Geminiviridae*) is subjected to degradation via its binding to ATG8.[93]

VSRs also promote infection by escorting REMORIN 1,[67] a protein that inhibits cell-to-cell movement, to autophagy. Interestingly, RSV infection is downregulated by autophagy-mediated degradation of VSR p3 through its interaction with host protein P3PI[116] and by proteasomal degradation via its interaction with ubiquitinlike protein 5.[32] Furthermore, an RSV-derived vsiRNA supports activation of antiviral autophagy by downregulating the mRNA of eIF4A, a negative autophagy regulator.[346]

Ubiquitin Proteasome System, SUMOlylation, and Plant Virus Infection

Ubiquitin is a highly conserved eukaryotic protein that becomes attached to cellular or viral proteins as a post-translational modification that identifies them for degradation by the 26S proteasome. Studies have shown that the ubiquitin proteasome system (UPS) plays a role in plant proviral and antiviral functions by degrading viral replicases, VSRs, MPs, and CPs to limit virus infection.[52] Many plant viruses exploit UPS by targeting E3 ligases or other components of the SCF (SKP1/Cullin1/F-box/RBX1) complex. F-box proteins contribute to SCF complexes, which form a scaffold for recruiting target proteins for ubiquitination. For example, geminivirus beet severe curly top virus (BSCTV)-encoded C4 protein promotes expression of the RING-type E3 ligase RKP, which in turn degrades cell cycle inhibitors (ICK/KRPs).[152] Geminivirus replication is linked to cell cycle regulation and disruption of host cell cycle control is beneficial for virus infection. Turnip yellow mosaic virus (TYMV; family *Tymoviridae*) replicase protein contains a cysteine protease domain that de-ubiquitinates the viral polymerase and prevent its proteasomal degradation.[63] The rice grassy stunt virus (RGSV; family *Nairoviridae*) P3 protein includes a U-box type E3 ubiquitin ligase that targets the nuclear RNA polymerase D1a (NPRD1a). NPRD1a in rice is an RNA polymerase IV enzyme, which is required for RNA-directed DNA methylation and its degradation via UPS enhances host susceptibility to RGSV infection.[342] A tobacco ubiquitin E3 ligase RFP1 interacts with βC1 and mediates its ubiquitination and proteasomal degradation, which leads to symptom attenuation (Fig. 18.4).[259]

SUMOylation involves ligation of a 10 kDa small ubiquitin-related modifier, SUMO, to modulate protein activities, interactions, and subcellular localization. Interaction of SUMO conjugating enzyme SUMO3 with RNA polymerase NIb of TuMV regulates the nuclear-cytoplasmic partitioning of NIb and attenuates the host NONEXPRESSER OF PR GENES1 (NPR1)-mediated antiviral defense, thereby promoting infection.[37] NIb's activity is inhibited via its direct interaction with ATG6/Beclin1, which forms a protein complex that likely acts as the cargo receptor for autophagic degradation of NIb through a specific interaction with ATG8a.[161] SUMOylation of Rep proteins of geminiviruses likely creates a favorable environment for geminivirus replication as well.[10]

Effector-Triggered Immunity and Cross-Talk With Other Cellular Pathways

Effector-triggered immunity (ETI) is activated upon specific recognition between a viral factor and the corresponding nucleotide-binding leucine-rich repeat receptor (NLR) that is encoded by a dominant R (resistance) gene. Plant genomes encode hundreds of R genes for resistance to fungal, bacterial, viral, and other pathogens.[11] Plant NLRs carry either a Toll-Interleukin-1-receptor (TIR) homology domain or coiled-coil (CC) domain at their N-terminus. The main domains of NLRs, the CC or TIR domain, the leucine-rich repeat (LRR) domain, and the nucleotide binding (NB) domain play important roles in recognition and translating the recognition into a defense response. Molecular interactions leading to perception are still poorly understood. Broad-spectrum tospovirus resistance is conferred when the LRR domain of tomato Sw-5b, which is a CC-NLR, directly associates with a conserved 21 amino acid peptide within the NSm MP (NSm^{21}), which activates Sw-5b by releasing the interaction between NB and LRR domains.[354] Activation of TIR-NLR N that confers broad-spectrum tobamovirus resistance upon recognition of the p50 helicase domain depends on N self-association/dimerization and other unidentified factors, since this is not sufficient for downstream signaling.[193]

Recognition often requires more than a simple effector/NLR interaction and can include coreceptor sensor proteins bound to the N-terminal portion of NLRs.[131] The essential role of coreceptors in NLR function is supported by the widespread presence of integrated decoys recognizing pathogen effectors in NLR sequences.[148] The Solanaceae domain (SD) in the N-terminal portion of Sw-5b,[35] whose 3-D structure was recently solved,[164] increases the sensitivity of NSm perception by providing a second binding site for NSm^{21}.[163] A high-resolution cryo-EM structure of a wheel-like pentamer protein complex called ZAR1 resistome revealed a pentamer of the Arabidopsis CC-NLR ZAR1 receptor that functions in recognition of a bacterial pathogen, associated with coreceptors pseudokinase RKS1 and kinase PBL2. These data demonstrate the oligomerization upon dATP binding that is required for immuno activation[302] and will likely provide further insight into the function of NLR receptors that recognize viruses. Figure 18.9 shows more examples of the most studied NLR receptors, the proteins involved in the function of each receptor, and the localization of the function in the cell.

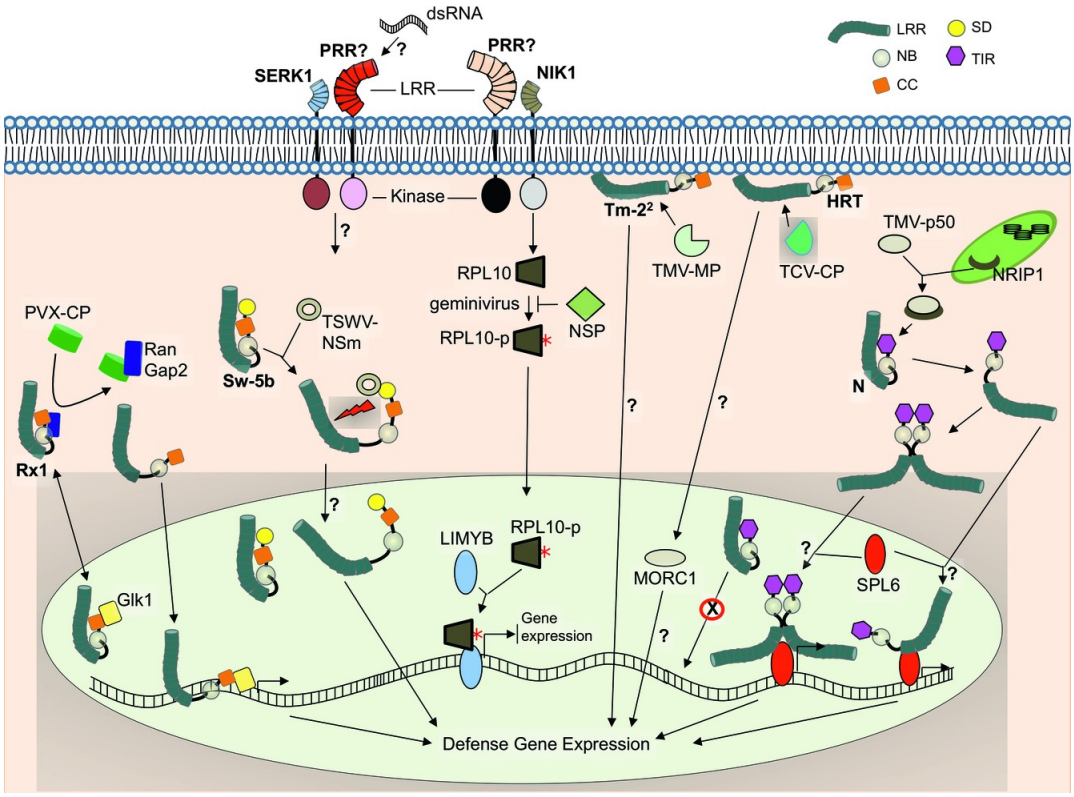

FIGURE 18.9 **Recognition of viral pathogens by cell surface and intracellular NLRs**. In the absence of infection, the intracellular NLRs exist in an autoinhibited states. Upon recognition of the viral elicitor, the NLRs change to active conformations. Cell surface NLRs trigger signaling cascade sending factors into the nucleus to regulate gene expression. Some intracellular NLRs move to the nucleus to regulate defense gene expression. (Courtesy of Savithramma Dinesh-Kumar. Modified from Meier N, Hatch C, Nagalakshmi U, et al. Perspectives on intracellular perception of plant viruses. *Mol Plant Pathol*. 2019;20(9):1185-1190. Reprinted by permission of John Wiley & Sons, Inc.)

The activation of plant NLRs arrests virus amplification through induction of a variety of defenses. Typically induced is a hypersensitive response (HR) associated with visible necrotic lesions caused by a form of programmed cell death (although NLR activation without HR induction can still lead to a resistance response). Activation of the N NLR results in translational repression of PVX (family *Alphaflexiviridae*) transcripts and their redistribution to protein bodies but does not shut down global host translation.[194] Translational arrest of PVX transcripts during potato Rx1 NB-LRR–induced response requires the nucleocytoplasmic redistribution of Rx1 and likely is a major component in the Rx1-mediated extreme resistance response.[242]

Several phytohormones (eg, SA and JA) and other signaling molecules like ROS are upregulated in the local leaf upon HR induction. SA stimulates genetic and physiological responses across signaling networks that regulate effective basal resistance and induced systemic acquired resistance for viral and nonviral pathogens.[28] Perception of pathogen effectors in ETI triggers strong downstream responses including Ca^{2+} influxes and activation of MAPKs. Increase in cytoplasmic Ca^{2+} concentration and phosphorylation of RbohD by calcium-dependent kinases (CDKs) contribute to ROS signaling.[230] Activation of MAPKs leads to production of ethylene, camalexin, and indole glucosinolates and to transcriptional and proteome reprogramming. mRNAs encoding signaling-related proteins are upregulated in the Arabidopsis translatome after NB-LRR RPM1 activation by *Pseudomonas* effector AvrRpm1, whereas production of many proteins related to primary metabolism and the key growth-regulator protein target of rapamycin kinase (TOR) were downregulated.[194] These results predict a central role for translation in plant immune reactions and a role for TOR in the growth to defense transition needed for immune reactions.

Pathogen-Associated Molecular Pattern Triggered Immunity

Pathogen-associated molecular pattern triggered immunity (PTI) is the first line of plant defense against pathogens. Pattern recognition receptors (PRRs), such as the transmembrane receptorlike kinases, nuclear shuttle protein (NSP)-interacting kinase 1 (NIK1), the BRASSINOSTEROID INSENSITIVE 1 (BRI1)-ASSOCIATED RECEPTOR KINASE 1 BAK1, and the somatic embryogenesis receptor kinase 1(Serk1), and their coreceptor kinases are involved in plant PTI responses against bacterial and fungal pathogens. PRRs sense and recognize pathogen-associated molecular patterns (PAMPs) or endogenous host signals released upon infection known as danger-associated molecular patterns (DAMPs). Typically, PTI results in ROS production, activation of MAP kinases, induction of defense genes, synthesis of ethylene and SA, and deposition of the polysaccharide callose.

Since PRRs are cell-surface–located receptors, viruses as intracellular pathogens were not anticipated to trigger PTI, but an increasing body of evidence from recent studies show that they have a role in antiviral defenses to RNA and DNA viruses.[145,220,248,251] Arabidopsis plants become more susceptible to three RNA viruses, namely oilseed rape mosaic virus (ORMV; family *Virgaviridae*), TMV (family *Virgaviridae*), and TCV (family *Tombusviridae*), in the absences of BAK1 receptor.[144] The marker PTI responses of nonviral PTI are also induced during viral PTI, which suggests common mechanisms. How extracellular PAMP perception occurs in intracellular virus infection is not yet well understood.

Plant viruses both trigger and suppress antiviral PTI responses. In addition to viral proteins, viral dsRNAs can serve as PAMPS in plants and

trigger typical PTI responses.[222] NIK1-mediated antiviral response, which is activated by begomovirus-derived nucleic acids, have both similarities with PTI-like responses and its own special characteristics. Upon activation by phosphorylation, NIK1 phosphorylates ribosomal large subunit protein 10 (RPL10). Phosphorylated RPL10 is transported into the nucleus, where it partners with an RPL10-interacting MYB transcription factor to repress ribosomal protein genes, which subsequently results in global suppression of translation (Fig. 18.9).[241,355] As a viral counter defense, begomovirus nuclear shuttle protein inhibits the NIK1-mediated antiviral signaling. The CP of plum pox virus (PPV; family *Potyviridae*) suppresses PTI.[204] The MP of CMV (family *Bromoviridae*) suppresses ROS produced by other PTI responses as can the VSR P6 protein of CaMV (family *Caulimoviridae*),[140,356] indicating that P6 has a role both in suppression of RNA silencing and innate immunity.

Unfolded Protein Response in Regulation of Virus Infection

The unfolded protein response (UPR) machinery is important for plant viruses that rely extensively on the ER network for translation, replication, and cell-to-cell movement. Activation of UPR ameliorates necrotic symptoms caused by ER stress and gives the virus more space and time to replicate. Three ER stress sensors that contribute to the outcome of viral infection regulate separate but combined signaling cascades.[296] The major sensor is the inositol-requiring enzyme IRE1a and its isoform IRE1b, which are type 1 transmembrane protein kinase/endoribonucleases that recognize potyvirus 6K2 or potexvirus TGB3 proteins. As a response, IRE endonucleolytic cleavage of bZIP60 mRNA occurs, leading to production of a truncated, active bZIP60 transcription factor. Two other plant specific sensors are transcription factors bZIP28 and bZIP17, which have transmembrane domains that are proteolytically cleaved in response to environmental stresses. Once activated, bZIP60, bZIP28, and bZIP17 induce expression of genes involved in managing ER stress including chaperones for protein folding, cell fate determination, and innate immunity. A model was proposed in which bZIP60 and bZIP28 coordinate or overlap in their ability to activate genes that support potexvirus infection, while bZIP60 and bZIP17 coordinate to suppress infection.[71] bZIP60 and bZIP28 appear to restrict potyvirus infection while bZIP17 does not play a role.

CPR5, which anchors near the nuclear pore complex and restricts nuclear entry of bZIP60 and bZIP28, is a crucial inhibitor of ETI and modulates SA-dependent UPR. CPR5 is also associated with the recessive rym1 resistance to RYMV (family Solemoviridae) and resistance to CaMV (family *Caulimoviridae*), pepper mild mottle virus (PMMV; family *Virgaviridae*), and tobacco mild green mosaic virus (TMGMV; family *Virgaviridae*). The heterotrimeric G protein β subunit regulates the loads of CMV and TuMV as well as the spread of necrosis in Arabidopsis plants. Additional ER-resident factors that are involved in cell death regulation, autophagy, and Ca^{2+} signals include Bax inhibitor-1 (BI-1), C-cell lymphoma-2 (Bcl-2)-associated athanogene 7 (BAG7), NAC089, and NAC103, and their activities are coordinated with UPR responses that represent a complex network of interactions impacting potexvirus and potyvirus infection in Arabidopsis.[296]

Plant Viruses and Insect Vectors

More than 75% of plant viruses are transmitted by insect vectors such as aphids, leafhoppers, planthoppers, trips, and whiteflies. As climate change and global warming continue, insect populations are expanding; the number of migrations is rising; and migration distances are growing. This has led to an increase in insect vector-borne viral diseases affecting both cultured and uncultured plants.[165,334] This section summarizes some intriguing facets of plant-virus-vector interactions.

Transmission of viruses by insect vectors can be classified as either nonpersistent or persistent. Viruses transmitted in a nonpersistent fashion include CMV (family *Bromoviridae*), CaMV (family *Caulimoviridae*), and potyviruses, which are acquired by aphids feeding on epidermal cells of the host plant and then must be transmitted in a short timespan (seconds to hours) to uninfected plants. In nonpersistent transmission, virions are loosely bound to insect stylets and are not internalized into the gut (Fig. 18.10).[217] In persistent transmission, insect vectors require extended feeding time (hours to days) on an infected plant and stylets must penetrate the phloem for acquisition of the virus. Virions are then internalized in the insect gut system before moving out into the salivary glands. BYDV (family *Solemoviridae*) is transmitted by aphids in a persistent fashion but does not replicate within the aphids. Some plant viruses enter and replicate in the insect cells in these tissues, thus blurring the boundaries between insect and plant viruses. Most of the viruses transmitted by planthoppers, leafhoppers, whiteflies, and thrips, such as rice stripe virus (RSV; family *Phenuiviridae*), rice black streaked dwarf virus (RBSDV; family *Geminiviridae*), rice dwarf virus (RDV; family *Reoviridae*), and TSWV (family *Tospoviridae*), belong to this category (Fig. 18.11).[308]

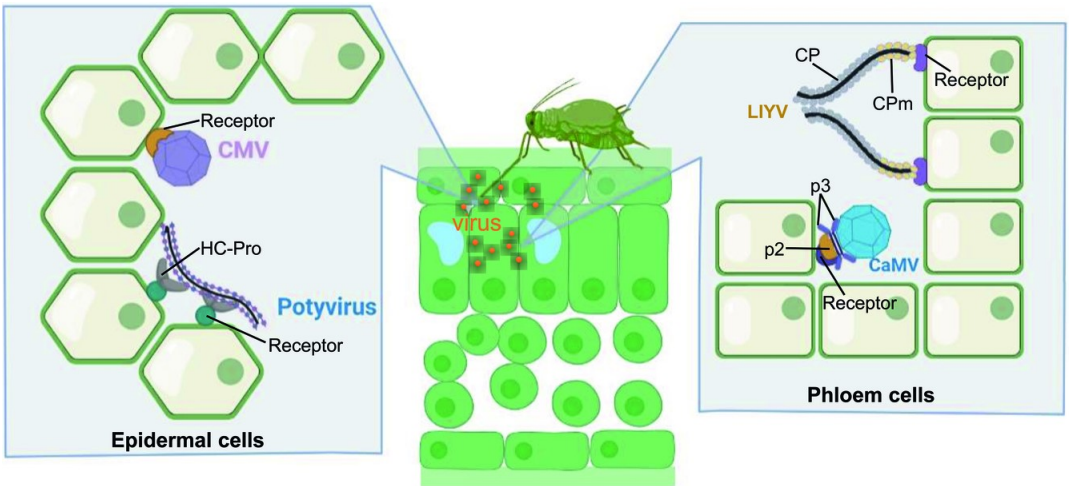

FIGURE 18.10 **Model depicting nonpersistent (*left*) and semipersistent (*right*) transmission of viruses by aphids**. Views in the *two black circles* are enlarged, showing the consequences of stylet penetrating the epidermis (*upper circle*) or phloem. Schematic diagram at *left* shows two strategies that nonpersistent viruses bind to aphid receptors. In the helper strategy, HC-Pro is indispensable for

binding between potyvirus CP and aphid receptors, which acts as a molecular bridge for potyvirus binding to the aphid stylet. In the capsid strategy, binding of CMV to vector receptors rely on amino acids in the CP directly. Diagram at *right* illustrates interactions between the sites in the vector's foregut and a semipersistent virus. CaMV binds to the insect's foregut with the help of viral-encoded protein p2 and p3. Two adjacent p3 can form a dimer on the surface of CaMV, with p2 helping the complex bind to the insect foregut. For lettuce infectious yellows crinivirus (LIYV), binding is mediated by the minor coat protein (CPm). (Figure is modified from Ng JCK, Falk BW. Virus-vector interactions mediating nonpersistent and semipersistent transmission of plant viruses. *Annu Rev Phytopathol.* 2006;44:183-212.)

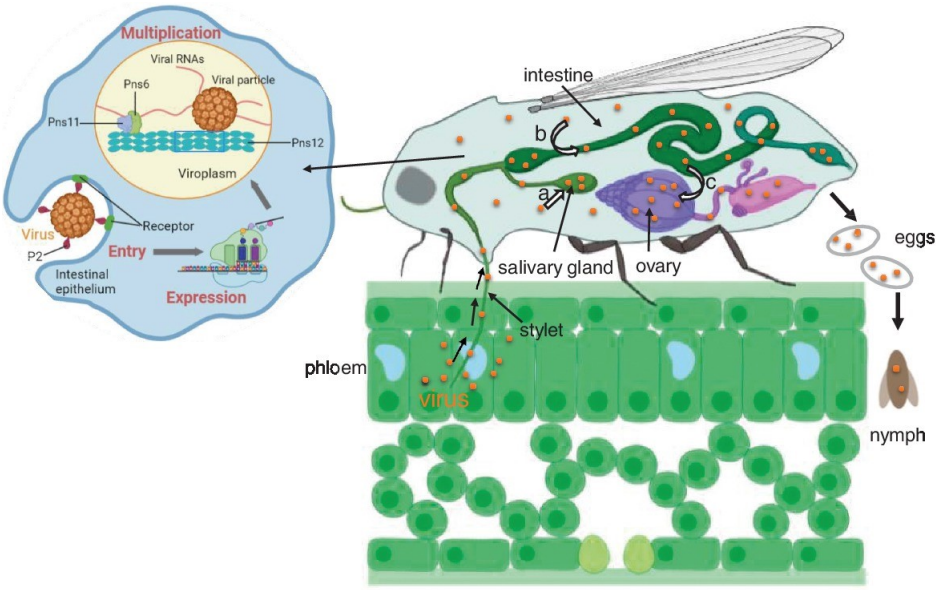

FIGURE 18.11 **Overview of infection routes of *Rice dwarf virus* (RDV) in its insect vector**. After the vector acquires RDV from infected plants, virions enter intestinal epithelium cells through outer capsid P2 protein-mediated membrane fusion and initiate replication cycles within insect cells. Letters (*a*, *b*, *c*) indicate three types of transmission barriers for RDV in the insect vectors: (*a*) salivary gland, (*b*) intestine, and (*c*) ovary, which are composed of different cell types and act as physical barriers to prevent viral infection. Diagram at left shows detailed replication cycle in insect cells. (Figure is modified from Wei T, Li Y. Rice reoviruses in insect vectors. *Annu Rev of Phytopathol.* 2016;54:99-120.)

Insect Vectors That Benefit From Feeding on Virus-Infected Plants

In a study published 70 years ago, the aphid population feeding on infected sugar beet plants grew faster than when fed on healthy plants.[128] Almost 40 years later, Fereres et al.[60] found that aphids [*Macrosiphum* (Sitobion) *avenae* (F)] feeding on BYDV-infected wheat had significantly shorter developmental times, greater fecundity, and a greater intrinsic rate of natural increase than aphids feeding on wheat that was virus free. More recent studies found that thrips (*Frankliniella occidentalis*) feeding on TSWV-infected pepper plants have greater juvenile survival and a shorter developmental rate, and invasive whiteflies (but not native whiteflies) feeding on plants infected with tobacco curly shoot virus (TbCSV; family *Geminiviridae*) or tomato yellow leaf curl China virus (TYLCCNV; family *Geminiviridae*) showed greater fecundity, longevity, and higher population density.[117] How these viruses increase insect vector fitness is not known, but evidence continues to accrue that coevolution between some viruses and their insect vectors can result in a mutualistic association.[28]

Viruses Modify Plant Metabolism to Enhance Transmission by Vectors

Phytohormones play essential roles regulating many aspects of a plant's life cycle, including seed germination, growth, development, responses to abiotic and biotic stress, and senescence. Phytohormones can also play a role in the plant's antiviral response as illustrated by infection of rice by RSV (family *Phenuiviridae*), whose CP enhances biosynthesis of JA, inducing a quicker and stronger antiviral response[308] (Fig. 18.12). To counter these antiviral properties, viruses also modulate phytohormone biosynthesis and signaling to benefit viral infection or the insect vector.[349] For example, the CMV 2b suppressor of RNA silencing suppresses JA-induced degradation of host jasmonate ZIM-domain proteins, thus increasing host attractiveness to insect vectors[315] (Fig. 18.12). JA is also reduced in TYLCCNV-infected tobacco plants by the virus ßC1 protein (also the suppressor of RNA silencing), making plants more attractive to B biotype whiteflies, thus increasing their population.[344] Virus infections can also modify the synthesis and/or signaling of other plant hormones such as SA, ethylene, and auxin.[349]

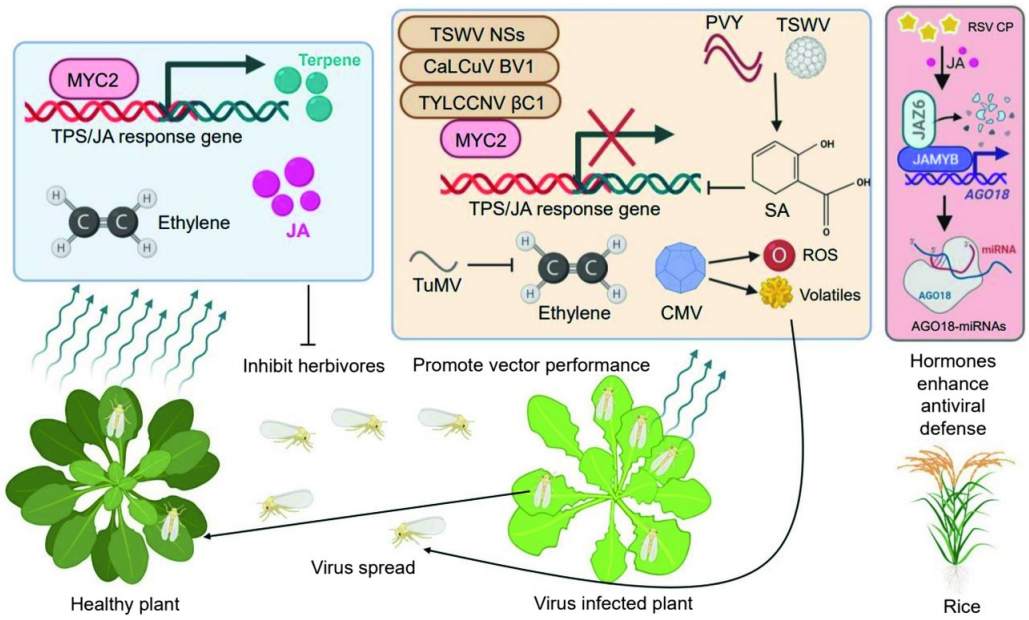

FIGURE 18.12 **Virus infection alters plant metabolism to promote insect vector performance**. Being a sessile organism, plants have evolved sophisticated mechanisms to manipulate plant hormones and volatiles to defend against insect herbivores. In healthy plants (*left panel*), feeding of herbivores actives JA signaling and other metabolic pathways. The virus can change the interplay between insect vectors and plants hormones/volatiles, thereby establishing a more attractive condition for their insect vectors (*middle and right panel*).

Guo et al.[83] found that WT CMV-infected tobacco plants produce higher concentrations of plant ROS than CMV that lacks the 2b gene (CMVΔ2b). Aphids feeding on WT CMV-infected tobacco plants engage in shorter probes and less phloem feeding compared with CMVΔ2b infected plants, which enhance virus acquisition and virus load, which is attributed to virus-induced accumulation of H_2O_2.

Other Virus-Induced Metabolic Modifications That Benefit the Vector

As described earlier, plants initiate sophisticated defenses when attacked by pests or viral infection. In addition to plant hormones and ROS, other signaling pathways also result in the production of defensive compounds. Terpenoid synthesis is induced in whitefly-infected plants but repressed in TYLCCV-infected plants by the ßC1 protein interacting with transcription factor MYC2.[174] This interaction suppresses activation of MYC2-regulated terpene synthase genes, thereby reducing whitefly resistance[166] (Fig. 18.12). In nonpersistent transmission, viruses like BYDV, potato leafroll virus, and CMV induce the production of plants volatiles to attract aphids. However, aphids with already acquired viruses are repelled by volatile cues released from viruses-infected host plants, leading them to feed on uninfected plants to enhance virus spread.[20,28,55,187]

In many virus-vector-host combinations, virus infection makes host plants more fit for insect colonization and in turn, the insect vector spreads the virus to new host plants. For aphid-CMV and leafhopper-RDV combinations, insect vector transmission is also important for filtering virus mutations and maintenance of genomic stability.[162,235] These intricate virus-insect-vector-host interactions, which can also be affected by environmental factors such as red-light[348] and involve symbiotic bacteria, are not always mutualistic, and many more studies are needed before a more complete understanding of these complex interactions is available.

Beneficial Plant Viruses

Plant Viruses That Benefit Their Hosts

Plant-virus interactions span the spectrum of parasitic to mutualistic.[245] Mutualism was recently recognized when some viruses were found to enhance the physiological performance of plants under abiotic stress, especially drought stress.[42] For example, BMV (family *Bromoviridae*), CMV (family *Bromoviridae*), TMV (family *Virgaviridae*), or tobacco rattle virus (TRV; family *Virgaviridae*) delay the onset of drought symptoms in *N. benthamiana* plants.[328] BMV also confers drought tolerance to rice plants, and CMV has the same affect in nine other host plants,[328] with changes linked to differences in host transcriptomes. Under normal watering conditions, CMV, PPV (family *Potyviridae*), and PVX (family *Alphaflexiviridae*) reduce plant growth and cause obvious foliar diseases. However, when water was deprived for 8 or more days, virus-infected plants showed better growth response than mock-treated plants.[2] The CMV 2b and the PVX TGB1 silencing suppressor proteins were implicated as important factors regulating stomatal conductance and transpiration, which were implicated in increased drought tolerance.[2,313] Interestingly, these conditional benefits were independent of antiviral gene silencing.

Drought tolerance in plants is regulated by a complex dynamic signaling network involving plant hormones SA, ABA, and JA. SA levels are elevated early in the infection by a wide range of plant viruses and contribute to induced systemic resistance to virus infection. ABA levels are induced by TMV, TuMV (family *Potyviridae*), CMV, BMV, TRV, and BaMV (family *Alphaflexiviridae*).[5,183,335] Combined elevation of SA and ABA can offset the hormones' normally antagonist roles impacting virus defenses.[4] The 2b and TGB1 proteins of CMV and PVX interfere with the balance of SA and ABA, which is linked to improving host tolerance to drought.[2,4] These studies are the key to gaining new understandings of disease, emergence of new pathogenic strains, and the evolution of plant defenses.[97]

Plant Viruses as Delivery Vehicles for siRNAs and Proteins

Both RNA and DNA plant viruses can serve as VIGS vectors, an RNA interference-based method for production of siRNAs that can control host gene expression and target other viruses, fungi, bacteria, nematodes, and insect pathogens without modifying the host genome.[16,149,173,257,352] VIGS can be used for any plant species following identification of a mild or asymptomatic virus that can infect the designated plant, and identifying suitable sites within the viral genome that can be disrupted by inserts without compromising infectivity of the virus. Inserts are commonly made between two ORFs in a virus that expresses its genome through synthesis of a polyprotein (eg, potyviruses) or by generation of a new sgRNA through manipulation of a sgRNA promoter (eg, PVX). VIGS vectors are usually delivered manually (by rub inoculation) or by agroinfiltration, a method where a cDNA copy of the (+)RNA virus genome is sandwiched between a strong plant promoter (usually the 35S promoter from CaMV) and a transcription termination sequence and added to a segment of the Ti plasmid of *Agrobacteria tumefaciens*, followed by syringe or vacuum infiltration of the bacteria into the plant. The bacteria then naturally excise and deliver a portion of the plasmid (the T-DNA) into a cell's cytoplasm, which eventually enters the nucleus where the viral genome is transcribed and then delivered into the cytoplasm where it is translated and replicated. Since viruses are naturally targets of RNA silencing, and the process (for RNA viruses) results in the generation of fully dsRNAs (by transitive silencing—described above) that are excellent templates for cellular dicer enzymes,[343] any additional sequence added to the viral genome will be in the siRNA population derived from the virus, which spread through the plant.

Prior to VIGS, downregulation of gene expression required the generation of transgenic plants, a process that can take years. With VIGS, transient downregulation of a gene of interest is achieved within weeks.[130] Viruses with wide host ranges, such as TRV and PVX, have become common tools in a plant molecular biologist's tool box for transient downregulation of host gene expression.[49] A recent important application of VIGS was for altering gene expression during the growing season in annual crops.[283] Viral genomes were delivered by either spraying virions or Agrobacteria carrying the viral genome directly onto annual crops to induce or repress flowering, change plant stature, alter drought sensitivity and fruit color, as well as other traits. The major drawback to VIGS vectors is the lack of stability of even short inserts, which currently preclude their use in long-lived trees and vines.

Plant Viruses and Biotechnology

Virions of plant viruses can be defined as biologically generated nanoscale structures with uniform physicochemical properties including icosahedral virions in the range of 30-70 nm and high-aspect-ratio rods and filaments of 300-2000 nm in length and 10-20 nm in width. Atomic resolution crystallographic and cryo-EM structures of plant viruses have paved the way for their development into nanobiotechnology devices.[269] Plant viral nanoparticles (VNPs) and empty viruslike particles (eVLPs) have been investigated as nanocarriers of a diverse number of reagents, including imaging compounds, immunomodulators, therapeutics, enzymes, and agrochemicals, for use in applications as nanoreactors, biosensors, and components in tissue engineering, batteries, photovoltaics, plasmonics, nanowires, transistors, and memory devices.[46,54,136,312]

The repetitive nature of CP subunits in virions provides a chemically uniform, multivalent platform for the selective loading of various active ingredients through genetic engineering, chemical bioconjugation, biomineralization, and encapsulation. Genetic engineering can be utilized both to modify surface-exposed amino acids and to fuse useful peptides and proteins that exist external to the virus particles.[26] The inner central channel and the surface of viruses can also be exploited as biotemplates for metal and semiconductor nanowire formation, with genetic modification of the surface to improve the affinity of different metals.[66] As examples of mineralized rod-shaped TMV (family *Virgoviridae*) templates, Au/Pd-TMV alloy nanowires have potential uses as high temperature resistors, hydrogen permeation membranes, multilayer capacitors, and magnetic memory storage materials,[168] and TMV-CdS nanowires with photocatalytic activities have been produced.[331] Encapsulation of cargo molecules to eVLPs is triggered by the surface charge, electrostatic interactions, and other binding properties of the CP sequences forming the internal surface of the eVLPs. The icosahedral cowpea chlorotic mottle virus (CCMV; family *Bromoviridae*) particle, 18 nm in diameter, has excellent properties for use as protein cages.[19] Disassembled CCMV CP subunits can reassemble under suitable pH conditions into eVLPs capable of encapsulating enzymes to form nanoreactors, as well as other types of molecules. In a recent study, nanodiamonds were encapsulated by CCMV CPs to be used as a tool in cell biology studies, given their excellent optical properties and high stability under physiological conditions.[324]

Ease and cost of production and purification affect the viability of nanobiotechnology platforms.[268] Examples of plant viruses that are frequently used for biotechnological applications include icosahedral cowpea mosaic virus (CPMV; family *Secoviridae*), flexuous rodlike structure PVX (family *Alphaflexiviridae*), or rigid rodlike shape TMV.[293] When produced via infection, these viruses are high yielding, but modifications to engineer VNPs are restricted to those that still retain infectivity of the virus. eVLPs have no such restrictions, and those produced from recombinant CPs expressed in bacteria, yeast, or in planta provide more flexibility than infection-derived VNPs. Expression of the CP and self-assembly into eVLPs is often effective with isometric plant viruses such as CPMV, where eVLPs can easily be produced in gram amounts in *N. benthamiana*.[250] *In vitro* assembly of viral CP with RNA operates in small-scale applications with TMV RNA, where the origin of assembly sequence (OAS) is sufficient to control capsid formation.[204] Skillful use of OAS allows for the construction of VLPs with the most imaginative shapes, such as nanoboomerangs and tetrapods.[53] A recent study showed that in planta production of eVLPs from papaya mosaic virus (PapMV; family *Alphaflexiviridae*) and alternanthera mosaic virus (AltMV; family *Alphaflexiviridae*) was more efficient when the CPs were expressed from a replicating PVX-based expression vector compared with expression from a nonreplicating vector, suggesting that replicating vectors make more effective scaffolds for VLP assembly.[279]

An asset of plant VNPs, especially in medical applications, is that they are noninfectious in mammals. Plant VNPs are currently in development as efficient generators of next generation of thermostable vaccines for regional fabrication and as immunomodulators with remarkable efficacy in animal models of various cancer types.[39] Examples of plant VNP-based approaches for *in vivo* medical applications include targeting of VNPs to tumors, VNPs for high-resolution imaging purposes, and VNPs for drug delivery.[54] Filamentous viruses are well suited for drug delivery and bioimaging applications because they can penetrate tissues and colonialize tumors efficiently.[263] A recent study comparing PVX and pepino mosaic virus (PepMV; family *Alphaflexiviridae*) filaments as VNPs showed that despite their similar sizes, they have different tumor homing properties and tissue specific distribution.[154] This indicates that full exploitation of the potential of plant VNPs for health applications requires that the optimal VNP is identified for each purpose.

Epilogue

Since the last edition of Field's Virology, there has been a revolution in our understanding of the complex relationships between plant viruses and hosts and we regret the limited amount of information that could be presented in this single chapter. Plant viruses are now envisioned as both exploitive of their hosts for replication and their insect vectors for transmission, and as existing in mutualistic associations for the benefit of one or both partners under certain environmental conditions. The arms race between viruses and their hosts has been further clarified with the addition of an ever-increasing number of co-opted proviral host factors leading the host to deploy similar proteins to disrupt these finely tuned processes. Increasing numbers of asymptomatic viruses are being identified from large scale sequencing studies and novel viruslike infectious agents are being discovered (e.g., ulaRNAs that use host MPs) that do not conform to the traditional definition of plant viruses. The likely linkage between replication and movement at MCS near PD has finally provided an explanation for one of the enduring mysteries of plant viruses: how MPs traffic cognate viruses exclusively without binding the gRNA specifically. Plant viruses are also increasingly finding usages in biotechnology, as manipulatable nanoparticles and as vectors for delivery of beneficial components into plants. While these remarkable advancements have been highlighted here, we also note that climate change and increasing cultivation of natural acreage are leading to the emergence of viruses that are threatening food security and the economies of countries overly dependent on a few crops. The continued lack of products for combatting virus infections in both annual crops and long-lived trees and vines cries out for researchers to convert their maturing understanding of host-virus-vector interactions into real life solutions (since genetic engineering of resistance into plants is unfortunately being rejected by growers and consumers). With bright minds entering the field, and with the availability of sufficient resources, we hope that these solutions will occupy a significant portion of the Plant Virus chapter in future editions of Field's Virology.

Acknowledgments

The authors would like to thank all of the investigators in our labs and in labs throughout the world, past and present, whose dedication to deciphering the interactions between plant viruses and their hosts have made this chapter possible. Research in the Simon lab is supported by USDA NIFA ECDREP-2020-08455, NSF-EAGER MCB-2034359, NSF-EAGER 1912025, and NSF MCB-1818229; Research in the Mäkinen lab is supported by Academy of Finland 332950; and research in the Li lab is supported by NSFC (32090010) and 2021YFA1300702.

Impact of Insect Viruses

Insects comprise well over half of the existing animals on earth. They include an estimated 5.5 million species and represent some of the most diverse and successful animals on the planet.[302] Accordingly, the RNA and DNA viruses infecting insects are also highly diverse, the likely result of 350 million years of coevolution with their hosts. Because insect viruses inflict disease and mortality in their hosts and multiple virus species can cross over into vertebrates and plants, they have long been of concern for human health and agriculture. Hence, much of the early research on these diverse viruses was dedicated to understanding the impact of pathogenic insect viruses on human health and agriculture, insect control included. As molecular studies of insect viruses advanced, it was recognized that these obligate parasites also provided valuable tools for investigating fundamental questions in cellular and molecular biology. Such studies have led to advances and direct applications in many fields, including biochemistry, cell biology, biotechnology, gene therapy, vaccine production, epidemiology, and insect management.

Discovery and Classification of Insect Viruses

Insects are susceptible to highly diverse families of DNA and RNA viruses (Table 19.1). While some insect virus families contain members that exclusively infect arthropod hosts, other virus families contain members that infect both invertebrate and vertebrate hosts. Indeed, many insect virus families have the capacity to multiply in vertebrate hosts upon introduction by an insect vector, causing numerous well-known and prevalent diseases. Some insect virus families have closely related counterparts that exclusively infect vertebrate hosts. For example, the invertebrate subfamily *Entomopoxvirinae* and the vertebrate subfamily *Chordopoxvirinae* are both part of the larger *Poxviridae* family. Interestingly, insect viruses often have novel properties that are common amongst insect-specific virus families and function to facilitate invertebrate infection. A striking example is the existence of an occluded virus particle for virus transmission between insect hosts. This morphological feature is conserved among diverse virus families, including the baculoviruses (*Baculoviridae*), entomopoxviruses (*Poxviridae*), cypoviruses (*Reoviridae*) and possibly the nudiviruses (*Nudiviridae*).

TABLE 19.1 Virus families infecting the insects

Characteristics	Virus Family	Genus	Representative Member
dsDNA, enveloped	Baculoviridae	*Nucleopolyhedrovirus*	*Autographa californica* multiple NPV (Ac*M*NPV)
		Granulovirus (GV)	*Cydia pomonella* GV (CpGV)
	Polydnaviriformidae	*Ichnovirus*	*Campoletis sonorensis* ichnovirus (CsIV)
		Bracovirus	*Cotesia melanoscela* bracovirus (CcBV)
	Ascoviridae	*Ascovirus*	*Spodoptera frugiperda* ascovirus 1a (SfAV-1a)
	Nudiviruses	*Alphanudivirus*	*Oryctes rhinoceros* virus
		Betanudivirus	*Heliothus zea* virus 1 (HzV-1)
	Poxviridae	*Alphaentomopoxvirus*	*Melolontha melolontha* entomopoxvirus
		Betaentomopoxvirus	*Amsacta moorei* entomopoxvirus "L"
		Gammaentomopoxvirus	*Chironomus luridus* entomopoxvirus
dsDNA, nonenveloped	Iridoviridae	*Iridovirus*	Invertebrate iridescent virus 6 (IIV-6)
		Chloriridovirus	Invertebrate iridescent virus 3 (IIV-3)
ssDNA, nonenveloped	Parvoviridae	*Densovirus*	*Junonia coenia* densovirus
		Pefudensovirus	*Periplaneta fuliginosa* densovirus
		Brevidensovirus	*Aedes aegypti* densovirus
		Iteravirus	*Bombyx mori* densovirus
dsRNA, nonenveloped	Reoviridae	*Orbivirus*	Bluetongue virus
		Cypovirus	Cypovirus 1 (ie, BmCPV)
		Coltivirus	Colorado tick fever virus
		Seadornavirus	Banna virus
		Idnoreovirus	Idnoreovirus 1
		Fijivirus	Fiji disease virus
		Phytoreovirus	Wound tumor virus
		Oryzavirus	Rice ragged stunt virus
	Birnaviridae	*Entomobirnavirus*	*Drosophila* X virus
ssRNA, enveloped	Togaviridae	*Alphavirus*	Sindbis virus
	Flaviviridae	*Flavivirus*	Yellow fever virus
	Rhabdoviridae	*Vesiculovirus*	Vesicular stomatitis Indiana virus
	Bunyaviridae	*Orthobunyavirus*	Bunyamwera virus
		Phlebovirus	Rift Valley fever virus
		Nairovirus	Dugbe virus
Retrotransposons	Metaviridae	*Errantivirus*	*Drosophila* gypsy virus
		Semotivirus	*Bombyx mori* Pao virus
ssRNA, nonenveloped	Nodaviridae	*Alphanodavirus*	Nodamura virus, Flock House virus
	Tetraviridae	*Betatetravirus*	*Nudaurelia capensis* β virus
		Omegatetravirus	*Nudaurelia capensis* ω virus
	Dicistroviridae	*Cripavirus*	Cricket paralysis virus
			Drosophila C virus
	Iflavirus	*Iflavirus*	Infectious flacherie virus (IFV)
			Deformed wing virus
			Slow bee paralysis virus

Many insect viruses were originally discovered by their associated disease and subsequently classified by using standard methods for virus isolation, biochemical characterization, and genetic analyses. Recently, high throughput, next-generation sequencing of invertebrate genomes has led to the discovery of an enormous number of hitherto unknown insect viruses.[27] On the basis of sequence similarities, some of these new viruslike entities are members of previously known virus families infecting both invertebrates and vertebrates while others represent newly discovered families.[291,351] In surveys of >200 insect species, the RNA viruses predominate; the scale is enormous. These putative viruses were identified by their gene sequences that share distant similarity to known RNA-dependent RNA polymerases, which represent the most conserved of the RNA virus genes. Fewer DNA viruses related to known DNA virus families or having similarity to known DNA-dependent DNA polymerases have been identified in these surveys. These RNA and DNA elements are putative viruses as they have only been identified by metagenomic analyses.[291,351] While some of these putative viruses could represent chronic, latent, or asymptomatic infections, others could be derived from microorganisms associated with the insect or the insect's meal acquired prior to analysis. Interestingly, another source of virus-related sequences in insects are those likely derived by reverse-transcription (the activity of endogenous retro-elements) of insect RNA virus genomes that integrate within the host genome or are stably maintained.[109] These full-length or partial genomic sequences can function in an antiviral response that uses the well-characterized RNA interference (RNAi) machinery of insects.[258] Much work remains to verify the infectious nature of viruslike metagenomic sequences and to subsequently evaluate their potential applications.

This chapter describes those characterized viruses that multiply primarily or exclusively in insects: baculoviruses, polydnaviruses (within *Polydnaviriformidae*), ascoviruses, nudiviruses, nodaviruses, tetraviruses, and the dicistroviruses. Viruses such as the arboviruses in which insects serve as host vectors during transmission to vertebrates are described in other chapters. Insect virus families such as the

entomopoxviruses, densoviruses, iridescent viruses, cypoviruses, and iflaviruses have also been described elsewhere.[3,117,155,160,355]

Biology, Virus Interactions, and Virus Evolution

Biochemical and genetic studies on insect virus multiplication and host pathogenesis have contributed enormously to our understanding of molecular and cellular biology, virus structure and assembly, virus-host interactions, and disease states. These advances are due in a large part to the diversity of insect viruses and the availability and convenience of cell cultures or live insects in which to propagate viruses. Such systems, when combined with the ease with which insect viruses can be engineered or genetically manipulated, provide remarkably high yields of virus particles or virus-encoded macromolecules for studies of gene structure and biochemical function. There are also distinct experimental advantages to the use of many insect hosts, including those with sequenced and annotated genomes. Compared to vertebrates, insects exhibit limited genetic redundancy, a property that has simplified studies on host-virus interaction pathways. Finally, there exists a striking conservation of genes and genetic pathways between insects and mammals. Thus, discoveries from studies of insect viruses and their hosts have led to important biological insights for all animals, humans included.

Insect viruses have provided fundamental information on cell biology and virus-host interactions. For example, the insect cypoviruses of the family *Reoviridae* were the first to reveal the critical nature of the 7-methyl GpppN cap on eukaryotic mRNAs.[100] Novel internal ribosomal entry sites (IRES) and new mechanisms for initiation of protein synthesis[143] have been revealed by studies of cricket paralysis virus of the family *Dicistroviridae*. The nodaviruses provided the first example of an animal (insect) virus-encoded suppressor of host RNA silencing (RNAi)[192]; RNAi suppressors have now been identified in multiple animal viruses. Studies on the nodaviruses have also revealed new macromolecular structures responsible for RNA-dependent RNA polymerase-mediated RNA replication in membrane-bound vesicles, which may be common among multiple positive-sense RNA virus families.[325,326] The discovery of baculovirus-encoded inhibitor of apoptosis (IAP) genes led to the identification of IAP homologs in animals and subsequently established the critical role of IAPs in regulating apoptosis in normal development, immune function, and human diseases, including cancer and neurodegeneration.[59,231,298] The baculoviruses encode other novel suppressors of apoptosis that have provided important insight into the role of apoptosis as an antiviral defense in insects and mammals.[58] Lastly, the polydnaviruses have disclosed a remarkable advantageous relationship between virus and host that involves virus-mediated immune suppression that facilitates virus and host survival.[304,305] Thus, insect viruses have collectively provided key understanding in numerous aspects of cell biology, pathogenesis, and host-virus interactions.

Insect viruses have also provided unique insight into virus evolution. Due to the close association of insects with plants and other animals, natural exchange and mixing of viruses is accelerated. Insect viruses within the families *Poxviridae*, *Rhabdoviridae*, *Reoviridae*, *Picornaviridae*, and *Parvoviridae* have vertebrate counterparts, leading to speculation that viruses of higher animals arose from insect virus ancestors. Certain insect viruses have coevolved with unrelated insect virus families. For example, it is likely that the DNA baculoviruses and the retroviruslike errantiviruses, both of which coexist or multiply in lepidopteran hosts, have exchanged envelope fusion protein genes as suggested by the striking the sequence similarity of these proteins.[252,275] Thus, despite their dissimilar replication strategies, these viruses may have coevolved. The striking conservation of specific genes among diverse insect virus families, including baculoviruses, entomopoxviruses, orthomyxoviruses, ascoviruses, and iridoviruses as well as the recently discovered relationship between viruses of *Polydnaviridae* (*Polydnaviriformidae*) and *Nudiviridae* is consistent with coevolution of invertebrate viruses. It is noteworthy that certain DNA viruses of insects also readily accommodate host-derived transposons and retroid elements, which are especially abundant in arthropods. Stable retention of such host-derived mobile genetic elements facilitates virus evolution and likely contributes to the exchange of genes between virus and its host organism.[105,107]

Expression Vectors for Foreign Genes

Among eukaryotic viruses, the insect viruses are among the best known for their use as vectors for foreign gene expression because of their productivity, efficiency, and utility. The most widely used vectors are those derived from the helper-independent baculoviruses.[44,50,157,166,173,327] This widespread biotechnological application is the direct result of intense molecular studies on baculovirus genetics, biochemistry, and multiplication strategies; it represents a striking example of the utility of insect viruses for basic and applied research. The remarkable strength of very late baculoviral promoters, the high level of virus multiplication, the extraordinary capacity for protein synthesis in cultured insect cells, and the ability to maintain large foreign DNA inserts are the principal factors that contribute to the efficiency and popularity of baculoviruses as eukaryotic expression vectors. The most used baculovirus expression vector system is that derived from *Autographa californica* nucleopolyhedrovirus (Ac*M*NPV), a nuclear-replicating DNA virus that can generate virus-specific macromolecules that comprise well over one-third of the mass of the infected cell. Thousands of different heterologous proteins have been expressed and subsequently studied by using the Ac*M*NPV vector system since its original development in the early 1980s by the independent laboratories of Max Summers and Lois Miller.[255,295]

Baculovirus vectors have been improved significantly for speed of recombinant virus generation, purification, and production of a large variety protein types, including cytoplasmic, nuclear, secreted, and membrane-associated polypeptides.[259] Methods for recombinant vector production are now efficient and routine. Strategies for insertion and simultaneous expression of multiple genes or for temporally regulated, promoter-specific expression are available. Since posttranslational modifications and biological activity of the resulting protein products often mimic or parallel that of mammalian cells, these vectors have provided abundant material for applications in diagnostics, therapeutics, and vaccine development, as well as general studies on protein structure and function. Like other expression systems, however, baculovirus vectors have advantages and disadvantages that depend on the type of protein to be produced.[157,259,327] Insect cell lines have also been improved by adaptation to serum-free media and specific engineering for glycosylation of protein products that mimics that of mammalian cells.[157] Live insect larvae have also been used as effective and convenient large-scale bioreactors for the production of high levels of many important proteins. For example, *Bombyx mori* nucleopolyhedrovirus (BmNPV) has been used as an efficient vector for protein production in silkworms.[166] For FDA-approved antigen preparation, baculoviruses have also been used to express heterologous proteins and peptides.[173,327]

The promoters for certain immediate early baculovirus genes are highly active in the absence of virus proteins.[175,178,266,318] As a result, several of these baculovirus promoters, including those for the IE1 and IE2 genes, have been used extensively for high-level gene expression in diverse lepidopteran and dipteran insects by transient transfections or the generation of stable cell lines.[137] This approach allows long-term, high-level expression in the absence of virus vectors.

It is noteworthy that other insect viruses, including the entomopoxviruses,[256] densoviruses, and alphaviruses, have also been exploited as expression vectors. Likewise, flock house virus of the RNA virus family *Nodaviridae* has been used to express foreign epitopes on the surface of its icosahedral virion particle.[333] FHV has also been used as a dsRNA delivery vector for RNAi-mediated gene silencing.[314]

Gene Transduction, Delivery, and Gene Therapy

As a result of recent advances, the baculovirus Ac*M*NPV has been used effectively as a gene transfer vector for a surprising variety of vertebrate cells, including those from mammals.[50,239,281] Although baculoviruses can enter mammalian cells, they do not multiply nor cause widespread cell death. Thus, when inserted into the baculovirus genome under control of appropriate mammalian transcriptional signals (promoters and enhancers), foreign genes can be delivered and expressed after inoculation of mammalian cell lines in a process referred to as "transduction." Expression is transient and levels vary depending on the protein, the mammalian promoter used, and the target cells. The mechanism of virus entry is poorly understood and is likely different depending on cell or tissue type. The Ac*M*NPV envelope fusion protein GP64 (see below) is required (see below).

Because of its lack of multiplication in mammalian cells, its low cytotoxicity, the capacity for foreign gene expression, and its high transduction efficiency, Ac*M*NPV has also been evaluated as a gene therapy vector.[50,239,281,344] Applications have included its use in cancer therapy, regenerative medicine, vaccine vectors, and gene product ablation by RNA interference. In the case of baculovirus-mediated cancer therapeutics, tested approaches include virus-mediated expression of tumor-specific antigens for anticancer vaccines, introduction of functional tumor suppressors (eg, P53) or proapoptotic genes, and the delivery and expression of suicide genes that confer tumor-specific susceptibility to select toxins or chemotherapeutics drugs. It is expected that these novel therapeutic approaches that exploit insect viruses will receive more attention in the future. Indeed, Ac*M*NPV vectors have already found use in the production of adenovirus-associated virus gene therapy reagents.[161,259,280]

Biopesticide Viruses for Insect Control

While comprising over 80% of the existing animal species on earth, many insects present serious biomedical adversity for humans and cause significant agricultural and forest damage on a worldwide scale. Thus, environmentally safe means of controlling insect populations is a major objective. Insect populations are naturally held in balance by predation, parasitism, and infection by microbial pathogens. Of these diverse factors, viruses have numerous practical advantages for deployment as insect control agents and already represent viable components in current integrated pest management strategies.[45,183,275]

In nature, viruses cause widespread epizootics and morbidity in insects, especially within dense populations. Spontaneous epizootics by viruses have occurred frequently in agricultural and forest settings.[275] Nonetheless, dependence upon epizootics for insect control has been impractical due to the unacceptable levels of crop damage that occur before the pest population declines. Thus, much effort has been invested in the development of viral biopesticides for agricultural purposes. Several viruses have already been used as effective, safe, and highly specific biocontrol agents that have the added benefit of reducing dependence on broad-range, toxic chemical insecticides. Of these viruses, the DNA baculoviruses have received the most attention due to their relative safety in the environment, their insect-specific virulence, the capacity for large-scale production, and the availability of effective formulations for field application.[308]

As one of the most successful applications of viral pesticides, the baculovirus *Anticarsia gemmatalis* multiple nucleopolyhedrovirus (AgMNPV) has been used widely to control the soybean looper on a large scale, especially in Brazil.[221,309] Gaining popularity, *Helicoverpa armigera* nucleopolyhedrovirus (HearNPV) is also used extensively for control of *Helicoverpa* species (cotton bollworm or corn earworm), which are serious global agricultural pests. Marketed commercially in multiple countries, HearNPV rapidly prevents insect host feeding and causes high levels of mortality. It also has utility in integrated pest management programs for protecting genetically engineered field crops from *Helicoverpa* species,[358] which have developed synthetic insecticide resistance. In 1975, the Environmental Protection Agency registered the first baculovirus as an insecticide in the United States. Other baculoviruses have also been registered and their implementation has been pursued by U.S. companies and more recently by those of other countries.[23,221,308] Commercial development of virus insecticides has been sporadic due in part to restricted markets and limitations in efficacy of these biopesticides, including kill speed. Nonetheless, because the baculoviruses are amendable to genetic engineering, progress has been made to improve insecticidal efficacy by the insertion of insect-specific toxin or hormone genes.[180,309] Carefully controlled field tests of genetically improved baculoviruses have been conducted in several countries, including the United States and Great Britain.[29,221,275] It is expected that viral insecticides will have an expanded role in integrated pest management programs as insects acquire resistance to chemical pesticides and environmental concerns increase. This practical application should expand with continued discovery and characterization of other virus families (ascoviruses, iridoviruses, tetraviruses, entomopoxviruses, nodaviruses, dicistroviruses, and cypoviruses) that are also potent pathogens of insects.

Description of Insect Virus Families

Baculoviridae

Classification of Baculoviruses

Members of the family *Baculoviridae* have a large, circular genome of double-stranded DNA that is packaged within an enveloped, rod-shaped virion.[316] The family name is derived from the Latin term "baculum" (stick or staff) to describe the shape of the virion. These viruses are characterized by their two morphologically distinct forms of infectious particles: occluded virus (OV) comprised of enveloped virions embedded within a crystalline matrix of protein and budded virus (BV) consisting of a single nucleocapsid surrounded by a plasma membrane–derived envelope. The family consists of four genera.[316] The alphabaculoviruses and betabaculoviruses infect lepidopteran insects (moths and butterflies), whereas the gammabaculoviruses and deltabaculoviruses infect hymenopteran insects (wasps and sawflies) and dipteran insects (mosquitoes), respectively.[275,341] The alpha- and betabaculoviruses include the nucleopolyhedroviruses (NPVs) and granuloviruses (GV), respectively; these two virus groups are the best characterized of *Baculoviridae*. For GVs, a single virion is embedded within a large ovicylindrical-shaped OV particle, which collectively appears as "granules" in the light microscope. By contrast, the polyhedral-shaped OV

particle (polyhedra) of the NPVs has numerous (>20) virions. The OV are produced and accumulate in the nucleus of NPV-infected cells, whereas in GV-infected cells, intracellular OV assemble after the nuclear membrane disintegrates.

Baculoviruses infect well over 500 different species of insects. To date, virus isolates have only been identified in arthropods, mostly from insects of the order Lepidoptera. The NPV type species is *Autographa californica* multicapsid nucleopolyhedrovirus (Ac*M*NPV), which was isolated originally from and named after the alfalfa looper *Autographa californica*. The GV type species is *Cydia pomonella* granulovirus (CpGV), isolated from the codling moth *Cydia pomonella*. Baculoviruses usually have distinct and relatively narrow host ranges that are limited to insects within a single genus or family. However, some baculoviruses, such as Ac*M*NPV, have broad host ranges that include >40 lepidopteran species.

In the next sections, the molecular biology and biochemical mechanisms of baculovirus multiplication are described with the intention to compare these unique viruses to the DNA viruses of vertebrates and to highlight the properties of baculoviruses that have been exploited for important applications in biology, biotechnology, and insect management. Recent reviews describe additional details of baculovirus biology, host and cellular interactions, evolution, host range, and pathology.[26,63,135,246,275,320,341]

Baculovirus Structure: OV and BV

Baculoviruses have a biphasic multiplication cycle in which BV is produced before OV.[275,341] Both virus forms (Fig. 19.1) are infectious and contain one or more rod-shaped nucleocapsids (30-60 nm in diameter, 250-300 nm long). The nucleocapsid contains a single covalently closed circle of double-stranded genomic DNA that is associated with a 6.9-kDa protaminelike core protein.[342] The outside proteins of the nucleocapsid interact to form ringlike subunits stacked every 4.5 mm; these include one major ~40-kDa capsid protein plus additional minor proteins.[343] The apical end of the virion has a distinct structure consisting of several unique proteins and suggesting a specialized function.[334] One of these virion end-structure proteins is pp78/83, a Wiskott-Aldrich syndrome (WASP)-like protein that contributes to actin-mediated propulsion of nucleocapsids within the cell and facilitates nuclear actin assembly; pp78/83 is essential for the production of infectious progeny virus.[110]

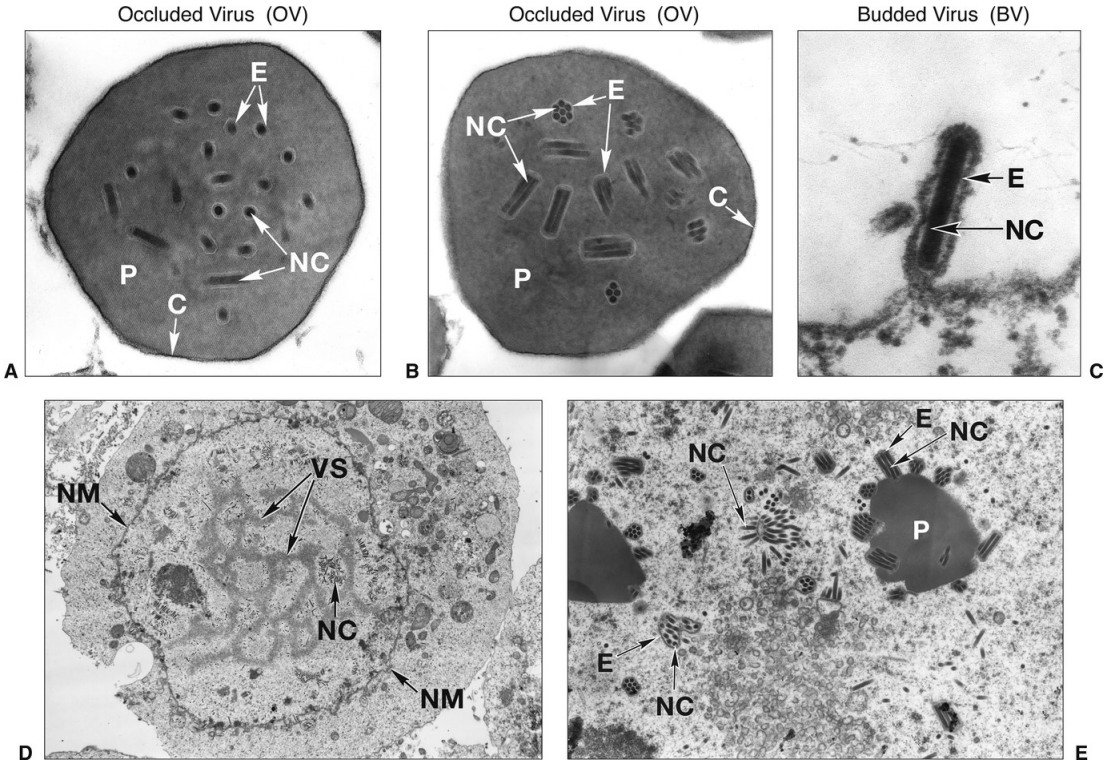

FIGURE 19.1 **Nucleopolyhedrovirus OV and BV particles**. **A**. Cross section of an OV particle from a single-capsid NPV (*S*NPV). Single nucleocapsids (NCs) are enveloped within a unit membrane (E) and embedded within a matrix of polyhedrin protein (P). The carbohydrate-rich calyx (C) covers the external surface of the particle, which is ~2-3 µm in diameter. **B**. Cross section of an OV particle from a multicapsid NPV (*M*NPV). The membrane envelopes (E) contain multiple nucleocapsids and are embedded within the polyhedrin matrix (P) of the particle. **C**. Budded virus (BV) particle during budding. The BV contains a single nucleocapsid (NC) (~30 × 250 nm) surrounded by a virus glycoprotein–containing envelope derived from the plasma membrane of the NPV-infected cell. **D**. Thin section of a typical cell in the late phase of *M*NPV infection. The virogenic stroma (VS) and associated nucleocapsids (NCs) are generated within the infected nucleus still contained by the nuclear membrane (NM). **E**. Enlarged thin section of an *M*NPV-infected cell nucleus early during the very late, occlusion-specific phase. Newly assembled nucleocapsids (NCs) associate with intranuclear membranes, are enveloped (E), and embedded within the polyhedrin matrix (P). (Electron micrographs were kindly provided by Dr. Malcolm J. Fraser Jr, University of Notre Dame.)

A distinctive feature of the baculoviruses is the large size (0.6-2 µm diameter) and polyhedral or oval shape of their OV particles (Fig. 19.1). The OV mediates virus transmission between insect larvae (caterpillar), which is the most susceptible developmental stage for infection. Upon ingestion, the OV protein matrix dissolves in the alkaline pH of the larva's midgut to release the occlusion-derived virions (ODV) that initiate infection of the midgut epithelium. The crystalline matrix of the OV is comprised primarily of a single ~29-kDa protein, designated either polyhedrin or granulin for the NPVs and GVs, respectively; these two proteins are closely related. The ODV of NPVs (Fig. 19.1A and B) are embedded in the matrix either as single nucleocapsids (*S*NPVs) or multiple nucleocapsids (*M*NPVs) that are surrounded by a single membrane

envelope. This nuclear-derived envelope contains virus-encoded proteins that are responsible for binding to midgut epithelial cells, the initial site of infection.[26,275,341] The membrane envelope is assembled *de novo* or represents a modified form of the nuclear membrane. On their surface, the mature OV particle has an additional covering of protein and carbohydrate known as the polyhedron envelope or calyx.

The BV form is produced prior to OV during infection. BV is responsible for cell to cell transmission within the infected insect. It is the infectious particle for inoculating cultured cells and thus is the form used for baculovirus-vector infections. The BV consists of a nucleocapsid surrounded by a loose-fitting membrane envelope that is acquired by budding from the plasma membrane of the host cell (Fig. 19.1C); it is, therefore, distinct from nucleocapsids embedded within OV. The envelope fusion protein (EFP) is the most abundant viral protein associated with the BV membrane. The NPVs are subdivided by their EFP type.[26,275,341] The EFP of group I NPVs (ie, Ac*M*NPV, Op*M*NPV) is GP64, whereas the group II NPVs (ie, Ld*M*NPV, Se*M*NPV) contain an F protein. GP64 is the best characterized of the baculovirus EFPs. It is a class III transmembrane glycoprotein that is required for efficient virus budding and BV infectivity[219]; BV can be neutralized by GP64-specific antiserum.[335,373] GP64 likely interacts with the host cell receptor or membrane components (still undefined in insects) and mediates membrane fusion upon activation by low pH in the endosome. Prefusion cleavage is not required. Detailed molecular studies[195,373] and the postfusion crystal structure[163] have revealed that GP64 is a stalklike, cross-linked trimer with an internal peptide domain comprised of fusion loops (similar to those of the vesicular stomatitis virus G protein) that are required for membrane fusion. However, the exact mechanism of GP64-mediated membrane fusion remains unclear. Because GP64 is essential for virus entry of mammalian cells during baculovirus-mediated gene transduction, it is used to facilitate entry of a variety of enveloped viruses into mammalian cells by using pseudotype strategies.[50,128,243,293]

Baculovirus Genome Structure

The baculovirus genome is a large (80-180 kbp) covalently closed, supercoiled circle of double-stranded DNA. To date, the complete nucleotide sequence of >170 baculoviruses, including viruses from each genus, has been reported. This abundance of genetic information has provided important clues regarding baculovirus functions, evolution, and host interactions.[275,341] There are ~30+ core genes that are shared by all baculoviruses and confer the distinctiveness to this unique family of insect viruses.[135,319] Certain conserved genes are essential for baculovirus transcription (during the early and late phases), viral DNA (vDNA) synthesis, vDNA packaging, and assembly of the OV and BV particles. Other core genes contribute specifically to baculovirus host range and the virus' unique life cycle within insects. Not surprisingly, certain genes are nonessential and thus dispensable for virus multiplication, especially in cell culture.

Ac*M*NPV is the best-studied baculovirus. Its 134-kbp DNA genome consists almost entirely of unique sequences that encode ~150 open reading frames (ORFs).[5,275] The ORFs are closely spaced on both DNA strands with no apparent organization with respect to temporal expression. Early, late, and very late genes are interspersed throughout the genome. Most ORFs are separated by only 2-200 nucleotides. These intergenic regions have a high adenosine/thymidine content and function as promoter or termination sequences. In addition, the translational termination codon (usually *UAA*) often overlaps the polyadenylation signal, AA*UAA*A. Multiple examples of overlapping ORFs exist. Interestingly, there are few introns in baculovirus genomes. A rare example of splicing involves the nonessential *ie*-0 gene and yields protein IE0 (see below), which is nearly identical to transcriptional activator IE1.[54]

Ac*M*NPV RNA transcripts often initiate from within or extend through adjacent genes, a phenomenon especially prevalent among viral RNAs late in infection.[51,94,205] Thus, numerous genes are transcribed into bi- or multicistronic RNAs wherein the upstream ORF is preferentially translated. The biological implication of this arrangement is unknown. There are also multiple examples of the transcription of overlapping and in some cases, antisense RNAs.[51] Thus, the interspersion of temporal classes of RNA transcripts may have functional or regulatory significance. For example, activation of the very late promoter of *polh*, the gene encoding the major structural protein (polyhedrin) of OV, downregulates overlapping, antisense RNAs initiated downstream of *polh*.[241]

A distinguishing feature of the baculovirus genome is the presence of multiple copies of interspersed repetitive sequences ranging in size from 30 to 800 bp that are designated homologous regions or *hr*s.[64,121] The *hr*s act as transcriptional enhancers[121,125] and probably function as origins of viral DNA replication.[170,251] Ac*M*NPV contains eight *hr*s, which account for 3%-4% of the genome. The *hr*s have a complex modular organization consisting of ~60-bp repeats, each with a highly conserved 28-bp imperfect palindrome (28-*mer*). The 28-*mer* is the minimal sequence required for orientation- and position-independent enhancement of promoter activity and DNA replication.[188,272] The *hr*s bind host- and virus-specific proteins. In particular, the transcriptional activator IE1 binds as a dimer to the palindromic 28-*mer* in an interaction that is required for IE1-mediated stimulation of enhancer activity.[174,188,273] Deletion of a single *hr* (either *hr1*, *hr1a*, *hr2*, *hr3*, *hr4a*, *hr4b*, or *hr5*) from the Ac*M*NPV genome reduces transcription of proximal genes but has no significant effect on vDNA replication or virus multiplication.[41,272] Sequential removal of all eight *hr*s from the AcMNPV genome compromised but did not eliminate virus production.[31] Whereas the *hr*s are not absolutely required for virus multiplication in cell culture, their functional significance remains unclear. Nonetheless, the novel distribution and repetition of the *hr*s or *hr*-like elements within the genome of multiple baculoviruses suggest that they have a critical role in the virus life cycle.

Stages of Baculovirus Replication

Primary and secondary infection

Baculovirus multiplication in the insect larva is divided into primary and secondary stages, which refer to the initial infection of larval midgut cells and the subsequent infection of secondary tissues, respectively (Fig. 19.2). Although virus binding to the host cell initiates infection in both stages, aspects of primary and secondary infections differ. Secondary infection in the larva (caterpillar) most closely resembles that of cultured cells. Most of the details of Ac*M*NPV replication (described below) have been obtained through studies of high multiplicity infection of cultured SF21 (or clonal SF9) cells, a convenient cell line derived from the nocturnal moth *Spodoptera frugiperda* (Lepidoptera; noctuidae). It should be appreciated that the timing of replication events often varies between viruses and insect hosts.

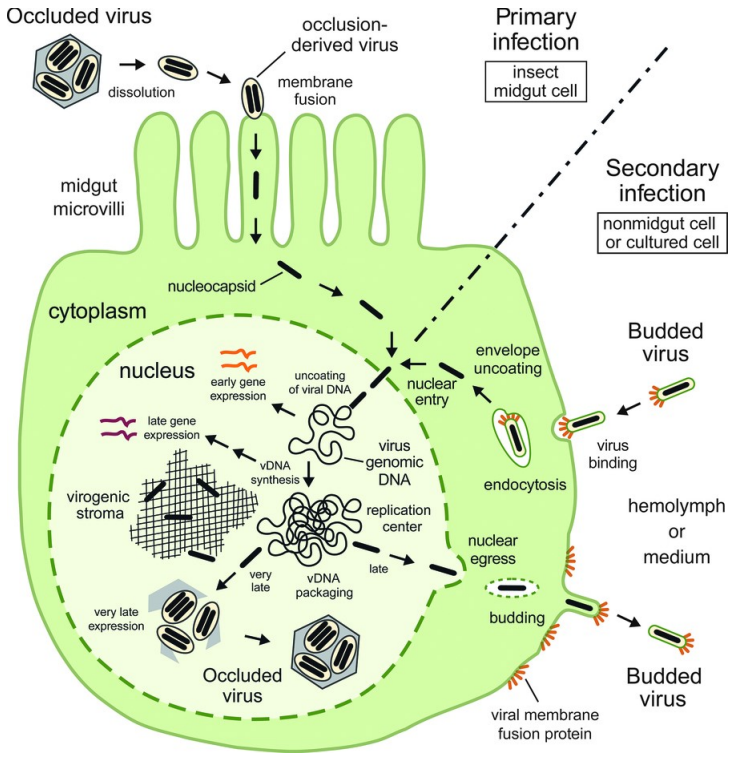

FIGURE 19.2 **Baculovirus multiplication cycle**. Except for the virus particle and the route of its entry, most steps in the baculovirus infection cycle are identical for an insect midgut epithelial cell (primary infection) or a subsequently infected nonmidgut cell (secondary infection). The steps for BV infection of a permissive cultured cell are the same as that for a secondary infection. Upon infection of a midgut cell by OV (*top*), the polyhedrin matrix of larval-ingested OV dissolves in the midgut lumen to release occlusion-derived virions that cross the peritrophic membrane and gain access to the columnar epithelial cells. These enveloped virions fuse with the microvilli membranes, thereby releasing nucleocapsids into the cytoplasm for nuclear entry or transport to the basal membrane side of the midgut cell for budding into the hemocoel or tracheal epithelium. In secondary infections (*right*), enveloped BV in the infected larva's hemolymph or growth medium from infected cell culture attaches to unidentified cell surface receptors and enters by endocytosis. As the endosome acidifies, the viral and endosomal envelopes fuse to release nucleocapsids into the cytoplasm. Occlusion-derived or BV-derived nucleocapsids both proceed to the nucleus where they interact with the nuclear pore. The viral DNA genome is released by uncoating and the early phase of transcription and gene expression begins. Once the appropriate early gene products appear, viral DNA is synthesized in association with the newly formed virogenic stroma. Late gene expression occurs after DNA replication begins and produces structural components for the nucleocapsid, which then package just-replicated viral genomic DNA. During this late phase, newly assembled nucleocapsids exit the nucleus, migrate to the plasma membrane, associate with an envelope fusion protein, and exit the cell by budding to yield infectious BV. By contrast, during the very late phase, nucleocapsids are retained in the nucleus, acquire a nuclear-derived envelope, and become embedded within a crystalline matrix of polyhedrin to yield OV particles. Mature OV are released by virus-mediated cell lysis. (The author acknowledges contributions of Dr. Nadine Dalrymple and Dr. David Taggart to this illustration.)

Attachment, endocytosis, and uncoating

Budded virus (BV) of Ac*M*NPV enters the host cell (Fig. 19.2) by what appears to be receptor-mediated endocytosis.[26,275,341] Although the host cell receptor(s) have historically eluded identification, recent evidence suggests the Niemann-Pick C1 (BmNPC1) cholesterol transporter contributes to entry of the *Bombyx mori* NPV.[196] For group I alphabaculoviruses, the predominant glycoprotein of BV, EFP GP64 is required for receptor interaction and envelope fusion of the endosomal membrane. EFP GP64 binds to BmNPC1.[196] Other studies suggest that GP64 interactions with the membrane-bound phospholipids may be the critical determinant for BV binding to the host cell.[26] After release within the cytoplasm, nucleocapsids migrate to the nucleus in a process that coincides with virus-induced actin polymerization.[48,110] Nucleocapsids interact end-on with the nuclear pore, enter the nucleus, and release their genome. Phosphorylation of the 6.9K protaminelike core protein by a virus-encapsidated protein kinase promotes DNA release.[342,356] These processes are rapid since new viral RNA transcripts can be detected within 15 min after inoculation.[54,126,177,226,317]

Early phase

By definition, the early phase of infection precedes virus DNA replication. During this period that extends to 6 hours, baculoviruses express genes encoding transcriptional activators, a virus-specific RNA polymerase activity, DNA replication factors, apoptotic suppressors, and other critical factors. These early gene products prepare the cell for the enormous burden imposed by the synthesis of viral nucleic acid and structural components that can constitute more than a third of the cell's mass (Fig. 19.3A and Fig. 19.5). The level and timing of early and late gene expression is orchestrated to insure proper temporal assembly of infectious BV and OV. Early viral gene products also block cell cycle progression forcing cells to accumulate within the S phase and G_2/M boundary.[34,154] In addition, filamentous actin and microtubules are redistributed, causing a dramatic rearrangement of the host cell cytoskeleton that is manifested by nuclear hypertrophy and cell rounding; these changes are characteristic of the early stages of baculovirus infection.[48,110,276]

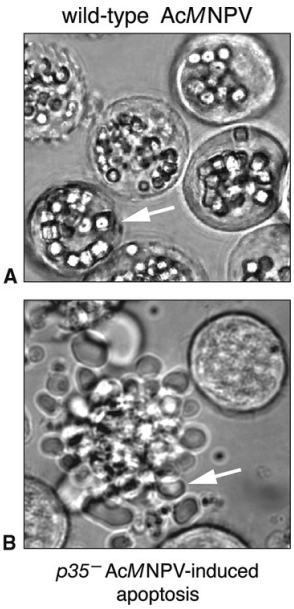

FIGURE 19.3 **Fates of baculovirus-infected cells**. **A**. Wildtype Ac*M*NPV infection of *Spodoptera frugiperda* SF21 cells. Upon successful inhibition of apoptosis by viral P35, the highly refractile OV particles (*arrow*) accumulate in the hypertrophied nucleus of each cell by 48 hours after infection. **B**. Late stages of apoptosis triggered by an Ac*M*NPV *p35*-deletion mutant. When virus-induced apoptosis is not suppressed, SF21 cells undergo widespread apoptosis that includes the formation of membrane-enveloped apoptotic bodies (*arrow*). (Magnification, 200×.) (Micrographs provided by Gulam Manji, University of Wisconsin-Madison.)

Baculovirus gene expression involves a highly coordinated cascade of gene activation events that is regulated primarily at the level of transcription.[51,93,275] Transcription of strictly defined early genes usually peaks between 6 and 12 hours after infection and declines thereafter as late viral transcription accelerates. During this early time, at least a portion of the incoming viral DNA genome adopts a nucleosomelike structure.[357] Early viral transcription is mediated by the host's RNA pol II.[24,119,146,152,266] Early promoters resemble host RNA pol II promoters, complete with a consensus TATA element located ~30 bp upstream from the RNA start site.[25,71,123,176,200,266,317] A tetranucleotide CAGT motif positioned at the RNA start site is common to many early promoters and functions as a transcriptional initiator element.[24,51,265] These core promoter elements also cooperate with upstream activating elements or more distal transcription enhancers (including the *hr*s) to interact with sequence-specific transcription activators. The *cis*-acting transcriptional control elements for multiple Ac*M*NPV early genes have been defined, including those for *ie-1*, *gp64* EFP, *pp31*, *he65*, *p143*, and *p35*. Many early promoters are highly responsive to virus-encoded transactivators, especially the multifunctional protein IE1 (see below). As expected, host factors also participate in early transcription events.[104,167,176,270] Remarkably, purified baculovirus genomic DNA devoid of protein is infectious. Thus, host factors are sufficient to initiate infection albeit at rate slower than that of infectious virus particles. This feature is exploited in the generation of the baculovirus expression vectors.[157,259,327]

Immediate early protein IE1 is the principal early transregulator of many baculoviruses. This nuclear phosphoprotein is highly conserved among the lepidopteran baculoviruses and is essential for virus multiplication by virtue of its transcriptional and DNA replication activities.[249,286,300,311] IE1 transactivates early baculovirus promoters and contributes to a critical but unknown virus DNA replication function.[25,123,124,175,179,200,226,248,249,271,311,317] Typical of transcriptional activators of DNA viruses, IE1 has a modular structure (Fig. 19.4). The N-terminal third consists of a potent transactivation domain that is largely acidic.[174,274,294] A small stretch of residues at the extreme N terminus of IE1 is required for viral DNA replication.[249,311] This N-terminal replication domain possesses phosphorylation sites within a highly conserved cdc/cyclin B kinase–like motif (TPXR/H) that are required for viral DNA replication and virus multiplication but not transactivation.[311] Thus, phosphorylation may serve as a molecular switch to ensure the proper regulation of IE1's transcriptional activities and its DNA replication duties in a temporally controlled manner. The responsible kinase remains to be identified. Ac*M*NPV IE1 contains a highly conserved patch of basic residues (designated basic domain I) within its N-terminal transactivation domain (Fig. 19.4) that is required for DNA binding.[238] DNA binding by IE1 is essential for virus multiplication.[310] IE1 binds as a dimer to the repetitive 28-bp palindromes that constitute the *hr*s; this DNA binding is required for optimal transcriptional enhancer function of the *hr*s.[121,125,174,188,226,272,273] The IE1 C terminus possesses a domain that also contributes to DNA binding (Fig. 19.4). Here, IE1 contains an oligomerization domain and a novel nuclear localization signal.[236,237] IE1 dimerization is required for nuclear import. Once in the nucleus, IE1 interacts with the *hr*s of the virus DNA genome as suggested by colocalization of IE1 and DNA replication factors and the requirement of basic domain I for virus multiplication.[224,234,310] IE1 is required for transient DNA (plasmid) replication assays and contributes to viral DNA replication.[249,269,271,311] It is likely that by binding to the *hr*s, IE1 recruits critical DNA replicative factors to the origins of viral DNA replication. However, the exact replicative functions of IE1 are unclear.

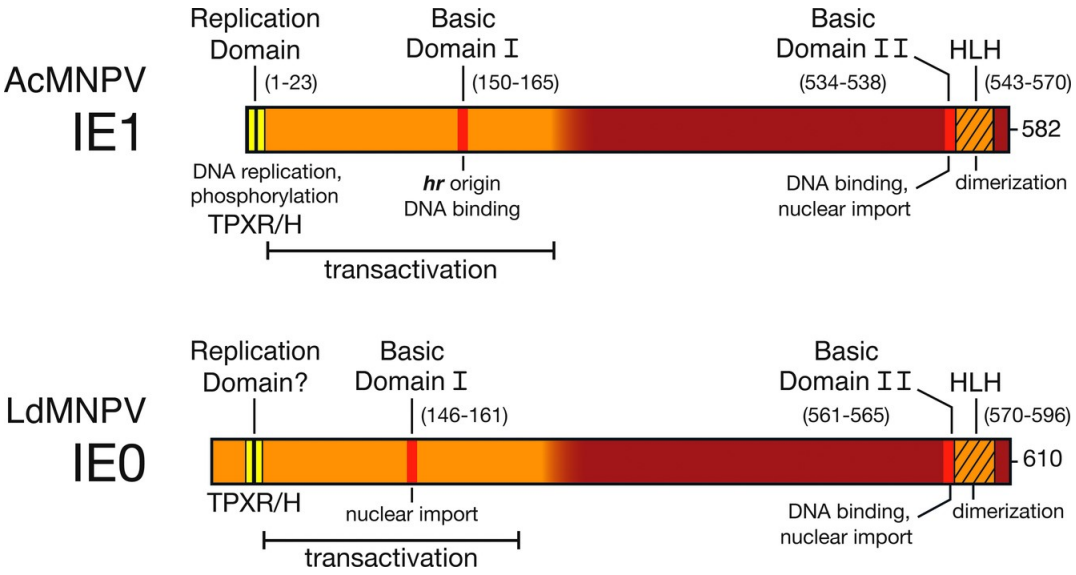

FIGURE 19.4 **Structure of baculovirus transactivator IE1**. NPV immediate early IE1 is a potent transcriptional activator essential for virus gene expression, DNA replication, and virus propagation. It has a conserved modular organization consisting of an N-terminal transactivation domain and a C-terminal helix-loop-helix (HLH) domain required for dimerization and nuclear import. The small basic domains (I or II) are required for DNA binding. IE1 from Ac*M*NPV and IE0 from Ld*M*NPV share structural organizations but have very divergent sequences. Both possess N-terminal TPXR/H motifs required for DNA replication and phosphorylation[311] but differ with respect to the function of their basic domains[68]; Ac*M*NPV IE1 basic domain I is required for *hr* DNA binding, whereas the same domain in Ld*M*NPV IE0 is required for nuclear import.

Baculoviruses encode additional transcription activators, including IE0, IE2, and PE38, which are conserved among the baculoviruses. Derived by RNA splicing, IE0 is identical to IE1 except for an additional 54 residues, encoded by *exon 0*, at its N terminus. IE0 has redundant regulatory activities with IE1 and is dispensable for virus replication.[54,175,203,273,300] Additional studies have indicated that IE0 preferentially transactivates certain viral genes at very early times in infection.[296] IE2 is a 47-kDa leucine zipper, RING finger–containing transactivator.[40,318,368] Ac*M*NPV mutants containing loss of function *ie-2* alleles are viable but exhibit delays in virus replication.[261] Upon overexpression in plasmid-transfected cells, *ie-2* causes cell cycle arrest,[262] but the significance of this activity is unknown. IE2 and the transregulator PE38 both localize to punctate nuclear structures in transfected cells.[178] PE38 is a promoter-specific transactivator with a leucine zipper and RING finger.[177,200,248] Ac*M*NPV *pe38*-deletion mutants exhibit reduced levels of DNA synthesis and BV production but are viable.[214]

Late phase

The late phase of the baculovirus infection cycle starts with viral DNA replication, which begins ~6 hours after Ac*M*NPV infection. The synthesis of new genomic DNA and the expression of late structural genes are necessary for production of BV, the predominant infectious form during this period. Late gene expression requires viral DNA replication. This dependence is illustrated by inhibiting viral DNA synthesis through use of a temperature-sensitive (*ts*) mutant in the essential helicase *p143* gene (see below) that subsequently blocks late gene expression and eliminates BV production.[111] Likewise, RNA silencing (RNAi)-mediated ablation of virus DNA replication factors prevents Ac*M*NPV DNA synthesis, blocks late viral transcription, and prohibits the characteristic shut-off of host protein synthesis.[285] The molecular basis for the coupling of late gene expression to DNA replication is unknown, but common among large DNA viruses.

At least six baculovirus genes, which include *p143*, *ie-1*, *lef-1*, *lef-2*, *lef-3*, and *dna pol*, are required for DNA replication (Table 19.2). These genes were originally identified using transient DNA replication assays conducted in cultured cells with plasmids containing a viral *hr* enhancer/origin.[168,202] Replication factors include a DNA binding helicase (p143), a putative primase (LEF-1), a primase-associated protein (LEF-2), a single-stranded DNA-binding protein (LEF-3), and a virus-encoded DNA polymerase (dna pol). The essential function of these replication genes during infection has been confirmed through the analysis of conditionally lethal mutants and deletion mutants generate by using *Escherichia coli*–replicating bacmid technology (Table 19.2). Besides its positive transcriptional activities, IE1 promotes origin (*hr*)-specific plasmid DNA replication.[168,202,269] A stretch of 23 residues at the IE1 N terminus is required for this activity.[249,311] IE1's capacity to act as a DNA origin (*hr*)-binding protein and to stimulate homologous recombination suggests that it has a direct role in DNA replication,[66,188,273] but its specific functions are still unclear. The *dna pol* gene[324] is also essential for Ac*M*NPV replication as demonstrated by the loss of virus viability upon its deletion.[330] Other genes, including *ie-2*, *lef-7*, *pe38*, and *p35*, directly or indirectly stimulate replication in transient replication assays.[201] Viral factors localize to centers of viral DNA replication within the virogenic stroma that forms within the nucleus (see below).[234] As these replication centers expand, host chromatin becomes marginalized to the inner edge of the nucleus; viral factors IE1, LEF3, and helicase P143 in the presence of a viral hr element are sufficient for this marginalization.[224]

TABLE 19.2 Baculovirus DNA replication and late expression factors

Virus Gene	Essential Gene[a]	DNA Replication	Late Expression	Function/Homology	Virus Mutants
ie-1	YES	+	+	Transcription transactivator, origin of DNA replication binding protein	*ts*B821
ie-2/ie-n	NO	+	+	Transcription activator, E3 ligase, cell line–specific cell cycle regulator	
p47	YES	–	+	Late RNA polymerase subunit	*ts*317
p143	YES	+	+	Helicase, DNA binding protein with ATP binding, host range determinant	*ts*8
dnapol	YES	+	+	DNA polymerase, 3′→5′ exonuclease, proofreading activity	
pp31/39K	NO	–	+	Virogenic stroma association, phosphoprotein, binds DNA	
p35	NO	+	+	Caspase substrate inhibitor, apoptosis suppressor, related to p49	
lef-1	YES	+	+	DNA primase activity, DNA binding, LEF2 association	
lef-2	YES	+	+	Primase-associated protein, amplifies DNA replication, L and VL expression	VLD1
lef-3	YES	+	+	ssDNA binding, p143 helicase association and nuclear import	
lef-4	YES	–	+	Late RNA polymerase subunit, 7′ methyl G-capping activity, 5′ triphosphatase	*ts*538
lef-5	YES	+	+	Late RNA polymerase subunit, transcriptional initiation, has TFIIS homology (Zn ribbon), highly conserved	
lef-6	NO	–	+	Involved in late gene expression, vaccinia virus RNA pol homology	
lef-7	NO	+	+	Cell line–specific DNA replication, modulation of the DNA damage response, SCF complex association	vlef-7-AG
lef-8	YES	–	+	Largest late RNA polymerase subunit, catalytic active site for RNA synthesis	*ts*S1
lef-9	YES	–	+	Largest late RNA polymerase subunit, part of the catalytic active site	
lef-10	YES	–	+	Prionlike activity	
lef-11	YES	+	+	Upregulates host ATPase to modulate energy metabolism	
lef-12	NO	–	+	TFIIA similarity, transcriptional initiation	
pe38	NO	+	+	Transactivator of helicase *p143*	
an	YES	+	–	Alkaline nuclease, 5′→3′ exo- and endo-nuclease, DNA maturation and packaging	
hcf-1	NO	+	+	Cell line–specific, protein synthesis shutdown, late and very late expression	
vlf-1	YES	–	+	Hyperexpression of very late genes, structural protein, integrase/resolvase, vDNA packaging	*ts*B837

[a]Gene is designated “essential” as determined by direct deletion or replacement within the Ac*M*NPV genome.

As with many large DNA viruses, the precise mechanisms of baculovirus DNA replication are poorly understood. The *hr* repeats are likely origins of viral DNA replication,[170,188,251,272] but this function has not been demonstrated yet. Non-*hr* sequences have also been implicated as genome replication origins.[169,187,361] During infection, multiple unit-length genome fragments and concatemers of viral genomes have been detected.[187,244] Although these potential replicative forms are consistent with a rolling circle mechanism, no obvious mechanism for DNA replication has emerged from various studies.[275] Experimental evidence also suggests that recombination-dependent DNA replication contributes to the generation of baculovirus genomic DNA. For example, all baculoviruses encode an alkaline nuclease (*AN*) gene with sequence similarity to that of the phage lambda *red* exonuclease, which is involved in phage DNA recombination. Deletion of the alkaline nuclease gene *AN* from Ac*M*NPV causes loss of virus viability even though viral DNA synthesis is normal.[235] *AN* contributes to production of longer than genome length DNA fragments in infected cells, a property consistent with a role in recombination. The endonuclease and 5′→3′ exonuclease activity of the alkaline nuclease may also participate in viral DNA maturation and packaging. Newly replicated, unit-length circles of DNA are packaged into individual nucleocapsids within the virogenic stoma.

Early in infection, one or more of the processes associated with baculovirus DNA replication is sufficient to trigger the host’s DNA damage response and apoptosis.[150,218,285] Baculovirus-encoded apoptotic suppressors (see below) are necessary to block premature cell death caused by apoptosis and to allow completion of the virus’ life cycle. Recent studies suggest that the host’s DNA damage response is necessary for optimum virus DNA replication.[150,218] For example, pharmacological inhibition or RNAi-mediated ablation of the host kinases that initiate the DNA damage response reduce Ac*M*NPV DNA replication and severely restrict virus production. Thus, baculoviruses likely modify specific aspects of the host’s DNA damage response for their own benefit.[218]

Nineteen baculovirus genes are required for late gene expression (Table 19.2), as first determined for Ac*M*NPV.[193,202,269] These genes, designated late expression factors (*lef*s), were identified by their ability to support high level expression of a reporter gene placed under control of a virus late promoter and *cis*-linked to an *hr* origin/enhancer element.[248] Due to the link between DNA replication and late gene expression, several genes required for late gene expression (*ie-1*, *p143*, *lef-1*, *lef-2*, *lef-3*, and *dnapol*) are essential DNA replication factors (Table 19.2). Because they are dispensable for late gene expression in certain cell lines, multiple *lef*s (*ie-2*, *lef-7*, and *hcf-1*) confer tissue or species specificity. In addition, a variety of viral genes contribute to host range, including helicase *p143* and host range factor-1 (*hrf-1*).[49,65] Several *lef*s function

directly or indirectly at the level of transcription or mRNA stabilization (Table 19.2). Of these genes, four (*p47*, *lef-4*, *lef-8*, and *lef-9*) encode components of the baculovirus RNA polymerase[127] that is specific for late and very late gene expression (see below). The roles of transcription-specific *lef*s during infection have also been characterized by using conditionally lethal mutations (Table 19.2).

The baculoviruses are unique among nuclear-replicating DNA viruses in that they switch to a novel RNA polymerase for late and very late transcription.[247,275] The virus-encoded RNA polymerase retains specificity for late virus promoters *in vitro* and is distinguished from other host RNA polymerases by its resistance to α-amanitin and tagetitoxin, which are inhibitors of RNA pol II and III, respectively.[108,364] The late RNA polymerase complex includes virus proteins p47, LEF-4, LEF-8, and LEF-9 as well as other proteins.[15,127] The viral-encoded polymerase recognizes and initiates transcription within a nucleotide motif (A/G/T)TAAG that functions as the primary sequence element for late and very late promoter activity. All genes encoding proteins that are synthesized in abundance during the late phase (eg, major capsid protein vp39, 6.9K basic core protein, gp64 EFP) possess this late TAAG motif.[51] Fewer than 18 nucleotides surrounding this initiation site are sufficient to direct high-level late gene expression.[220] Some late genes, including the *vp39* capsid gene, have multiple TAAG motifs, each of which serve as an independent RNA start site.[321] This redundancy boosts production of gene products needed in abundance for virion assembly. It is noteworthy that some early genes (*p35*, *gp64*, *pp31*, and *ie-1*) are also transcribed late in infection. Late transcription of these genes is often mediated by late TAAG motifs that overlap the early promoter elements.[25,123,226,265]

Very late phase

The final, very late stage of baculovirus infection is characterized by the hyperexpression of occlusion-specific genes and the production of mature OV from 18 through 76 hours after infection or until cell lysis (Figs. 19.3A and 19.5). The very late phase is marked by a dramatic increase in transcription of *polh*, which encodes the major matrix protein polyhedrin of OV. The very late hyperexpression of *polh* and its nonessential nature for BV production form the basis of the baculovirus expression vector system (see above). Foreign genes are commonly placed under control of the *polh* promoter replacing the *polh* ORF to obtain high levels of expression very late in infection of cultured cells.[44,157,327] The promoter for the very late, hyperexpressed *p10* gene (see below) has also been used.

The baculovirus-encoded RNA polymerase also mediates very late gene transcription. The promoters of the hypertranscribed genes (*polh* and *p10*) contain the late TAAG motif and are positively regulated by the 50 nucleotides constituting the noncoding leader of their gene.[247,275] This region is responsible for the very late burst of transcriptional activity that distinguishes very late genes from late genes. These "burst" sequences may interact with activation factors responsible for the stimulation of transcription at this late time. Host and virus-specific factors likely participate in transcription of very late genes.[247,275] Indeed, the baculovirus very late factor-1 (VLF-1) is a candidate for a positive activation. VLF-1 forms a complex with the "burst" sequences and stimulates very late transcription.[209,217,367] Interestingly, VLF-1 is an essential protein (Table 19.2); in the absence of VLF-1, very late gene expression is compromised and virus DNA accumulation and packaging is reduced.[329] Thus, VLF-1 may also contribute to viral DNA replication and nucleocapsid assembly.

p10 is the other very late, hyperexpressed gene of baculoviruses. It encodes a small 10-kDa coiled-coil domain protein that associates with expansive fibrillar structures (Fig. 19.5), which assemble in the nucleus and cytoplasm late in infection.[228] P10 is a nonessential protein that may disrupt the nuclear membrane or stabilize OV particles.[115,354]

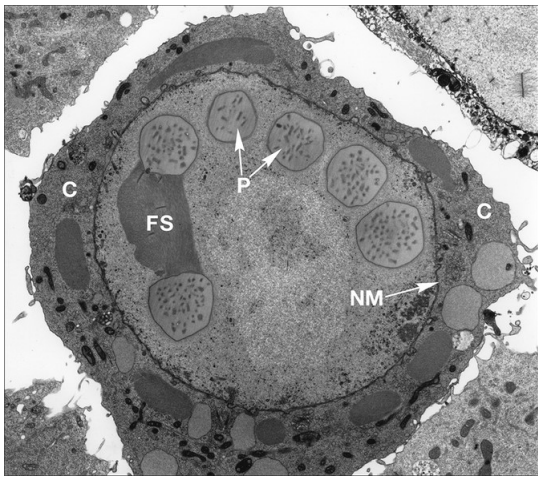

FIGURE 19.5 **The very late occlusion stage of Ac*M*NPV infection**. Multiple OV particles (P) form on the inside edge of the hypertrophied nucleus near the inner nuclear membrane (NM). Dense fibrillar structures (FS) often form within the nucleus. The characteristic swelling of the nucleus forces the densely packed cytoplasm (C) to the cell's edge. (Electron micrograph was provided by Dr. Peter Faulkner and Dr. Gregory Williams, Queens University.)

Virus assembly, budding, and occlusion

Nucleocapsids assemble during the late and very late phases of infection.[275,372] Newly assembled nucleocapsids appear at the edge of the stromal matte located in the virogenic stroma (Fig. 19.1D), a poorly understood viral nucleoprotein structure centered within the nucleus. Consisting of DNA, RNA, and virus protein, the virogenic stroma is the likely site of viral DNA replication, condensation, and encapsulation.[89,369] As infection proceeds, the viral replication center (virogenic stroma) expands and host chromatin becomes marginalized to the nuclear periphery. This process involves the combined activities of the *ie-1*, *lef-3*, and *p143* genes and requires the presence of an *hr* element.[224] Baculovirus phosphoprotein pp31 is a principal component associated with the virogenic stroma; it binds DNA by a phosphorylation-dependent mechanism, but its exact function is unclear.[35,122] pp31 appears to stimulate viral transcription rather than

regulating vDNA replication.[366] Newly assembled nucleocapsids exit the nucleus by budding or transport through nuclear pores (Fig. 19.2).[275,372] Nuclear actin plays a critical role in the maturation of these nucleocapsids.[48,110,233] The nuclear envelope is removed during transport to the plasma membrane. By interacting end-on with the plasma membrane, single nucleocapsids bud from the cell surface (Fig. 19.1C) and acquire the envelope fusion protein EFP GP64.[242] The rate of BV release from Ac*M*NPV-infected cells increases exponentially from 10 to 20 hours and then declines through 36 hours.

Late in infection, OV particles assemble and accumulate in the nucleus of infected cells (Figs. 19.3A and 19.5). For Ac*M*NPV, OV production begins about 18-24 hours after infection and accelerates as production of BV declines. Not surprisingly, OV assembly involves a multitude of virus genes and processes, including virus modification of nuclear membranes and vigorous import of polyhedrin into the nucleus.[275] Nucleocapsids align along newly assembled membrane segments in the nucleus and subsequently acquire an envelope prior to encasement by polyhedrin (Fig. 19.1E). Studies of the generation of this nuclear membrane envelope and nuclear import of critical membrane proteins have revealed new facets to integral membrane protein trafficking.[33] OV formation is first observed on the inside edge of the nucleus (Fig. 19.5). Time-lapse video microscopy has suggested that the number of OV per cell is established early, and with time each particle increases in size.[207] Maturation of the OV includes deposition of the polyhedron envelope (calyx) over the particle's surface. Finally, OV are released upon disintegration of the nucleus and loss of plasma membrane integrity very late in infection.

Disease Progression in Insects

Horizontal transmission of baculoviruses is mediated by the OV, the form of the virus that is most stable and resistant to environmental degradation. Primary infection occurs in the midgut epithelium (Fig. 19.2) of the insect larva.[275] Infection is initiated by larval ingestion of virus-contaminated food. Upon entry in the midgut lumen, the OV particles dissolve in response to the alkaline environment and release occlusion-derived virions (ODV). Passage of virus through the peritrophic membrane (Fig. 19.2) is facilitated by virus-encoded proteases (called enhancins), first discovered in the GVs.[189] ODV subsequently bind to the brush border membrane of columnar epithelial cells and enter by direct fusion with the plasma membranes (Fig. 19.2). Infection proceeds by pathways comparable to that in cultured cells with the interesting exception that newly synthesized EFP GP64 is transported unidirectionally to the basal membrane side of the midgut cells.[246] This targeting of GP64 allows nucleocapsid budding at the basal lamina and promotes rapid access of enveloped virus to the hemocoel and tracheal epithelium for systemic spread. Indeed, reduction of early GP64 synthesis selectively lowered the *per os* virulence of an Ac*M*NPV mutant,[349] suggesting an important role for this directional transport. The production of OV in these midgut cells is rare for lepidopteran hosts. However, multiplication of certain baculoviruses, including mosquito NPVs, is restricted to the midgut. Thus, OV is produced there.

BV first generated in the midgut is next spread through infection of hemocytes (blood cells) and the epithelial cells that line the tracheal network.[246] Interestingly, the lepidopteran baculoviruses encode v*fgf*, which bears sequence similarity to fibroblast growth factor. Recent studies with Ac*M*NPV suggest that v*fgf* activity in infected midgut cells activates extracellular metalloproteases that permeabilize the basal lamina, attracts susceptible tracheal cells, and allows BV to rapidly gain access to the trachea network and hemocoel.[211] This secondary infection affects virtually all internal tissues of highly susceptible larva. Within several days, the larva is converted into a milky white liquid, consisting mostly of OV particles. This process, referred to as "melting" or "liquification," is facilitated by a virus-encoded chitinase and a cathepsin, which cooperate to breakdown the larval cuticle (skin) that includes chitin.[139,144,145] The activation and secretion of these enzymes is carefully regulated so as not to prematurely destroy infected cells or the larva before virus production is maximized.[144,145] A typical Ac*M*NPV infection produces over 10^8 OV particles, a yield that constitutes >10% of the dry weight of the insect. Upon rupture of the cuticular exoskeleton, OV are liberated into the environment. Liquification represents the successful conclusion to the baculovirus life cycle as the release of OV is required for virus dissemination through the host population. Nonetheless, there is limited evidence that baculoviruses establish persistent infections in some hosts.[275]

Baculovirus-Mediated Alterations of the Host

Besides causing mortality, baculoviruses can exert dramatic effects within their host. At the cellular level, infection induces major changes in the cytoskeleton and nucleus of infected cells. Transcription of most host genes is significantly reduced in Ac*M*NPV-infected cells.[240,278] Nonetheless, certain host proteins used by the virus are upregulated, including heat shock proteins, membrane trafficking proteins, and TATA-binding proteins.[268,278] In general, host protein synthesis declines rapidly after the onset of baculovirus DNA synthesis. When Ac*M*NPV DNA replication is blocked, virus-mediated arrest of host protein synthesis is prevented.[285] Conversely, when Ac*M*NPV late gene expression is selectively blocked, arrest of host protein synthesis is unaffected. Because vDNA replication also triggers Ac*M*NPV-induced apoptosis (see below), the shutoff of host protein synthesis and apoptosis may be caused by the same host cell response to vDNA synthesis. The biochemical mechanisms involved are not yet understood.

Remarkably, the baculoviruses also exert control of their hosts at the physiological and behavioral level as a means to enhance virus production and dissemination.[228,320] For example, baculovirus-infected larvae often display a classical behavior of wandering that involves climbing to the top of vegetation, where they succumb and liquefy while hanging from a leaf or branch. This strategy facilitates virus dispersal by wind and rain. A baculovirus-encoded protein tyrosine phosphatase gene (*ptp*) contributes to this virus-induced behavior.[165] Uninfected caterpillars in late stages of development also wander. Because this behavior is controlled by a cellular *ptp*, it is postulated that baculoviruses acquired a host ancestral *ptp* because of the conferred selective advantage for dissemination. Recent studies have revealed another fascinating virus-mediated alteration of the host's visual perception at the levels of photoreception and phototransduction that serves to induce vertical climbing in host larvae and thus enhance virus dissemination.[198] Baculoviruses block development of their larval hosts by controlling the activity of ecdysone, the steroid hormone that triggers molting.[229] The baculovirus *egt* gene encodes an ecdysteroid UDP-glucose/galactose transferase that is secreted from infected cells and transfers glucose or galactose to these ecdysteroids, thereby inhibiting uptake of the hormone by cells. Virus-encoded *egt* blocks larval molting,[228,320] which is correlated with increased virus production; indeed, *egt* deletion mutants cause early mortality and yield less virus.[230] The increased speed of kill of *egt* deletion mutants has already been adapted for the generation of engineered baculoviruses for improved insecticidal activity. Interestingly, the inhibition of molting by baculovirus *egt* is also associated with enhanced wandering (climbing) of gypsy moth (*Lymantria dispar*) caterpillars upon infection with *Lymantria dispar* NPV.[147] The extent of this effect depends on virus dose and the developmental stage at the time of inoculation.

Baculovirus Manipulation of Apoptosis

The remarkable replicative success of baculoviruses often depends on their capacity to suppress host cell apoptosis, a dynamic suicide response that can function as an effective antiviral defense. As such, the baculoviruses have provided a wealth of information on the mechanisms by which viruses impede host apoptosis (also referred to as programmed cell death) to facilitate their multiplication.[17,58] These DNA viruses have revealed highly conserved genes that regulate apoptosis in insects and mammals alike. Apoptosis is critical for many normal processes in animals, including development, differentiation, immune function, and elimination of damaged, oncogenic, or pathogen-infected cells. Thus, misregulation of apoptosis is associated with many disease states.[99,337] By virtue of the discovery of multiple baculovirus genes that function as potent suppressors of apoptosis in phylogenetically diverse organisms, these viruses have provided valuable insight and important tools for studying the pathways by which apoptosis is either suppressed or amplified in human diseases and how apoptosis can be manipulated in treatment regimens thereof.

Baculovirus mutants that lack suppressors of apoptosis trigger widespread, species-specific cell death.[60,61,141,164] In some cases, apoptotic death approaches 95% of the infected cells within a 24-hour period, a response level that is unmatched by mammalian viruses. Baculovirus-induced apoptosis is characterized by premature cell death that includes activation of host prodeath components, fragmentation of host and viral DNA, and dismemberment of the cell into extracellular vesicles called apoptotic bodies (Fig. 19.3B). Accordingly, apoptosis severely limits production of virus. In the case of Ac*M*NPV mutants deficient in apoptosis suppressors, virus yields are reduced as much as 10 000-fold in a cell-specific manner.[61,141] Moreover, the infectivity of these mutants in certain permissive insects (ie, *Spodoptera frugiperda*) is 25-1000 fold lower than that of wild-type virus.[61] This reduced infectivity is correlated with increased apoptosis in larvae and reduced virus spread.[57] Thus, apoptosis impedes baculovirus multiplication and can function as an effective antivirus defense in insects.

Cultured insect cells have proven invaluable in studies of baculovirus-induced apoptosis. In particular, lepidopteran *Spodoptera frugiperda* (SF21) cells and dipteran *Drosophila melanogaster* (DL-1 or S2) cells have been used as model systems for these studies and those of invertebrate apoptosis.[43,60,61,149,184-186,207,223,285,286,290] Many of the cellular components comprising the apoptotic pathways of these cells have been identified. Moreover, these cells are sensitive to diverse apoptotic stimuli, including that caused by viruses, DNA damaging agents, transcription and protein synthesis inhibitors, calcium ionophores, phosphatase inhibitors, and others (Fig. 19.6A). Nonetheless, baculovirus-permissive cell lines refractory to virus-induced apoptosis have been identified. For example, cultured *Trichoplusia ni* TN368 cells fail to undergo apoptosis upon infection with Ac*M*NPV mutants that cause apoptosis of SF21 cells.[61,141] The infectivity of these mutants in *T ni* larvae is comparable to that of apoptosis-suppressing wild-type virus. The molecular basis of this interesting resistance to virus-induced apoptosis is unknown.

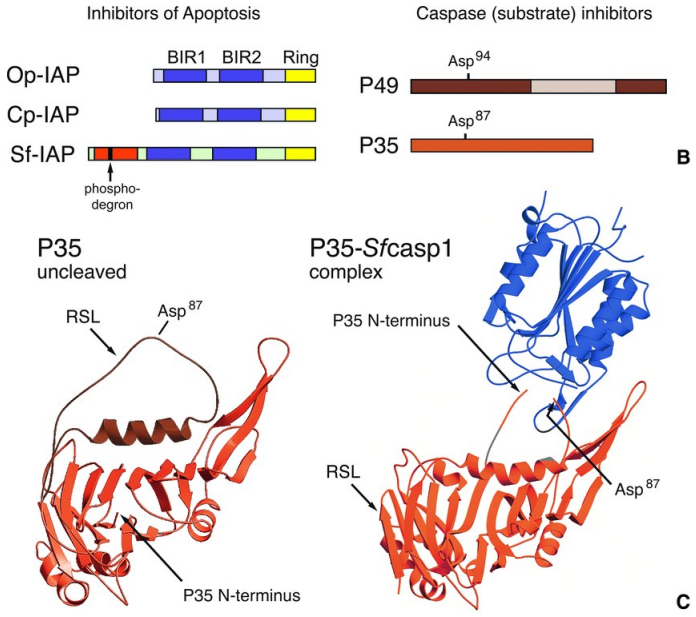

FIGURE 19.6 **Baculoviruses and apoptosis**. **A**. Model pathway for virus-induced apoptosis. Ac*M*NPV triggers widespread apoptosis of model *Spodoptera frugiperda* (order Lepidoptera) cells due to events associated with virus DNA replication. Such replication triggers a DNA damage response, which produces an apoptotic signal that depletes host cell IAP (cIAP). Loss of cIAP activates initiator and effector caspases, which if uninhibited cause proteolysis and apoptotic cell death. Virus-induced cIAP antagonists may be prodeath factors, like HID and reaper, activated host kinases, or the arrest of protein synthesis that accompanies baculovirus infection. Virus-encoded apoptotic suppressors produced early in infection prevent apoptosis. P35 inhibits active caspases, including *Sf*-caspase-1, whereas P49 inhibits an activated initiator caspase, probably S*f*Dronc. Baculovirus-encoded IAPs block procaspase activation at an unknown (?) step upstream of P49. **B**. Baculovirus apoptotic regulators. The IAPs contain two BIRs motifs and a C-terminal Ring finger motif. The viral IAPs, Op-IAP and Cp-IAP, closely resemble SfIAP, a cellular IAP from *S. frugiperda*. Caspase inhibitors P49 and P35 are 49% identical and contain aspartate residues (Asp[94], respectively and Asp[87]) required for caspase cleavage. P49 contains a 120-residue insertion (pink) unrelated to P35. **C**. Caspase inhibition by baculovirus P35. In uncleaved P35 (*left*), the prominent reactive site loop (RSL), with the Asp[87]caspase cleavage site at the apex, is solvent exposed while the N-terminus is buried. During cleavage, P35 undergoes a dramatic conformation change (*right*) in which the RSL folds backward and the N-terminus is liberated so that it enters the active site of the targeted caspase, forming a stable, inhibited complex.

Baculovirus-encoded apoptotic suppressors

To counteract the host suicide response and thus promote multiplication, baculoviruses have evolved novel apoptotic suppressors. These viral proteins regulate apoptosis at different steps in the death pathway (Fig. 19.6A) and in a surprising diversity of organisms. Among different baculovirus species, two mechanistically distinct apoptotic suppressors have been identified: the caspase inhibitors (P35 and P49) and the IAP proteins (Fig. 19.6B). The discovery of cellular IAPs with structural and biochemical properties comparable to those of viral IAPs suggests that baculoviruses originally acquired these apoptotic regulators from their insect hosts.[43,151,289] The same is most likely true for the baculovirus-encoded caspase inhibitors, but cellular homologs have not yet been reported. The strong selective advantage conferred to baculoviruses by expression of an apoptotic suppressor, like P35,[191] is consistent with the acquisition and maintenance of such host genes. Interestingly, a single functional regulator per virus appears sufficient. For example, Ac*M*NPV encodes one copy of the *p35* gene along with two nonfunctional *iap* genes.[62,116] By contrast, Op*M*NPV encodes a single functional *iap* (Op-*iap3*), three nonfunctional *iap*s, and no *p35*.[22,210]

Baculovirus P35 is a potent caspase inhibitor, often considered a universal suppressor of apoptosis due to its function in phylogenetically diverse organisms. First discovered in Ac*M*NPV,[60] *p35* prevents programmed cell death in plants, nematodes, flies, moths, and mammals (human cells included), among others, when expressed ectopically.[17,58] Accounting for its widespread effectiveness, P35 (35 kDa) is a broad-specificity substrate inhibitor of the effector caspases, which are the proteases that execute the cleavages that dismember the apoptotic cell.[39,99] P35 is cleaved by its target caspase at a requisite aspartate residue (Asp[87]) and forms a stable, stoichiometric complex with it.[16,36,374] The 2.2-Å crystal structure of P35 reveals that the Asp[87] cleavage site is located at the apex of a novel solvent-exposed reactive site loop (Fig. 19.6C), the orientation of which is critical to P35's anticaspase activity.[86,376] Caspase-mediated cleavage induces a dramatic conformational change in the reactive site loop that stabilizes the covalent link between P35 and the caspase (Fig. 19.6C) in a novel mechanism for substrate-protease inhibition.[69,365] Baculovirus P49 is a related substrate inhibitor of the caspases. First identified in *Spodoptera littoralis* NPV,[77] P49 exhibits 49% amino acid identity with P35 (Fig. 19.6B) and likewise possesses a reactive site loop that is cleaved at a requisite aspartate residue (Asp[94]) by the participating caspase. Interestingly, P49 targets apical initiator caspases in permissive insect cells. Thus, P49 inhibits the caspase(s) that proteolytically cleave and activate the effector caspases that are inhibited by P35.[130,253,377] This target specificity is conferred in part by the cleavage site residues of P49.[130,377] Thus, baculoviruses have evolved multiple caspase inhibitors with different specificities. A functional P35-like caspase inhibitor is also encoded by the insect entomopoxviruses.[212]

The baculovirus IAPs were the first discovered members of the larger IAP family resident in diverse organisms and their viruses. The cellular IAPs are highly conserved regulators of cell fate that function during cell stress, immunity, tumorigenesis, and pathogen invasion.[59,99,131] In insects, these short-lived (~30 minute half-life) cellular proteins regulate the caspases, among other death components. The IAPs are defined by the presence of one or more essential baculovirus IAP repeat (BIR) domains (~80 residues), consisting of a conserved Zn^{+2}-coordinating arrangement of Cys and His residues (CCHC). Many IAPs also possess a critical C-terminal RING domain, which functions as an E3-ubiquitin ligase. The antiapoptotic activity of some, but not all, IAPs is derived from the ability of the BIRs to bind directly to and neutralize initiator and effector caspases through ubiquitination by the RING. During apoptosis initiated by certain signals, the BIRs also interact with proapoptotic IAP binding motif (IBM) proteins, which bind to and dissociate the IAP-caspase complex to liberate active caspases and execute apoptosis.[59,99,131]

Several insect virus families, including the baculoviruses, entomopoxviruses, iridoviruses, African swine fever virus, and the nudiviruses, encode functional and nonfunctional IAPs.[17,58] Of these, the baculovirus IAPs are the best characterized. The viral IAPs share many structural and biochemical features with the cellular IAPs.[38,43,151] Despite these striking similarities and their potent antiapoptotic activity, the viral IAPs use a mechanism that does not involve direct inhibition of active caspases. The best-studied viral IAP is Op-IAP3 from *Orgyia pseudotsugata* NPV.[22,38,360] This small 268-residue IAP contains two BIRs and a C-terminal RING (Fig. 19.6B); each of these motifs is required for antiapoptotic activity.[149,359] Upon its overexpression, Op-IAP3 blocks apoptosis triggered by various signals in cells from insects and mammals, consistent with a broad, conserved mechanism.[58] In baculovirus-infected *Spodoptera* cells, Op-IAP3 functions upstream of baculovirus caspase inhibitors P49 and P35 and thus likely inhibits initiator caspase activation.[208,377] Consistent with these findings, Op-IAP3 blocks the proteolytic activation of *Sf*-caspase-1 by an upstream initiator caspase.[185,208,288] However, unlike host insect IAPs, viral Op-IAP3 fails to bind and inhibit active caspases.[360] The Op-IAP3 BIRs interact with *Drosophila* proapoptotic IBM proteins, including Reaper, Hid, and Grim.[338,339] The relevance of these interactions is unknown since Op-IAP3 fails to block apoptosis in *Drosophila*.[360,377] Importantly, the Op-IAP3 BIRs mediate homo- and hetero-oligomerization, which is also necessary for functionality of lepidopteran cellular IAPs.[43,149] Recent studies indicated that Op-IAP3 interacts with the cellular IAP of the permissive host *Spodoptera frugiperda*, SfIAP, and that this protein-protein interaction preserves the antiapoptotic function of SfIAP through a novel stabilization mechanism.[38] Without cellular SfIAP, Op-IAP3 fails to prevent apoptosis, indicating that Op- IAP3 requires SfIAP as a cofactor.[38] These findings suggest a new model wherein Op-IAP3 interacts directly with SfIAP to maintain its intracellular level, thereby suppressing virus-induced apoptosis indirectly.

Baculovirus-induced signaling of apoptosis

The host cell signal for apoptosis originates early in baculovirus infection. A critical link between virus DNA replication and the initiation of apoptosis has been established. Host caspase activation is one of the earliest events in execution. Proteolytic activation of the proform of *Sf*-caspase-1, the principal executioner caspase in the host *Spodoptera frugiperda*, coincides with the initiation of virus DNA replication.[184,185,208,288] Consistent with this finding, caspase-mediated cleavage of substrate inhibitors P35 and P49 is first detected when Ac*M*NPV DNA synthesis begins from 6 to 9 hours after infection.[16,377] P35 must be synthesized early before vDNA replication to effectively block virus-induced apoptosis.[142] Thus, apoptotic signaling occurs early before or at the start of viral DNA replication. Studies using vDNA polymerase inhibitors and conditional Ac*M*NPV mutants defective for vDNA synthesis indicated that vDNA replication or viral late gene expression was required to trigger apoptosis.[62,184] However, subsequent studies using RNA silencing for selective ablation of Ac*M*NPV factors required for vDNA replication or late gene expression demonstrated that vDNA replication, but not late gene expression, is required to trigger apoptosis.[285,286] Thus, like vertebrate DNA viruses, baculovirus DNA replication events are sufficient to trigger the apoptotic response.

Recent studies have uncovered important facets by which baculovirus DNA replication triggers apoptosis. In invertebrates, the short-lived cellular IAPs are central regulators of apoptosis. In cell lines of dipteran and lepidopteran origin, a threshold level of IAP is necessary to block constitutive signaling toward apoptosis. Thus, when intracellular IAP drops below this level, caspases become active and apoptosis ensues. Coincidental with the beginning of vDNA synthesis, Ac*M*NPV causes a dramatic loss of cellular IAP that forces caspase activation.[332] This IAP loss is independent of caspase activity and is mediated by residues within the N-terminal leader of the cellular IAP (eg, SfIAP) and the ubiquitin

ligase activity encoded by its C-terminal RING domain.[43,332] The N-terminus of SfIAP and multiple lepidopteran IAPs possess a conserved phosphodegron, which upon activation by phosphorylation causes rapid loss of the IAP by a ubiquitin-mediated pathway.[331] SfIAP's phosphodegron contains conserved mitogen-activated kinase (MAPK)-like regulatory sites suggesting that the phosphodegron responds rapidly to a signal-activated kinase cascade, possibly triggered by DNA damage.

The vDNA replication *lef*s of Ac*M*NPV are required for the virus-induced loss of cellular IAP. Thus, vDNA replication likely triggers a host cell response that depletes cellular IAP and executes apoptosis, likely through kinase activation. DNA replication of vertebrate viruses is a potent inducer of the host's DNA damage response, which subsequently triggers apoptosis.[353] Thus, it is likely that baculovirus DNA replication is interpreted as DNA damage, which is a potent cause of apoptosis in insects as well. Indeed, Ac*M*NPV DNA replication induces a DNA damage response in lepidopteran and dipteran cell lines.[150,218] Additional study is required to determine the link between the DNA damage response and phosphorylation-mediated depletion of cellular IAP in baculovirus-infected cells.

Host Transposons

The baculoviruses are one of the few families of animal viruses that accommodate the frequent and spontaneous insertion of host-derived transposable elements.[92,199,275] By virtue of their replication in the transposon-rich insect cell nucleus and the flexibility with respect to size of their DNA genome, baculoviruses are highly vulnerable to transposon insertion. This novel property has led to the identification of new families of transposons, which have been further developed as vectors for stable transformation of insects. It is likely that baculovirus evolution has been significantly influenced by arthropod transposons, which represent potent insertional mutagens that generate genetic diversity and provide new genes and genetic regulatory sequences to recipient viruses.[133,199,275]

Baculovirus mutants with transposon insertions are often distinguished by altered plaque morphology, including the "few polyhedra" (FP) phenotype in which reduced nuclear accumulation of OV facilitates mutant identification by light microscopy. Several FP-causing lepidopteran transposons, including PiggyBac, IFP2.2, IFP1.6, TFP3, and hitchhiker, have been identified by their insertion within or near the 25K protein gene (Ac61) of Ac*M*NPV.[12–14,42,90,91] Loss of function Ac61 mutants have reduced polyhedrin gene transcription and limited intranuclear envelopment of nucleocapsids that lowers OV accumulation.[13,32,138] The most prevalent baculovirus-associated transposons possess terminal inverted repeats flanking a transposase gene with specificity for the sequence TTAA. For example, PiggyBac is a small (2.47 kb) autonomous transposon identified in the moth *T. ni*.[90] It was the first nondrosophilid transposon used for stable germline transformation. PiggyBac and other related transposons have now been used for gene transfer in Lepidoptera, Diptera, Coleoptera, and Hymenoptera, and most importantly in insect species (ie, mosquitoes) of medical and agricultural significance for which P-element transformation has not been possible.[133,227,279]

The retrotransposon TED (transposable element D) was also discovered as an insertion within Ac*M*NPV.[92,95,213,216] TED is a 7.5-kb middle-repetitive retrotransposon that is actively transcribed within the Ac*M*NPV-permissive host *T ni*. Classified as an errantivirus (family *Metaviridae*), TED has a retroviruslike organization with *gag*, *pol*, and *env* genes that are flanked by long terminal repeats. It is closely related to errantiviruses of other lepidopteran and dipteran (*Drosophila*) insects.[95,213] Like a functional retrovirus, TED assembles viruslike gag-containing particles, complete with protease and reverse transcriptase activities.[132,190] The TED *env* gene also encodes a membrane-associated glycoprotein with properties expected of a retroviral envelope protein.[245] Interestingly, the *env* gene of TED and other errantiviruses bear a striking similarity to the baculovirus group II envelope fusion (F) proteins. Thus, it has been suggested that lepidopteran errantiviruses acquired their *env* gene from baculoviruses through an ancient integration/excision event.[206,252] Not ruled out is the alternative possibility that baculoviruses have acquired *env* (F) genes through errantivirus insertion, as is the case for the Ac*M*NPV insertion mutant carrying TED.[95,216] Nevertheless, the novel association between baculoviruses and active transposons has also led to studies demonstrating that virus-mediated shuttling of mobile genetic elements between insect species occurs in nature.[76,92,106,199,275]

Polydnaviridae (*Polydnaviriformidae*)

Classification and Structure of Polydnaviruses

The polydnaviruses have been historically classified as novel DNA viruses, which have their replication genes embedded within the genome of their insect host, the endoparasitic wasps. This novel arrangement allows for gene expression strategies that provide beneficial activities to the host wasp by facilitating development of the wasp's progeny within a parasitized host organism. However, these viruses do not replicate outside of the host wasp as they do not package a replicative genome or replication-specific gene products into their viruslike particles. Thus, as molecular studies of these viruses, the wasp host, and related virus families have progressed, debate about their classification as either viruses or viriforms (replication-incompetent gene transfer agents) have intensified. Recently, the International Committee on Taxonomy of Viruses (ICTV) ruled that members of the family *Polydnaviridae* are to be considered viriforms in classification and nomenclature and thus should be designated *Polydnaviriformidae*. For purpose of discussion here, these agents (polydnaviruses) will be referred to as "domesticated" endogenous viruses[75] (see below).

The polydnaviruses are large DNA viruses that are distinguished by their beneficial activities for their insect host, the endoparasitic wasps (order Hymenoptera). These wasps lay their eggs in the body of a living lepidopteran larva, wherein the wasp's offspring hatch and develop. Polydnavirus DNA-containing particles accompany the wasp egg upon oviposition and subsequently express virus-encoded virulence genes, which compromise the caterpillar's immune response and thereby protect and facilitate development of the wasp larva (Fig. 19.7). These viruses do not replicate in the parasitized caterpillar.

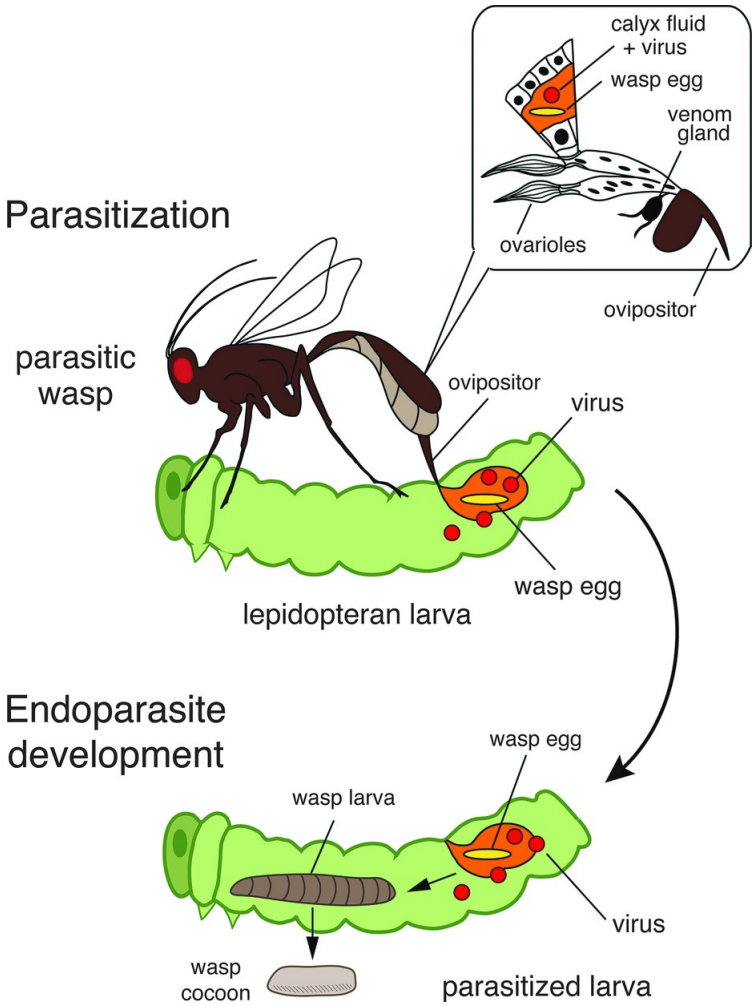

FIGURE 19.7 **Transmission of the polydnaviruses (*Polydnaviriformidae*)**. DNA-containing particles form in the epithelial cells of adult female ovaries and are released into the calyx fluid (**inset**) where they accumulate to high densities. In the first step of parasitization (*Top*), the wasp egg is injected along with virus and venom into a lepidopteran larva during oviposition. During endoparasitic development (*Bottom*), *Polydnaviriformidae*-encoded gene products suppress the larval immune response allowing the wasp egg to develop. After parasitization, the wasp larva spins a cocoon, pupates, and emerges as an adult to repeat the process. (From Dr. Bruce A. Webb, University of Kentucky; modified with permission.)

The family *Polydnaviridae* derived its name from the taxonomically characteristic "polydisperse" DNAs that comprise the multisegmented genome of these agents.[181,301,303] Polydnavirus particles contain numerous double-stranded, supercoiled DNA molecules with sizes ranging from 2 to >30 kbp. The particle's DNA is generated from the polydispersed proviral DNA embedded within the host wasp's genome. These genomic DNA fragments are amplified and packaged selectively as circular segments within the particle.[19,303] Remarkably, genome replication and particle assembly occur only in the wasp, not in the parasitized, immune-compromised caterpillar. Compelling metagenomic evidence suggests that the polydnaviruses are domesticated endogenous virus elements derived originally from the large DNA nudivirus family.[75,305] The close relationship between polydnaviruses and the nudiviruses was originally suggested by sequence similarities[18,336] between polydnavirus RNA transcripts expressed in the ovaries (the site of virus replication) of endoparasitic wasps with transcripts of nudivirus-infected insects. In contrast to the polydnaviruses, the nudiviruses have an autonomous life cycle, yet interestingly they also have the capacity to integrate into the host insect genome[257] (see below).

Polydnaviruses have been isolated from the *Ichneumonidae* and *Braconidae* families of wasps and are correspondingly divided into the ichnoviruses and bracoviruses, respectively.[19,181,303] The ichnovirus particles are ellipsoid with a uniform size of ~90 × 300 nm (Fig. 19.8); they resemble particles of the insect ascoviruses (see below). The nucleocapsid is enveloped by two-unit membranes, one derived from the nucleus during particle morphogenesis and the other by budding from the plasma membrane. In contrast, bracovirus particles consist of enveloped rod-shaped nucleocapsids with a uniform diameter (35-40 nm) and variable length (30-200 nm); they more closely resemble the nucleocapsids of nudiviruses and baculoviruses. Bracoviruses have a single membrane envelope, which is derived from the nucleus and surrounds one or more nucleocapsids (Fig. 19.8). Polydnavirus particles contain twenty or more virus-encoded polypeptides associated with the nucleocapsid and the membrane envelope. These structural proteins are produced in the wasp through the expression of proviral DNA.[19,181,303]

An inner (IM) and outer (OM) membrane surrounds the nucleocapsid (NC). **B**. Electron micrograph of an ichnovirus. Inner and outer membranes envelope the lenticular nucleocapsids (NC) of uniform size. **C**. Electron micrograph of bracovirus in the calyx fluid (CF) of a female parasitoid wasp. A single membrane envelope (E) surrounds multiple nucleocapsids (NC) viewed end-on or laterally. An epithelial cell (EC) of the calyx is shown. (Micrographs provided by Dr. Donald B. Stoltz, Dalhousie University. Modified from Stoltz DB, Vinson SB. Viruses and parasitism in insects. *Adv Virus Res*. 1979;24:125-171. Copyright © 1979 Elsevier, with permission.)

Polydnavirus Genome Organization

The polydnavirus genome is unique among animal viruses. It consists of an interrelated assortment of covalently closed, double-stranded DNA circles that exist in multiple topologies that include superhelical and relaxed circular forms. The complete genome sequence of many bracoviruses and ichnoviruses is known. The packaged DNAs (designated by letters) are nonequimolar and polymorphic in length.[181,301,303] For example, the 568-kbp genome of *Cotesia congregata* bracovirus (CcBV) consists of 30 dsDNAs ranging from 10 to >30 kbp.[79] Although each segment encodes at least one gene, a majority of the CcBV genome is comprised of noncoding DNA, in contrast to that of most autonomous DNA viruses. Not surprisingly, the aggregate size of polydnavirus genomes varies greatly and can be as large 600 kbp.[303] Many polydnavirus genes contain introns and thus resemble host genes. In the case of the ichnovirus prototype, *Campoletis sonorensis* polydnavirus (*Cs*IV), the encapsidated 247-kbp genome is comprised of 24 nonredundant circular DNA segments.[350] However, the *Cs*IV genome also contains multiple redundant segments and multiple repetitive elements. These higher copy number segments may provide increased expression of genes encoded therein. Each *Cs*IV genome segment encodes at least one gene but also contains portions that are homologous to other segments. Several of the ichnovirus segments are likely derived by recombination from larger segments and are thus described as "nested" segments.[181,303] This phenomenon also increases the copy number of certain virulence genes.

The packaged DNA of the bracoviruses and the ichnoviruses lack genes that are characteristic of known virus families, including those involved in DNA replication.[19,303] Instead, the particle DNAs encode several novel gene families that contribute to the pathology and immune modulation by these viruses in the parasitized host (see below). Thus, in the absence of any virus multiplication outside the wasp itself (ie, in the parasitized caterpillar), replicative genes are dispensable. Relevant to the origin of polydnaviruses, specifically the bracoviruses, is the finding that provirus genes expressed in the wasp ovaries include a set of 22 genes that are most closely related to those encoded by the autonomous nudiviruses that also infect lepidopteran caterpillars.[18] Of these bracovirus genes, 14 individual genes exhibit sequence similarity to those baculovirus genes involved in late gene transcription, virus DNA packaging, particle assembly, and membrane envelopment. However, there is no evidence for expression of those genes known to contribute to baculovirus DNA replication, including the *lefs* encoding DNA helicase, DNA polymerase, or DNA binding proteins. These findings and others support the notion that these polydnaviruses evolved from an ancestral nudivirus infection in the braconid wasps ~100 million years ago.[19,303,305] Sequence analyses of nonencapsidated ichnovirus structural genes expressed in ovaries of ichneumonid wasps suggest that the ichnoviruses may also have evolved from a yet to be identified ancestral virus unrelated to the bracoviruses.[305,336]

Proviral DNA of the polydnaviruses is present as integrated segments that are clustered at different loci of the wasp genome; thus, the provirus is inherited in a mendelian fashion. The mechanisms by which the polydnavirus genome is amplified, excised, and packaged into virus particles are poorly understood.[181,303] Evidence exists that proviral DNA segments within the wasp genome are amplified before excision and encapsulation. Where the relationship between the particle's DNA and the proviral DNA is known, the largest or "master" DNA segments within the wasp genome are flanked by direct repeats. For example, the 16-kbp integrated W segment of *Cs*IV is flanked by 1.2-kb repeats.[67,181] Within the W segment, additional 350-bp repeats generate nested segments R and M, apparently by homologous recombination during amplification in the female wasp. In the wasp genome, *Cs*IV segment B is flanked by 59-bp direct repeats that are removed during excision and circularization.[88] This finding and others are consistent with a mechanism in which *Cs*IV proviral segments are excised from the wasp genome, possibly by recombination, prior to amplification.[118] The presence of chromosomal sites lacking proviral DNA in tissues that accommodate viral replication is consistent with this later mechanism.

Polydnavirus Contributions to the Host's Life Cycle

Polydnaviruses play a critical role in the life cycle of endoparasitic wasps and contribute to their reproductive success. These endogenous viruses

multiply in the oviducts of female wasps as a normal step in the development of the reproductive tract (Fig. 19.7). Virus multiplication is under hormonal control and initiates during development of the wasp as a pupa.[181,303] Virus DNA production, encapsidation, and particle assembly occurs in the nucleus of epithelial calyx cells of the wasp's oviducts (Fig. 19.7). In mature females, the particles are released from the calyx cells into the oviduct lumen, either by budding (ichnoviruses) or by cell lysis (bracoviruses). Polydnavirus particles accumulate to high density in the calyx fluid and are deposited along with the egg and other wasp secretions in the target larva during oviposition (Fig. 19.7). Virus gene expression in the wasp differs from that in parasitized caterpillar hosts.[181,303] Despite the presence of high concentrations of particles, polydnaviruses cause no obvious pathology in provirus-carrying wasps. The predominant form of viral DNA in the wasp male is the integrated provirus.

Polydnavirus Modulation of Larval Responses During Parasitization

Upon oviposition, the female wasp delivers her egg accompanied by virus particles to the recipient caterpillar (Fig. 19.7). The caterpillar normally mounts an immune response that encapsulates and destroys the intruding egg in a process mediated in part by hemocytes of the larva's circulatory system. However, in the case of polydnavirus-carrying ichneumonid and braconid wasps, the virus suppresses encapsulation and other aspects of the larva's immune response, which allows proper development of the wasp's offspring. In experiments where the egg is artificially injected into the larva in the absence of virus, the egg is destroyed, thereby demonstrating a definitive role for virus-mediated abrogation of the larva's immune response.[78] Thus, gene expression of the delivered virus particles function to protect the wasp egg from the immune response of the recipient larva.

The most obvious physiological effect of the polydnaviruses is in the parasitized insect host, where larval immunity and development are altered.[181,303] Neither virus replication nor virus assembly occurs in parasitized larva. However, particle DNA is long-lived and viral RNA transcription occurs throughout parasitization, principally in larval hemocytes and fatbody (the equivalent of the vertebrate liver). In caterpillars, the primary immune response to parasitization is encapsulation of the wasp egg and includes direct attachment of larval hemocytes in layers. Polydnaviruses suppress encapsulation by altering the physiology of the capsule-forming hemocytes (granulocytes and plasmatocytes).[303] Some polydnavirus gene products are secreted and may affect surrounding hemocytes and tissues. In the case of *Microplitis demolitor* bracovirus (MdBV), virus-induced apoptosis kills a subclass of hemocytes that mediate the encapsidation response.[306] Nonetheless, some hemocytes survive to express polydnavirus genes that alter their function.

Polydnavirus particles carry the genes for suppression of the caterpillar's immune response.[181,303] Multiple gene families contribute to immune modulation. This repetition and variation of related pathogenicity genes may enhance expression levels or facilitate tissue targeting during parasitization. One such gene family expressed during parasitization includes the viral ankyrin (*vankyrin*) genes, which encode factors with ankyrin repeat domains belonging to the Iκβ family of proteins.[182,322] Two *vankyrin* genes of MdBV exhibit normal Iκβ activity by inhibiting NF-κβ responsive genes when exogenously expressed in *Drosophila* cells.[322] Suggestive of their importance in immune modulation, *vankyrin* genes are encoded by both the ichnoviruses and the bracoviruses. NF-κβ is an important regulator of insect genes encoding antimicrobial peptides and factors involved in cellular immunity.[303] Thus, the Iκβ-like activity of the *vankyrin*s could disrupt NF-κβ activation of these immune response genes in the parasitized larva. Polydnaviruses also carry a family of genes (*ptp*) that encode tyrosine phosphatase–like proteins (PTPs). Cellular PTPs regulate receptor–mediated signal transduction pathways, suggesting that the virus-encoded PTPs function similarly to downregulate the immune response. Indeed, two bracovirus *ptp*s are involved in suppression of encapsulation and phagocytosis.[264,307] Polydnavirus pathogenesis genes can also have either proapoptotic or antiapoptotic effects on lepidopteran cells,[80,307] suggesting that virus-mediated control of apoptosis contributes to immune suppression. Other polydnavirus-encoded immune modulator genes, including those predicted to encode epidermal growth factor–related proteins, cysteine-rich motif proteins, vinnexin, and *rep* proteins, have been identified.[79,181,303]

The *Polydnaviridae* family is a fascinating group of agents that challenge the definition of a virus. On the basis that the polydnaviruses represent a type of mobile genetic element, incapable of autonomous replication, but which evolved from host wasp genes and virus capsid genes in order to contribute positively to the wasp's life cycle (see above), the ICTV has recognized these entities as a category distinct from viruses, designating them "viriforms" (*Polydnaviriformidae*). On the other hand, persuasive evidence has suggested that the polydnaviruses are a type of "domesticated" endogenous virus.[75,305] The multiple proliferative genes conserved between the bracoviruses and the autonomous-replicating insect nudiviruses, as well the abundance of functional virus particles, suggest that the "polydna" bracoviruses were derived through genomic integration of an ancient nudivirus, which was followed by evolutionary loss of autonomy. Likewise, the nonautonomous ichnoviruses may have evolved from a yet to be identified ancestral virus, which was capable of genomic integration. Continued study of *Polydnaviridae* or *Polydnaviriformidae* will undoubtedly provide key insight into the evolution of these novel virus elements and promises to reveal fundamental understanding of the insect immune system and its regulation.

Ascoviridae

Classification and Structure of Ascoviruses

Ascoviridae is a family of large DNA viruses that primarily infect insects of the order Lepidoptera (moths and butterflies) and cause a slow fatal disease.[84,85,355] The name ascovirus is derived from the Greek word *askós* (sac), which describes the large membrane-bound vesicles that are associated with virus development. The formation of these virion-containing vesicles represents the family's distinguishing feature[81,82,85] and is critical to the virus' dissemination strategy that involves endoparasitic wasps (see below). The ascoviruses are one of the newest DNA virus families to be discovered, with a limited number of species identified to date. Depending on the species, ascovirus particles are reniform (kidneylike) or bacilliform in shape (Fig. 19.9A). The virions (~400 × 130 nm) have an electron dense core surrounded by two-unit membrane envelopes (Fig. 19.9B). At least 21 different proteins, ranging in size from 9 to 120 kDa, are present in virions of the prototype ascovirus, *Spodoptera frugiperda* ascovirus 1a (SfAV).[312] The ascovirus genome is a double-stranded circle of DNA ranging in size from ~150 to 190 kbp, depending on the species and encodes from 120 to 180 open reading frames.[84,355] Nucleotide sequence analyses indicate that the ascovirus family is unique but exhibits some relatedness to the invertebrate iridoviruses.[21,355]

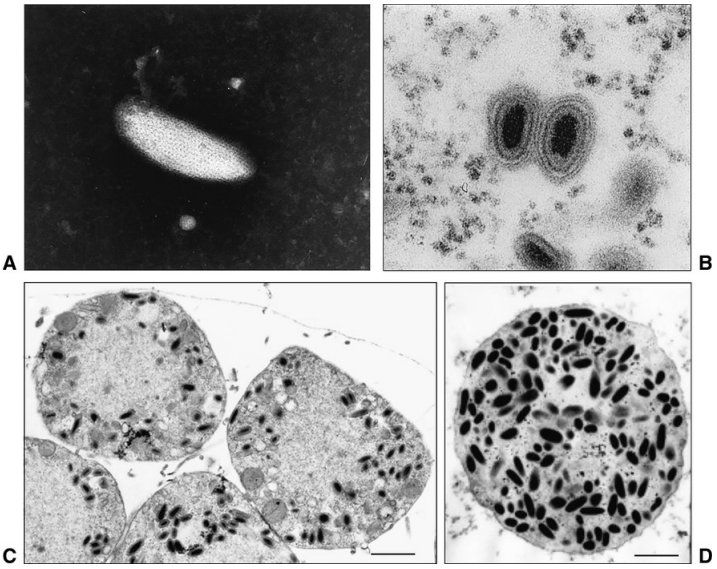

FIGURE 19.9 **Ascoviruses**. **A.**A single virion of *Trichoplusia ni ascovirus* (TnAV). The kidney-shaped virion has a reticular surface when negatively stained and examined by electron microscopy. **B.** Cross section of two ascoviruses. Virions in the larval fat body of *Scottogramma trifolii* (Lepidoptera, family Noctuidae) are imaged through the middle of their long axis. A multilayered membrane surrounds the central nucleocapsid. **C.** Intracellular vesicles formed from a TnAV-infected fat body cell. The electron micrograph shows four nascent viral vesicles bordered by the fat body's basement membrane (*thin line* at the *top*) that has not yet ruptured to release these vesicles into the hemolymph. Both mature (enveloped) and immature (nonenveloped) TnAV nucleocapsids (dark stained, kidney shapes) are present. **D.** A mature TnAV viral vesicle circulating in the hemolymph. The grazing peripheral electron micrograph shows mostly mature virions ready to be released into the hemolymph. Bars: 800 nm. (**A** courtesy of Dr. Brian A. Federici, University of California-Riverside and Dr. J. J. Hamm, USDA-ARS, Tifton, GA; **B** modified from Federici BA. Extended in vivo transcriptomes of two ascoviruses with different tissue tropisms reveal alternative mechanisms for enhancing virus reproduction in hemolymph. *Sci Rep*. 2021;11(1):16402. http://creativecommons.org/licenses/by/4.0/.

Stages of Ascovirus Replication

The first visible sign of ascovirus infection is hypertrophy of the cell and its nucleus; the infected cell's diameter can increase up to 10-fold.[83,85] The nucleus subsequently fragments and the infected cell is divided into 20-30 membrane-bound vesicles containing assembling virions (Fig. 19.9C). This process involves extensive invagination of the plasma membrane and mimics that which occurs during apoptosis. Once virus-containing vesicles dissociate from the infected cell, they are released into the larva's hemolymph. The larva's basement membranes are then disrupted and the hemocoel fills with ~10^8 vesicles/mL, which gives the hemolymph a distinguishing milky white color.[81,82] These vesicles with their associated virus are subsequently picked up during the egg laying process by the parasitic wasp's ovipositor.

Interestingly, a hostlike effector caspase encoded by the ascovirus SfAV likely contributes to this unusual vesicle formation during infection.[20] Thus, the ascoviruses may have exploited host cell apoptosis to expedite virus transmission by endoparasitic wasps (see below). *Heliothis virescens* ascovirus (HvAV) also encodes a caspase, but multiplication in cell lines fails to induce comparable vesicle formation.[2] Thus, the role of ascovirus caspases or that of the host's caspases during larval infection remains to be clarified. The ascoviruses encode several lipid metabolism enzymes, which may also contribute to vesicle production.[84]

To date, ascovirus replication mechanisms are poorly understood. RNA-sequencing studies that surveyed the SfAV transcriptome in infected caterpillars revealed that transcription occurs predominantly in virus-generated vesicles, not in the originally infected tissues consisting mostly of the fat body.[370,371] This finding suggests that the assembly of infectious virions also occurs in the virus-generated vesicles. Thus, the ascovirus vesicle may represent a viral factory that is unique among DNA viruses.[371] Multiplication in lepidopteran cell cultures has revealed possible roles for viral and cellular microRNAs in regulation of *Heliothis virescens* HvAV.[4] Interestingly, HvAV and other ascoviruses encode an RNAse III gene, which exhibits nuclease activity for double-stranded RNA and appears to be essential for virus multiplication.[153] Encoded by few other viruses, RNAse III proteins play an important role in RNA silencing.

Ascovirus Transmission, Disease, and Host Range

In nature, the principal transmission route of ascoviruses involves endoparasitic wasps, which carry virus-containing vesicles on their ovipositor as a result of egg laying. In the laboratory, ascovirus inoculation is accomplished mechanically by pricking the host larva with a needle containing virus-containing vesicles.[84] A dose of 10 larva-derived vesicles is sufficient for 90% infection. The viruses cause a slow, chronic infection in larvae or pupae. The disease causes reduced feeding, developmental arrest, and death within 2-6 weeks. There is little obvious pathology during the early stages of infection. Some larvae exhibit the characteristic milky discoloration due to the abundance of virus-containing vesicles. The host range of ascoviruses may include only a few closely related insect species, mostly of the order Lepidoptera.[84] However, the lack of obvious pathology early in infection may mean that the host range is broader than that suggested by entomological surveys.

Nudiviruses

Classification, Structure, and Genomics of the Nudiviruses

Historically, the nudiviruses were thought to be nonoccluded baculoviruses because of their common characteristics, including rod-shaped nucleocapsids, a circular, double-stranded DNA genome, and nuclear replication.[37] However, nucleotide sequence analyses subsequently revealed that the nudiviruses are only distantly related to the baculoviruses.[257,347,355] Thus, the new family *Nudiviridae* accommodates these novel insect pathogens. The nonoccluded nature of the virion confers the virus family name "nudi" from the Latin word "*nudus*" (naked). Nudiviruses infect multiple orders of insects, including the Diptera, Lepidoptera, Coleoptera, and Orthoptera, as well as some aquatic crustaceans. They are divided into four genera: the alpha-, beta-, delta-, and gamma-nudiviruses.[136,257]

Varying in size from 97 to 232 kbp, the nudivirus DNA genome is packaged into a nucleocapsid that is surrounded by a membrane envelope acquired within the nucleus and one obtained upon budding from the plasma membrane. As determined from nucleotide sequence analyses, there are 32 core genes present in all nudivirus genomes.[136,257] Of these conserved core genes, 20 exhibit sequence similarity with baculovirus and bracovirus genes that are involved in transcription, DNA replication, and nucleocapsid structure or assembly.[257,347] In general, nudivirus replication mechanisms are poorly understood, so the exact functions of these nudivirus core genes are unknown. Infection can cause cell lysis and insect mortality or establish a persistent or latent infection (see below). Although characterized as nonoccluded viruses, certain nudiviruses also possess a gene related to polyhedrin or granulin used by baculoviruses for occlusion. It is interesting to speculate that this occlusionlike gene is the remnant of a common ancestor of the nudiviruses and baculoviruses.

Nudivirus Latency and Transmission

Originally isolated from a *Heliothis zea* (corn earworm) cell line, HzV-1 is one of the best-characterized nudiviruses (genus *Betanudiviridae*). The HzV-1 genome is a large (~228 kbp) circle of double-stranded DNA[52] that possesses ~154 ORFs, many of which have striking sequence similarity to the core baculovirus replication genes. A hallmark of HzV-1 is its capacity to establish persistent or latent infections.[37] HzV-1 persistence involves stable integration of the genomic DNA and low-level, spontaneous replication of virus that can cause lytic infection of naive cells.[197] The establishment of viral persistence or latency is associated with the presence of a single 2.9-kb HzV-1 RNA transcript, designated the persistency-associated transcript (PAT1).[47] PAT1 is a noncoding RNA that is the only HzV-1 RNA detected during latency. PAT1 appears to suppress the HzV-1 *hhi*-1 gene by a mechanism that involves the generation of microRNAs that target and destabilize *hhi*-1 RNA transcripts.[363] Transcription of HzV-1 *hhi*-1 gene occurs early in infection and mediates reactivation from latency, thereby contributing to a productive infection.[362] Consequently, HzV-1 may use microRNAs derived from its single latency transcript in an RNA interference mechanism that is required for establishment of latency.[363] Thus, HzV-1 will serve as a useful model for mechanistic studies of insect virus latency.

Oryctes virus is another notable nudivirus (genus *Alphanudivirus*). Distinguished by its unique tail-like structure protruding from one end, this 128-kb DNA virus shares many genes with other nudiviruses and certain replication, transcription, and nucleocapsid genes with the baculoviruses.[346] Oryctes virus causes fatal infections of the rhinoceros beetle *Oryctes rhinoceros*, which is a serious pest species of palm trees in South-East Asia and the Pacific region.[156] Consequently, this virus is a very effective biological control agent used in coconut and palm oil plantations of the area.[250] Virus is transmitted by contaminated food sources or mating. Typical of most nudiviruses, little is known about its replication mechanisms.

Nodaviridae

Classification and Host Range of Nodaviruses

Members of the family *Nodaviridae* are small RNA viruses with a single-stranded, positive-sense genome consisting of two RNAs. The bipartite genome is packaged within a single, nonenveloped virion (~30 nm dia) with T = 3 icosahedral symmetry.[9,11,333] The genome organization and replication strategy of the nodaviruses is among the simplest of known viruses (Fig. 19.10). As such, they are powerful models for exploring strategies of virus RNA replication, virion assembly, host interactions, and RNA silencing.

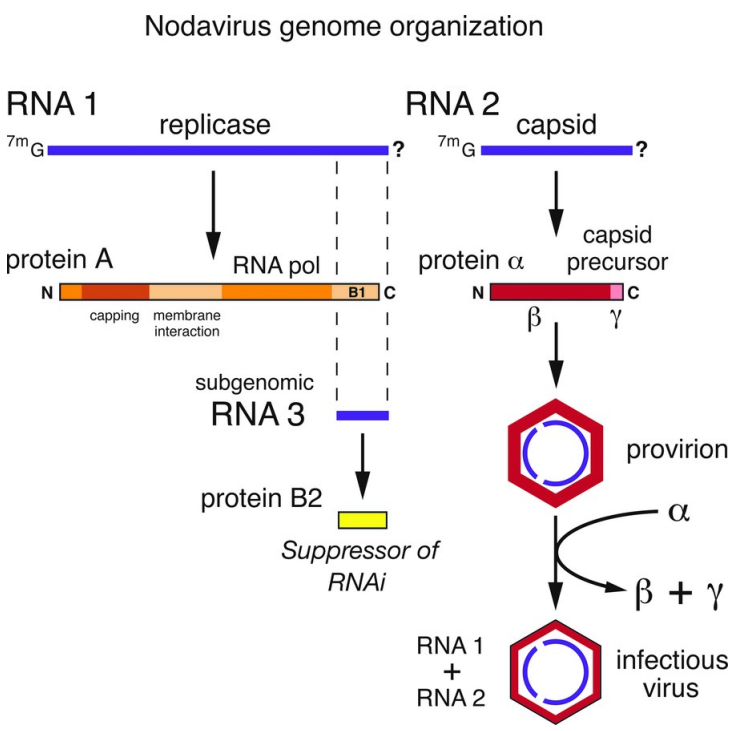

FIGURE 19.10 **Nodavirus genome organization and assembly**. Positive-sense genomic RNAs 1 and 2 encode the replicase (protein A) and capsid precursor protein (protein α), respectively. Protein A possesses RNA capping, membrane interaction, and RdRp domains. Derived from RNA 1, subgenomic RNA 3 encodes protein B2, which functions as a suppressor of host cell RNA silencing (RNAi). Assembled from capsid precursor α, nodavirus provirions undergo a required maturation cleavage, which yields capsid proteins β and γ. Infectious virions contain an equimolar ratio of genomic RNA 1 and 2.

The nodaviruses are divided into two genera, the alphanodaviruses and betanodaviruses, which infect insects and fish, respectively. Distinct from alpha- and betanodaviruses, another group of nodaviruses associated with crustaceans, including shrimp or pawn, have been recently identified and tentatively classified as gammanodaviruses.[277] The Nodavirus family name originated from Nodamura virus, which was first discovered in mosquitoes near the Japanese village of Nodamura.[282] The best-studied insect nodaviruses include flock house virus (FHV), black beetle virus (BBV), Nodamura virus (NoV), and Wuhan nodavirus (WhNV). These viruses were isolated from the grass grub *Costelytra zealandica* (Coleoptera) in New Zealand, the scarab beetle *Heteronychus arator* (Coleoptera) also in New Zealand, the mosquito *Culex tritaeniorhynchus* (Diptera) in Japan, and the Small Cabbage White butterfly *Pieris rapae* (Lepidoptera) in China, respectively.[333] Most members of the alphanodavirus genus were isolated from insects of Australasia. Other alphanodaviruses include Pariacoto virus (PaV), New Zealand Virus, Boolarra virus, and Manawatu virus. NoV is the only nodavirus with the capacity to multiply in vertebrates.[9] Nonetheless, upon transduction of their genomic RNA, many nodaviruses can replicate in cells from highly diverse organisms, including mammals, nematodes, plants, and the yeast *Saccharomyces cerevisae*.[6,204,260,287]

Nodavirus Virion Structure

The nodaviruses have provided enormous insight into icosahedral virus assembly and maturation. The structures of BBV, FHV, NoV, PaV, and others have been determined at atomic resolution (go to: http://bcrf.biochem.wisc.edu or http://viperdb.scripps.edu/).[11,87,148,313,375] Each virion contains 180 copies of the same capsid protein (Fig. 19.11A). Sixty triangular units, consisting of three similarly folded capsid proteins, form an icosahedral lattice with T = 3 symmetry.[158,283] Three capsid proteins form a prominent peak at the quasi-threefold axis. At the twofold axes, conserved C-terminal residues of the capsid protein make contact with duplexed genomic RNA that is highly ordered and stabilize the capsid protein interface.[87] The structures of nodaviruses, including that of PaV and FHV, reveals a dodecahedral cage of ordered double-stranded RNA (Fig. 19.11B) that constitutes 35% (1500 nucleotides) of the single-stranded RNA genome.[313,323] The RNAs interact extensively with the basic N-terminal region of the capsid protein. C-terminal residues of the capsid protein are required for RNA encapsulation.[333] At the fivefold axis, the capsid proteins form a pentameric helical bundle that has been proposed to participate in release of the genomic RNA upon virus penetration into the host cell's cytosol.[53]

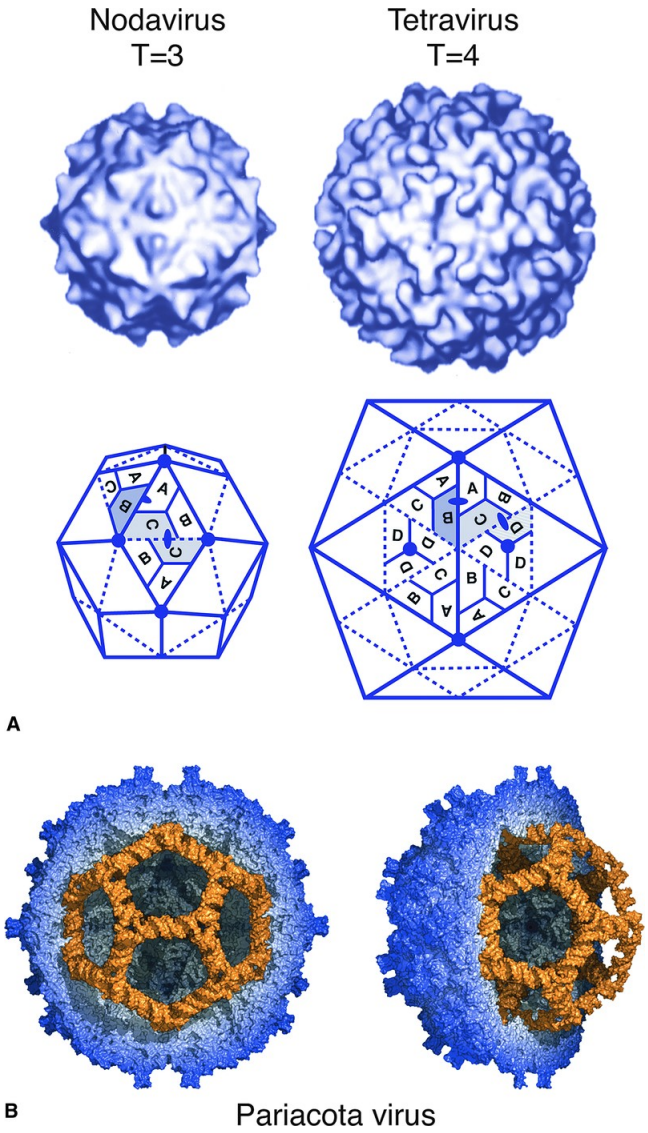

FIGURE 19.11 **Comparison of nodavirus and tetravirus structures**. **A**.(*Top*) Image reconstructions of a T = 3 nodavirus (flock house virus) and a T = 4 tetravirus (*Nudaurelia capensis* ω virus). The average particle diameter for the nodaviruses and tetraviruses is 320 and 415 Å, respectively. (*Bottom*) Subunit arrangement of the nodavirus (T = 3) and the tetravirus (T = 4) virions. Each subunit is indicated by a trapezoid. Nodaviruses contain 60 subunits of three similarly folded capsid proteins (A, B, and C) that form a prominent peak at the quasi-threefold axis (*top* image). Tetraviruses contain 240 capsid protein subunits (A, B, C, and D) in which 12 subunits comprise each triangular face of the virion (see images at http://bcrf.biochem.wisc.edu or http://viperdb.scripps.edu/). **B**. Arrangement of genomic RNAs within the virion of the nodavirus Pariacoto virus. The symmetrically arranged shell of helical RNA (*orange*) contacts capsid proteins on the inside surface of the virion (*blue*). (Adapted with permission from Dr. John E. Johnson, Scripps Research Institute, La Jolla, CA. Images of Pariacoto virus were kindly provided by Jean-Yves Sgro, Department of Biochemistry, University of Wisconsin-Madison.)

The nodavirus provirion is assembled from 180 copies of the ~43-kDa capsid precursor α. During virion maturation (Fig. 19.10), α is cleaved very near its C terminus to generate capsid proteins β and γ.[96,103] For FHV, this autocatalytic postassembly cleavage occurs between residues Asn^{363} and Ala^{364} which are located on the inside surface of the virion. This cleavage event is required for infectivity and virion stability.[103,284]

Nodavirus Genome Organization

The nodavirus genome consists of two single-stranded, messenger-active RNAs, designated RNA 1 and 2. Both RNAs are 7-methyl GpppN capped but not polyadenylated (Fig. 19.10). The 3′ ends of both RNAs have an unknown structure or unidentified factor attached. RNA 1 (~3.1 kb) encodes the functions required for RNA transcription and replication, whereas RNA 2 (~1.4 kb) encodes the single coat protein α. Both RNAs are required for infectivity and are packaged within the same virion.[333] RNA 1 carries all the information necessary for autonomous replication.[102] It encodes at least three polypeptides: proteins A, B1, and B2 (Fig. 19.10). Protein A (~112 kDa) is an RNA-dependent RNA polymerase (RdRp) that is required for virus RNA replication.[8,102] Encoded by the 3′ end of RNA 1, protein B1 has an unknown function. Protein B2 (~12 kDa) is translated from subgenomic RNA 3 (Fig. 19.10), which is derived from the 3′ end of RNA 1. In infected cells, RNA 3 is abundant but not packaged into virions.[97,120] Protein B2 is a suppressor of host-mediated RNA silencing (see below). Nodavirus genomic RNA 2 encodes the capsid precursor protein α, which is autocatalytically cleaved to yield capsid protein β and peptide γ (Fig. 19.10) during maturation. Thus, the functions necessary for genome replication (RNA 1) and virus transmission (RNA 2) are segregated onto different genetic elements.

Stages of Nodavirus Replication

As the best-studied nodavirus, FHV multiplies prolifically in *Drosophila melanogaster* cell lines.[333] This system has proven highly tractable for molecular studies of virus replication mechanisms. Although the *Drosophila* receptor is unknown, it is likely that FHV enters by receptor-mediated endocytosis. The endosome's acidity triggers an irreversible exposure or release of the capsid γ peptides, which disrupts the endosomal membrane and facilitates release of the genomic RNAs into the cytoplasm.[340] Required for membrane penetration, the lipophilic γ peptide is generated by autoproteolytic cleavage of capsid protein precursor α (Fig. 19.10) within the assembled virion.[10,232]

Immediately upon release in the cytoplasm, translation of the positive-sense genomic RNAs begins. RNA 1 produces protein A, the RdRp that carries RNA capping activity and membrane-association domains. Protein A interacts with the outer mitochondrial membrane to form spherical (~50-nm diameter) lipid vesicles called spherules[215] (Fig. 19.12A and 12B). Both protein A and replicating FHV RNA are required for spherule formation.[171] Mitochondrial phospholipids and cellular chaperones are critical for FHV RNA replication and thus are also likely important for spherule assembly.[299,352] A single replicating RNA intermediate, located inside the spherule, is connected to the outside cytoplasm by a single necklike portal rimmed with protein A (Fig. 19.12C). CryoEM studies[326] have indicated that protein A oligomerizes to form a 12-fold symmetrical crown structure on the cytosolic side of the membrane portal (Fig. 19.12D). The striking crown contains 12-fold symmetrical projections that rim the portal's entrance/exit. It is thought that the protein A–containing crown assembly plays a critical role in viral RNA production as protein A has both RdRp and RNA-capping functions.[326] Remaining to be explained is how protein A recruits the initiating positive-sense RNA template to generate the spherule with negative-sense replicative intermediate RNA on the inside that ultimately yields high levels of positive-sense RNA for translation and packaging.[326] Newly synthesized nodavirus RNAs are detected within 2 hours after inoculation and continue to accumulate through 20 hours. By then, viral RNA represents up to 50% of the total cellular RNA, an astounding level considering that it is comparable to that of ribosomal RNAs.[96,98,103] It is noteworthy that many RNA viruses replicate their RNA in association with membranes and some in spherulelike vesicles, including the alphaviruses and distantly related coronaviruses. The nodaviruses offer many experimental advantages in probing the mechanistic details of this conserved replication process (Fig. 19.12).

Curr Opin Virol. 2021;51:74-79.)

During infection, nodavirus RNA synthesis is temporally regulated. Late in infection, the replication of genomic RNA 1 and 2 is coupled, which ensures production of an equal molar ratio of both RNAs required for virion packaging. However, early in infection, subgenomic RNA3, which produces B2 to suppress the host RNAi response, transactivates RNA2 replication.[7] As the level of RNA2 increases, it represses RNA3 production[102] through a feedback inhibitory mechanism.[333] *Cis*-acting sequences required for (+) and (−) strand RNA transcription and RNA 3 suppression have been identified.[9] The FHV RNA 1 nucleotide sequences that direct self-replication and RNA 1 recruitment to the mitochondrial membranes have also been defined.[328]

Translation of nodavirus RNA 2 yields abundant levels of the capsid precursor α, which is cleaved during capsid assembly (Fig. 19.10). Despite equal levels of intracellular RNA 1 and 2, synthesis of capsid protein α predominates late in infection as a direct result of the ability of RNA 2 to out compete RNA 1 for rate-limiting translation factors.[98] As capsid precursor α accumulates, an equimolar ratio of RNA 1 and 2 are packaged within the provirion; the mechanism that ensures this 1:1 stoichiometry is unknown. Before cell lysis, extraordinary yields of assembled particles (2 mg per 10^8 cells) accumulate in the cytosol of the infected cell and extensive crystalline arrays in the cytoplasm are often observed. Owing to the segmentation of the genome, reassortment of genomic RNAs occurs in mixed infections. Defective interfering particles appear often and can establish persistent nodavirus infections in cell culture.[162,333]

Permissive *Drosophila* cells respond to nodavirus FHV infection by undergoing caspase-dependent apoptosis.[290] Indeed, both alphanodaviruses and betanodaviruses can trigger apoptosis during multiplication.[129,290] FHV-mediated depletion of the endogenous inhibitor of apoptosis DIAP1 triggers apoptosis in *Drosophila*, as it does during baculovirus-induced apoptosis in these cells.[290,332] Because host caspases are not required for nodavirus assembly or maturation, the process of apoptosis and the resulting membrane-protected vesicles may facilitate virus release and subsequent dissemination to tissues within the infected host insect.

Nodavirus Suppression of Host RNA Silencing

Nodaviruses have also provided important understanding of the molecular mechanisms by which RNA viruses trigger the antiviral RNA silencing response in host cells and how viruses suppress the response through the activity of virus-encoded RNA-binding proteins.[1,72,333] RNA silencing or RNA interference (RNAi) is a critically effective antiviral defense in invertebrates.[30] Capable of targeting and destroying RNAs from viruses and transposons, RNAi may be a primordial form of innate immunity.[70] Nodavirus protein B2 functions to suppress RNA silencing that is mounted by the host cell in response to virus RNA replicative intermediates.[192] B2 of FHV was the first discovered example of an RNAi suppressor from an animal virus. B2 enhances FHV multiplication and virus-mediated killing in cultured cells as well as adult *Drosophila* flies.[101,159,192,345] Demonstrating the effectiveness of the RNAi response in insects, mutant flies with defective RNAi components are more susceptible to killing by FHV.[101,345] Interestingly, Nodamura virus B2, which grows in both vertebrates and invertebrates, can suppress the RNAi response in both.[192,194]

The anti-RNAi function of nodavirus B2 is attributed to its sequence-independent dsRNA binding activity.[1,333] B2 binds to dsRNA (probably dsRNA replicative intermediates generated during virus RNA synthesis) and prevents cleavage by the RNAaseIII-like endonucleases (Dicer) of the RNAi pathway. Thus, B2 suppresses the generation of small interfering RNAs that are complementary to viral RNAs and used to degrade viral messenger RNA. The crystal structure of FHV B2 in complex with dsRNA shows B2 as a small four-helix polypeptide that binds as a dimer to a single face of duplex RNA in a sequence-independent manner.[46] Nodamura virus B2 has a similar protein fold despite its divergent sequence.[172] It is likely that multiple copies of nodavirus B2 bind to viral dsRNAs, thereby protecting them from cleavage by Dicer and blocking incorporation into the RNAi silencing complexes.[46,267] It will be of interest to determine where B2's dsRNA binding activity occurs in the infected cell relative to the nodavirus RNA-replicating spherules on the mitochondrial membranes.

Tetraviridae

Classification of Tetraviruses

The tetraviruses are small RNA viruses that multiply almost exclusively in lepidopteran insects (moths and butterflies). They contain a single-stranded, positive-sense RNA genome that is packaged into a nonenveloped, icosahedral virion. The family name *Tetraviridae* ("tetra" from Greek *tettares*, meaning "four") is derived from the virion's T = 4 symmetry, which is the only known T = 4 symmetry among nonenveloped viruses.[73,74,158] A major contribution of these viruses has been their use as models for defining molecular mechanisms of assembly and maturation of icosahedral viruses. Recently, cell culture systems have been identified—thus, more information on tetravirus replication strategies will be available. Tetraviruses are represented by three families: *Alphatetraviridae*, *Permutotetraviridae*, and *Carmotetraviridae*. *Alphatetraviridae* is divided into two genera, *Omegatetravirus* and *Betatetravirus*, in which *Nudaurelia capensis* β virus (NβV) and *Nudaurelia capensis* ω virus (NωV) are the prototype species, respectively.[73] The tetravirus-encoded RNA-dependent RNA replicase distinguishes each family.

Virion Structure

The T = 4 structural features of the tetraviruses (Fig. 19.11) is indicated by cryo-EM reconstructions and X-ray crystallography, including that of NωV and Providence virus (PrV), a *Carmotetravirus*.[222,297] The tetravirus particle contains 240 capsid protein subunits. Twelve chemically identical capsid proteins comprise each triangular face of the virion. The T = 4 capsid arrangement is readily distinguished from the T = 3 symmetry of the smaller nodaviruses that have 60 fewer capsid proteins per particle (Fig. 19.11). Remarkably, the tertiary structures of the

capsid proteins of the virus families are similar. Moreover, the NωV capsid precursor is cleaved after Asn^{570} near the C-terminus in a postassembly mechanism that generates capsid protein β and a smaller peptide γ in a pattern analogous to the required maturation cleavage of the nodavirus capsid precursors (see above). The surface exposure of the lipophilic nodavirus γ peptide disrupts membranes,[10,232] suggesting a comparable role for tetravirus virus membrane penetration. The capsid precursor of PrV is also autocatalytically cleaved to produce a larger β capsid protein and a small C-terminal γ peptide. However, the PrV γ peptide has a structure and function unlike that of NωV.[297] Instead, the PrV γ peptide contributes to genomic RNA binding within the virion particle, like the nodavirus γ peptide. The striking similarities between the PrV and nodavirus γ peptides suggest that PrV is more closely related to the T=3 nodaviruses. It has been suggested that the tetraviruses and nodaviruses may have evolved from a common ancestor.[158,297]

Tetravirus Genome Organization

The tetravirus RNA genome is either mono- or bipartite. The single, monopartite RNAs range in size from 5.6 to 6.6 kb, contain a 7-methyl GpppN cap structure at the 5′ end, and possess a unique tRNA-like structure at the 3′ end.[73] The monopartite genome of NβV has two large ORFs. The 5′ proximal ORF encodes a 214-kDa RNA-dependent replicase–like protein with motifs characteristic of a methyltransferase, nucleotide-binding helicase, and an RNA polymerase. As expected, the RNA replicase–containing polyproteins of the tetraviruses are proteolytically processed.[74] The 3′ proximal NβV ORF encodes the 66-kDa capsid protein. The capsid ORF overlaps the replicase ORF but uses a different (+1) reading frame. It is, therefore, likely that the capsid is translated from a 2.5-kb subgenomic RNA.[114] Indeed, *Thosea asigna* virus (TaV) synthesizes a 2.5-kb subgenomic RNA that encodes the capsid protein.[263]

The omegatetraviruses have a bipartite RNA genome.[73] For example, the bipartite genome of *Helicoverpa armigera* stunt virus (HaSV) consists of RNA1 (5300 bases), which encodes the RNA replicase and smaller proteins, and RNA2 (2478 bases), which encodes the 71-kDa HaSV capsid protein and a smaller protein (p17), which may be involved in packaging of viral RNA during capsid assembly.[73,113] Characteristic of the tetraviruses, the HaSV capsid precursor is cleaved near its C-terminus to generate a ~62-kDa β protein and a smaller 7-kDa γ peptide during assembly. It is unclear whether the omegatetraviruses package both genomic RNAs into a single virion, like the nodaviruses.

Tetravirus Replication, Transmission, and Pathology

Tetraviruses multiply in the cytoplasm of infected cells whereupon crystalline arrays of virus particles accumulate within vesicles.[140] Before permissive cell lines were identified, replication studies were limited to ectopic expression of individual virus genes in heterologous cell lines.[292] Recently, *Helicoverpa armigera* stunt virus (HaSV) was found to multiply productively in cultured *Spodoptera frugiperda* Sf9 cells.[254] Limited multiplication of PrV also occurs in lepidopteran cell lines and newly synthesized genomic and subgenomic RNAs, as well as virus-encoded capsid proteins, are detected.[297] As expected, tetravirus replication occurs on host membranes in the cytoplasm.[73] The availability of permissive cell lines will allow further study of these RNA viruses.

Currently, the tetraviruses are the only known RNA viruses restricted to insects, specifically those within the order Lepidoptera (PrV may represent an exception). Larval infection can be initiated by the ingestion of virus-contaminated foods.[134] Virus multiplication is often restricted to the foregut and midgut cells, even upon injection of infectious virus into the hemolymph of larvae. Virus-mediated killing of midgut cells may account for the stunting pathology associated with HaSV. Susceptible insect larvae exhibit a wide range of pathogenic effects that include rapid death, an extended wasting disease, or a delay in pupation.[74] Death occurs within 4-7 days and is usually accompanied by discoloration, flaccidity, and sometimes liquefaction. Tetravirus infections occur sporadically in natural populations. Thus, ecological aspects of virus spread and the existence of virus reservoirs are poorly understood. Nevertheless, these insect viruses are natural biopesticides that have been observed to control certain insects and several viruses, including *Darna trima* virus and *Thosea asigna* virus, have been successfully applied as biopesticides in oil palm plantation settings.[112]

Dicistroviridae

Classification and Structure

Members of *Dicistroviridae* are small, nonenveloped RNA viruses named for the unusual bicistronic arrangement of their single genomic RNA (Table 19.1). Although these icosahedral insect viruses resemble the vertebrate picornaviruses, they form a taxonomically distinct family.[28,55,143] The best-characterized dicistrovirus is cricket paralysis virus (CrPV), the type species within the *Cripavirus* genus of *Dicistroviridae*. Other cripaviruses include the well-studied dipteran *Drosophila* C virus, hemipteran (aphids and leafhoppers) *Rhopalosiphum padi* virus, and hymenopteran (bees and wasps) Black Queen Cell virus. The dicistroviruses, including Israeli acute paralysis virus, have received increased attention recently due to their association with colony collapse disorder in honeybees.[28,117]

The physicochemical properties of the *Cripavirus* virion are strikingly similar to those of the vertebrate picornaviruses. The icosahedral virion (<40 nm diameter, ρ = 1.35-1.37 g/mL) contains four capsid proteins (VP1, VP2, VP3, and VP4) that are arranged in a pseudo T = 3 lattice with 60 protomers per particle. High-resolution crystal structures of several dicistroviruses, including that of CrPV,[315] show a picornavirus-like capsid conformation and morphology.[348] The proteolytic processing of VP0 → VP3 + VP4 appears to be autocatalytic and VP4 is found in the infectious particle. However, unlike the picornaviruses, CrPV lacks the deep depression (canyon) at the fivefold axis or a VP1 pocket.[315] Also, the residues of VP4 are located between those of VP2 and VP3. Thus, *Cripavirus* assembly may more closely resemble that of the insect nodaviruses and tetraviruses rather than the vertebrate picornaviruses.[315]

Genome Organization and Novel Translation Initiation

Dicistroviruses possess a single-stranded, messenger-sense RNA genome of 8-10 kb. The genome is distinguished by its bicistronic organization of two large ORFs (Fig. 19.13). Upon translation, each ORF produces two different polyproteins, which are proteolytically processed.[28,143,348] Preceded by a 5′ UTR, ORF1 encodes proteins with predicted RNA helicase, picornavirus 3C-like protease, and RNA-dependent RNA polymerase activities. The ORF1 polyprotein is processed by the activity of the 3C-like protease (Fig. 19.13). In addition, the N-terminal end of ORF1 of CrPV and DCV encodes novel RNAi suppressors.[225] These suppressors act by distinct mechanisms but represent a common function

encoded by insect viruses, including the nodaviruses (see above). The capsid proteins are encoded by ORF2, which is preceded by a ~200-nucleotide intergenic UTR that possesses a novel IRES (see below). Thus, unlike the picornaviruses, the capsid proteins and nonstructural replication proteins are encoded by the 3′ and 5′ halves of the genome, respectively (Fig. 19.13). To date, dicistrovirus replication mechanisms are derived mostly from studies of DCV infections of *Drosophila* cell lines. Also, full-length infectious clones are now available for several viruses. As expected, viral RNA replication is mediated by the virus-encoded RNA-dependent RNA polymerase on the membranes of infected cells. Mechanistic details remain to be uncovered.

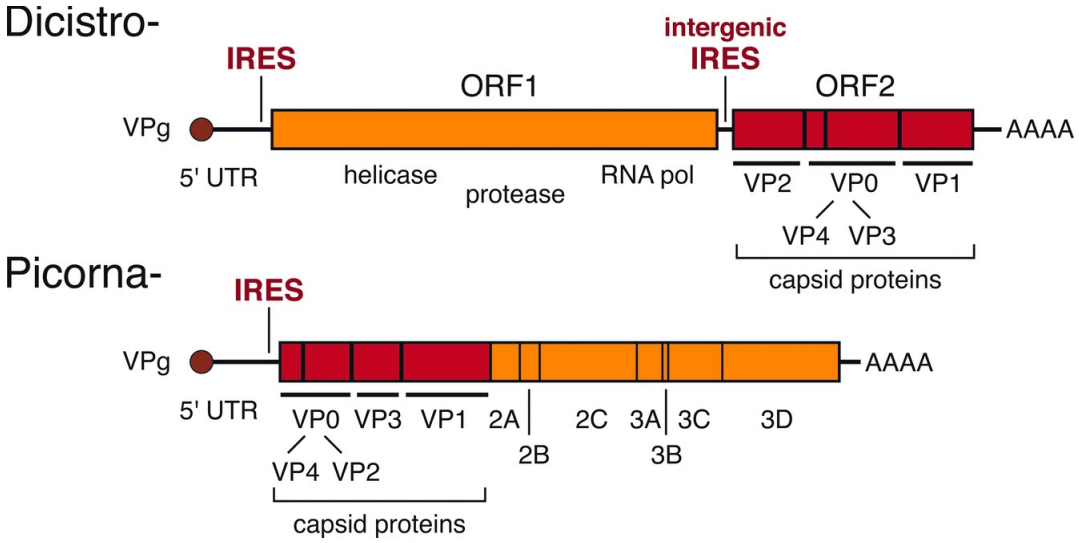

FIGURE 19.13 **Genome organization of the dicistroviruses**. The single-stranded RNA genome of the dicistroviruses, including CrPV and DCV, possess two open reading frames (ORF1 and ORF2) separated by a ~200 nucleotide spacer. An internal ribosome entry site (IRES) precedes both ORFs. ORF1 encodes virus replicative functions (helicase, protease, and RNA-dependent RNA polymerase), whereas ORF2 encodes capsid proteins VP0, VP1, and VP2. VP3 and VP4 are generated by processing of precursor VP0.[315] The small protein VPg and an untranslated region (5′ UTR) are located at the 5′ end of the genomic RNA. By contrast, the vertebrate picornavirus genome possesses a single ORF and must, therefore, produce equimolar levels capsid proteins and replicative functions from the 5′ and 3′ ends of the genome, respectively.

During infection, the dicistrovirus capsid proteins are produced in great excess compared to the nonstructural proteins despite being encoded by the 3′ half of the messenger-active genome. Accounting for this difference, an internal ribosome entry site (IRES) regulates translational initiation from each of the two ORFs. Characterized from CrPV, DCV, *Rhopalosiphum padi* virus, *Plautia stali* intestine virus, and other viruses, these structures are common features of the *Dicistroviridae* and have provided novel insight into mechanisms of translational initiation.[143,348] The use of an IRES avoids the need for a 5′ 7-methyl GpppN cap on viral mRNAs, thereby allowing the virus to escape host- or virus-mediated shutdown of cap-dependent protein synthesis during infection. Thus, invertebrates and vertebrates share these antivirus mechanisms. The intergenic IRES preceding ORF2 (Fig. 19.13) is particularly interesting in that unlike a typical picornavirus IRES, this dicistrovirus IRES does not require any host initiation factors and it initiates translation at a non-AUG codon.[143,348] Rather, the intergenic IRES assembles an 80S ribosome in the absence of initiator Met-tRNA$_i$ or canonical initiation factors to initiate protein synthesis from the second triplet (GCU), which is positioned within the A site of the ribosome. This novel mechanism for IRES-mediated translation initiation involves a pseudoknot structure within the IRES that substitutes for required interactions between Met-tRNA$_i$ and the P-site initiator codon.[143,348] Thus, the intergenic dicistrovirus IRES has provided important understanding of the molecular mechanisms of IRES function.

Dicistrovirus Prevalence and Transmission

The dicistroviruses are widely disseminated in animal populations.[28,143] CrPV was originally isolated from Australian crickets *Teleogryllus oceanicus* and *Teleogryllus commodus*; the CrPV name is derived by its capacity to cause paralysis of the hind limbs of early-instar cricket nymphs. Interestingly, CrPV has one of the widest experimental host ranges of any of the invertebrate viruses and can infect diverse species of multiple insect orders, including those of Diptera, Lepidoptera, Orthoptera, Hymenoptera, and Hemiptera.[56] Experimental inoculation by injection leads to virus multiplication and death of multiple insect species. CrPV transmission can also occur *per os* through contaminated food sources. In contrast to CrPV, DCV has a more restricted host range. DCV has been isolated from wild or laboratory strains of *Drosophila melanogaster*.[56] It can be transmitted *per os* to adult flies or larvae and cause death. In addition, DCV is transmitted horizontally between infected and uninfected adults. Thus, the transmission routes and pathology of dicistroviruses among insects is highly variable but most often follows a fecal-oral route.

Perspectives

Considering the abundance and diversity of insect life on earth, it is likely that only a small fraction of the potential viruses that infect insects have been discovered thus far. Metagenomic analyses promise the discovery of many new viruses of insects. Nonetheless, studies of the viral pathogens characterized to date have revealed novel mechanisms for virus replication, have identified unique viral genes with functions important in human disease (cancer, neurodegeneration, immunodeficiency), and have provided highly useful applications for biotechnology, insect pest management, and gene therapy. It is fully expected that future studies of the insect viruses will uncover fundamental aspects of host-virus interactions, including novel strategies by which these prolific viruses modify and exploit host processes to enhance multiplication and evade antiviral responses. On the basis that many of these responses are conserved in mammals, such studies will provide important insight into the mechanisms of antiviral defenses and virus pathogenicity in humans. In light of the expansion of the natural range of many arthropod vectors due to climate change and the encroachment of humans into new ecological domains, insect viruses will play an even more important

role in human disease and agriculture. Because of this likelihood, along with the enormous contributions of insect viruses to basic biology and biotechnology, there is a critical need for funding for continuing the studies of the insect viruses and their hosts at the molecular level.

CHAPTER 20

Viruses and Prions of Yeasts, Fungi, and Protists

Reed B. Wickner

Double-stranded RNA viruses

Totivirus type species L-A of *Saccharomyces cerevisiae*

Partitiviridae

Reovirus of Cryphonectria

Single-stranded RNA viruses

Viruses reducing virulence of chestnut blight fungus

Negative strand RNA mycoviruses

Narnaviridae 20S RNA, 23S RNA, and mitoviruses

Hadaka [naked] viruses and *yadokari [home-borrowing] viruses*

Chromosomal genes affecting mycoviruses

Single-stranded DNA gemini-like mycovirus

Retroviruses (retroelements)

Retroviruses, retrotransposons, retroposons, and retrointrons

Structure of Tys

Replication cycle of *Saccharomyces cerevisiae* Ty elements

Expression of Tys

Schizosaccharomyces pombe retroelements

Candida albicans plasmid retrotransposon and line elements

Prions of *Saccharomyces* and *Podospora*

[URE3]—a transmissible amyloidosis of Ure2p

[PSI+]—a transmissible amyloidosis of Sup35p

[PIN+]—a prion that generates other prions

[Het-s]—a prion of podospora responsible for a normal function

Prion variants

Structures of yeast prion amyloids explain variant propagation

HET-s prion amyloid structure

[URE3] and [PSI+] are diseases of yeast

Chaperone involvement in prion propagation

Antiprion systems in *Saccharomyces cerevisiae*

Perspectives

Acknowledgments

Prions, retroviruses, double-stranded RNA (dsRNA) viruses, (+) and (−) single-stranded RNA (ssRNA) viruses and single- and double-stranded DNA (ssDNA and dsDNA) viruses have all been found in simple eukaryote hosts, and the experimental advantages of these systems have made some of them the most thoroughly characterized of their classes. This is an overview of these infectious entities and their unique aspects, with some emphasis on recent developments. We focus on the most-studied virus of each group because of space limitations (Table 20.1).

TABLE 20.1 Representative viruses of simple eukaryotes

Virus	Family	Typical	Features
dsRNA viruses	*Totiviridae*	L-A of *S cerevisiae*	One segment, Gag-Pol, "T = 2" icosahedral, killer toxin satellites
	Partitiviridae	*Atkinsonella hypoxylon virus* (AhV) [291]	2 (or 3) segments separately encapsidated, "T = 2" capsid[390]
	Mycoreoviridae	MRV1 *C parasitica*	11 segments, similar to *Coltivirus*, hypovirulence
(+)ssRNA viruses	*Hypoviridae*	CHV1-EP713 of *Cryphonectria parasitica*	1 segment, in vesicles, no capsid, hypovirulence, two proteases, anti-RNAi
	Narnaviridae	20S, 23S RNAs of *S cerevisiae*	No coat, RDRP encoded, similar to Qβ
	Mitoviridae	CpMV1 of *C parasitica*	No coat, RDRP encoded, similar to Qβ, UGA = Trp, intra-mitochondrial
(–) ssRNA viruses	*Mymonaviridae* (mononegavirus)	SsNSRV-1 of *Sclerotinia sclerotiorum*	filamentous particles, 1 segment, 6 ORFs [248]
ssDNA viruses	*Genomoviridae* (*Gemini*-like)	SsHADV-1 of *S*	Infectious for fungus and insect
Retro-elements	Retrotransposon (Ortervirales)	Ty1, Ty3 of *S cerevisiae*	LTR retrotransposons, Ty1 in *copia* group, Ty3 in *gypsy* group
	Retroposon	Zorro3 of *Candida albicans*	no LTR, LINE-like
	Retrointron	introns aI1 and aI2 of *COX1* mitochondrial gene of *S cerevisiae*	no LTR, retro-mobile intron

dsRNA, double-stranded RNA; ssRNA, single-stranded RNA; ssDNA, single-stranded DNA; LTR, long terminal repeat. Based on amino acid sequence homology and gene order, retrotransposons may be divided into those similar to the *copia* element or the *gypsy* element of *Drosophila*.

Nearly all of the viruses, prions, and retrotransposons (or retroviruses) of yeast and fungi have wholly intracellular life cycles. These viruses have forsaken the extracellular route of transmission, being passed from cell to cell either vertically or by cytoplasmic mixing, such as occurs in mating, or in hyphal anastomosis (fusion) of filamentous fungi. They resemble, in this regard, the plant cryptoviruses and the intracisternal A type particles (retroelements) and LINEs (retroposons) of mammals. The high frequency of mating and hyphal fusion of fungi in nature makes an extracellular phase dispensable for these viruses. Indeed, many wild *Saccharomyces cerevisiae* carry the RNA viruses, and it is difficult to find strains of *S cerevisiae* that lack the Ty retrotransposons. Nor is the direct cell-to-cell route of infection completely neglected by mammalian viruses—those of the herpes group and human immunodeficiency virus being prime examples. However, a *Totivirus* of the human parasite *Giardia lamblia* and a Gemini-like ssDNA virus of the plant pathogenic fungus *Sclerotinia sclerotiorum* are each infectious by an extracellular route for their respective hosts (see below).

Recently, sequences of many yeast genomes have revealed occasional (diverged) copies of the yeast L-A viral and M_2 killer toxin genomes.[376] Interestingly, the integrated viral sequences from distantly related yeasts were less diverged than their hosts, indicating horizontal transfer.[376] The means by which this transfer occurs is not yet clear.

The largely intracellular mode of transmission means that viruses must balance the need to spread and propagate against consideration for the viability of their host. This is clearly seen in the Ty elements, which tend to target sites that can tolerate an insertion. Ty1 limits its transposition by making a fragment of Gag that inhibits particle assembly and other functions of Gag.[162,334] The Ty elements, particularly Ty3, regulate their transcription such that most transposition occurs on mating.[219] This design optimizes the chances of infecting the potentially unoccupied genome of the mating partner. Furthermore, the fact that most of these elements are widespread means that the hosts have been selected for the ability to protect themselves. The copy numbers of several of the RNA replicons (L-A dsRNA, L-BC dsRNA, and 20S RNA) are repressed by the host Ski proteins acting in translation,[261,343] messenger RNA (mRNA) stability,[198] and positive strand stability.[143] The Nuc1 endonuclease also protects the host from the dsRNA viruses, particularly during meiosis.[155] The host blocks Ty1 retrotransposition at several levels: translation, virus particle and DNA stability, structure of the chromatin target (eg, see Refs.[28,74,191,266]).

Most of the viruses and prions discussed in this chapter can best be viewed as selfish RNA or DNA (or selfish protein); however, the killer satellite dsRNAs clearly benefit their hosts (and promote the L-A helper virus) by allowing them to kill competitors. The [Het-s] prion of *Podospora* is unique among prions described to date in being necessary for a normal cellular function—namely, vegetative (heterokaryon) incompatibility that is expected to block horizontal transfer of viruses and transposons (see below).[81]

Yeast and fungal prions have led the way in proving the prion concept, defining the structure of prion amyloids, and in relating those structures to prion biology and heritability (reviewed in Ref.[404]). Moreover, the study of yeast prions has explored myriad chaperones and other host components affecting prion generation and propagation (reviewed in Ref.[27,263]). Host antiprion systems dramatically limit the frequency of prions arising and cure many that do arise; their manipulation may provide a means of treating human amyloid/prion diseases the way the immune systems are manipulated to deal with bacterial and viral diseases (reviewed in Ref.[401]).

It is striking that many of the viruses and retroelements discussed use some form of ribosomal frameshifting to make a "Gag-Pol" fusion protein. The fusion of the capsid protein and the RNA polymerase provides packaging of the polymerase and, by the polymerase binding to the (+) RNA strand, a means of packaging the genome (see below). Read-through of stop codons could do the same thing.

The use of *S cerevisiae* as a model host for viruses of plants, mammals, and insects promises to facilitate the understanding of these viruses[282,283,306] but will not be dealt with here.

Double-Stranded RNA Viruses

Fungal dsRNA viruses were first detected in 1948 as “La France” disease of cultivated mushrooms in Pennsylvania, and its study led to the first description of fungal viruses in 1962. The antiviral agents helenine and statolon, discovered in *Penicillium* in the 1950s, later proved to be fungal virus dsRNA that was inducing interferon production. The dsRNA viruses found in many fungal species include the single-segment *Totiviridae*, the oligosegmented *Partitiviridae*, and the 10-11 segmented Mycoreovirus.

Totivirus Type Species L-A of *Saccharomyces cerevisiae*

Some strains of *S cerevisiae* secrete a protein toxin that is lethal to other strains but to which they are themselves immune (Fig. 20.1). This killer character of some strains is inherited as a non-mendelian genetic element, and its study led to the discovery of the L-A dsRNA virus and its separately encapsidated satellites M_1, M_2, M_{28}, and so on, each M encoding a different toxin-immunity specificity.

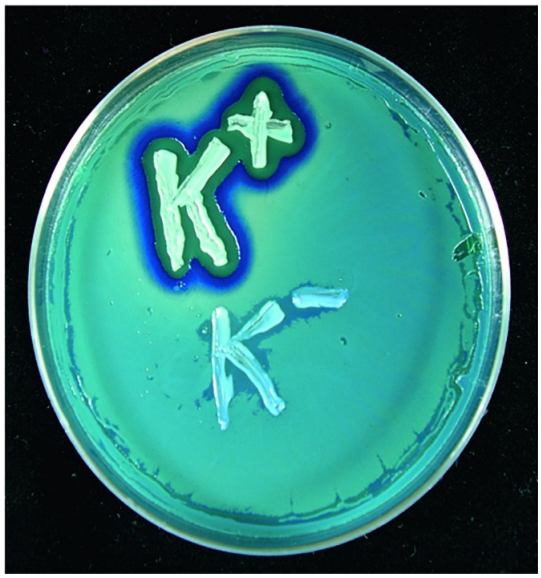

FIGURE 20.1 **The killer phenomenon of *Saccharomyces cerevisiae*.** A sensitive strain of yeast was spread as a lawn, and streaks of a killer strain (*above*) or a nonkiller strain (*below*) were applied. After 2 days of incubation, the lawn of the sensitive strain has not grown in a zone around the killer strain. The secreted protein killer toxin, and immunity to the toxin, are encoded by M_1, a satellite double-stranded RNA (dsRNA) of the L-A dsRNA virus.

L-A Virion Structure

The icosahedral structures of L-A and all Totiviruses examined to date combine T = 1 icosahedral symmetry with 120 coat protein molecules per particle[134,284] (Fig. 20.2). This same symmetry is found in the cores of most other dsRNA viruses examined, including partitiviruses, reovirus, rotavirus, bluetongue virus, aquareovirus, and bacteriophage φ6 (reviewed in Ref.[265] and see Chapters 3 and 21). Because sequence data suggest that different dsRNA virus groups each arose independently from different ssRNA viruses,[223] rather than one being descended from each other, their common structure suggests that there is something about this structure that is well adapted to the intraviral replication pattern of dsRNA viruses.

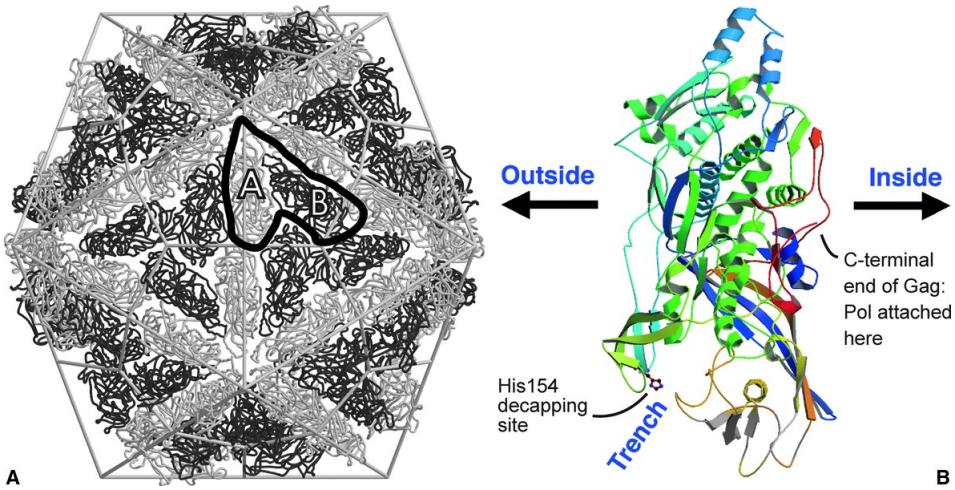

FIGURE 20.2 **L-A double-stranded RNA virus capsid at 3.4-Å resolution from X-ray crystallography.** **A**. Overall organization of the L-A capsid. Identical subunits occupy two different environments, with “A” subunits (*light blue*) contacting the two- and fivefold axes and “B” subunits contacting the threefold axes. **B**. A single A subunit is shown with the trench on the outside surface including

His154, the site of the decapping activity. (Adapted from Naitow H, Tang J, Canady M, et al. L-A virus at 3.4 A resolution reveals particle architecture and mRNA decapping mechanism. *Nat, Struct Biol*. 2002;9(10):725-728; Adapted from Tang J, Naitow H, Gardner NA, et al. The structural basis of recognition and removal of cellular mRNA 7-methyl G 'caps' by a viral capsid protein: a unique viral response to host defense. *J Mol Recogn*it. 2005;18(2):158-168.)

The combination of 120 subunits and T = 1 icosahedral symmetry implies that individual coat protein monomers can be in either of two environments. This expectation has been verified as subtly different morphology of the nonequivalent Gag protomers[284] (see Fig. 20.2). The packing of the dsRNA within the particles is less dense than is typical for dsDNA viruses, possibly reflecting the fact (see later discussion) that in both replication and transcription, the genome must translocate sequentially past the RNA-dependent RNA polymerase immobilized on the particle wall, and this requires more space than is required by the static DNA genomes.[46] The L-A virions also have 10- to 15-Å pores, which allow entry of nucleotides and exit of positive-strand transcripts but do not allow the dsRNA genome to exit or degradative enzymes to enter.[284] A trench on the outer virion surface contains His154 of Gag, the site of the mRNA decapping activity, and several nearby residues essential for this activity have been identified.[375]

L-A Genome Structure

The L-A positive strand has two overlapping open reading frames (ORFs)[195] (Fig. 20.3A). They are *gag*, encoding the 76-kd major coat protein, and *pol*, encoding the 100-kd Pol domain of the Gag-Pol fusion protein.[149,195] The pol ORF includes the consensus amino acid sequence patterns typical of viral RNA-dependent RNA polymerases. Three *in vitro* ssRNA binding domains have also been localized to Pol,[149,315] the central one cryptic unless an adjacent inhibitory region is deleted (see Fig. 20.3A). Pol residues 67-213 are necessary for packaging of the viral positive strands.[147,315] Neither 5′ cap structure nor 3′ poly(A) has been found on either strand of genomic L-A dsRNA or M_1 dsRNA.[144] The genome has 5′ diphosphates on both strands [144]and an uncoded base (A or G) at each 3′ end.[41]

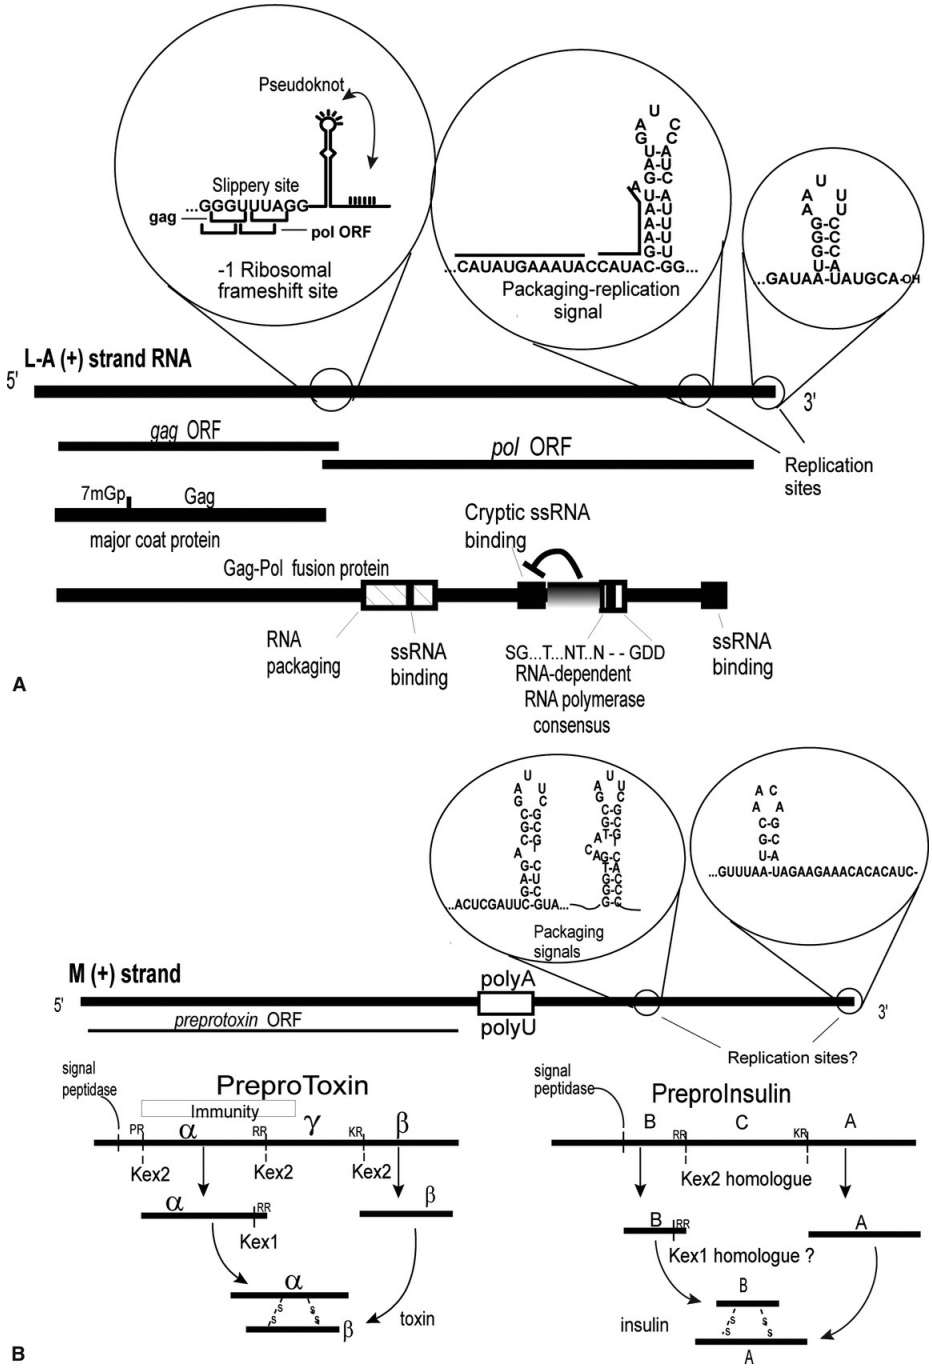

FIGURE 20.3 **A**. Sites and encoded proteins of the L-A positive strand. The sites responsible for -1 ribosomal frameshifting, positive single-stranded RNA packaging, and replication are shown. The packaging signals include direct repeat sequences (shown by an overline for L-A). The pseudoknot makes the ribosome pause over the slippery site, where the transfer RNAs can unpair from the messenger RNA and re-pair in the -1 frame with correct base pairing of the nonwobble bases. Functional domains in the Pol region are also indicated. 7mGp indicates the cap-binding site at His154 of Gag. **B**. Coding and *cis* sites of M1 positive strand. The analogous and homologous processing of the K1 preprotoxin encoded by M1 is compared to that of preproinsulin.

The M dsRNAs each encode, in their 5′ portion, a preprotoxin protein[36,103,251,342] (Fig. 20.3B). The M_1 positive strand has an internal encoded poly(A) region whose length shows frequent clonal variation, presumably owing to transcriptase stuttering, and a substantial 3′ region that encodes no protein but contains essential *cis* sites.[131,145,165,331,350] Sites on the L-A and M_1 positive strands necessary for packaging and negative-strand synthesis have been determined (see later discussion and Fig. 20.3), and some limits have been set on the possible transcription signals.

Stages in the Replication Cycle

The L-A replication cycle and the closely related cycle of its satellites are shown in Figure 20.4.[134,146] L-A dsRNA-containing viral particles synthesize positive ssRNA in a conservative reaction,[146] and these new positive strands are then extruded from the particle. There, they serve as mRNA for the production of the Gag and the Gag-Pol fusion proteins. These proteins then assemble with a viral positive strand to form new particles. The newly assembled viral particles carry out the synthesis of negative strands on the positive-strand template to form dsRNA and

complete the cycle (see Cap-snatching below).

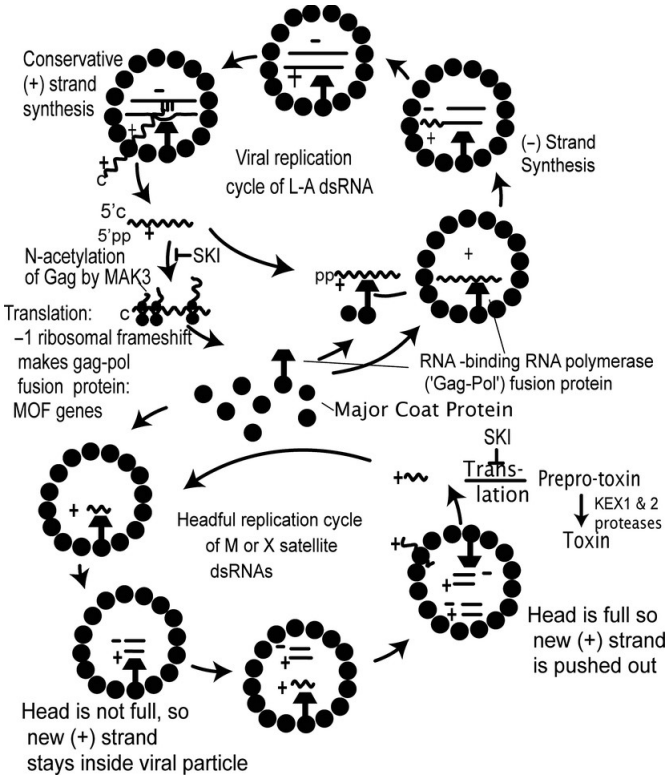

FIGURE 20.4 **Replication cycles of L-A virus and its satellite double-stranded RNAs (dsRNAs), M and X**. The packaging region of the Pol domain of Gag-Pol binds to the packaging site of positive strands as the Gag domain associates with other Gag molecules. This ensures packaging of viral positive strands.[147,149] L-A particles have only one dsRNA molecule per particle. However, the smaller M or X dsRNAs replicate within the viral coat until they fill the head.[134,136] The (+) strand transcripts that are capped by Gag are translated, while those with an uncapped 5′ diphosphate end are packaged.[144]

In addition to their appropriating viral proteins from L-A, the replication cycle of the satellite dsRNAs, M_1, S (deletion mutants of M_1), and X (a 530 base pair [bp] deletion mutant of L-A) are similar to that of L-A itself except that they replicate more than once within the viral particle until it is full (see Fig. 20.4). Only a single positive ssRNA is packaged per particle[145]; thus, L-A and M are separately encapsidated. Because the particle capacity is determined by the structure of Gag to be sufficient to accommodate one full-length L-A dsRNA molecule, positive-strand transcripts of the smaller M and X dsRNAs are often retained within the particles, where they are converted to new dsRNA molecules. All new positive strands are extruded from the full particles.[134,136] This headful replication mechanism contrasts with the headful packaging mechanism of many DNA bacteriophage. This implies that extrusion of the transcripts is a mechanical consequence of the head being full rather than an active process. Both positive and negative strands are synthesized within the viral particles, but at different points in the cycle; therefore, the replication is conservative, intraviral, and asynchronous, and it fills the capsid (headful mechanism).

Transcription Reaction (Positive-Strand Synthesis)

As in the *Reoviridae*, the transcription reaction for L-A is conservative, resulting in the overall process of viral replication being conservative. However, in *Aspergillus foetidus* slow virus and *Penicillium stoloniferum* slow virus, dsRNA transcription is semiconservative. The difference between conservative and semiconservative reactions concerns whether or not there is re-pairing of the template negative strand with the parental positive strand that was (in either case) displaced during the synthesis.

Treatment of L-A virus particles with very low ionic strength results in their rupture and release of the dsRNA. These opened empty particles can be reisolated free of RNA and carry out a dsRNA template-dependent reaction that is, like the *in vivo* reaction, conservative.[151] This reaction is highly template specific, using only L-A, M, and X dsRNAs (all physiologic templates) but not L-BC, p6, or rotavirus dsRNAs.[151] Because X dsRNA retains only 25 bp of the end of L-A from which the transcription reaction starts,[136] the signal recognized by the transcriptase is most likely within this region, perhaps within the terminal 6 bp that are in common among L-A, M_1, and M_2. The template-dependent transcription reaction requires very high concentrations of polyethylene glycol (20%), suggesting that the transcriptase has a low affinity for the dsRNA template.[151] Because the dsRNA is normally formed within and stays inside the viral particles, the RNA polymerase sees a very high effective concentration and need not have a particularly high affinity.

Translation

The translation apparatus is a prime battleground for the fight between an RNA virus and its host. For example, interferon acts primarily by blocking viral translation. Picornaviruses cleave a cap-binding protein inactivating host translation, and influenza virus steals caps from cellular mRNAs (Chapter XX). RNAi also blocks translation of target mRNAs or promotes their degradation. Studies of the L-A virus and its satellites likewise suggest that translation of viral proteins is a critical event determining the balance between virus and host.

Ribosomal frameshifting

The *gag* and *pol* ORFs of L-A overlap by 130 nucleotides, and the Pol protein is expressed only as a fusion protein with the major coat protein, Gag[149,195] (see Fig. 20.3A). The mechanism of formation of this Gag-Pol fusion protein is a −1 ribosomal frameshift,[105] very similar to those described in many retroviruses, coronaviruses, and several plant viruses (reviewed in Ref.[9]).

The frequency of −1 ribosomal frameshifts is determined by the "slippery site," a sequence of the form X XXY YYZ, where the *gag* reading frame is shown, and by a downstream pseudoknot (see Fig. 20.3A). The slippery site allows the tRNAs reading XXY and YYZ to move back one base on the mRNA and still have their nonwobble bases correctly paired.[196] X can be any base, although Y can be only A or U, probably because the frequency with which unpairing of the tRNAs from the 0 frame codons (XXY and YYZ) is also important, and because A site pairing is stronger than P site pairing.[42,105] Z can be any base but G, suggesting that specific tRNAs are more able to frameshift than others.[50] The RNA pseudoknot, just downstream of the slippery site, slows ribosomal movement at this point.[42,105] The location of this secondary structure is particularly critical,[42] and a pseudoknot is far more effective in promoting frameshifting than a simple stem loop of the same overall melting energy. The pseudoknot, more than the simple stem loop, should halt melting of the stem at a unique point because the rotation of the stem is limited by the downstream stem. This precisely positions the ribosome with the slippery site in the A and P sites.[303]

The efficiency of −1 frameshifting, and thus the ratio of Gag-Pol fusion protein to Gag protein produced, is critical for viral propagation,[107] as is the efficiency of +1 frameshifting for Ty1 retrotransposition frequency (see later discussion). A twofold change away from L-A's normal 1.9% efficiency results in failure to propagate the M_1 satellite dsRNA. L-A propagation is less sensitive; however, the antibiotics sparsomycin, which increases ribosomal frameshifting, and anisomycin, which has the opposite effect, can cure L-A.[106] The Gag-Pol to Gag ratio is likely to be important for viral assembly. Excess Gag-Pol (high frameshift efficiency) may result in starting too many particles and winding up with too little Gag to complete any of them. In contrast, excess Gag might result in particles closing before the packaging domain of Pol has had a chance to find a viral positive strand.[106]

Host genes affecting the efficiency of −1 frameshifting are referred to as *MOF* (maintenance of frame).[107] The differential effects of specific host mutations on frameshifting at specific slippery sites suggests that drugs similarly affecting frameshifting might target specific viruses. *MOF9* is the 5S ribosomal RNA (rRNA), showing a role for this 60S subunit component in maintenance of reading frame.[108] *MOF6* is *RPD3* encoding a histone deacetylase; the *mof6-1* allele affects rRNA processing in such a way that ribosomal frameshifting is increased.[276] Ribosomal frameshifting is also used in some mammalian genes, such as Edr (embryonal carcinoma differentiation regulated),[353] and various yeast genes affected by a frameshifting site have been identified.[25] Whereas viral ribosomal frameshifting produces two viral proteins in a desired ratio, that of yeast cellular genes increases mRNA instability by diverting translating ribosomes to termination codons in another frame and inducing nonsense-mediated decay.[25] Viral sequences suggest that many Totiviruses use −1 ribosomal frameshifting to make fusion proteins, but a −2 shift occurs in a *Trichomonas vaginalis* Totivirus[294] and a +1 frameshift appears in a dsRNA Amalgavirus infecting the grasshopper pathogen fungus (microsporidian) *Antonospora locusta*.[308] The 190S virus of *Helminthosporium victoriae* (Hv190SV) is a totivirus that makes separate coat protein and RNA polymerase by a re-initiation: the termination codon for the coat protein overlaps with the initiation codon for the RNA polymerase, the sequence being...GGA CA**A TG A** GT G....[193]

60S subunits—critical to viral propagation

Mutations in any of 20 chromosomal genes (called *MAK* [maintenance of killer]) that result in diminished levels of free 60S ribosomal subunits also produce loss of M dsRNA and decreased copy number of L-A dsRNA.[120,292] Mutations diminishing the supply of free 40S subunits had no such effect.[292] The deficiency of 60S subunits results in selectively decreased rates of translation of mRNAs which, like L-A mRNA, lack 3′ poly(A).[120] These *mak* mutations are suppressed by the *ski* mutations that derepress translation of non-poly(A) mRNAs.[261]

Cap-snatching by Gag separates (+) strands for translation from those for replication

The L-A and L-BC Gag proteins each covalently bind the 5′ cap from any RNA *in vitro*.[30] L-A Gag covalently attaches ^{7m}GMP from the cap to His154 in a reaction that requires only Mg^{2+}. L-A virions can then transfer the cap structure to nascent L-A (and presumably M) mRNAs as they are synthesized.[142,143] Modification of His154 destroys Gag's ability to covalently bind cap, resulting in loss of killer toxin expression from M_1.[31,142] However, the (+) strands of viral dsRNA do not have detectable cap; both (+) and (−) strands have mostly diphosphate 5′ ends with a minority of 5′ triphosphate ends.[144] Using opened empty viral particles that can carry out *in vitro* transcription with specificity for L-A or M related templates,[151] Fujimura and Esteban have shown that only templates with a (+) strand 5′ diphosphate can serve as transcription templates, but the (−) strand synthesis reaction is indifferent to this modification.[144] It is suggested that not all transcripts emerging from the viral particles are capped, and that capped transcripts will be translated, and those that are uncapped will be packaged and propagate.[144] Influenza virus polymerase uses 5′ cap structures with 10-13 nucleotides that it cuts from a host RNA to prime viral mRNA synthesis, in contrast to the L-A cap-snatching, which appears to be added after the mRNA 5′ end has been synthesized.

The *SKI1/XRN1* gene encodes a 5′-3′ exoribonuclease, specific for uncapped RNAs that is responsible for the major mRNA decay pathway.[190] Overexpression of Ski1p can cure the L-A virus.[133] Mutation of the *SKI1/XRN1* gene restores expression of killer toxin despite mutation of His154 of Gag,[261] indicating that cells can translate an mRNA lacking both cap and poly(A).

Antiviral Systems

Ski2 antiviral system blocks translation of viral [non-poly(A)] messenger RNA

The sole essential function of *SKI2, 3, 7*, and *8* of *S cerevisiae* is the repression of viral copy number.[26,155,314,357,407] The SKI proteins repress three unrelated viral systems: L-A and its satellites, L-BC (a dsRNA virus), and the ssRNA replicon referred to as 20S RNA.[15,136,267,310,383] The *ski2*Δ, *ski3*Δ, *ski7*Δ, and *ski8*Δ mutants are each cold-sensitive for growth if they carry M_1 dsRNA,[26] and *ski2*Δ strains can become sick or die at

any temperature if, in addition, the [D] cytoplasmic element is present.[135] The molecular nature of [D] is as yet unknown.

Detailed studies of *SKI2* suggested that the system acts by limiting translation of viral mRNA.[261,407] None of these cytoplasmic replicons has 3′ poly(A) structures, and electroporation of reporter mRNAs into spheroplasts shows that the Ski2, Ski3, Ski7, and Ski8 proteins inhibit the translation of mRNA specifically if it lacks a 3′ poly(A) structure.[26,261] Both the initial rates and the duration of translation are affected by the Ski proteins, suggesting that both translation and mRNA stability are affected.

Ski2p is a helicase conserved from yeast to man,[407] Ski3p is a TPR repeat protein,[314] and Ski8p has a repeat first identified in β-transducin.[357] Ski2p, Ski3p, and Ski8p form a cytoplasmic complex[43] that is bound to ribosomes[341] where it extracts translation-arrested mRNAs from the ribosome.[429] These mRNAs are transferred for degradation to a complex of 3′ to 5′ exoribonucleases called the RNA exosome[198] (reviewed by Ref.[211]). The removal of stalled mRNAs from ribosomes and its transfer to RNA exosomes may explain the combined effects on translation and degradation of non-poly(A) mRNAs.

SLH1 is a yeast homolog of *SKI2*, and like *ski2Δ*, *slh1*Δ has elevated L-A copy number.[260] Like the Ski2-3-8 complex, the Slh1 helicase is also involved in dissociating stalled ribosomes.[269] The *ski2Δ slh1*Δ double mutants show dramatically increased L-A, L-BC, and M_1 dsRNA copy numbers but grow normally in the absence of the L-A and M_1 viruses.[343] Remarkably, the *ski2Δ slh1*Δ cells show the same *in vivo* translation kinetics of Cap+ non-poly(A) mRNA as they do for Cap+ poly(A)+ mRNA, despite the presence of normal amounts of competing poly(A)+ mRNA.[343] The translation apparatus seems indifferent to the 3′ poly(A) structure except for the action of the Ski proteins and Slh1. This suggests that one role of the eukaryote 3′ poly(A) is to allow cells to distinguish their own mRNAs from those of invading viral genomes.

Nuc1 and Ski3 Block Viral Lethality in Meiosis

Mutation of either *POR1*, encoding the major mitochondrial outer membrane porin, or *NUC1*, encoding the major mitochondrial nuclease, results in derepression of L-A copy number.[104,250] [A similar effect results from mutation of *scs1/lcb2*,[163] encoding a subunit of serine palmitoyltransferase.]

Recently, Gao et al. have found that Nuc1 and Ski3 cooperate to limit viral pathogenesis particularly in the meiosis-sporulation process.[155] Sporulation of *ski3Δ/ski3Δ* M_1^+ diploids produces only dead spores, although the parent diploids are quite healthy. In contrast, *ski3Δ/ski3Δ* diploids without M dsRNA produce all viable spores and *kex1Δ/kex1Δ ski3Δ/ski3Δ* M_1^+ diploids produce mostly viable healthy segregants. Kex1 is involved in M protoxin maturation, suggesting that toxin overproduction is killing the sporulating *ski3Δ/ski3Δ* M_1^+ cells. Examination of sporulating cells shows that while normal cells have little or none of the mature (secreted) killer toxin, *nuc1Δ/nuc1Δ* K_1^+ and *ski3Δ/ski3Δ* K_1^+ cells accumulate a great deal of toxin. If M_1 is present *during meiosis and sporulation*, *nuc1Δ* and *ski3Δ* are synthetic lethal. Nuc1 is normally confined to the mitochondria but partially enters the cytoplasm during sporulation. A *por1Δ* or *por2Δ* mutant does not release Nuc1 into the cytoplasm during sporulation and so behaves like a *nuc1Δ* strain in causing lethality if M_1 is present and the cells are *ski3Δ*.[155]

While the previous paragraph describes pathology due to derepressed M_1, probably due in each case to the toxin, derepressed L-A also is toxic to cells.[155] M-o L-A^+ cells have elevated copy number if they carry either *nuc1Δ* or *ski3Δ* mutations and much higher levels still in a *nuc1Δ ski3Δ* strain. These double mutants with L-A are sick at any temperature and do not grow at all at 37° with ethanol as a carbon source.[155] The similarity of Nuc1 to the mitochondrial EndoG of mammals, which is involved in generating the DNA ladders typical of apoptosis in mammalian cells, leads the authors to suggest that the apoptosis process may have evolved from an antiviral role of Nuc1/EndoG.[155] In the process of meiosis and sporulation, the mother cell (but not the spores) undergoes a programmed cell death apoptosis.[156]

Posttranslational Modification

KEX1 and KEX2 proteases and prohormone proteases

The *kex1* and *kex2* mutants (*KEX*, from killer expression) do not produce the "killer" toxin but do propagate the M_1 satellite dsRNA. The *kex2* mutants also have a defect in mating specific to cells of the α mating type and do not make α pheromone, and *kex2/kex2* homozygous diploids are defective for sporulation.[241] *KEX2* encodes a protease cleaving C-terminal to pairs of basic amino acid residues,[200] and *KEX1* encodes a carboxypeptidase that removes the pair of basic amino acids.[77] These are the cleavages needed to convert the toxin and α pheromone proproteins to their mature forms (Fig. 20.3B). The same specificities are needed to process preproinsulin (Fig. 20.3B), pre-proopiomelanocortin, and other mammalian prohormones, and examination of enzymes with homology to Kex2p led to the discovery of the prohormone processing enzymes (reviewed in Ref.[324]). Kex2p-homologous enzymes are also involved in the proteolytic processing of some mammalian viral proteins.

N-acetylation of Gag by Mak3p—necessary for assembly

MAK3, *MAK10*, and *MAK31* are necessary for the propagation of the L-A dsRNA virus. Mak3p is homologous to *N*-acetyltransferases,[380] and the N-acetylation of the L-A Gag protein is lost in a *mak3* mutant host, resulting in failure of viral assembly.[381] Mak3p recognizes the N-terminal four amino acid residues of Gag.[379] Like L-A, the major coat proteins of Rous sarcoma virus, tobacco mosaic virus, turnip yellow mosaic virus, alfalfa mosaic virus, and potato X virus are N-terminally acetylated. The only three host proteins known to be necessary for L-A propagation, Mak3p, Mak10p, and Mak31p, form a complex,[318] indicating that Mak10p and Mak31p are also involved in N-acetylation of the coat protein. In addition to its action on Gag, the Mak3p acetylase also is responsible for modification of the α5 and α6 proteasome subunits,[215] and both *mak3* and *mak10* mutants grow poorly on ethanol or glycerol.[240]

Viral Assembly

Residues 67-213 of the Pol domain of the Gag-Pol fusion protein binds to the packaging site of a single (+) strand,[147] and the Gag domain of the fusion protein associates with the free Gag protein[149,315] (Figs. 20.3 and 20.4). This leads to encapsidation of a single positive strand per particle if there is only one Gag-Pol fusion protein (or one dimer) per particle.

The *packaging site* recognized is an internal stem-loop sequence about 400 nucleotides from the 3′ end of (+) strands with an A residue bulging from the 5′ side of the stem[131,145] (Fig. 20.3A). Binding requires the stem structure but not the sequence of the stem. In contrast, the sequence of the loop is important. The protruding A residue must be present and must be an A.[145] A similar packaging site, similarly located on the M_1 positive strand, was found[145] by examining the predicted folded structure of the M_1 sequence,[165] and another was found by studying sequences involved in exclusion of M_1.[350] Either the L-A or M_1 stem loops are sufficient for binding; however, the addition of 10 bp from the 5′ side of either one improves the binding and replication substantially.[131,145,350] The added 10 bp gives the L-A and M_1 sites 11 and 10 bp direct repeat sequences, which may be responsible for the improved binding and replication. A site with the same structure has also been found in a similar location in the M_{28} satellite dsRNA.[342]

The L-A and M_1 sites can each serve as a portable packaging signal *in vivo*, directing packaging of heterologous transcripts by L-A virus or by RNA produced from the L-A complementary DNA (cDNA) clone.[145,147] The heterologous transcripts were packaged alone in viral particles, confirming the prediction of the headful replication model that a single positive strand is initially packaged per particle.

Replication (Negative-Strand Synthesis)

Newly assembled viral particles contain an L-A positive strand and are capable of converting it to the dsRNA form when supplied with nucleoside triphosphates.[146] The particles formed in this reaction have all the properties of mature L-A particles and can carry out the transcription reaction.

The opened empty particles (see earlier discussion), when supplied with viral positive strands, Mg^{2+}, nucleoside triphosphates, and a low concentration of polyethylene glycol, carry out negative-strand synthesis to form dsRNA.[150] Only L-A, M, or X positive-strand templates are active in this reaction, supporting the notion that it accurately reflects the *in vivo* reaction.

A maximally active template requires both sequences at the 3′ end of the L-A (or X) positive strand and internal sequences (the internal replication enhancer) overlapping the packaging signal.[136] The 3′ end of L-A positive strands has a stem loop whose structure is necessary for template activity. Whereas the sequence of the loop and that of the 3′ terminal 4 nucleotides are important, that of the stem is not. Despite the requirements for these structures and sequences in the context of L-A, the 3′ terminal 33 nucleotides of M_1's positive strand can substitute for the L-A 3′ end, although there is little or no similarity between the two sequences[136] (see Fig. 20.3). The internal replication enhancer and the 3′ end site must be bound together for optimal template activity in the replication reaction.[152] However, they need not be covalently attached and can simply be hydrogen bonded. This suggests that the RNA polymerase binds first to the internal site and is thus brought close to the 3′ end site where polymerization is to begin.

Because the RNA-dependent RNA polymerase consensus domains defined by Kamer and Argos[205] have since been found in essentially all positive ssRNA and dsRNA viruses examined, the detailed mutagenesis of the most highly conserved of these regions was carried out using the L-A cDNA clone.[316] This has defined the extent of the domains necessary for the propagation of the M_1 satellite dsRNA. Interestingly, homologous regions from reovirus or Sindbis virus RNA polymerases could partially substitute for that of L-A.[316]

Partitiviridae

The *Partitiviridae* have a bipartite genome with the two segments separately encapsidated in particles containing the proteins encoded by both segments.[390] This group includes viruses of the filamentous fungi *Penicillium* and *Aspergillus* and the mushroom *Agaricus*, as well as many other fungi. It also includes a large group of plant cryptoviruses,[32,287] whose genome is dsRNA and whose biology is much like that of the systems discussed in detail here.

Strain 2H of *Atkinsonella hypoxylon* has three dsRNA segments of 2180, 2135, and 1790 nucleotides. Segment 1 encodes an RNA-dependent RNA polymerase, and segment 2 encodes a 74-kd protein that may be the major coat protein.[291] The third segment does not appear to encode a protein.

Reovirus of *Cryphonectria*

Reoviruses associated with hypovirulence have been found in two strains of *Cryphonectria parasitica* and one strain each of *Rosellinia necatrix* and *Sclerotinia sclerotiorum*.[124,247,293,298] The *C parasitica* mycoreoviruses C-18 and 9B-2-1 have 11 dsRNA segments each ranging in size from about 0.7 to about 4.1 kb and associated with 80-nm virus particles, unlike the vesicles in which the potyvirus-like *Hypoviridae* are found. These 11 segments are present in equimolar amounts, and transmission studies show that either all or none of the segments is transmitted, suggesting that they are parts of a single viral genome. The C-18 and 9B-2-1 genomes are not closely related, and sequencing shows that they are related to the *Coltivirus* group (eg, Colorado tick fever virus).[372] The reovirus particles can be introduced into *Cryphonectria* spheroplasts and transmit the hypovirulence traits.[185] This system adds new dimensions to the study of both hypovirulence and the *Reoviridae*.

A Mycoreovirus Facilitates Infection by Preventing Heterokaryon Incompatibility

One important limitation to the use of mycoviruses to control fungal diseases of plants is the heterokaryon incompatibility systems that each filamentous fungus uses to prevent vegetative asexual matings between all but very closely related strains (reviewed in Ref.[168]). Cellular processes of two fungal colonies (hyphae) will fuse as the colonies grow toward each other and test identity of alleles at 6-12 loci (called het for heterokaryon or vic for vegetative incompatibility). Allele differences at any one of these loci results in programmed cell death of the fused

hyphae and formation of a barrier to further fusions. This system serves as a defense against pathogenic plasmids and viruses (such as the hypovirulence viruses) by limiting cell-cell fusions to strains likely to already carry the same viruses (if any).

Wu et al. reported a reovirus (SsMYRV4, 12 dsRNA segments) of the plant pathogen *Sclerotinia sclerotiorum*, which not only has a hypovirulence effect on the fungal host toward rapeseed plants but also blocks heterokaryon incompatibility that would otherwise limit its spread.[415] Heterokaryon incompatibility requires the induction and action of certain G proteins,[252] most of whose induction is blocked by the virus.[415] The virus also lowers the expression of many of the genes containing HET domains.

Single-Stranded RNA Viruses

Traditionally, viruses are classified as ssRNA viruses if the encapsidated form is ssRNA. However, the CHV-1 hypovirus RNA are found in vesicles,[109,177] *Mitoviridae* are in mitochondria[184] not encapsidated, and 20S RNA, 23S RNA are *Narnaviridae*, naked RNA viruses, or nearly so.[159,406] In addition, for the many viruses discovered by sequencing projects, virus particle information is not yet available. As a result, viruses with homology to ssRNA viruses are so designated in such studies and here.

Viruses Reducing Virulence of Chestnut Blight Fungus

The American chestnut tree was devastated by the accidental introduction, in 1905, of the pathogenic fungus *C parasitica*, along with an oriental variety of the chestnut tree (reviewed in Refs.[186,290]). The fungus virtually eliminated the upper parts of the chestnut trees in the eastern United States, although the root systems were not killed and shoots continued to emerge, only to have their growth limited by the reattack of the fungus. *C parasitica* had a similar effect in Europe; however, in the 1950s, the emergence of fungal strains in Italy with markedly reduced virulence to the trees was noted. These "hypovirulent" strains (Fig. 20.5), later also found in Michigan, could transmit their hypovirulence by hyphal anastomosis to virulent strains, and this was used successfully for the biologic control of chestnut blight in Europe. Hypovirulent strains also show decreased asexual spore formation, decreased production of laccase (a phenol oxidase possibly involved in pathogenesis), and reduction in pigment formation (reviewed in Ref.[290]).

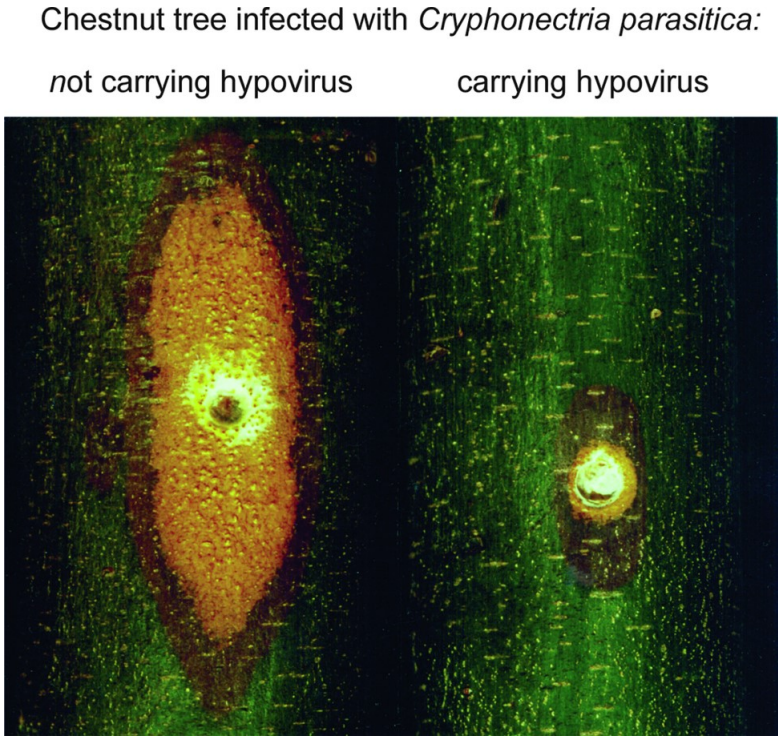

FIGURE 20.5 **Virulent (uninfected, left) and hypovirulent (virus-infected, right) *Cryphonectria parasitica* (chestnut blight fungus) inoculated into chestnut trees**. Infection of the fungus by any of several hypoviruses attenuates its virulence toward the trees. (Courtesy of Dr. Donald Nuss.)

The cytoplasmically inherited factor that reduced the pathogenicity of the fungus and produced these hypovirulence-associated traits was CHV1-EP713, a single segment dsRNA related to the (+) ssRNA plant potyviruses and thus called an ssRNA virus[8,95,224,275] (reviewed in Ref.[290]). CHV1 is the type species of the genus Hypovirus, and four other related Hypoviruses have been found in *C parasitica* as well as many related isolates from other fungi. Not all Hypoviruses reduce host virulence, but many do. Other viruses with a similar hypovirulence effect include the reoviruses.

Genome Structure

CHV1-EP713 is a 12,712-bp molecule whose positive strand has two long ORFs: ORFA and ORFB[347] (Fig. 20.6). Each ORF encodes a papainlike cysteine protease in its N-terminal portion that self-cleaves the primary translation products at least once[69,348] (Fig. 20.6). ORFA and ORFB overlap by a single nucleotide, with the UAA termination codon of the first overlapping with the AUG codon of the second,[347] resulting in a reinitiation mechanism for the expression of ORFB.[174] The translation of ORFA is initiated by internal ribosome entry.[64]

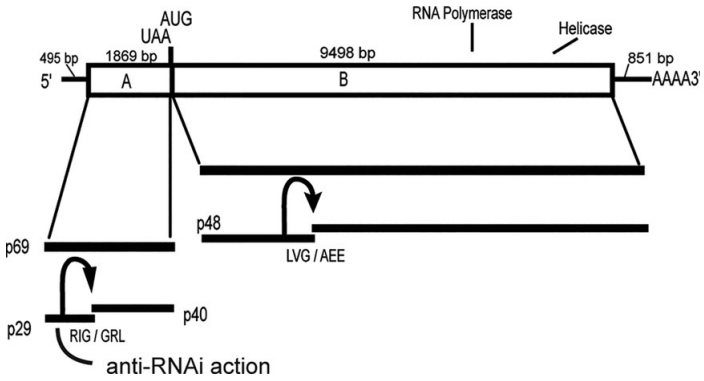

FIGURE 20.6 **Coding information and protein processing of the *Cryphonectria parasitica* virus, L**. The sites of action of the p29 and p48 proteases are indicated. This virus is now designated CHV1-EP713, the type member of the *Hypoviridae*. (Adapted by permission from Nature: Nuss DL. Hypovirulence: mycoviruses at the fungal-plant interface. *Nat Rev Microbiol*. 2005;3(8):632-642. Copyright © 2005 Springer Nature.)

Virus Replication in Intracellular Vesicles

Unlike other mycoviruses, CHV1 is not associated with virus particles but is found in intracellular vesicles,[109,177] with an RNA polymerase activity producing both ssRNA and dsRNA.[137] The vesicles have markers typical of the *trans*-Golgi network.[197]

RNAi in *Cryphonectria parasitica*, *Aspergillus nidulans*, *Sclerotinia sclerotiorum*, *Neurospora crassa*, and *Saccharomyces cerevisiae*

The chestnut blight fungus has an RNA interference (RNAi)-based antiviral system that limits the effects of infection by the hypovirus CHV1-EP713.[345,369,427] *Cryphonectria parasitica* has two homologs (*dcl1* and *dcl2*) of Dicer, the dsRNA-specific endoribonuclease that produces 21- to 24-bp fragments from larger dsRNAs (viral replicative forms or hairpin molecules), and four homologs (*agl1* to *agl4*) of Argonaute, the protein that brings these dsRNA fragments to the complex that "slices" or (at least in animals and plants) blocks translation of target RNAs. The *Cryphonectria* antiviral system involves only *dcl2* and *agl2*. Hypovirus infection induces transcription of both *agl2* and *dcl2*, with the induction of *dcl2* transcription dependent on *agl2*.[369] This antiviral response is muted by the viral p29 protein,[290,344,369] a papainlike protease homologous to the potyvirus suppressor of RNA silencing.[206] Mutation of *dcl2* or *agl2* also prevents accumulation of defective interfering viral particles and blocks viral recombination.[369,426]

In *Aspergillus nidulans*, *Sclerotinia sclerotiorum*, and *Neurospora crassa* RNAi systems have also been defined.[176,187,278] These systems act to limit virus replication. *S cerevisiae* lacks the RNAi system, but the closely related *Saccharomyces castellii* has it.[112] Expressing Dicer and Argonaut from *S castellii* in killer *S cerevisiae* results in loss of M dsRNA and L-A (but not L-BC). The presence of RNAi systems in yeast species correlates with the absence of killer systems, leading the authors to propose that the advantage of having a killer system resulted in loss of the RNAi system.[112] An alternative explanation suggested for the *Kluyveromyces lactis* DNA plasmid-based killer system[274] is that the toxin is there to punish the occasional cell in a clone that loses the plasmid/virus. In this model, the killer systems fail to establish infection in species with RNAi.[400] Wild *S cerevisiae* are only rarely killers or resistant to killing[285] and the killing ability of cells requires a large majority of killers over nonkiller to be effective, both facts arguing against the first model.

Virus Induction of Hypovirulence

CHV1-EP713 infection produces an array of phenotypes, not all of which are responsible for hypovirulence. For example, expression of laccase, a phenol oxidase believed to be involved in pathogenesis, is repressed by CHV1-EP713 infection[66,319] via the p29 protease,[68] but this effect is neither necessary nor sufficient to cause hypovirulence.[84]

G protein signaling is central in the induction of hypovirulence by CHV1-EP713. Hypovirus infection leads to decreased expression of the host Giα (an inhibitory subunit of G protein) and a concomitant increase in cAMP levels.[54,65] Moreover, disruption of *cpg-1*, the gene for Giα, results (in an uninfected strain) in elevated cAMP levels, total loss of virulence, and the development of the same associated phenotypes seen on virus-induced hypovirulence.[157]

Infectious Complementary DNA Clones and Biological Control of Chestnut Blight

Introduction of complete cDNA clones of the CHV1-EP713 genome under control of the *C parasitica* glyceraldehyde-3-phosphate dehydrogenase promoter resulted in both a complete hypovirulence phenotype of the fungus and the launching of the RNA replicon in a form transmissible to other strains.[67] In addition to its usefulness in studying the mechanism of the effects of CHV1-EP713 dsRNA on the cell, this infectious cDNA clone method is an important advance in attempts to control chestnut blight. Although artificial inoculation of trees with hypovirulent fungal strains in Europe resulted in spread of the hypovirulence dsRNAs to virulent strains and control of the blight, this approach has not succeeded in the United States. CHV RNA spreads by fusion between fungal cells, a process called *hyphal anastomosis*, but not by sexual crosses.[7] As discussed above, hyphal anastomosis (heterokaryon formation) is limited by vegetative (heterokaryon) incompatibility determined by alleles at several different *vic* loci. The number of *Cryphonectria parasitica* compatibility groups is apparently much greater in the United States than in Europe,[277] limiting the spread of the hypovirulence virus. In fact, limiting the spread of debilitating viruses is the presumed function of this heterokaryon incompatibility system (see section [Het-s]—a Prion of *Podospora* Responsible for a Normal Function).

In contrast, infectious cDNA incorporated into the *C parasitica* genome, while generating dsRNA replicons, will also naturally spread to other

mating and vegetative compatibility groups through sexual transmission.[67,290] It is thus expected to be more effective in the biological control of chestnut blight than the natural virus (reviewed in Ref.[290]). Another approach is to make strains missing most of their *vic* loci, and therefore able to form heterokaryons with almost any strain.[367,424]

The virus launching from a cDNA approach has also been used to introduce CHV1-EP713 into other plant-pathogenic fungi of the order *Diaporthales*.[337] Infection produced both phenotypic changes and a decrease of virulence in these heterologous hosts. There are, of course, a wide variety of plant-pathogenic fungi, and many cases of hypovirulence due to infecting viruses have been found (reviewed in Ref.[183]).

Negative Strand RNA Mycoviruses

A search of sequence databases revealed chromosomal sequences from *Erysiphe pisi* (pea powdery mildew fungus) homologous to the L-protein (RNA-dependent RNA polymerase) of the Mononegavirus group (includes the (–) ssRNA single segment viruses rabies, measles, mumps, Ebola, and respiratory syncytial viruses).[222] Also, transcriptome shotgun assembly sequences of *Sclerotinia homoeocarpa* (an ascomycete fungus causing dollar spot of grasses) revealed long contigs similar to the L-protein and methyltransferase (capping enzyme) of Nyamanini virus, a Mononegavirus of birds.[222] These sequences were not found in two sequence libraries of *Sclerotinia homoeocarpa*, suggesting that they were from a virus, not the genome.[222]

Such a Mononegavirus was then found in several hypovirulent isolates of *Sclerotinia sclerotiorum* (a plant pathogen), and transfection of virulent *Sclerotinia sclerotiorum* strains made them hypovirulent.[248] The filamentous viral morphology and sequence characteristics of this *Sclerotinia sclerotiorum* negative-stranded RNA virus 1 (SsNSRV-1) were typical of the Mononegaviruses.[248] Transcripts are made of each of the six open reading frames. Similar viruses were found in the plant pathogens *Fusarium graminearum*[394] and *Botrytis cinerea*.[179]

Narnaviridae 20S RNA, 23S RNA, and Mitoviruses

20S RNA and 23S RNA (and their dsRNA forms W and T) are low copy ssRNAs in normal cells but massively amplified in sporulation medium (acetate, no nitrogen source) or at 37 °C.[203,396] Each shows nonchromosomal inheritance and is amplified independent of sporulation/meiosis competence of the host cell.[164,396] 20S RNA[267] and 23S RNA[130] are independent RNA replicons whose copy number is inducible. The sequences of 20S (2.5 kb)[268,326,327] and 23S RNAs (2.9 kb)[129,326] shows that they encode related RNA-dependent RNA polymerases with some similarities to the RNA-dependent RNA polymerases of RNA phages and RNA viruses.

20S RNA is linear,[325] is cytoplasmic, and lacks a coat protein[406] but is found in a 1:1 complex with its encoded 91-kd RNA polymerase.[158] These complexes synthesize 20S RNA and its complementary strand.[159] An infectious clone of 20S RNA has now been developed and used to show the importance of terminal nucleotides.[132] The RNA polymerase binds to three sites on 20S RNA, at the 5′ end, the 3′ end, and in the middle of the sequence, and all three sites are important for propagation of the genome.[141] Intermediates in replication are positive and negative single strands, not dsRNA.[148]

23S RNA is likewise associated with its encoded RNA polymerase in extracts,[128] and an infectious cDNA clone of 23S RNA has been developed and used to study the terminal sequence requirements for replication.[130]

The copy numbers of 20S RNA and 23S RNA are controlled by media conditions, requiring acetate as the carbon source and the absence of a nitrogen source for their 10 000-fold induction.[128,203,267] Both are also induced by growing cells at 37 °C, and at least 20S is repressed by the *SKI* system.[267,396] The *SKI* effect apparently reflects the absence of 3′ poly(A) on 20S mRNA (see earlier discussion).

Cryphonectria parasitica Mitochondrial RNA Replicon NB631

Polashock and Hillman[305] have described a mitochondrial dsRNA species in *C parasitica* strain NB631 (*Mitoviridae*). Assuming the mitochondrial genetic code (UGA = Trp), the NB631 dsRNA has a single long ORF that encodes an RNA-dependent RNA polymerase. This RNA polymerase is most closely related to those of 20S and 23S RNAs, and all are more closely related to RNA phage such as Qβ, than to RNA viruses of higher organisms.[304,327] The degree of similarity is such that these elements must be very close relatives. Nevertheless, 20S RNA and 23S RNA are primarily ssRNA replicons, whereas NB631 has been identified as a dsRNA element. NB631 dsRNA is transferred by hyphal anastomosis, like other *C parasitica* RNA replicons; however, unlike those, and other viruses of filamentous fungi, it is also efficiently transmitted by meiotic spore formation if the female parent had the virus.[304]

Hadaka [naked] Viruses and *Yadokari [home-borrowing] Viruses*

Like the *Narnaviruses*, the *Hadakaviruses* lack a coat, but have 10 or 11 viral segments of (+) ssRNA, not closely related to the single segmented *Narnaviruses*.[338] Members of this group have been found in *Fusarium oxysporum* and *Fusarium nygamai*. In spite of lacking a capsid, the virus segments stably propagate together.

In a phytopathogenic fungus, *R necatrix*, a Calicivirus-related (+) ssRNA single-segment virus has been found encoding its own RdRp, not encoding a coat protein, but instead is encapsidated in the coat of a totivirus in the same strain.[425] This is distinct form the usual helper virus-satellite relation in which the satellite may encode nothing (eg, defective interfering particles) or proteins not involved in its replication (eg, the killer M satellite dsRNAs). In this case, the *Yadokari* [home-borrowing] virus depends on the *Yadonushi* [home-owning] virus for its coat, but incorporates its own RdRp in the viral particles.[425]

A number of other interactions of mycoviruses with their hosts and with each other are being described, although in most cases, the mechanisms involved are as yet unclear, all ably reviewed in Ref.[183].

Chromosomal Genes Affecting Mycoviruses

Infection of Fusarium graminearum with the 6.6 kb ssRNA hypovirulence virus FgV1 leads to overexpression of the HEX1 protein, the major component of the Woronin body, a peroxisome-derived structure that acts as a channel between cells controlling cytoplasmic transfer.[359] In the absence of the virus, deletion of HEX1 does not affect growth but decreases the virulence of the fungus for wheat. However, hex1Δ strains carrying FgV1 have lower levels of viral RNA and less prominent hypovirulence.[359] The HEX1 protein binds specifically to the 5′ and 3′ ends of the viral (+) strand, suggesting that the effect on viral propagation is direct.[358]

Single-Stranded DNA Gemini-like Mycovirus

Sclerotinia sclerotiorum is a pathogen of many crop plants, and among hypovirulent isolates one was found to harbor a single-stranded circular DNA virus which was shown to be the basis for the hypovirulence.[421] Like the plant-pathogenic Geminiviruses, this *Sclerotinia sclerotiorum* hypovirulence-associated DNA virus (SsHADV-1) encodes proteins on both strands, the capsid protein on the (+) strand and a replication initiation protein (Rep) on the (−) strand. SsHADV-1 Rep is most homologous to those of three viruses in the genus *Mastrevirus* in the family *Geminiviridae*. The SsHADV-1 particles are 20-22 nm in diameter without the twinned appearance that gives the *Geminiviridae* its name.[421] This is the first DNA virus to be found in fungi.

SsHADV-1 is exceptional among mycoviruses in having an extracellular phase and can pass during co-culture between strains of *Sclerotinia sclerotiorum* that cannot fuse cellular processes.[421,422] Like the plant-infecting *Geminiviridae*, SsHADV-1 can also infect an insect, the damselfly *Lycoriella ingenua* that feeds on fungi, from a virus-infected fungal strain.[249] The virus replicates in all stages of the insect life cycle (or insect tissue culture cells), and can transmit to an uninfected fungal host. Thus, the virus uses the insect as a vector, like the plant-pathogenic *Geminiviridae*.[249]

Retroviruses (Retroelements)

Retroviruses, Retrotransposons, Retroposons, and Retrointrons

Retroelements (Table 20.1) all share their use of reverse transcriptase in their propagation. The retrotransposons of fungi and parasitic microorganisms resemble mammalian retroviruses in all essentials except for their lacking an *env* (envelope) gene and, in part for this reason, are restricted to propagation without leaving the intracellular environment (Fig. 20.7). Nonetheless, the frequency with which these cells mate in nature is high enough that most of these elements are widely distributed in their respective species. The retroposons are one step further removed in that they lack the long terminal repeat (LTR) structure, and their transposition process differs from those of the other groups. These elements resemble the mammalian LINE elements but have the advantage of readily detectable transposition and facile host genetics for their study. For example, Tad, of *Neurospora*, can retrotranspose between nuclei of a heterokaryon.[218] Excellent reviews of retrotransposons are available.[34,85,162,393]

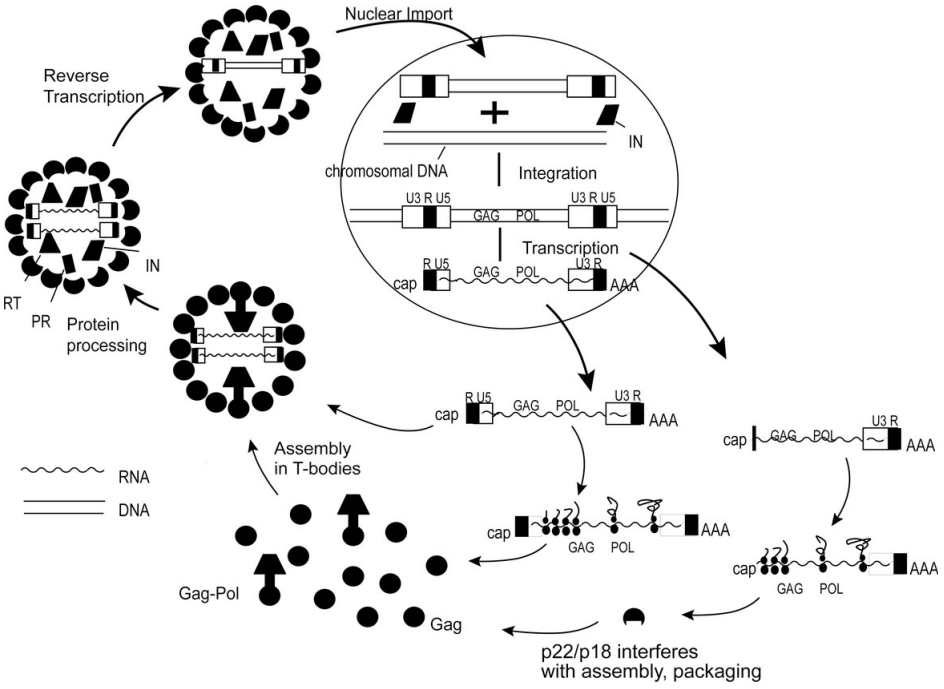

FIGURE 20.7 **The Ty replication cycle**. It is likely that all retrotransposons follow this cycle.

A group of reverse transcriptase encoding introns in mitochondrial DNA of *S cerevisiae* has also been identified[210] (reviewed in Refs.[236,237]). These are introns aI1 and aI2 of the cytochrome oxidase subunit I (COX1) gene. These introns are capable of retrotransposition both into their normal location and into heterologous locations, both *in vitro*[210] and *in vivo*.[281] These retroelements lack LTRs and have only a single ORF. Their properties suggest that introns may have begun as parasitic elements.

The retrotransposons are also divided based on amino acid sequence homologies and gene order in the *pol* domain into the *copia*-like and the

gypsy-like elements. *Copia* and *gypsy* are retroelements of *Drosophila*. Because Ty3 is more similar to gypsy than to Ty1, it is likely that Ty3 and Ty1 entered the yeast genomes at different times and that horizontal transfer of these elements occurs.

Structure of Tys

The Ty elements of *S cerevisiae* each have LTRs of 245-371 bp, separated by a unique region of 4.7-5.6 kb[33] (Fig. 20.8). The major Ty RNA transcript begins within the 5′ LTR (at base 241 from the 5′ end in Ty1) and ends at base 289 of the 3′ LTR, 45 bp from the 3′ end of the element (see Fig. 20.8). This provides the basis for the conventional division of retroviral LTRs into the U3 region (present only at the 3′ end of the Ty RNA but located at the 5′ end of the LTR), the R region (repeated at both ends of Ty RNA), and the U5 region (present only near the 5′ end of Ty RNA but at the 3′ end of the LTR).

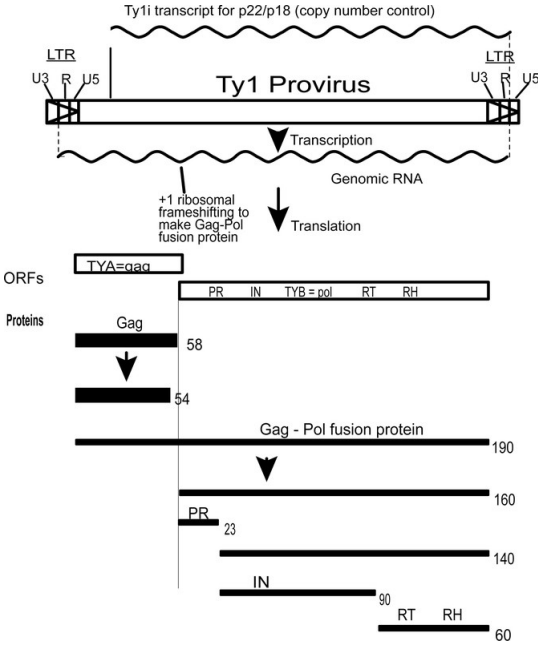

FIGURE 20.8 **Genome structure and expression of Ty1**. Gag and Gag-Pol are the primary translation products, which are processed by cleavage with the viral protease to form the proteins shown. (Adapted with permission of American Society for Microbiology from Garfinkel DJ, Hedge AM, Youngren SD, et al. Proteolytic processing of *pol-TYB* proteins from the yeast retrotransposon Ty1. *J Virol*. 1991;65(9):4573-4581; permission conveyed through Copyright Clearance Center, Inc.)

Ty1 through Ty4 all have two overlapping ORFs: TYA, corresponding to *gag*, and TYB, homologous to the *pol* of mammalian retroviruses. Like mammalian retroviruses and *gypsy*, Ty3 has the gene order protease (PR)–reverse transcriptase (RT)–RNase H (RH)–integrase (IN) in the *pol* ORF,[178] whereas Ty1 and Ty2 have the *copia* order PR-IN-RT-RH.[71]

Replication Cycle of *Saccharomyces cerevisiae* Ty Elements

The Ty replication cycle resembles that of mammalian retroviruses but begins and ends with the integrated form of the genome (see Fig. 20.7). Ty transcripts made with RNA polymerase II are translated to make the Gag and Gag-Pol fusion proteins. These proteins assemble, packaging the Ty RNA to make particles that are homologs of the core particles of retroviruses. The reverse transcriptase and RNase H make a dsDNA copy of the genome, and integrase inserts this into the genome, producing a short repeat of the chromosomal integration site.

Reverse Transcription

The reverse transcriptase and RNase H–homologous domains are present in the Ty1 particles as a 60-kd protein that is produced by proteolytic processing of the 190-kd Gag-Pol fusion protein[160] (see Fig. 20.8). Isolated Ty1 particles have reverse transcriptase that is active on either the endogenous Ty1 RNA or externally added templates. The Ty particles are also open to externally added enzymes, indicating that they are not impermeable shells but have pores. This porous structure may help explain how pseudogene formation can occur.[101] Extraction of active polymerase requires that the C-terminal part of integrase be covalently attached, reflecting the likely cooperation of reverse transcriptase and integrase in virions.[408]

The mechanism of reverse transcription of Ty RNA is largely the same as that for mammalian retroviruses. The primer for reverse transcription is $tRNA_i^{Met}$, with ten nucleotides of the 3′ acceptor stem complementary to a site on the Ty1 positive strand just 3′ to the 5′ LTR, called the negative primer binding site (–PBS).[52] This tRNA is specifically packaged in viral particles. Interestingly, although the primer function of the initiator tRNAMet depends on its complementarity with the –PBS, its packaging is independent of this complementarity.[52] This indicates that the $tRNA_i^{Met}$ is recognized by some other component of the Ty virus particle and that it is probably not the acceptor stem of the tRNA that is recognized. Ty1 cDNA synthesis unexpectedly requires *DBR1*, encoding the enzyme that debranches the lariat structure produced by intron excision by cleaving the 2′-5′ linkage at the branchpoint.[51] Ty1 is reported to have a 2′ to >5′ linkage between the ribonucleotide at the 5′ end of Ty1 RNA and an internal Ty1 ribonucleotide, explaining the requirement for Dbr1p action,[57] but the presence of the branched structure has been questioned.[76]

Integration

Ty3 shows a tight specificity for target sites, integrating 16 or 17 bp upstream of the 5′ ends of tRNA coding regions.[49] The DRE element of *Dictyostelium discoideum* and the spliced leader-specific elements SLACS, CZAR, and CRE1 of trypanosomes have a similar integration target specificity.[3,154,259] Other genes transcribed by RNA polymerase III, such as 5S rRNA and U6 small nuclear RNA, similarly are targets for Ty3.[49] The basis for this site specificity is a specific interaction of Ty3 integrase with the PolIII transcription factor TFIIIC[11] and recognition of the TPB and Brf1 subunits of TFIIIB.[420] Thus, the integration apparatus recognizes the transcription apparatus, not the transcription initiation site or the promoter itself.

Other Tys are capable of insertion at many different sites, with Ty1 producing a five-bp duplication of the target DNA[139]; however, these sites tend to be within 750 bases of a tRNA gene or other RNA polymerase III–transcribed gene.[214] Ty1 insertions in RNA *pol* II–transcribed genes tend to be in the 5′ part of the *URA3*, *LYS2*, and *CAN1* genes,[122,245,286] with control regions targeted far more often than the ORFs.

An *in vitro* integration system using Ty1 viral particles produced from an element carrying a copy of the *Escherichia coli supF* gene and, as target, λ DNA from a multiple amber mutant suppressible by *supF* shows that linear dsDNA substrates carrying the terminal 12 bp at each end of the LTR are sufficient for the integration reaction to occur at normal efficiency.[123] There are also no nucleotide requirements. The substrate DNA must have 3′ hydroxyls, suggesting that the reaction involves covalent attachment of these 3′ ends to the target DNA. Unlike mammalian retroviruses, Ty1's integrase does not remove two terminal bases in the process of integration,[123] probably because in Ty1 the primer binding site is immediately adjacent to the U5 part of the LTR. In fact, the purified integrase protein is capable of carrying out an integration model reaction without other components of the viral particle.[279]

Expression of Tys

Control of Transcription

Transcription of Ty1, Ty2, Ty4, and Ty5 is inhibited in diploid cells by the action of the a1/α2 encoded by the *MAT* locus.[73] In the wild, the haploid phase for yeast is transient, and cells soon mate and spend most of their time as diploids. The 20 times higher transcription of Ty1 in haploids may be a preparation for mating and the possible opportunity to hop into a new genome.

Transcription of Ty3 and Ty5 are derepressed by exposure of cells to the mating pheromones.[72,208,391] Ty3 transposition is, in fact, induced in mating cells, and Ty3 transposing from the genome of one mating partner to that of the other occurs at high rates.[219] Here, the interpretation of preparation to transpose into the potentially Ty3-free genome of the mating partner seems clear.

Filamentous growth, associated with starvation, also mobilizes Ty as a result of elevated transcription produced by the Kss1 MAP kinase cascade.[74] Again, a stressful condition results in Ty mobility.

DNA damage, induced by ultraviolet irradiation or 4-nitroquinoline-1-oxide, also induces Ty1 transposition by inducing transcription of the element.[40] Is this effect adaptive for Ty1 as a first step in finding a new home, or is it a consequence of a failure of the host anti-Ty system?

Retroelements all must cajole the cellular RNA polymerase II into transcribing their proviral form to make viral RNA. They are constrained, however, to place the controlling sequences inside the limits of the element. Whereas most mammalian retroviruses have enhancers in their LTRs upstream of the start site of transcription, Ty1 and Ty2 elements have major transcriptional control sequences downstream of both the transcript start site and the translation start site, most of them inside the unique region. Ty1 has two major downstream sites responsible for its haploid-specific transcription: the sterile-responsive element (SRE) binds Ste12p, and another site (block II or PRTF) binds Mcm1p.[73,125]

Effect of Ty Insertion on Cellular Genes

Insertion of Ty elements into the control regions of cellular genes can activate, inactivate, or alter the control of the target gene[126,410] (reviewed in Ref.[242]). The Ty insertions often move the normal regulatory sequences 5 kb away from the target gene, eliminating the normal regulation. Insertions of Ty whose 5′ end is close to the 5′ end of the target gene impose the Ty transcriptional control on the target gene. This produces a divergent transcription of the Ty element and the target gene; however, both are under mating type control because of the effect of the Ty control region.

Chromosomal Genes Regulating Ty Transcription

Mutant cellular genes that have come under control of Ty1 have been used extensively to investigate the cellular genes affecting the transcription of Ty1 itself.[70,413,414] Second-site mutations (suppressors) that restore the normal expression of the target genes have defined a large group of genes, called *SPT*, that include the TATA binding factor TFIID, the genes encoding histones, and many general transcription factors with effects on many genes (eg, *SNF2*, *SNF5*, *SNF6*, *GAL11*, *SIN1*). In addition, the control of the target genes by mating type and mating pheromones have led to studies of effects of the mating type and pheromone control pathway genes on Ty itself. For example, *STE12* controls Ty1 transcription, as do the genes upstream of *STE12* in the mating type control kinase cascade.[127]

+1 Ribosomal Frameshifting

Like mammalian retroviruses, Ty elements direct the synthesis of a Gag protein and a Gag-Pol fusion protein (see Fig. 20.9). For reasons that are not yet clear, each of the *Saccharomyces* Ty elements uses +1 ribosomal frameshifting, whereas animal retroviruses all use −1 frameshifting (or read-through of a terminator) to make Gag-Pol (reviewed in Ref.[366]). As shown by studies of the L-A dsRNA virus, yeast can perform −1 ribosomal frameshifts by the same simultaneous slippage mechanism used by retroviruses.

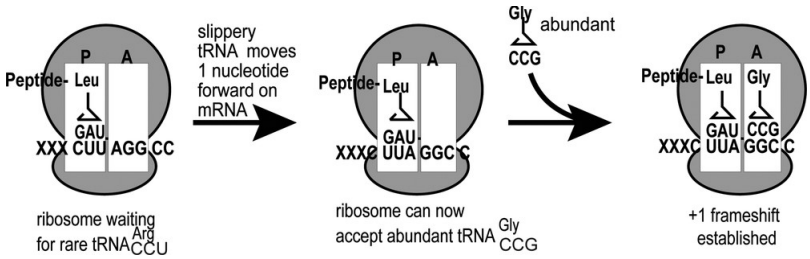

FIGURE 20.9 **Mechanism postulated for +1 ribosomal frameshifting of Ty1**. Ty3 frameshifting involves the new tRNA pairing in the +1 frame without a shift of the peptidyl transfer RNA as for Ty1.[392] (Adapted from Belcourt MF, Farabaugh PJ. Ribosomal frameshifting in the yeast retrotransposon Ty tRNAs induce slippage on a 7 nucleotide minimal site. *Cell*. 1990;62(2):339-352. Copyright © 1990 Elsevier, with permission.)

The mechanisms of the +1 frameshifts in Ty1 or Ty2 (see Fig. 20.9) and Ty3 all involve the combination of starvation for a rare tRNA and an unusual tRNA able to perform the frameshift.[24,140] The Ty1 slippery site on the mRNA is CUU-AGG-C. The low abundance of $tRNA^{Arg}_{CCU}$ recognizing the "hungry" AGG codon at the ribosomal A site slows ribosomes. The $tRNA^{Leu}$, located at the P site while the A site is waiting for the AGG codon to be occupied, has as its anticodon UAG, and it is capable of pairing with either the 0 frame CUU codon or the +1 frame codon UUA. When it slips into the +1 frame, the GGC codon can be easily recognized by an abundant $tRNA^{Gly}$ species, and the ribosomes then continue in the +1 pol reading frame to make Gag-Pol fusion protein.[24]

Oversupply of $tRNA^{Arg}_{CCU}$ lowers frameshift efficiency[24] and transposition frequency[417] as expected. Deletion of the $tRNA^{Arg}_{CCU}$ gene increases frameshifting as expected, but lowers the frequency of transposition[207] indicating that the ratio of *Gag* and *Gag-Pol* is important and that drugs affecting frameshifting efficiency might be useful as antivirals.

The Ty3 frameshift site is GCG-AGU-U, and, like that of Ty1, is based on a hungry codon in the ribosomal A site, namely AGU.[140] AGU is recognized by a low-abundance $tRNA^{Ser}$, thus the ribosome pauses at this point. However, the $tRNA^{Ala}_{CGC}$ that decodes the GCG codon in the P site cannot slip +1 and re-pair. Rather, it is believed that the valine tRNA simply pairs out of frame.[392] A downstream sequence may stimulate Ty3 frameshifting by interacting with rRNA.[366]

Proteolytic Processing and Phosphorylation

Ty1 Gag is expressed as a primary translation product of 49 kd, most of which is processed by the Ty1 protease to form the 45-kd major particle protein. After Pol is synthesized as a 199-kd Gag-Pol fusion protein, it is processed through several intermediates to form the protease, integrase, and reverse transcriptase–RNase H[160] (see Fig. 20.8).

Packaging and Assembly

The Ty1 RNA site determining packaging has been localized to within a 381-nucleotide region between nucleotides 239 and 620.[418] An RNA pseudoknot at the 5′ end is important for retrotransposition,[35,192] but the RNA structure recognized for packaging and the parts of Gag or Gag-Pol proteins that recognize this region have not yet been determined.[173]

Ty5 and Ty1 mRNA and Gag localize in cytoplasmic particles (T-bodies) thought to be involved in viral particle assembly.[23,53,255,256] Assembly of T-bodies requires components of the mRNA-processing bodies referred to as P-bodies (Dhh1p, Lsm1p, Pat1p); however, T-bodies are distinct from P-bodies in the case of Ty1[53,114] but may be identical in the case of Ty3.[23] Mutants in these P-body components are defective for retrotransposition, as well as for cDNA accumulation. Retrotransposition requires not only the P-body structure but also its RNA-degrading enzymatic activities, such as the decapping enzyme *Dcp1/2* and 5′-3′ exoribonuclease *Xrn1p/Ski1p*.[53,114]

Ty Self-imposed Copy Number Control

Wild strains of *S cerevisiae* carry up to about 40 copies of Ty1, most of which are probably transposition competent, but not more.[89] Moreover, transposition in a host carrying only a single Ty1 is over 100-fold more frequent than the usual host (S288C has 32 Ty1s).[161] In another comparison, 20 copies of Ty1 produced a 4800-fold decrease in transposition.[161] This phenomenon is called copy number control (CNC). CNC is due to each Ty1 making a small amount of a C-terminal fragment of Gag called p22 (and its protease-processed form p18) made from an internally promoted transcript called Ty1i starting at nt 1000 of Ty1 with the same 3′ end as Ty1 genomic RNA[334] (Fig. 20.8). Unlike the genomic Ty1 transcript, the Ty1i transcript is independent of Spt3, a subunit of the SAGA transcription regulation complex required for production of the full-length genomic Ty1 RNA (gRNA).[334]

Both p22 and p18 are incorporated into the T-bodies (Ty1 assembly factories) and Ty1 virus-like particles, and interact with Gag to prevent proper assembly and function of the particles.[80,334,385] Because p22/p18 have the C-terminal part of the capsid domain of Gag, they can assemble with Gag by interacting with its C-terminus, but the absence of the N-terminal domain apparently prevents completion of proper assembly and function.[80] The effectiveness of p22/p18 is proportional to its level in the cell, with the highest levels completely shutting off retrotransposition.[334] Although Ty1 tends to insert at relatively safe (for the host) places, Ty1 copy number is inversely correlated with fitness.[409] Thus the CNC makes Ty1 a smart parasite.

Antisense RNA transcribed from the 5′ end of the Gag ORF and incorporated into viral particles was thought to play a role in copy number control and can indeed inhibit transposition,[28,266] but its status is now uncertain because p18/p22 interference with Ty1 assembly and activity now provides a complete explanation of CNC.[334]

Host Limitations on Ty Transposition Efficiency

Studies of the mechanism and control of transposition have often used a plasmid with a GAL1-promoted Ty1 (inducible on galactose) carrying a marker (such as *HIS3*) in the antisense orientation with an artificial intron in the sense orientation) to facilitate detection of transposition.[86] When Ty1 transposition is induced with such a plasmid, although Ty1 RNA is increased only a few fold over that derived from the normal chromosomal Ty1 copies, the frequency of transposition increases about 100-fold, suggesting a block to transposition that is saturable by Ty1 mRNA.[87] Many host genes have been identified whose mutation derepresses Ty1 transposition, analogous to the effect of ski mutations on RNA virus copy number (see earlier discussion).

Mediator is a large complex that connects DNA-binding transcription activators to RNA polymerase II. Deletion of nonessential subunits of Mediator increase or decrease Ty1 transposition frequencies on the order of 100-fold and show only modest effects on Ty1 antisense transcript or Ty1 sense full-length transcripts, generally not correlated even in direction with the effects on transposition.[335] However, there are substantial changes in Ty1i transcript and levels of p22 and p18 that correlate well with the effects on transposition.[335]

Xrn1p is a 5′-3′ exoribonuclease involved in mRNA decay, and *xrn1* mutants have elevated Ty1i transcript, elevated p18, and decreased Ty1 transposition.[334] Spt3 is a component of the SAGA chromatin-remodeling complex and is necessary for Ty1 full-length transcription. However, *spt3* mutants also have elevated Ty1i transcript and increased levels of p22/p18, which must contribute to their decreased Ty1 transposition.[334]

Loc1p, a nucleolar protein involved in ribosome biogenesis and the asymmetric localization of *ASH1* mRNA between mother and daughter cell, inhibits CNC.[1] Like several mutants in genes for ribosomal proteins, *ash1*Δ strains show modest effects on transposition of lone Ty1s, but substantially decreased transposition in strains with the normal complement (~32 copies) of chromosomal Ty1.[1]

Mutation of the cellular *rad6* gene, encoding a ubiquitin-conjugating enzyme, increases the frequency of Ty transposition at either *URA3* or *CAN1* and changes the distribution of insertions.[301] This effect is not caused by altered Ty transcript levels and was seen even when retrotransposition from a GAL1-promoted Ty1 was studied. Rad6p alters chromatin structure by monoubiquitination of histone H2B on Lys123,[323] suggesting that the Rad6p effect on Ty1 transposition is on the nature of the target. Mutation of *CAC3*, encoding a subunit of chromatin assembly factor I, and *HIR3*, a histone transcription regulation gene,[309] also affect both the frequency of integration and the distribution of insertions by alterations of the structure of the target.[191]

Mutation of the *FUS3* MAP kinase results in a more than 20-fold increased Ty1 transposition frequency.[74] Ty1 transcript levels and primary translation products were not affected by *fus3*; however, virus particle–associated processing products of Pol and Ty cDNA were each elevated 10-fold or more in the mutant. The Fus3 kinase is activated by exposure to the mating pheromones via a cascade of kinases, thus explaining the inhibition of Ty1 transposition by exposure to mating pheromones.[419] Fus3 acts by stimulating the invasive growth pathway.[75]

Mutations in more than 20 genes encoding DNA replication and repair components show derepression of Ty1 retrotransposition (reviewed in Ref.[272]). For example, mutants in *SSL2* and *RAD3*, encoding excision-repair DNA helicases, show elevated retrotransposition,[239] as do mutants in *RRM3*, encoding a helicase that promotes replication through DNA-protein complexes.[88] Rad3 represses Ty1 transposition (28×) even in a cell with only a single Ty1,[161] while it shows a 170-fold repression in a cell with many Ty1s.[239] So at least Rad3 is not working solely (if at all) through CNC,[161] but other mutations have not yet been tested.

These mutations do not elevate Ty1 transcripts; however, the level of Ty1 cDNA is elevated.[88,239,370] This group of mutations is known to activate the DNA damage checkpoint pathway or the DNA replication stress pathway, and their derepression of Ty1 transposition is prevented by mutation of elements of the checkpoint pathways, such as *rad53*, *rad9*, *rad24*, *mec1*, and *dun1*.[88] Thus, DNA damage or replication arrest from a host of sources, by activating the checkpoint pathways, turns on Ty1 retrotransposition. Although the mechanism of this effect is not yet clear, the best explanation appears to be that cellular conditions at the arrest point in the cell cycle are particularly favorable for transposition.[272] There is no evidence that this derepression favors either the yeast host or Ty1.

Ty5 integration is concentrated in regions of heterochromatin, unlikely to be detrimental to the host.[430] A nine-residue section of the Ty5 integrase determines association with Sir4p, a heterochromatin protein, and hence the site specificity.[416] However, this interaction and the corresponding targeting to heterochromatin only occur properly when this targeting domain site is phosporylated at S1095 by a host kinase.[91] Under stress conditions, this control system breaks down, the targeting domain is not fully phosphorylated, and integration is random, producing more serious mutations.[91]

Schizosaccharomyces pombe Retroelements

The Tf1 and Tf2 elements of *Schizosaccharomyces pombe* are unusual in that a single ORF encodes both Gag and Pol.[243] From the primary 140-kd translation product, the viral protease cleaves the proteins that form the viral particles.[244] In view of the strict requirement for the ratio of Gag to Gag-Pol in Ty1[207,417] and retroviruses, the assembly process in Tf1 and Tf2 must be significantly different. In log phase cells, the ratio of Gag to integrase in particles is close to 1, whereas in stationary cells, it is quite high.[10] Selective degradation of the non-Gag protein components alters the ratio after particle formation.[10]

The priming mechanism of Tf1 is also unique. Instead of tRNA priming as for other retrotransposons and retroviruses, Tf1 negative-strand DNA synthesis is primed by the first 11 nucleotides at the 5′ end of the viral RNA, which is complementary to the primer binding site.[246] A hairpin is formed, which is nicked to separate the first 11 nucleotides from the 5′ end of the RNA and give it a 3′-OH that can serve as a primer for strong-stop DNA synthesis.

Although the *piwi* RNAi system controls retrotransposons in mammals and many other organisms, two chromatin-modifying protein-based systems have been identified in *S pombe* that silence *Tf2* elements and *Tf2*-derived LTRs and prevent their recombination that could damage the genome.[45,172] The HIRA complex, a nucleosome-assembly apparatus that includes Hip1, Slm9, and Hip3, is important for the assembly of silencing heterochromatin at various sites, including the *Tf2* retrotransposon.[172] Three homologs of human CENP-B—Abp1, Cbh1, and Cbh2—

are involved in a different chromatin silence system that works by binding to *Tf1* and *Tf2* loci (and lone LTRs) and recruiting the histone deacetylases Clr6 and Clr3 to those sites.[45] In addition to the silencing produced by localized histone deactylation, the CENP-B homologs draw together the *Tf* loci into intranuclear bodies, which may facilitate their silencing.[45]

Candida albicans Plasmid Retrotransposon and Line Elements

Most retrotransposons have minute amounts of cDNA present in normal strains; however, that of *Candida albicans* (pCal) produces 50-100 copies per cell of linear dsDNA in a particular strain of *Candida*.[270] pCal is a member of the Ty1/*copia* group found in integrated form in most strains, and the basis for its high free levels is not yet known. pCal is also unique among retrotransposons in that it uses read-through of a stop codon to make its Gag-Pol fusion, as in murine leukemia virus.[270]

C albicans also carries several families of non-LTR retrotransposons (LINEs), homologous to the mammalian L1 LINE elements.[169] One of these elements, Zorro3, has been shown capable of transposition in *S cerevisiae*.[111] Non-LTR retroelements have also been identified in *Cryptococcus neoformans*.[170]

Prions of *Saccharomyces* and *Podospora*

The concept of an infectious protein arose in studies of the transmissible spongiform encephalopathies (TSEs), such as scrapie of sheep, mad cow disease, and Creutzfeldt-Jakob disease of humans (see Chapter 22). Based on genetic evidence (Fig. 20.10), two non-mendelian genetic elements of *S cerevisiae*—[URE3] and [PSI+]—were identified as prion (infectious protein) forms of Ure2p and Sup35p, respectively.[397] This conclusion is supported by extensive further evidence, and both are transmissible amyloidoses, a remarkably close parallel to the mammalian disease. Two further amyloid-based prions—[Het-s] of the filamentous fungus *Podospora anserine*[81] and [*PIN*$^+$] of *S cerevisiae*[98] —were next found and have been studied extensively. An infectious protein consisting of an enzyme whose active form is essential for activation of its own inactive precursor can also be an infectious protein, and two such cases have been described.[212,235,322] A recently described prion, [SMAUG+], consists of a nonamyloid aggregation of Vts1p, a site-specific RNA-binding protein that stimulates mRNA degradation by inducing its deadenylation.[48] [SMAUG+] cells have increased sensitivity to UV irradiation but better growth at limiting dextrose levels.[48] Several other yeast prions have been reported (Table 20.2).

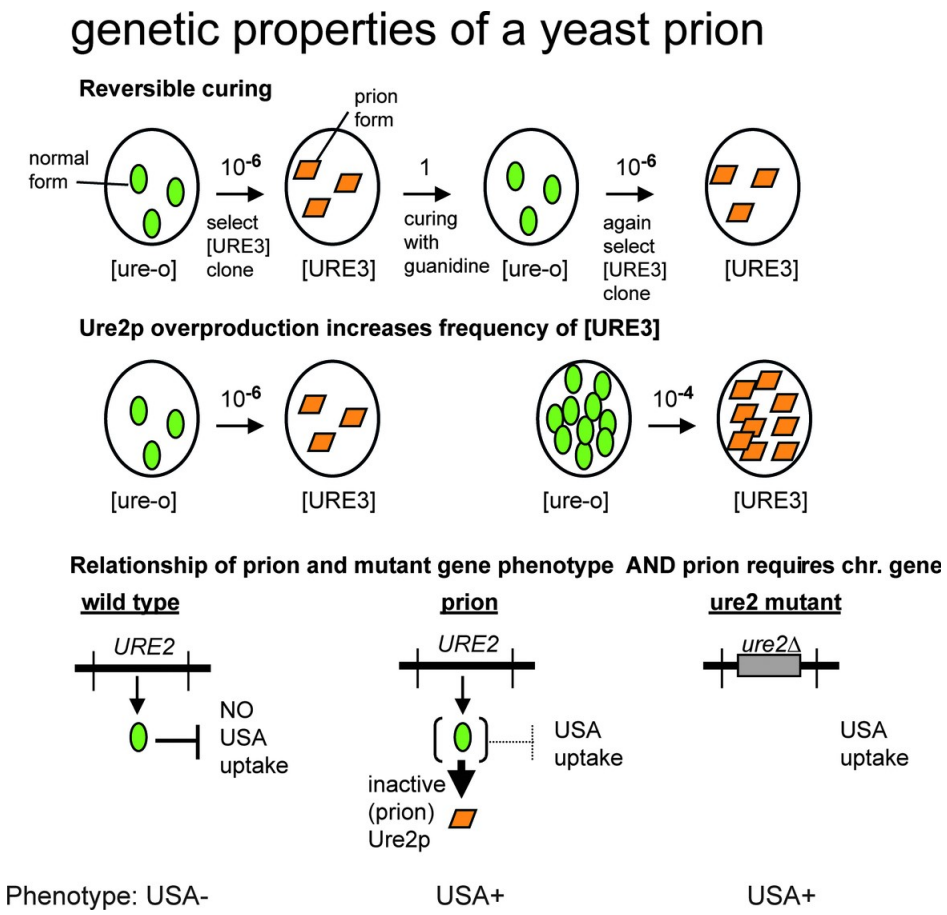

FIGURE 20.10 **Three genetic criteria for a prion**. These are unusual features, expected of a prion but not of a nucleic acid replicon. (Based on Wickner RB. [URE3] as an altered URE2 protein: evidence for a prion analog in Saccharomyces cerevisiae. *Science*. 1994;264:566–569.)

TABLE 20.2 Prions of yeast and fungi

Name	Prion Protein	Normal Function	Prion Phenotype (Variant Dependent)	Reference
[PSI+]	Sup35p	Translation termination, mRNA turnover	Termination codon read-through, slow growth, cell death	397
[URE3]	Ure2p	Nitrogen catabolite repression	Derepressed for transporters and enzyme for poor N sources, very slow growth	397
[PIN+]	Rnq1p	Unknown	Weakly primes [PSI+] generation	98
[SWI+]	Swi1p	Chromatin remodeling	Poor growth on raffinose or glycerol	113
[OCT+]	Cyc8p	Global transcription co-repressor	Derepression of multiple genes	295
[MOT+]	Mot3p	Transcription regulator	Derepression of anaerobic genes	4
[β]	Prb1p	Vacuolar protease	Active protease, survival in stationary phase, sporulation	322
[MOD+]	Mod5p	tRNA isopentenyl transferase	Slow growth, partial resistance to azoles (nocodazole, fluconazole)	371
[SMAUG+]	Vts1p	mRNA degradation	UV-hypersensitive, Improved growth in limiting glucose	48
[Het-s]	HET-s	The prion is the normal form	Heterokaryon incompatibility	81

The [β] prion is the active form of the self-activating enzyme, vacuolar protease B, and is not related to amyloid formation. Vts1p is a nonamyloid aggregate in [SMAUG+] strains. The other prions listed here are all self-propagating amyloids.

Domains from many yeast genes, a plant gene, and a bacterial gene have been shown capable of acting as prion domains replacing the prion domain of Sup35p, a few of which have been shown to be prions (*infectious* proteins) in their native context.[4,47,423]

[URE3]—A Transmissible Amyloidosis of Ure2p

When yeast has a good nitrogen source, such as ammonia, Ure2p, by binding the transcription factor Gln3p, shuts off transcription of genes encoding enzymes and transporters needed for the utilization of poor nitrogen sources, such as *DAL5*, encoding the allantoate transporter.[78] In 1971, Lacroute described a non-mendelian genetic element of *S cerevisiae* called [URE3], which allowed cells to take up ureidosuccinate despite the presence of a rich nitrogen source.[234] Ureidosuccinate is the product of aspartate transcarbamylase (*URA2*) in uracil biosynthesis. Because of chance resemblance to allantoate (a poor nitrogen source), it is taken up from the medium by Dal5p, and *DAL5* is repressed by ammonium via Ure2p action. Thus, [URE3] *ura2* strains can grow on ureidosuccinate in the presence of ammonia, whereas [ure-o] cells (lacking [URE3]) cannot. Fusing the *DAL5* promoter to the *ADE2* ORF allows assaying [URE3] by adenine prototrophy.[340]

Genetic Evidence That [URE3] is a Prion

Three lines of genetic evidence first showed that [URE3] is actually an altered form of Ure2p that has lost its activity in repressing nitrogen metabolic enzymes through Gln3p but has acquired the ability to convert the normal Ure2p to this altered form[397] (see Fig. 20.10). First, [URE3] is efficiently cured by growth of cells on guanidine HCl; however, the curing is reversible in that [URE3] derivatives may again be selected from the cured strain.[397] Second, transient overproduction of Ure2p leads to a 20- to 100-fold increase in the frequency with which [URE3] arises *de novo*.[397] Third, Ure2p is required for propagation of the [URE3] nonchromosomal gene, but the phenotypes of *ure2Δ* and [URE3] are essentially identical.[2,397] These three features are strongly predicted by the prion model, although not if [URE3] were a nucleic acid replicon—a virus or plasmid.[397] These three properties, none of which were known for the mammalian TSEs, also served to identify [PSI+] as a prion form of Sup35p,[397] [PIN+] as a prion of Rnq1p,[98] and other prions.

Ure2p is partially protease resistant in extracts of [URE3] strains, like the amyloid of PrP in brains of TSE-infected animals.[264] Moreover, the generation and propagation of [URE3] was unaffected by the repression or derepression of nitrogen regulation, eliminating some alternative models. [URE3] truly does arise *de novo*, and it is the Ure2 protein, not the *URE2* mRNA or the copy number of the *URE2* gene, that induces [URE3] to arise.[262]

Domains of Ure2p

Ure2p is composed of a C-terminal functional domain, whose structure resembles glutathione-S-transferases (residues 95-354),[37,264,389] and an unstructured N-terminal domain (residues 1-94).[302] Ure2p$^{90\text{-}354}$ is sufficient, if overexpressed, for nitrogen regulation but is rapidly degraded without the N-terminal residues.[351] This stabilization domain is also the part of the molecule responsible for the prion change (the prion domain) and comprises roughly the N-terminal 65 residues.[264] [URE3] is efficiently transmitted by cytoplasmic mixing to cells expressing only Ure2p$^{1\text{-}65}$ from cells expressing the full-length protein. The cells expressing only Ure2p$^{1\text{-}65}$ stably propagate the prion and efficiently transmit it again to cells expressing the full-length Ure2p.[262] On conversion to the infectious amyloid form, the C-terminal domain is largely unchanged in structure,[12] and the prion domain (residues 1-65) assumes an extremely stable amyloid form.[20,377] Residues 66 through 94 remain unstructured in the amyloid form and are called the *tether* because they attach the structured C-termini to the structured amyloid core.

Infectious Amyloid of Ure2p Is [URE3]

Ure2p–green fluorescent protein fusions are aggregated in [URE3] cells, indicating that aggregation is involved in the [URE3] change.[118] The Ure2p prion domain synthetic peptide can form amyloid, and this domain also directs the conversion of the full-length native Ure2p into amyloid[377] (Fig. 20.11). The product of this reaction can seed further amyloid filament formation *in vitro*, indicating that the [URE3] phenomenon is a transmissible amyloidosis of yeast,[377] and filaments of Ure2p can be seen by electron microscopy specifically in cells infected

with [URE3].[365] Ure2p is inactivated for its nitrogen regulation function apparently simply because it is aggregated and thus relatively inaccessible to Gln3p.[19]

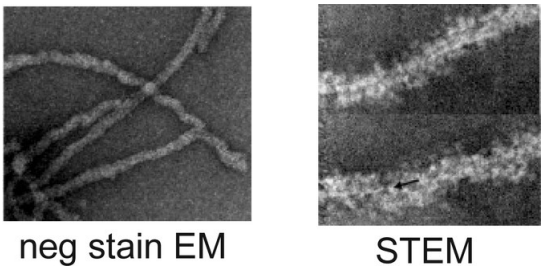

FIGURE 20.11 **Amyloid filaments of recombinant Ure2p**.[20,377] **Left**. Electron micrograph of negatively stained Ure2p amyloid filaments. **Right**. Scanning transmission electron micrograph of Ure2p amyloid filaments[20] with the amyloid core visible (*arrow* in one of the filaments).

Infection by amyloid of recombinant protein was first achieved for [Het-s] and then for [PSI+] (see later discussion). Amyloid formed *in vitro* from recombinant Ure2p efficiently infects yeast cells with [URE3].[38] The infectivity of Ure2p amyloid resides in particles that are no <20 nm in size, a minimum of about 40 molecules.[38] Very large filaments are not easily introduced into yeast cells but contain abundant infectivity that is revealed by sonication. Prion variants of [URE3] were described,[340] and amyloid made from recombinant Ure2p induces the appearance of at least three distinct variants of [URE3].[38] Extracts of each variant are again infectious and induce the appearance of the corresponding [URE3] variant.[38] Fractionation of amyloid of recombinant Ure2p produces some fractions in the 20- to 200-nm range whose infectivity is nearly as high as that of extracts. Infectivity resides entirely in the N-terminal prion domain, again showing its central role.[38]

[PSI+]—A Transmissible Amyloidosis of Sup35p

In 1965, Cox described [PSI+], a non-mendelian genetic element of *S cerevisiae* that increases the efficiency of nonsense suppression by classical tRNA suppressors.[82] Like [URE3] and Ure2p, [PSI+] is reversibly curable,[253,356] transient overexpression of Sup35p increases the frequency with which [PSI+] arises by 100-fold,[58,100] the phenotype of [PSI+] is like that of *sup35* mutants, and *SUP35* is necessary for propagation of [PSI+].[110,378] This logical parallel with [URE3] and Ure2p indicated that [PSI+] is also a prion form of Sup35p.[397]

Infectious Amyloid of Sup35p

Sup35p is aggregated in [PSI+] strains but not in [psi–] strains,[297,299] and the *in vitro* aggregation of native soluble Sup35p seeded by the prion form from [PSI+] cells will continue indefinitely as long as fresh native Sup35p is supplied.[300] The N-terminal 114 residues of Sup35p could propagate [PSI+], and so constitute the prion domain (Sup35N),[378] and as a synthetic peptide spontaneously forms amyloid *in vitro*.[217] In addition, the full-length Sup35p, made in *E coli*, forms β-sheet–rich filaments spontaneously when diluted out of denaturant, a process that can be accelerated specifically by an extract from [PSI+] cells.[166]

Amyloid formed from recombinant Sup35p transmits [PSI+] to cells, inducing the appearance of several prion variants.[216,373] Extracts of cells bearing a variant are infectious and transmit the variant carried by the strain from which the extract was made. Moreover, seeding soluble Sup35p with an extract amplifies amyloid transmitting that prion variant. Adjusting the conditions under which amyloid forms spontaneously strongly biases the variant encoded by the amyloid formed.[373] These results are useful in studies of the structural differences between prion variants.

[PIN+]—A Prion that Generates Other Prions

Derkatch et al. found that whereas overproduction of Sup35p induces the high-frequency appearance of [PSI+] in some strains, others did not show this effect.[99] Their analysis showed that this effect was attributable to the presence of a nonchromosomal genetic element in the strains in which [PSI+] generation was inducible. The Rnq1 (rich in N and Q) protein showed a self-propagating aggregation,[362] and indeed Rnq1 amyloid formation proved to be the basis of the [PIN+] nonchromosomal gene.[98] Overproduction of other N/Q rich proteins likewise has [PIN+]-like activity (without being themselves prions), as does the [URE3] prion.[98] Moreover, [PIN+] also modestly promotes *de novo* generation of [URE3].[39] [PIN+] probably promotes generation of prions by other N/Q rich proteins by rare cross-seeding. Recombinant Rnq1p also forms amyloid *in vitro*,[362] and this amyloid can infect yeast cells with the [PIN+] prion.[296] The promotion of prion seeding by [PIN+] is probably due to cross seeding by the Q/N rich Rnq1 amyloid of the prion domains of the other prion proteins, nearly all of which are also Q/N rich.

[Het-s]—A Prion of *Podospora* Responsible for a Normal Function

Hyphal anastomosis/vegetative fusion/heterokaryon formation (explained above “A mycoreovirus facilitates infection by preventing heterokaryon incompatibility”) depends on allele identity at 6-12 *het* loci (Fig. 20.12) (reviewed in Ref.[339]).

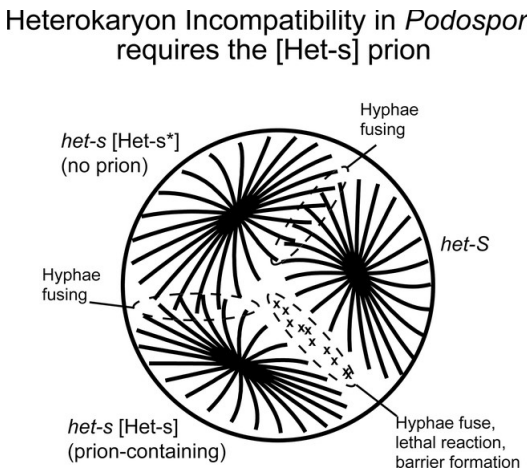

FIGURE 20.12 **The [Het-s] prion of *Podospora anserina* is required for heterokaryon incompatibility**.

(Adapted with permission from Coustou V, Deleu C, Saupe S, et al. The protein product of the *het-s* heterokaryon incompatibility gene of the fungus *Podospora anserina* behaves as a prion analog. *Proc Natl Acad Sci U S A*. 1997;94(18):9773-9778.)

One of the *het* genes of *Podospora anserina* is *het-s*, with alleles *het-s* and *het-S* encoding a 289-residue protein differing at 14 positions,[387] although the difference at residue 33 is sufficient to trigger the incompatibility reaction.[97]

Rizet found that *het-s* strains could show the incompatibility reaction only if they also carried a non-mendelian genetic element referred to as [Het-s].[321] [Het-s] could be "cured" from a male strain by mating; however, from the cured strain, [Het-s] cells arose at a frequency of about 10^{-7}.[22] This is the *reversible curing* criterion for a prion. Coustou et al showed that overproduction of the HET-s protein increased the frequency with which [Het-s] arose, and that the HET-s protein is relatively protease resistant in strains carrying [Het-s]. Moreover, deletion of the *het-s* gene makes a cell unable to propagate the [Het-s] non-mendelian genetic element.[81]

The prion domain of HET-s is the C-terminal residues 218 through 289, of which residues 228 through 289 are unstructured in the native form.[14] The HET-s prion domain is not N/Q rich but forms amyloid filaments *in vitro* that are infectious for cells not carrying the prion.[254] The demonstration that amyloid formed *in vitro* from recombinant HET-s protein was infectious was the first demonstration of its kind for any prion.[254]

Beyond its obvious interest as a new prion, [Het-s] is particularly important because it is the first case in which a prion appears to be responsible for a normal cellular function. Heterokaryon incompatibility is observed in most filamentous fungi, usually controlled by chromosomal genes that have no particularly unusual features. In this case, it requires the [Het-s] prion to be observed. This suggests that other prions may be found responsible for normal cellular functions.

However, another interpretation of [Het-s] is possible, based on a [Het-s]-based meiotic drive system. Mating a female *het-s* [Het-s] strain with a male *het-S* strain results in death of *het-S* meiotic segregants that received [Het-s] cytoplasm.[92] Thus, one could view the [Het-s] prion as a device for the preferential inheritance of the *het-s* allele by a meiotic drive mechanism.

Adjacent to the *het-s/S* gene is *Nwd2*, that includes an N-terminal sequence resembling the HET-s prion domain, and a nucleotide-binding oligomerization domain (NOD)-like receptor sequence. It was suggested that ligand binding by NWD2 induced oligomerization that leads to amyloid formation by the NWD2 N-terminal sequence which, in turn, activates HET-S by seeding its amyloid formation.[94] This hypothesized signaling process was suggested for a large number of fungal and mammalian proteins,[94] and strong support for this idea has now been obtained (reviewed by Refs.[93,317]).

Prion Variants

A single protein sequence can be the basis of many distinct prions, called "strains" in mammals and "variants" in yeast. Mammalian TSE strains were described early on, characterized by different incubation period, symptoms and signs, and distributions of brain lesions.[44] Independent isolates of [PSI+], [URE3], [PIN+], or other prions may likewise have various intensity of phenotype or stability.[39,100,340] These prion variants breed true, and extracts of a strain carrying a given variant of [PSI+] or [URE3] transmit almost exclusively that variant by transformation.[38,216,373] It is clear that different [PSI+] prion variants have different amyloid structures,[374] and one of the main challenges is to determine these structural differences (Fig. 20.13). Variants of [URE3] and [PSI+] have now been found differing in their pathogenicity or sensitivity to excess or deficiency of various chaperones or their sensitivity in normal cells to antiprion systems (see below).

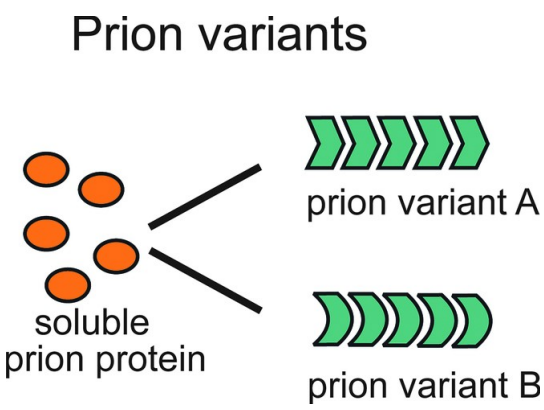

FIGURE 20.13 A single protein sequence can stably propagate any of several prion variants, each corresponding to a different amyloid structure.

It is striking that only one variant of [Het-s] has been described. Because [Het-s] is either carrying out a function for the host or is a part of a meiotic drive system, it is in either case selected in evolution to be a prion. The protein sequence has presumably been selected to efficiently form the single prion variant that carries out this function.

Structures of Yeast Prion Amyloids Explain Variant Propagation

Ure2p and Sup35p prion domain amyloids have the cross–β-sheet structure typical of amyloids, meaning that the β-strands run perpendicular to the filament long axis.[18,221,377] Infectious prion domain amyloids of recombinant Sup35p, Ure2p, and Rnq1p each have a parallel in-register β-sheet structure based on solid-state nuclear magnetic resonance (NMR) studies,[21,352,399] with identical residues in adjacent molecules aligned in a row along the long axis of the filament (Fig. 20.14). The mass per unit length of Ure2p, Sup35p, and Rnq1p prion domain filaments is in each case the one monomer per 4.7 Å expected for this structure.[20,56,102] The diameters of the filaments[217,377,399] show that these filaments must be multiply folded along the filament axis (see Fig. 20.14). This structure is like that found for amyloids of Aβ, amylin, α-synuclein, β2-microglobulin, tau, and most other human pathologic amyloids (reviewed in [258,388]).

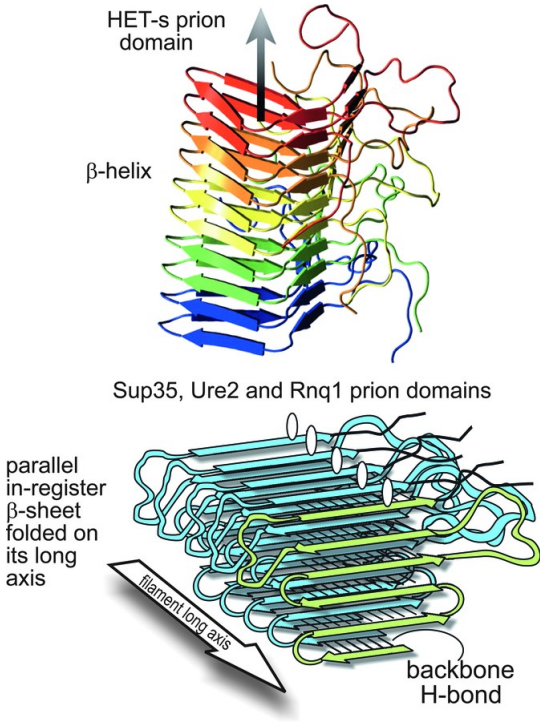

FIGURE 20.14 **Structures of prion amyloids**. **Above:** Infectious amyloid of HET-s$^{218-289}$ has a two-turn β helix structure. (Adapted from Wasmer C, Lange A, Van Melckebeke H, et al. Amyloid fibrils of the HET-s (218-279) prion form a beta solenoid with a triangular hydrophobic core. *Science*. 2008;319(5869):1523-1526. Reprinted with permission from AAAS.) **Below:** Infectious amyloid of Ure2p$^{1-65}$, Sup35p$^{1-253}$, and Rnq1p$^{153-405}$ each have an in-register parallel β-sheet architecture.[21,352,399]

The in-register parallel β-sheet structure is maintained by the positive interactions among identical aligned amino acid side chains—H-bonds between the amide side chains of glutamines or asparagines, H-bonds between the –OH groups of serine or threonine side chains, or hydrophobic interactions among hydrophobic amino acid side chains. These interactions demand that identical residues be aligned. The same interactions direct a monomer joining the end of the amyloid filament to assume the structure of the other molecules in the filament.[404,405] Thus, although any of many different parallel in-register structures may form at the time of filament initiation, the location of the folds of the sheet, and the extent of the β-sheet structure will be propagated as the filament is elongated by this mechanism (Fig. 20.15). This mechanism

[402,404] can explain how a protein can template its own conformation (just as DNA can template its own sequence), and thus how proteins can be genes. Recently, infectious PrP^{Sc} amyloid, the basis of the mammalian prions, has been shown to have an in-register parallel β-sheet structure.[225]

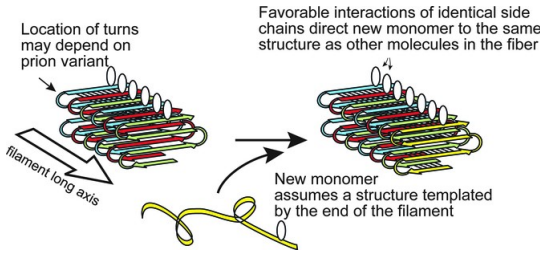

FIGURE 20.15 **Prion amyloid structure can be templated by the structure of molecules in the filament**. As a new monomer joins the filament interactions of side chains at the end of the filament with those of the new monomer force the new monomer to assume the same structure as the rest of the monomers in the filament. Different filaments may have different locations of the folds (different turn locations) and different extents of the β-sheet structure; however, this information is transmitted to new monomers joining the filament.[404,405]

HET-s Prion Amyloid Structure

Consistent with its forming only a single prion variant *in vivo*, the HET-s protein prion domain forms a very well-defined amyloid structure *in vitro*. This unique structure thus produces very sharp cross peaks in solid-state NMR, making possible the determination of its detailed structure.[320,395] This structure is a β helix, with two turns of the helix per HET-s molecule (see Fig. 20.14). Interestingly, the HET-s prion domain includes two imperfect direct repeat sequences, and these repeats are aligned in the β helix structure, producing an effect somewhat similar to the parallel in-register architecture of the yeast prions. How this structure is uniquely specified and how interaction of the HET-s amyloid and soluble HET-S produces cell death are important remaining problems.

[URE3] and [PSI+] Are Diseases of Yeast

Although mammalian prion infections are uniformly fatal, the yeast prions are often compatible with robust growth. This, and the [Het-s] prion carrying out a normal function in *Podospora anserina*, led to the suggestion that yeast prions could benefit their host. Reports of such benefits of [PSI+] and [URE3] have not been reproducible (reviewed in Ref.[404]). However, because the Sup35 of some species other than *S cerevisiae* can form prions,[59,233,336] it was assumed that prion-forming ability is selected by evolution and must therefore benefit the host,[355] a notion discredited by the finding that prion-forming ability of Ure2p and Sup35p is not conserved, even within *Saccharomyces*.[115,119,333] Similarly, the partial conservation of sequences in the prion domains of Sup35p and Ure2p was interpreted to mean that prion-forming ability was selected by evolution,[180] but sequence conservation is not needed for conserving prion-forming ability.[329,330] Therefore, sequences in the prion domains must be conserved for another reason, namely, the non-prion functions of these domains. The N-terminal domain of Sup35p of yeast and humans interacts with the poly(A) binding protein and poly(A) shortening enzymes to assist in general mRNA turnover.[79,153,188,189] The Ure2p prion domain protects the protein from rapid degradation and thus is necessary for proper nitrogen regulation.[351] These domains are preserved for their normal functions, not for prion formation.

Several approaches have been taken to evaluate whether yeast prions are diseases or beneficial. The premise that [PSI+] and [URE3] are generally not harmful to their host has been disproven by the finding that lethal or severely detrimental variants of [PSI+] are actually more common than the usually studied mild variants.[273] These “killer [PSI+]” variants probably inactivate nearly all of the essential Sup35p and are not found in the usual selection procedure because the cells are killed. [URE3] variants that severely impair growth in strains whose growth is not slowed by *ure2Δ* are also common and must be owing to a toxic effect of the Ure2p amyloid.[273]

Yeast prions are infectious and can be very stable. Moreover, they arise *de novo* in about one in 10^6 cells, thus no substantial population can be isolated from them. If they were advantageous to yeast, they would surely be often found in the wild. A survey of 70 wild yeast strains failed to turn up any strains carrying either [URE3] or [PSI+], indicating that both are a net disadvantage to the host. In contrast, the 2 μ DNA plasmid, the L-BC dsRNA viruses, and the 20S and 23S ssRNA replicons were found in 38, 8, 14, and 1 strains, respectively, although none of these selfish infectious nucleic acids encode anything but proteins to promote their own duplication and at least the 2 μ DNA plasmid is known to be detrimental.[285] A later study likewise found a very low incidence of [PSI+].[175] These data show that the *most mild* forms of [URE3], [PSI+], and [PIN+] produce a >1% growth/survival net detriment.[209] The more common toxic/lethal forms of these prions are devastating to the host. In contrast, the [Het-s] prion is found in 92% of wild *Podospora* strains carrying the *het-s* allele, consistent with it benefiting its host.[96] It appears clear that the yeast prions [URE3], [PSI+], and [PIN+] are diseases, like their mammalian counterparts.

Chaperone Involvement in Prion Propagation

Chernoff found that either overproduction of Hsp104p or deletion of the *HSP104* gene resulted in the inability of cells to propagate [PSI+][58,60] (Fig. 20.16). This finding was important as supporting the prion model for [PSI+], in opening the study of chaperones in prion phenomena, and providing a potential pathway to treatment of prion diseases. Hsp104 is necessary for the propagation of all known amyloid-based yeast prions. Normal levels of Hsp104 promote [PSI+] stability by breaking large filaments into smaller ones, providing new seeds for propagation and infection.[201,230,263,289,328,382,386] Hsp104 works with Hsp70s, nucleotide exchange factors (eg, Fes1) and Hsp40s in this activity.[167,312,412] A single molecule extracted from the middle of the filament is fed through the central pore of the Hsp104 monomer and has a chance to renature[382] (reviewed in Ref.[411]; Fig. 20.16). The mechanism of [PSI+] curing by Hsp104 overproduction is unclear[271]; however, the N-terminal domain of Hsp104 is necessary for the curing but dispensable for prion propagation, indicating that these are two distinct

activities.[194]

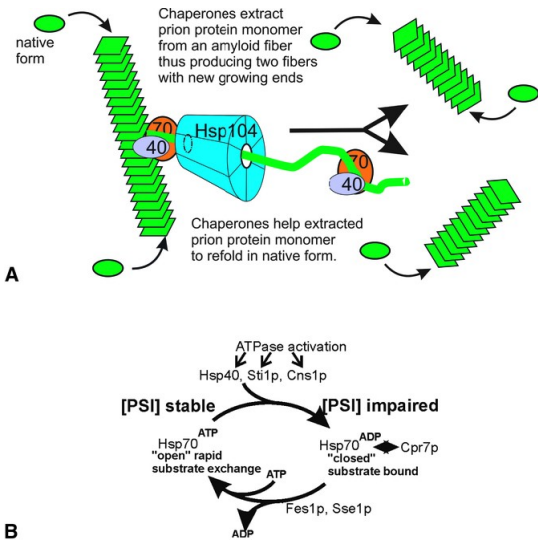

FIGURE 20.16 **A:** Role of chaperones Hsp104, Hsp70, and Hsp40 in propagation of the prions of *Saccharomyces cerevisiae*. Hsp104 is necessary for [PSI+] propagation[60,62] and for other prions (see text) for breaking filaments to form new seeds,[83,201,230,289] as are the cytoplasmic Hsp70s.[202] Hsp40s are also critical for yeast prion propagation.[182,363] Because Hsp104 cooperates with Hsp70 and Hsp40 in disaggregation,[167,382] it is proposed that they cooperate in extracting monomers from filaments, thereby breaking the fibers.[194] Overproduction of Hsp104 cures the [PSI+] prion by a different, but unknown, mechanism. Normal levels of Hsp104 are needed for [PSI+] propagation, because it has a role in breaking up aggregates to ensure that each daughter cell gets at least one aggregate. **B:** The bound ATP/ADP status of Hsp70 affects prion propagation as indicated (reviewed in Ref.[349]).

Hsp70s are important in prion propagation, with the cytoplasmic soluble Hsp70s (Ssa1,2,3,4) helping Hsp104 in propagating prions[202] (reviewed by Ref.[349]) and the ribosomal Hsp70 (Ssb1,2) antagonizing[61,213] (see below). Hsp40s play an important role in prion propagation and are believed to be the substrate-specifying component of the Hsp104-Hsp70-Hsp40 apparatus.[27,228,384] Sis1 is needed for propagation of [PSI+], [URE3], and [PIN+],[182] while Swa2 is specifically needed by [URE3].[384]

Hsp90s are also important in prion propagation, being involved in the Hsp104 overproduction curing of [PSI+][280,311] and, with their cochaperones, affecting variants of [PIN+].[238] Cpr7, a cochaperone of Hsp90, has been found necessary for the propagation of [URE3],[232] while overproduction of another Hsp90 cochaperone, Tah1, eliminates [URE3].[307] Cpr7 and Sti1, another Hsp90 cochaperone, also affect [PSI+] propagation, but both also interact with Hsp70 affecting its ATP/ADP balance, and this is the means by which they affect [PSI+].[199]

Sse1, the *S cerevisiae* version of mammalian p110, is an Hsp70 family member with a nucleotide exchange activity for Hsp70s. Overproduction or deficiency of Sse1 was found to cure [URE3-1],[229] while generation of the [PSI+] prion varied directly with levels of Sse1.[138,332] Sse1is reported to have a disaggregase activity similar to Hsp104 in requiring cooperation with Hsp70s and Hsp40s.[354] Deleting Fes1 (a nucleotide exchange factor) antagonizes [PSI+][199] and overexpressing it cures [URE3].[229]

Other cellular components also affect prion propagation (see also antiprion systems in the next section). The ubiquitin system is important in curing of [PSI+] by overproduction of Hsp104,[5,63] and the cytoskeletal protein Sla1p assists prion propagation.[13]

Antiprion Systems in *Saccharomyces cerevisiae*

Since [URE3] and [PSI+] are a net detriment to cells, it is not surprising that there is an array of cellular systems able to cure most variants, block their transmission from other cells, lower the frequency of prions arising, and limit the pathology produced by those prion variants that evade the other three types of barrier (Fig. 20.17). We consider an “antiprion system” to be components that cure prions without overexpression or deficiency of anything, an activity in normal cells.

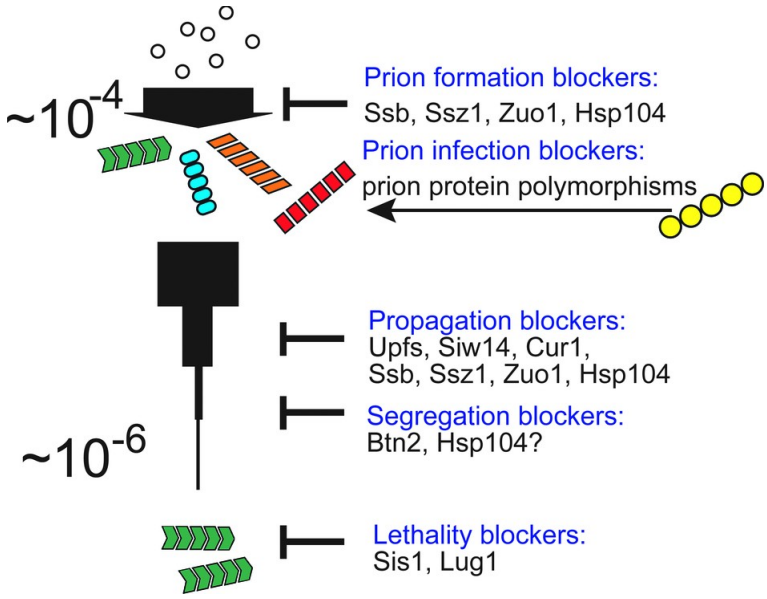

FIGURE 20.17 Antiprion systems in *S cerevisiae* partially block prion infection from another strain, block prion generation, cure most prions arising, and prevent pathology effects of those prions that survive the other three mechanisms (Adapted by permission from Springer: Wickner RB, Edskes HK, Son M, et al. Innate immunity to prions: anti-prion systems turn a tsunami of prions into a slow drip. *Curr Genet*. 2021;67(6):833-847.)

An Inter- or Intraspecies Barrier to Prion Transmission

Small differences in prion protein sequence between donor and recipient, sometimes even a single amino acid change, can partially or completely block transmission of a prion infection. Such blocking differences are found in the prion domains of Ure2p and Sup35p between mating-compatible Saccharomyces species, or even among wild strains of *S cerevisiae*.[17,55,121] The rate of sequence variation during evolution is much faster for the prion domains of Ure2p and Sup35p, than for the rest of these molecules,[121,313] in part because the protection afforded by these mutations are protective against a prion infection.[17] The polymorphism of the prion domain sequences serves as a protection against infection and thus is an antiprion system.

The degree of transmission blockage is sharply dependent on which prion variant is examined.[17,119] Prion strains can carry a mixture of variants, as was shown using the intraspecies barrier for [PSI+]. Extensive subcloning of a single [PSI+] isolate produced four distinct prion variants according to their transmission efficiency to three strains with different Sup35p prion domain sequences. Each of these variants, when again extensively grown and subcloned, gave rise to the same four variants. This phenomenon shows that prions mutate and segregate, both in the absence of any selective pressure.[16]

Btn2 and Cur1 Cure Most [URE3] Isolates Arising in Their Absence

Overproduction of Btn2 cures [URE3] by collecting the amyloid filaments at one place in the cell so that progeny cells often lack any amyloid and are cured (sequestration).[227] Overproduction of Cur1 (a paralog of Btn2) also cures [URE3] but does not collect the filaments, and its means of curing is not known.[227] Both require Hsp42 for their curing action and overproduced Hsp42 also cures [URE3].[364,398] However, normal levels of Btn2 or Cur1 cure ~90% of [URE3] isolates arising initially in a *btn2*Δ *cur1*Δ strain, and thus these are "antiprion systems".[398] The [URE3] isolates curable by normal levels of Btn2 are specifically those with the lower seed numbers (fewer amyloid filaments/cell), while [URE3] variants with higher seed number are only cured by Btn2 overproduction, consistent with the sequestration model.[398] Btn2 also has a role in endosome to Golgi protein sorting,[204] which is apparently unrelated to its prion-curing activity.[29] Btn2's "sequestrase" activity is not limited to prion amyloids but works on other aggregates.[226,257]

Btn2 and Cur1 are regulated by proteasome activity. In normal cells, Btn2 and Cur1 levels are extremely low (Btn2 ~170 molecules/cell; Cur1 ~110 molecules/cell), but in proteasome assembly or subunit mutants, their levels increase ~200-fold, the most of any of >4600 yeast proteins assayed by SILAC, a mass spectrometry method.[117] This results in rapid curing of the [URE3] prion. It is suggested that proteasomes fully occupied under stress conditions "automatically" induce the sequestration of protein aggregates by not degrading Btn2.[117]

Ribosome-Associated Chaperones

The Hsp70 family chaperones Ssb1, Ssb2, and Ssz1 and the Hsp40 member Zuo1 are largely ribosome bound and work together to insure the proper folding of nascent proteins as they emerge from the ribosome.[288,428] The frequency of [PSI+] arising is elevated dramatically in *ssb1/2*, *ssz1*, or *zuo1* mutants,[6,61,213] and over half of [PSI+] isolates arising in such mutants are cured by simply restoring the normal levels of the missing protein.[361] Possibly only improperly folded Sup35 molecules can be recruited to the amyloid filaments of many [PSI+] variants. Alternatively, since both Sup35p and these chaperones are on the ribosomes, there may be a direct interaction that competes with Sup35 adding to the ends of the filaments. In addition, Ssb1/2 freed from the ribosomes by *ssz1* or *zuo1* mutations can compete with the cytoplasmic Hsp70s (Ssa proteins) and prevent proper cleavage of prion filaments by Hsp104.[213]

Antiprion Activity of the Hsp104 Disaggregase

In addition to its filament-splitting activity (with Hsp40s and Hsp70s) that is the "replication" step in generation of new heritable prion seeds, Hsp104 overproduction cures the [PSI+] prion[60] and (weakly) [URE3].[227] The latter activity requires Hsp90 and its cochaperone Sti1[280,311] and is specifically lost by mutations in Hsp104's N-terminal domain, particularly *hsp104*^{T160M}.[194] In the *hsp104*^{T160M} mutant, [PSI+] arises spontaneously at >10-fold the rate of the wild type, and many of these isolates are cured by replacing the mutant protein with normal levels of normal Hsp104.[171] The mechanism of this curing is as yet unclear.

Inositol Polyphosphates and Prion Propagation

A general screen for antiprion systems active against [PSI+] showed that half of variants arising in an *siw14*Δ strain were cured by restoring the normal gene without overexpression.[403] Siw14 is a pyrophosphatase specific for inositol 5 pyrophosphates, and the *siw14*Δ mutant has a sixfold elevated level of these compounds.[368] Most variants of [PSI+] require some inositol poly/pyrophosphates, but evidently, some [PSI+] variants requiring an elevated level of these compounds are lost when normal levels of Siw14 lower these levels.[403] Inositol poly/pyrophosphates are signaling molecules with a variety of activities, and the means by which the curing occurs is not yet clear.

Nonsense-Mediated Decay Components Upf1,2,3 Have Antiprion Activity

mRNAs with premature stop codons are recognized and degraded rapidly, a process involving Upf1,2 and 3.[181] The anti-prion screen (above) also turned up Upf1 and Upf3 as anti-[PSI+] components.[360] In any upf mutant, [PSI+] arises at >10 fold higher rate, and most of the prion isolates are cured by replacement of normal levels of the missing protein.[360] Upf1p is associated with the Sup35 aggregates *in vitro*[90] and *in vivo* in [PSI+] cells,[360] and sub-stochiometric amounts of Upf1 inhibit amyloid formation *in vitro* by Sup35,[360] suggesting that Upfs binding to the ends of filaments may interfere with their growth. Alternatively, the normal association of Sup35 with Upf1,2,3 in a complex on the ribosome may compete for monomers with the growing filaments to block prion propagation.

Sis1 Blocks [PSI+] Lethality and Lug1 Lets [URE3] Grow

Sis1 is an Hsp40 that is essential for cell growth and also is necessary for propagation of [URE3], [PIN+], and possibly [PSI+],[182] probably because it cooperates with Hsp70s and Hsp104 in the filament cleavage reaction.[167] Certain *sis1* mutants (*sis1JGF*) able to support cell growth and prion propagation make "strong" [PSI+] variants lethal to the cell[220] by allowing the filaments to leave so little soluble Sup35p that the cells cannot grow.[231]

In a transposon mutagenesis screen, *lug1*Δ mutants were found to be lethal if a mild variant of [URE3] was present but not if it was absent, implying that Lug1 prevents the lethality of this prion.[116] Lug1 is an "F-box protein," a substrate-determining subunit of a Cullin-containing ubiquitin ligase,[346] but the ubiquitinated substrates determined by Lug1 are not yet known. Several chaperones, not previously known to be involved in [URE3], were also identified in this screen.[116] Thus, it seems that cells act to reduce the burden of carrying prions whose generation or propagation they cannot block.

Perspectives

The discovery of prions of yeast and fungi resolved the debate over whether infectious proteins could exist at all and widened the scope of this concept, showing that it is not unique to a single mammalian protein. The yeast system is now being used to explore the mechanisms of amyloid and prion generation and propagation, and to devise approaches to the many heretofore intractable amyloid diseases. Likewise, studies of retroelements, RNA viruses, and DNA viruses of unicellular eukaryotes have provided extensive information about each virus group, with much of it more easily obtained because of the facile genetics of these systems.

Prospects for therapeutic uses of phages

Acknowledgments

Bacteriophages—viruses that infect bacteria—collectively constitute a majority of biological entities on planet Earth. Virions of the tailed double-stranded DNA (dsDNA) phages, which are the most easily identified in environmental samples, are present at roughly 10^7/mL in coastal seawater and at comparably high numbers in numerous other environmental situations examined.[200] A rough calculation indicates that there are about 10^{31} individual tailed phage virions on the planet, a literally astronomical number, which means that if all the tailed phages were laid end to end, they would extend for 200 million light years into intergalactic space.[89,150] These numbers become even more impressive when we consider that most bacterial genomes contain from one to two dozen phage genomes as prophages.[36] Measurements of the persistence of phages in the environment suggest that the entire population of 10^{31} individual virions turns over every 4-5 days,[219] and this leads to the estimate that it takes roughly 10^{24} productive infections per second to maintain the population—speaking only of the tailed phages.[89] It should be no surprise that bacteriophages were incredibly diverse and that their genomes have complex evolutionary histories dominated by pervasive horizontal genetic exchange and genomic mosaicism.[85]

Brief History

Bacteriophages were discovered in 1915 and 1917, based on their ability to cause clearing (cell lysis) in bacterial lawns and to be propagated as infectious agents.[55,205] The first ~20 years of research on phages was aimed at understanding the basis of these phenomena, and in the process these studies contributed to developing ideas about the nature of viruses more generally. There was also keen interest during this time in phage therapy, the idea of using phages as agents to combat bacterial infections in human patients.[197] The "modern" era of phage research began in about 1940 when a diverse group of physicists and biologists who shared an interest in understanding the nature of the gene began to use phages as their experimental model system in this quest. This approach was wildly successful, playing a dominant role in the development of the field of molecular biology and leading over a period of ~35 years to much of our current understanding of not only the nature of the gene but also the ways that the information in genes is expressed and how that expression is regulated. Along the way, work on phages also made fundamental contributions to the field of virology. Phage research during this time was concentrated on a small number of phages, with the result that we now have a very deep understanding of a handful of individual phages. A crowning achievement of this era of phage-dominated molecular biology was the development in the early 1970s of the methods of recombinant DNA. This made many of the overwhelming technical advantages of phages as experimental systems available for other organisms, including eukaryotes, and the center of gravity of molecular biology research shifted away from phages, though important basic research on phage life cycles has continued to the present. In recent years, new themes have come to the fore in phage research that relate to natural phage populations and their effects on the environment and to phage evolution, including the influence of the phage population and its evolution on the evolution of their host bacteria.[57] These studies are inspired and made rational by the numbers cited in the first paragraph of this chapter, and they are made possible by the development of high-throughput sequencing technology and by the availability of the detailed knowledge of the biology of phages developed over the past 75 years.[85] Studies on the assembly and structure of phage virions have had central roles in structural virology and have given insights into biological structure and assembly more generally.[102] Finally, throughout the history of phage biology there has been interest in the application of phages and their components to practical problems, and this has continued to the present, including but certainly not limited to a renewed interest in phage therapy.[86]

This chapter will first consider the main features of the life cycles of the different groups of phages that have been identified, essentially summarizing the detailed studies of individual "model" phages with an emphasis on what general principles of viral lifestyle are illustrated by each. For some of these, particularly the dsDNA tailed phages, there are enough examples of different phages in the group that we can begin to identify which features of the life cycles are universal among the group and which are either "optional" or accomplished by different mechanisms by different phages. We will then consider questions about phage populations and phage evolution—questions that are informed by the very large numbers cited in the first paragraph of this chapter.

The International Committee on the Taxonomy of Viruses (ICTV) has made multiple changes to bacteriophage taxonomies over the past few years, with the inclusion of many new families and some restructuring of prior groups.[5] Perhaps the most highly represented taxonomic group in nature are the dsDNA tailed phages in the order *Caudovirales*, which has been expanded to include many additional families (*Autographiviridae*, *Chaseviridae*, *Demerecviridae*, *Drexlerviridae*, *Finnlakeviridae*, *Halspiviridae*, *Herelleviridae*, *Ovaliviridae*, and *Thaspiviridae*) in addition to its traditional *Myoviridae*, *Siphoviridae*, and *Podoviridae* families[4] (Table 21.1). These traditional families are based on their tail morphologies (Table 21.1). Seven additional families encompass groups of viruses with common ancestries, and shared features including nucleic acid chemistries (Table 21.1). Prototypes of each have been defined (Table 21.1) and will be described in further detail below. Nonetheless, the tailed phages (*Caudovirales*) are special in the sense that they are likely the numerically most abundant group of viruses on the planet and almost certainly the most genetically diverse. They are also the most extensively studied group of phages and so will occupy most of the space in what follows.

TABLE 21.1 Some ICTV-designated phage families and their prototypes

Family	Prototypes	Characteristics
Siphoviridae	λ	dsDNA, Long noncontractile tails
Myoviridae	T4	dsDNA, contractile tails
Podoviridae	T7	dsDNA, short, stubby tails
Tectiviridae	PRD1	dsDNA, linear 5′ proteins, internal membrane
Microviridae	ϕX174	ssDNA, circular, icosahedral
Inoviridae	M13	ssDNA, filamentous
Leviviridae	MS2, Qβ	ssRNA. small icosahedral
Cystoviridae	ϕ6	dsRNA, segmented; enveloped
Corticoviridae	PM2	dsDNA, circular; internal membrane
Plasmaviridae	L2	dsDNA, circular; enveloped

dsDNA, double-stranded DNA; ssDNA, single-stranded DNA.

CAUDOVIRALES: dsDNA TAILED PHAGES

The dsDNA tailed phages are tremendously diverse genetically, to the extent that a majority of the protein sequences encoded in a newly determined phage genome sequence typically fail to make any matches in a database search, other than to closely related relatives.[38,85] Genome sizes of known tailed phages range from a low of <15 kilobase pairs (kbp) up to around 500 kbp, a range of more than 30-fold.[90] As will become evident, they are also very diverse in the specifics of their life cycles, including how they interact with the host cell. On the other hand, the similarities these viruses share across this range of diversity are so extensive as to leave no doubt that they share (distant) common ancestry, at least for the genetic features like the capsid protein genes that they all have.[94]

The head of a tailed phage consists of a protein shell based on icosahedral symmetry that is usually a rather straightforward manifestation of the principles of capsid structure described by Caspar and Klug.[43] There is no lipid membrane. Replicated dsDNA is pumped into the empty protein shell through a 12-subunit grommetlike structure at one vertex of the icosahedral shell, known as the *portal*, or sometimes the *connector*. DNA is packaged in these viruses to an unusually high density, roughly the same as the density in a DNA crystal.[116] Following DNA packaging, the portal, together with some adaptor proteins, serves as the attachment point for the tail.[168] The morphology of the tail is quite variable among different tailed phages, but it always has the same functions, namely, to attach to the surface of the host cell and serve as a conduit for delivering the DNA into the cytoplasm of the cell. The bulk of the virion protein is left on the outside of the cell after DNA injection, a circumstance that made possible the classical Hershey/Chase experiment[95] that showed that the genetic material is DNA and not protein. Once the DNA arrives in the cytoplasm, the genetic diversity among different phages alluded to earlier is manifested as diversity in the details of their life cycles, and specific examples of the life cycles of a few well-studied phages are given later. At a fundamental level, these phages can be divided into "virulent" and "temperate" categories. Virulent phages always enter the lytic life cycle, in which infection always leads to production of progeny virions and their release by cell lysis, with cell death. Temperate phages, in contrast, make a "choice" soon after infection between lytic growth and entering the lysogenic cycle, in which gene expression from the phage DNA is largely repressed and the phage becomes a part of the genetic complement of the host cell—now called a *prophage*—and replicates as part of the cellular DNA without killing the cell for an indefinite number of generations.

In the following sections, we consider in moderate detail the life cycles of two very well-studied tailed phages, λ and T4, both phages of *Escherichia coli* and some of the most extensively studied viruses. These two have served as important model experimental systems since the 1940s and 1950s. They were the initial source of much of our understanding about the nature of tailed phages, and their numerous differences highlight the diversity seen among the well-studied tailed phages. There are numerous other tailed phages that have made similarly important contributions to our understanding, and we have chosen several of them to illustrate features of their life cycles that are not represented in the two phages that are discussed in detail. Some of the topics considered here have been the subjects of intensive study by multiple investigators for 50 years or more, and in such cases, it may not be possible to cite all the relevant primary literature; if so, useful reviews will be cited that give access to the primary literature.

Bacteriophage λ and the "Lambdoid" Phages

The K12 strain of *E coli* was isolated from a pediatric patient at Stanford University Hospital in 1922. Some 30 years later, in the course of bacterial genetics experiments with K12, Lederberg and Lederberg[121] discovered a temperate phage that was carried as a prophage in the K12 genome, which they named λ. Phage λ subsequently became the most extensively studied of a small number of temperate phages that were chosen for experimental investigation. Other phages that are similar to λ in gene organization and lifestyle, and which can form recombinants with λ at reasonably high frequency, have been termed *lambdoid* phages.[32] Some of the lambdoid phages have been studied in their own right, and all of them and their hybrids with λ have had an important role in illuminating some of the most fundamental aspects of the temperate phage lifestyle.[91]

Phage λ's dsDNA genome is 48 503 bp in length (Fig. 21.1).[92,185] The DNA molecule in the virion has its ends at discrete sequences, and there are 12 base single-stranded 5′ extensions at the ends. The extensions are complementary in sequence, allowing the linear molecule to circularize by base pairing between these "cohesive ends," which it does immediately upon being injected into the host cell. The two joined ends are then covalently joined by the host enzyme, DNA ligase.[222]

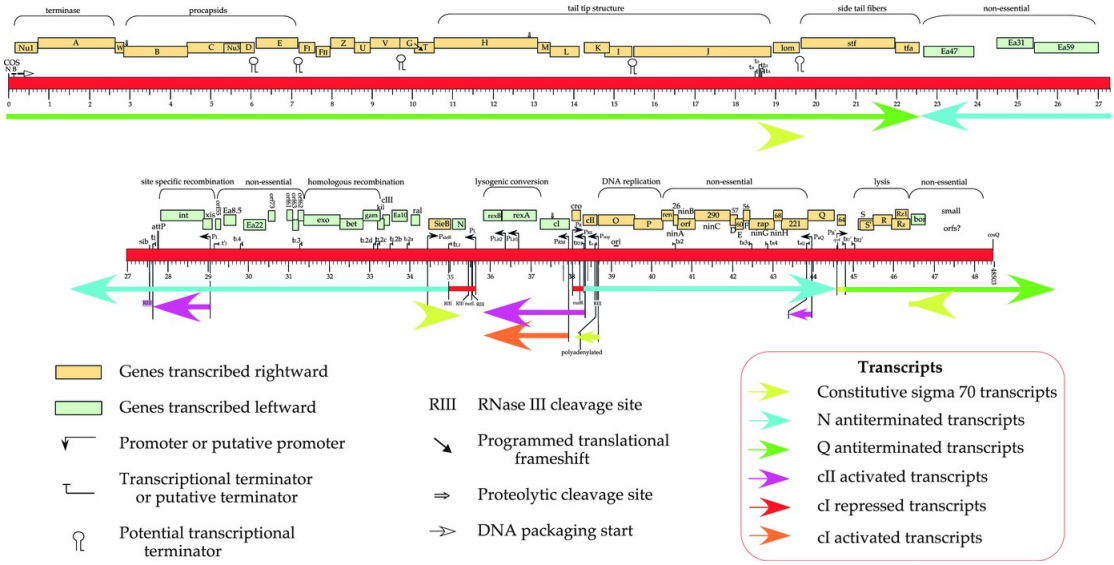

FIGURE 21.1 **Map of the phage λ genome**. λ DNA is represented as the *red bar* with genes shown as boxes above; functions are indicated.

The λ virion has an isometric head (capsid) with T = 7 icosahedral symmetry and a long noncontractile tail (Fig. 21.2). It infects its *E coli* host by binding to the surface of the cell first through its long "side tail fibers," which bind to the outer membrane protein OmpC, and then through an interaction between the host outer membrane protein, LamB, and the phage protein, gpJ, located at the tip of the tail.[214] Only this second interaction (gpJ:LamB) is essential for successful infection; the side tail fibers, which make adsorption kinetics faster, were lost through a mutation early in the laboratory history of λ.[92] (Note on nomenclature: in the phage literature, gpX refers to the protein encoded by gene *X*, with "gp" meaning "gene product" and *not* "glycoprotein.") Details of the DNA injection process are not well understood but are thought to include a rearrangement of some of the proteins that make up the tail tip to facilitate passage across the cell envelope, a process for which there is experimental support in some other phages but not yet in λ. One thing that must happen before the DNA can pass out of the head, down the tail tube, and into the cell is that the tail length tape measure protein, gpH, a few copies of which occupy much of the lumen of the tail, must exit. There is biochemical evidence that gpH is injected into membrane vesicles if the membranes contain the LamB receptor protein,[179] and there is genetic evidence that gpH must interact with an inner membrane sugar transport protein, PtsM, in order for injection to be accomplished successfully.[178]

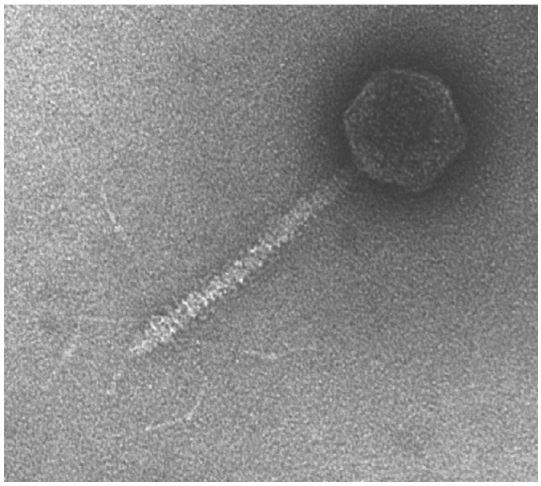

FIGURE 21.2 **The bacteriophage λ virion**. Electron micrograph of λ, negatively stained with uranyl acetate. Scale: the length of the tail, excluding fibers, is ~150 nm.

(Courtesy of Robert Duda.)

Following DNA injection and circularization, λ makes a decision between the lytic and lysogenic life cycles. We first describe the lytic cycle, in which the phage programs the cell to produce a crop of progeny virions and releases them by cell lysis at the end of the growth cycle. Following that, we describe the lysogenic cycle, in which the expression of most phage genes is repressed and the phage DNA integrates into the continuity of the host chromosome as a prophage.

The Lytic Cycle

All transcription of λ genes is carried out by the host RNA polymerase, unmodified for immediate early transcription and altered in its properties by interaction with phage-encoded proteins for subsequent temporal classes of transcripts.[78] The genes are generally arranged in large operons, making it possible to regulate their transcription by regulating a small number of promoters. Upon DNA entry, RNA polymerase initiates transcription at the two divergent immediate early promoters, P_L and P_R, completing transcription of just one gene in each case, gene *N* and gene *cro*, respectively, before encountering a ρ-dependent terminator and stopping.[153] The N protein, gpN, is a transcription antitermination factor that renders polymerase insensitive to termination signals by forming a complex with polymerase, several host factors, and a specific signal near the start of the nascent transcript called *nut*, for Nutilization. The RNA polymerase, altered in this fashion, now reads through the terminators and into early genes farther down the P_L and P_R controlled operons. The most relevant of these genes for the lytic cycle are the *O* and *P* genes, which mediate phage-specific DNA replication, and the *Q* gene, which has a central role in mediating late gene transcription, all transcribed from the P_R promoter, and three genes for recombination enzymes, transcribed from P_L.[53] An important feature of the *nut* sites is that they only act *in cis*—that is, gpN can cause antitermination only for a polymerase that starts from a promoter with a *nut* site near the beginning of the transcript, which in λ means only P_L and P_R. A consequence of this is that some transcribing polymerases can be insensitive to termination signals at the same time that others are susceptible to termination, depending on which promoter they started at. This differential sensitivity to termination signals figures in the regulation of the proteins responsible for integration and excision of the prophage, described later.

Transcription of the late genes starts about 10 minutes after the start of infection, from the P_R' promoter located downstream from the *Q* gene (Fig. 21.1). The P_R' promoter is a strong promoter, recognized by the unmodified host RNA polymerase, but the polymerase requires the action of the early phage protein gpQ to read through a strong pause site located soon after the promoter.[176] As with polymerase that has been acted on by gpN, polymerase acted on by gpQ is insensitive to termination signals and reads through the entire ~26-kb late gene operon, which includes the lysis genes, head genes, and tail and tail fiber genes. Despite the fact that all of the late genes are transcribed equally, the molar amounts of the proteins produced by translation of the messenger RNA (mRNA) vary more than 1000-fold due to differences in efficiency of translation initiation.[40] The amounts of the proteins produced appear to be appropriate to what is required for efficient assembly of virions.

Phage DNA replication is carried out by the host replication machinery, but that machinery is directed to the phage replication origin by two phage-encoded early proteins, gpO and gpP. gpO binds to the origin, four tandem imperfect 19-bp repeats within the gene *O* coding region, to form a compact complex to which gpP binds.[213] gpP recruits the host replication helicase, DnaB, to the complex; the rest of the host replication machinery joins; and gpO and gpP are removed by the host chaperones, DnaK, DnaJ, and GrpE, which allows the replication complex to start replication.[164] Replication is initially bidirectional, producing more unit-length circles by a "theta" mode of replication, but at 10-12 minutes after infection it shifts to a unidirectional rolling circle mode to produce the multigenome concatemer that is the DNA substrate for packaging into heads.

The heads and tails of phage λ are assembled separately and join to form virions after their assembly is complete.[88] Purified heads and tails will join efficiently *in vitro* to make infectious virions, implying that no additional factors are required for this step of assembly. Tail assembly starts with a complex of the proteins that will form the tip (head-distal) end of the tail. The initial complex is joined by a few copies of the *tape measure protein*, gpH, which extends the length of the tail as an α-helix and provides a template around which the major tail protein, gpV, polymerizes as 32 stacked rings of 6 subunits each.[106] This polymerization is thought to be mediated by two proteins, gpG and gpGT, which are essential for assembly but absent from the mature tail, and which are therefore regarded as tail assembly chaperones. The two chaperones are produced as the result of an inefficient translational frameshift between two overlapping open reading frames, an arrangement that is highly conserved among other long-tailed phages.[223] Following assembly of the tail tube, two adaptor proteins add to the top of the tail and it is ready to join to a head.

As with all other characterized tailed phages, λ head assembly first produces an empty protein shell—the prohead or procapsid—into which DNA is packaged. Four phage-encoded proteins participate in prohead assembly; the major capsid protein, gpE; the portal protein, gpB; the protease, gpC; and the scaffolding protein, gpNu3.[44] The details of how these proteins come together to assemble accurately into a T = 7 capsid are not entirely clear, but the assembly is thought to be nucleated by the portal, a 12-subunit grommetlike structure that occupies one vertex of the otherwise icosahedrally symmetric prohead.[168] Assembly of the major capsid (coat) protein requires the participation of similar numbers of the self-assembling scaffolding protein.[139] How the scaffolding protein contributes to this process remains the central mystery of how capsid assembly is achieved. In the absence of scaffolding protein, the capsid protein assembles into "monsters," sheets, tubes, and misshapen spirals of capsid protein that have apparently lost the ability to insert pentamer vertices into the hexagonal lattice of capsid proteins with sufficient accuracy and regularity to make an isometric, icosahedrally symmetric structure.

Roughly 10 copies of the protease are assembled into the prohead, and these are responsible for cutting the scaffolding protein into fragments that are lost from the structure. The portal subunit is also proteolytically processed, with 22 amino acids removed from the N-terminus, but unlike what is observed in some phages, the major capsid protein is not processed. The protease itself participates in a curious "protein fusion" reaction, in which a portion of each protease molecule is joined covalently to a copy of the major capsid protein.[138] Following, or concomitant with, the proteolytic maturation of the prohead, DNA packaging commences. DNA is pumped into the procapsid through the ring of portal protein subunits by a phage-encoded, adenosine triphosphate (ATP) cleavage–powered DNA translocase similar to that of phages T4 and ø29 (see later). This molecular motor also contains the nuclease that cleaves *cos* sites to release the packaged DNA from the concatemer that is the substrate for packaging.

Progeny λ particles are released from the cell through a tightly controlled lysis system that ensures the concluding act of lytic growth occurs at the optimal time.[211] λ lysis requires the products of four genes, *S, R, Rz*, and *Rz1*. gpR is the endolysin and cleaves the peptidoglycan layer in the cell wall, but it has no effect on the integrity of the cell until it has access to its substrate, which is prevented by the cytoplasmic membrane. Access, and the timing of lysis, is determined by the products of gene *S*, the 105-residue holin (S105), and the 107-residue antiholin that is translated from an initiation site two codons upstream of that used for S105. The ratio of S105 and S107 is critical for the timing of lysis, which occurs when S105 produces one or more large-sized holes in the membrane.[63] Rz and Rz1 form a *spannin* complex that spans the periplasm and leads to fusion of the inner and outer membranes to ensure efficient and complete lysis.[19,110]

Lysogenic Cycle

The lysogenic cycle starts the same way as the lytic cycle described earlier, with DNA injection and circularization, transcription from P_L and P_R, extension of that transcription by the action of the gpN antitermination protein, and the consequent expression of the early proteins. Among these early proteins are CII ("C-two"), transcribed from P_R, and CIII ("C-three"), transcribed from P_L.[53]

The CII protein plays the central role in the "decision" between the lytic and lysogenic cycles. CII is a transcription factor that binds to and activates the leftward-pointing promoter P_{RE} (*promoter for repressor establishment*). The resulting transcription from P_{RE} goes backward through the *cro* gene and then forward through the leftward-oriented *cI* gene, causing production of the λ repressor, the CI (*C-one*) protein. When it is produced in sufficient quantity, the CI repressor shuts off further transcription from P_L and P_R by binding to the overlapping operators, O_L and O_R, respectively, and occluding the promoters from RNA polymerase binding. In this way, repression is established and can persist for an indefinite number of bacterial generations.

The choice between the lytic and lysogenic cycles is determined by the level of CII protein in the infected cell—with enough CII, transcription from P_{RE} is activated sufficiently to produce enough CI repressor to establish repression, while with low levels of CII, too little CI repressor is made to stop transcription from P_L and P_R, and the lytic cycle goes forward as described earlier. The level of CII protein is determined in turn by environmental factors, principally the physiologic state of the infected cell. The readout of the state of the cell is the level of a cellular protease, FtsH, which degrades CII, and is modulated by HflKC and cyclic adenosine monophosphate (cAMP).[107] In this sense, CII is the sensor with which the phage assesses the state of the cell and decides between the lytic and lysogenic cycles. Another phage protein, CIII, biases the decision in favor of lysogeny by antagonizing the FtsH protease and disfavoring degradation of CII protein.[109] Finally, a high multiplicity of infection favors lysogeny; this is thought to be because a larger number of genomes in the cell means higher production of CII and CIII proteins. More recently, it has been shown that λ preferentially binds to the cell poles—especially at the low multiplicities of infection favoring lytic growth—where FtsH is also localized, suggesting there is a topologic component to the lytic/lysogenic decision.[69]

Once lysogeny is established, expression of the CI repressor maintains the prophage state (Fig. 21.3). CI binds to two tripartite operator sites, O_L and O_R, to repress the early lytic promoters, P_L and P_R, respectively.[125] However, CI also plays an important role in regulating its own expression, acting as an activator of the promoter for repressor maintenance (P_{RM}) when bound to the O_{R1} and O_{R2} sites in O_R, and as a repressor when concentrations are sufficiently high to permit binding to the weaker site, O_{R3}. An important component to repression is the formation of DNA loops formed by cooperative association of repressor tetramers bound at O_{L1} and O_{L2}, and at O_{R1} and O_{R2}; this looping also stimulates activation of P_{RM}.[8] Additional cooperative interactions between O_{R3} and O_{L3} enhance the repression of P_{RM} at high repressor concentrations.[125]

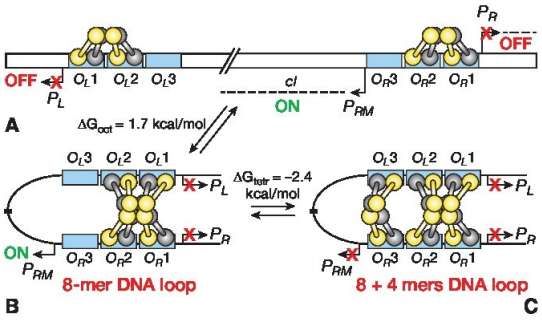

FIGURE 21.3 **DNA looping by the λ repressor**. Models of CI regulation by DNA looping. Detailed conformations of the structures are not known, and maps are not drawn to scale. **A**. Promoters (P_R, P_L, and P_{RM}); operators O_L (O_L1, O_L2, O_L3) and O_R (O_R1, O_R2, O_R3) are in *blue rectangles*; CI dimers (one monomer is shown in *yellow*, the other in *gray*). The bent arrows show the transcription start points of promoters. The dashed line indicates transcripts from P_R, P_L, and P_{RM}. The cI gene is transcribed from P_{RM}. **B**. DNA looping and octamer formation (8-mer) by CI tetramer binding to $O_L1 \sim O_L2$ interacts with that at $O_R1 \sim O_R2$. **C**. Octamer and tetramer (12-mer) of CI binding to O_L and O_R. Red X means promoter is turned off. (Reprinted with permission from Lewis D, Le P, Zurla C, et al. Multilevel autoregulation of λ repressor protein CI by DNA looping in vitro. *Proc Natl Acad Sci U S A*. 2011;108(36):14807-14812.)

The DNA replication genes of a λ prophage are repressed by the action of the CI repressor protein, and the prophage relies on the host replication functions for maintenance in the population as the cell grows and divides. To take advantage of these replication services, the prophage DNA must be integrated into (becomes part of) the host chromosome where it is replicated along with all the other host genes (Fig. 21.4). Integration is catalyzed by the phage-encoded integrase protein (Int), which carries out site-specific, reciprocal recombination between a site on the phage DNA, *attP* (attachment site, phage), and a site on the bacterial chromosome, *attB* (attachment site, bacterium). Because the phage DNA is at this point circular, having joined its cohesive ends immediately upon injection, the Int-mediated reciprocal recombination results in the insertion of a linear form of the phage DNA into the bacterial chromosome. Because the *attP* site, where the phage DNA is broken upon integration, is distant from the *cos* (cohesive ends) site, where the virion DNA was joined, the order of genes in the integrated prophage is a circular permutation of the gene order in the virion DNA. This mechanism of prophage integration, generally known as the *Campbell Model*, seems rather straightforward now; when it was proposed in 1962 by Allan Campbell (the author of this chapter in a previous edition), it was a major conceptual breakthrough.[31,33]

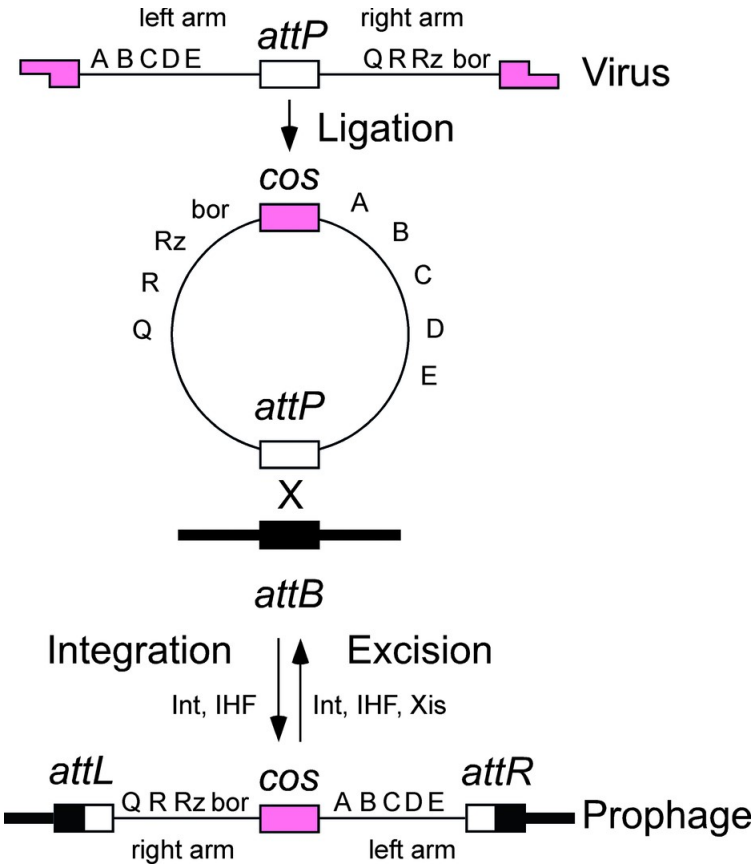

FIGURE 21.4 **Insertion of λ DNA into the bacterial chromosome**. λ virions contain linear DNA with short single-stranded cohesive ends that are ligated to circularize the genome following injection into the cell. *attP* is located near the center of the genome, and the order of some of the genes (A, B, C, etc.) is shown. A prophage is formed by site-specific recombination between the phage attachment site (*attP*) and the bacteria attachment site (*attB*), which is catalyzed by the phage-encoded integrase but also requires integration host factor (IHF). Prophage excision occurs only in the presence of the phage-encoded Xis, which redirects integrase to recombine the attachment junctions *attL* and *attR* to re-create *attP* and *attB*. The virion structure and assembly genes are typically represented as forming the left arm (between *cos* and *attP*) in the viral genome but are permuted relative to the right arm (between *attP* and *cos*) in the prophage.

The *attP* site has a 15-bp "core" sequence that is identical to the corresponding core sequence in *attB*, and it is within the core sequence that the strand exchanges of recombination take place.[117] *AttP* extends on both sides of the core sequence and requires ~240 bp in total. These flanking sequences contain binding sites for Int; for integration host factor (IHF), a host-encoded DNA binding/bending protein; and for Xis and Fis (see later). The *attB* site is only 30 bp long, having fewer such binding sites flanking its core sequence.[117] Integrative recombination takes place within a synaptic complex formed when an *attP*-intasome—containing Int and IHF—captures *attB* DNA.[174] The reaction proceeds with cleavage of the "top" strands of the two attachment sites by Int and reattaching them to the cut strand of the opposite *att* site to form a Holliday junction.[117] The energy of the phosphodiester bond is preserved by two successive transesterifications, first to the active site tyrosine of the integrase and then to the recipient DNA strand, and no additional chemical energy is needed to drive the reaction. Following the top-strand exchange, the complex branch migrates by 7 bp, and bottom-strand exchange takes place by the same mechanism. The reaction product is an integrated prophage flanked by two hybrid attachment sites, *attL* and *attR*.[118]

The lysogenic "cycle" is completed when, after an indefinite number of generations as a repressed prophage, the prophage enters the lytic cycle by the process known as induction. The proximate cause of induction is loss of repression. Induction occurs in about one cell in 10^4-10^6 in a culture of lysogenic cells under laboratory conditions (*spontaneous induction*), but it occurs in nearly 100% of the cells in the culture when they are activated by a moderate dose of ultraviolet light or similar DNA damaging agent. Such treatment causes high production of the cell's RecA protein, which when bound to single-stranded DNA (ssDNA) causes the CI repressor to undergo an autoproteolytic cleavage. This cleavage separates the protein's dimerization domain from its operator-binding domain,[54] and as monomers, the CI operator-binding domains do not have a high enough affinity for their operators to block transcription from P_L and P_R, and so the lytic cycle begins.

An essential part of λ prophage induction is the detachment of the prophage from the host chromosome, termed *excision*. Macroscopically, excision is the reverse of integration—that is, the *attL* and *attR* sites at the ends of the prophage undergo reciprocal recombination to release the circular phage DNA molecule. Excisive recombination requires two protein factors in addition to the Int and IHF needed for integration, namely, the host DNA binding/bending protein Fis and the phage-coded Xis (pronounced "excise") protein. Together, these four proteins and the *attL* and *attR* sites form the excision complex.

Both integration and excision require the catalytic action of integrase, but whether the reaction goes in the direction of integration or excision depends on the absence or presence of Xis (Fig. 21.4). Accordingly, the amount of Xis is differentially regulated by a mechanism that senses whether or not the phage DNA is integrated; if integrated, both Int and Xis are made, allowing excision, and if not, only Int is made, allowing integration. The crucial regulatory site is a sequence named *sib*, located downstream from and across *attP* from the *int* and *xis* genes.[135] *Sib* has the effect of destabilizing mRNA transcribed from P_L (antiterminated by gpN), which includes the sequences of both *xis* and *int*, but it does not

destabilize mRNA from P_I, a CII-dependent promoter within the *xis* coding sequence that encodes only Int. Thus, when *sib* is downstream from *xis* and *int*—that is, when the phage DNA is not integrated—only Int protein can be made and so (provided sufficient CII is made to activate P_I and the phage is headed into the lysogenic cycle) integration ensues. In the integrated prophage, on the other hand, *sib* is no longer downstream from *xis* and *int*, as a result of the integrative recombination. When the prophage is induced, the transcript from P_L, encoding both Xis and Int, is not destabilized, so both proteins are made and excision occurs. Perhaps surprisingly, this elegant and efficient mechanism has been seen only in λ and a few of its closest relatives; there appears to be a great variety of different pathways for achieving the appropriate regulation of prophage integration and excision that have evolved in different temperate phages.

Bacteriophage T4

Bacteriophage T4 is one of seven "type" phages isolated by Delbrück in the 1930s and 1940s that he declared warranted further study.[30] It has received considerable attention from that time to the current day and continues to be a source of new insights into virology, molecular biology, and structural biology.[104] It is virulent and reproduces quickly (<30 minutes), and particles with prolate (ie, elongated) heads and contractile tails contain a dsDNA genome of ~170 kb (Fig. 21.5). Many phages with similar features to T4 have been identified, including two other Delbrück "type" phages, T2 and T6, and phages of other *Proteobacteria* and of the *Cyanobacteria*. These contain genomes ranging from 160 to 250 kbp and range from those with close DNA similarity to T4 to those much more distantly related. Although these relatives contain a "core genome" of about 12%-15% of T4 that are typical of this group, they are otherwise mosaic with common segments interspersed with unrelated genes.[161] Although we will focus here on T4 as the most intensively studied of these, many of the other T4-like phages are likely to share much of its biology.

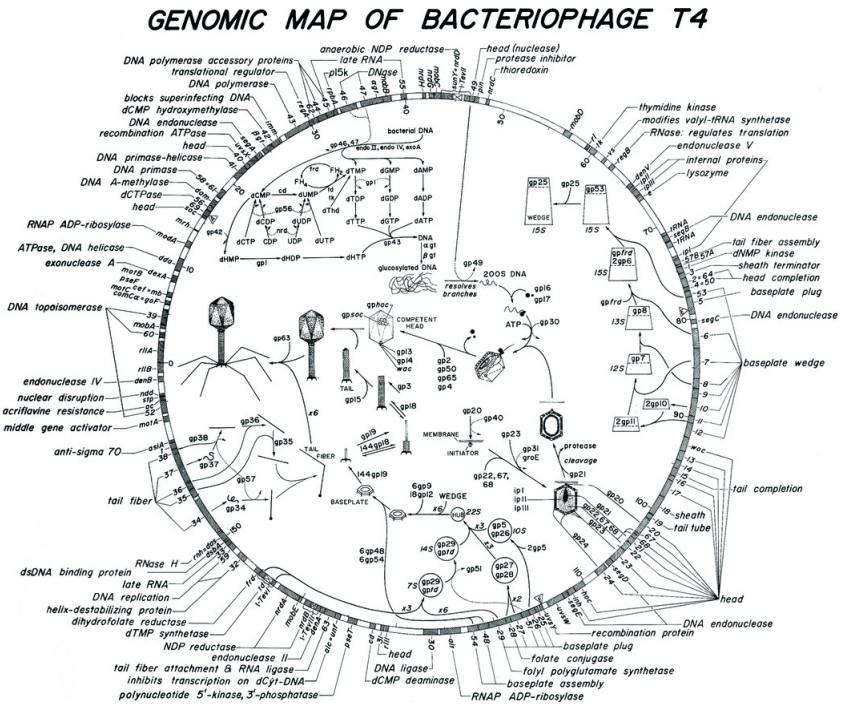

FIGURE 21.5 **Genomic map of phage T4**. The T4 genetic map is circular rather than linear because of the circular permutation of T4 phage chromosomes due to its headful packaging from long concatemers. The general structure of the map was established by standard genetic techniques using classical markers such as those affecting plaque morphology, as well as *amber* mutations that were used to identify many genes. This map shows many of the known and all of the essential genes, based on that classical mapping work and on genome sequence data; the small numbers just inside the circle show the coordinates of the genomic map in kilobase pairs. The names and functions of many genes and the grouping of genes into clusters of related function are shown on the periphery. The branched assembly map in the center shows how an efficient complex of enzymes is produced to make the deoxynucleotides and feed them directly into the T4 DNA polymerase complex (*upper left region*) as well as the branched virion assembly pathway, illustrating how components made in the various branches of the pathway merge to produce an infectious bacteriophage. The small numbers just inside the circle show the coordinates of the genomic map in kilobase pairs. This version of the T4 assembly genomic map is a reduction of a 3-foot-wide hand-drawn map representing an icon in bacteriophage biology. (Adapted by permission from Springer: O'Farrell PH, Kutter E, Nakanishi M. A restriction map of the bacteriophage T4 genome. *Mol Gen Genet*. 1980;179(2):421-435. Copyright © 1980 Springer-Verlag.)

T4 Genome

The T4 genome contains a unique sequence of 169 903 bp, and virion genomes are circularly permuted with terminal redundancies of ~5000 bp[143] (Fig. 21.5). It codes for 160 proteins with known functions, as well as about 120 open reading frames with unknown functions, and several small RNAs, including 8 transfer RNAs (tRNAs). Some parts of the genome are predicted to be mobile, and there are at least 15 homing endonucleases, 3 of which are within introns.[70] T4 DNA is somewhat unusual in that it contains glucosylated hydroxymethylcytosine (hmC), which protects it from host restriction systems and distinguishes it from host DNA that can be degraded and utilized for phage replication.

Expression and Regulation

Expression of T4 genes follows an orderly series of temporally controlled patterns, all involving the use of the host RNA polymerase.[96] However,

a complex series of both covalent and noncovalent modifications to RNA polymerase are required to successfully orchestrate this transcriptional ballet. Transcription of the first T4 genes involves recognition of promoters resembling strong host promoters by $\sigma^{(70)}$-associated host RNA polymerase, but two phage-encoded early products make important modifications to the RNA polymerase. Alt (a protein that is injected with the DNA into the infected cell) catalyzes adenosine diphosphate ribosylation of one α subunit of RNA polymerase, improving the activity of certain T4 early promoters. Two other T4 proteins, ModA and ModB, also adenosine diphosphate-ribosylate RNA polymerase or proteins used in translation during early stages of infection. Another protein, Alc, leads RNA polymerase to selectively terminate transcription prematurely on the host dC-containing DNA while ignoring the viral hmC DNA.[96] As a consequence of these events, transcription of T4 genes readily outcompetes that of the host, with a strong burst of activity within the first minute of infection. The functions of many of these early genes are not known, but two early products, MotA and AsiA, play important roles in the transition from early to middle transcription. Many early T4 mRNAs also disappear quickly at the end of the early phase, largely through the action of RegB, an endoribonuclease that targets early gene transcripts.

MotA is a transcriptional activator that functions along with a co-activator, AsiA, to redirect transcription toward T4 middle promoters. The middle period genes primarily encode functions for DNA metabolism and DNA replication, including *denA* and *denB*, that encode the functions for degrading dC-containing host DNA. About 60 middle promoters have been identified, which contain a host-like −10 sequence (Fig. 21.6) and a MotA box at position −30. MotA binds somewhat weakly to its DNA site but associates strongly with $\sigma^{(70)}$. The co-activator AsiA plays an important role in the transition by also binding to the $\sigma^{(70)}$ subunit of RNA polymerase and conformationally altering the helix-turn-helix DNA binding motif within region 4. As a consequence, recognition of promoter −35 sequences is interrupted (an "antisigma" activity), reducing transcription from both host and T4 early promoters. Thus, MotA and AsiA collaborate to effectively direct the host $\sigma^{(70)}$ to initiate transcription at the unique promoters preceding T4 middle genes.

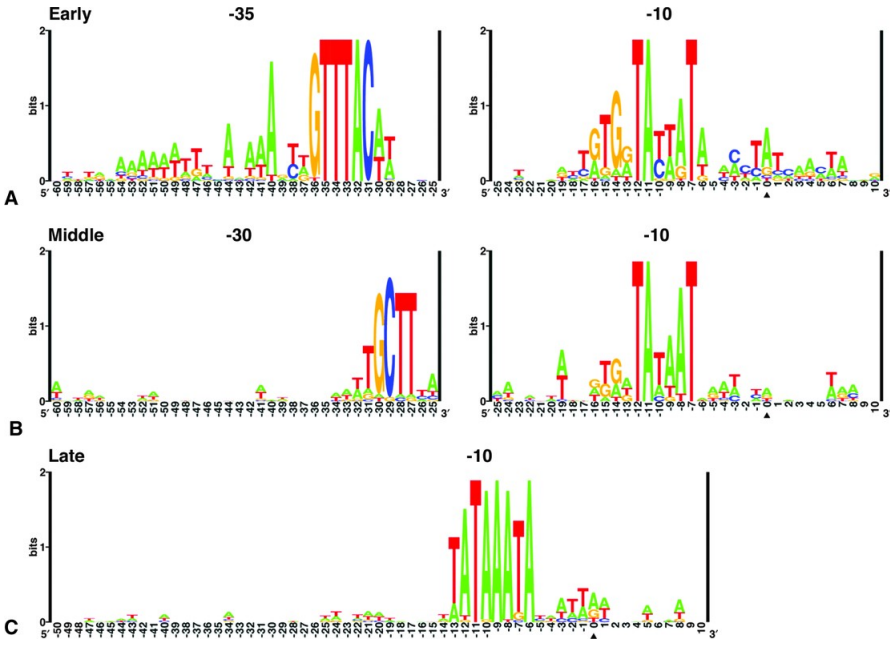

FIGURE 21.6 **Logo of T4 promoters**. Nearly all the sequences in each alignment have promoter activity, as demonstrated by primer extension, transcription from cloned DNA fragments, or RNA hybridization assays. Those promoters included whose start sites have not been mapped all precede a corresponding early, middle, or late gene and show significant similarity to the relevant promoter class. Sequences were independently aligned in the −10, −30, or −35 regions. The information content (Rs) is calculated in "bits" and is the sum of the Rs for each region (except for the late logo, which was calculated from the single alignment at −10). Alignments, logos, and Rs values were obtained as described elsewhere (143) and E. Miller, T. Dean, and T. Schneider, unpublished data). The triangle marks the +1 transcription start site. **A**. Thirty-nine early promoters, Rs = 38.3 bits. **B**. Thirty middle promoters, Rs = 21.1 bits. **C**. Fifty late promoters, Rs = 16.2 bits. (Used with permission of American Society for Microbiology from Miller ES, Kutter E, Mosig G, et al. Bacteriophage T4 genome. *Microbiol Mol Biol Rev*. 2003;67(1):86-156. permission conveyed through Copyright Clearance Center, Inc.)

The transition from early to middle gene expression is also mediated by extension of early T4 transcripts, as many middle genes lie immediately downstream of early genes (Fig. 21.6). Termination of the early transcripts likely occurs at Rho-dependent sites; however, readthrough or antitermination at these sites can give rise to some middle gene expression. However, the antitermination mechanism is unclear. The process could involve an as yet unidentified antiterminator factor (equivalent to λ N or Q; see earlier) or could simply be the consequence of transcription and translational coupling, such as seen when closely linked genes in bacterial operons overcome genetic polarity.[96]

The transition from middle to late T4 gene expression requires the products of genes *33* and *55*.[77] T4 gp55 is a highly divergent member of the $\sigma^{(70)}$ group of proteins and associates with host RNA polymerase to redirect it toward late promoters, which are characterized by an eight–base pair TATA box (5′-TATAAATA-3′) at the position where the −10 site is usually located (Fig. 21.6). There are about 50 related sites in the T4 genome, and many are used to direct late transcription. T4 gp33 binds to the flap tip of the RNA polymerase β subunit, which usually interacts with the region 4 of $\sigma^{(70)}$ such that gp33 mimics this association. T4 gp33 does not recognize a specific DNA sequence (there is no −35 region in T4 late promoters), but it may function by diminishing nonspecific DNA interaction, thus increasing the specific affinity of gp55–RNA polymerase for T4 late promoters.[77]

Interestingly, there is a close linkage between T4 late transcription and DNA replication. T4 gp45, the sliding clamp processivity factor for DNA replication, is strongly implicated in late transcription. It forms "split rings" that load onto DNA with a particular polarity (depending on how the DNA is nicked) and track along the DNA. T4 gp45 and the late transcription factor gp55 associate such that the sliding clamp facilitates the

search for promoters. gp33 is also required for replication-activated transcription at T4 late promoters.

Studies on T4 gene expression also contributed many seminal findings in the area of posttranscriptional control. These include the identification or discovery of translational stop codons, discovery of suppressor tRNAs, tRNA cleavage and subsequent repair by polynucleotide kinase and RNA ligase, protein-mediated translational repression, and group I autocatalytic introns ("ribozymes"). Details of these processes in T4 and T4-related phages are reviewed in Edgell et al.[70] and Uzan and Miller.[207]

Genome Replication

Soon after T4 infection, synthesis of DenA and DenB targets host DNA for degradation to mononucleotides, followed by subsequent conversion of deoxycytidine monophosphate to deoxyhydroxymethylcytosine monophosphate. This is incorporated into T4 DNA during its replication, and the deoxyhydroxymethyl cytosines are subsequently modified by glucosyltransferases. A T4-encoded deoxycytidine-triphosphatase keeps deoxycytidine-triphosphate levels low, so that deoxycytidine-triphosphate does not get errantly incorporated into the newly synthesized T4 genomes. DNA replication occurs in two distinct modes, one that is origin dependent and one that is recombination dependent.

T4 DNA replication is bidirectional and initiates at as many as seven major origins of replication (*oriAi* through *oriG*) early in infection.[112] Initiation requires assembly of a replisome containing several T4 proteins (DNA polymerase, sliding clamp loader, sliding clamp, helicase, primase, and SSB) and synthesis of primers by the host RNA polymerase (to form R-loops). RNA primers can arise from the MotA-dependent promoters at the *ori* sites, and for the lagging strand, from the activity of the T4 primase, gp61. These primers are processed by a phage-encoded RNase H. Coordinated leading- and lagging-strand synthesis then proceeds through to the ends of the viral DNA, generating 3′ extensions (because of the inability to prime synthesis at the extreme 5′ ends of the genomes). Subsequent reprogramming of the host RNA polymerase specificity (see earlier) results in the cessation of this early mode of DNA replication, and a late-expressed protein, UvsW, actively unwinds the RNA-DNA hybrids used for initiation.[67]

The second, late mode of T4 DNA replication is characterized by the dominant role played by homologous recombination and is known as recombination-dependent replication (RDR). The genome ends generated by early (origin-dependent) replication are good substrates and can engage in recombinational pairing with other (co-infecting) genomes or with the other end of the same genome because of the terminal redundancy. Genetic studies suggest that there are multiple pathways by which RDR can proceed, but the primary mode is the formation of D-loops by invasion of an ssDNA end into a DNA duplex, followed by either semiconservative synthesis or synthesis with branch migration.[112] Several T4 proteins are involved in RDR, including UvsX (a RecA-like protein), gp32 (ssDNA binding protein), UvsY (which loads UvsX onto gp32-coated DNA), UvsW (a helicase involved in strand invasion and branch migration), gp59 (for loading the helicase), and the replisome complex. The structures of several of these components have been described.[148] Overall, multiple pathways involving several different phage-encoded enzymes ensure effective replication of the genome. These pathways do not function entirely independently of one another, and thus the T4 system has allowed detailed study of genome replication, recombination, and repair that is germane to both viral and cellular processes.

DNA Packaging

The products of T4 replication are branched, concatemeric networks of DNA in which individual molecules are not distinguishable.[167] Packaging of the DNA into capsids is initiated by the binding of the terminase small subunit protein gp16 to the viral DNA. The small terminase subunit binds as rings (probably 11-mers), and then the gp17 large terminase subunit associates with the protein-DNA complex. This complex associates with the 12-fold symmetric portal protein that sits at a position of one of the capsid pentamers (see later). This "packasome" also contains T4 gp49, a Holliday junction resolvase that removes DNA branches that are otherwise detrimental to packaging. gp17 has two important catalytic domains involved in DNA packaging: an N-terminal adenosine triphosphatase (ATPase) domain and a C-terminal endonuclease domain. Both functions are important for the translocation "motor" activity of the packaging system.

An attractive model for the packaging mechanism is the portal rotation model.[87] The symmetry mismatch between the 5-fold capsid and 12-fold portal means that only one subunit of each can align in any given register. Activation of the terminase ATPase activity could then lead to rotation of the portal and translocation of the DNA, as if a bolt were turning within a nut.[167] Although attractive, single-molecule experiments with the ø29 packaging system (see later) argue against a portal rotation model,[100] other models include a terminase-driven packaging system in which cycles of ATP hydrolysis leads to DNA translocation.[198] Regardless of the mechanistic details, the T4 packaging motor is remarkably powerful when scaled to a macro level, being twice as powerful as a typical automobile engine.[167]

Once packaging begins, the process continues until the capsid is full of densely packed dsDNA (~500 mg/mL)—typically about 103% of the unique genome content—at which point the nuclease activity of the large terminase subunit is triggered to cleave the DNA. Although the terminase-DNA complex dissociates from the filled capsid-portal complex, it may associate with another empty capsid to begin packaging of the DNA from the previous cleavage event. This *headful packaging* process can then continue for as many unit genome lengths present in the concatemer and is the basis for the circularly permuted, terminal redundancy found at the ends of the packaged genome in each virion.

Virion Structure and Assembly

The lunar-lander–shaped T4 virion is one of the most widely recognized icons of molecular biology, and its complex shape requires a correspondingly complex assembly strategy that uses premade subassemblies. These are capsids, tails, and tail fibers that are each made *via* independent pathways that do not merge until the subassemblies are joined together to make a complete virion after DNA packaging is complete. The general outlines of T4 assembly were the result of decades of genetic, biochemical, and structural work. Our understanding of the structure and assembly of each of the subassemblies of the T4 virion has fortunately been enhanced in recent years through structural approaches, primarily cryoelectron microscopy (cryo-EM) and x-ray crystallography.[75,123]

The mature T4 capsid is composed of 960 copies of the cleaved major capsid subunit, gp23*, and 55 copies of the cleaved capsid vertex protein, gp24*, both of which have the HK97-fold. The angular head is a T = 13, Q = 21 elongated icosahedron 86 nm wide by 120 nm long[167] and also contains about 1000 molecules of proteolytically processed internal proteins. The capsid is made initially as a prohead composed of uncleaved proteins that are proteolytically processed only after all prohead components have been added, and after which the proteolytically processed proteins are denoted with a "*" (gp23 is converted to gp23*). Prohead assembly occurs at or around a scaffold core containing gp21 (protease), gp22, gp67, gp68 (scaffolding proteins), gpIPI, gpIPII, gpIPIII, and gpalt (internal proteins) that forms atop a cell membrane–bound portal

complex made of gp20, which later is the site of DNA packaging and tail addition. The prohead grows away from the membrane by simultaneous addition of capsid and core proteins (or in an alternative view, by addition of capsid proteins gp23 and gp24 around a preformed core) until assembly is halted by the formation of the distal cap when the correct length is reached. Assembly is also dependent on the host GroEL chaperone and the phage co-chaperonin T4 gp31 because their action is required for correct folding of the major capsid protein gp23. DNA packaging (see earlier) is accompanied by expansion of the prohead from its initial rounded shape into the angular prolate icosahedron form of the mature capsid. The DNA-filled head is completed by addition of specific proteins to the portal vertex and to the capsid surface. Proteins gp2 and gp4 are apparently added at the portal vertex, followed by neck proteins gp13 and gp14. T4 gp2 is thought to bind to the genome termini and protect the DNA from degradation by the host RecBCD nuclease after injection. Two *decoration proteins*, Hoc and Soc (155 and 870 copies, respectively), are also added to the outside of the shell. Hoc is located at the center of each hexameric gp23 capsomer, and six copies of Soc surround each capsomer, except for the vertices containing gp24. Both Hoc and Soc are dispensable, although Soc does confer additional stability to the capsid. Attached to the neck are also six trimeric whiskers of the Wac protein (also called fibritin), formed by extended coiled-coil structures.

A small set of T4 internal proteins (internal protein I [IPI], IPII, IPIII, and Alt) are specifically localized to the inside of the capsid where they are proteolytically cleaved at specific peptide bonds and subsequently injected into the host along with the DNA. These proteins contain a capsid targeting sequence that can be fused to other proteins such as GFP so as to target their introduction into the capsid.[149] The functions of some internal proteins are known; for example, IPI* protects the incoming DNA from an *E coli* nuclease that is capable of digesting glucosylated hmC DNA (not all *E coli* strains contain this activity, however).

Structure and assembly of the T4 tail is substantially complex, not only because of the larger number of protein components but also because of the dynamic nature of the contractile tail[122] (Fig. 21.7). As with the capsid, a combination of cryo-EM (Fig. 21.8) and crystallography has proven extremely informative in recent years, building on a wealth of genetic and biochemical experiments.[9,228] The tail is composed of the baseplate, a tail sheath surrounding a tail tube, and long tail fibers; altogether it contains about 430 individual polypeptides, and tail assembly requires a total of 22 genes.

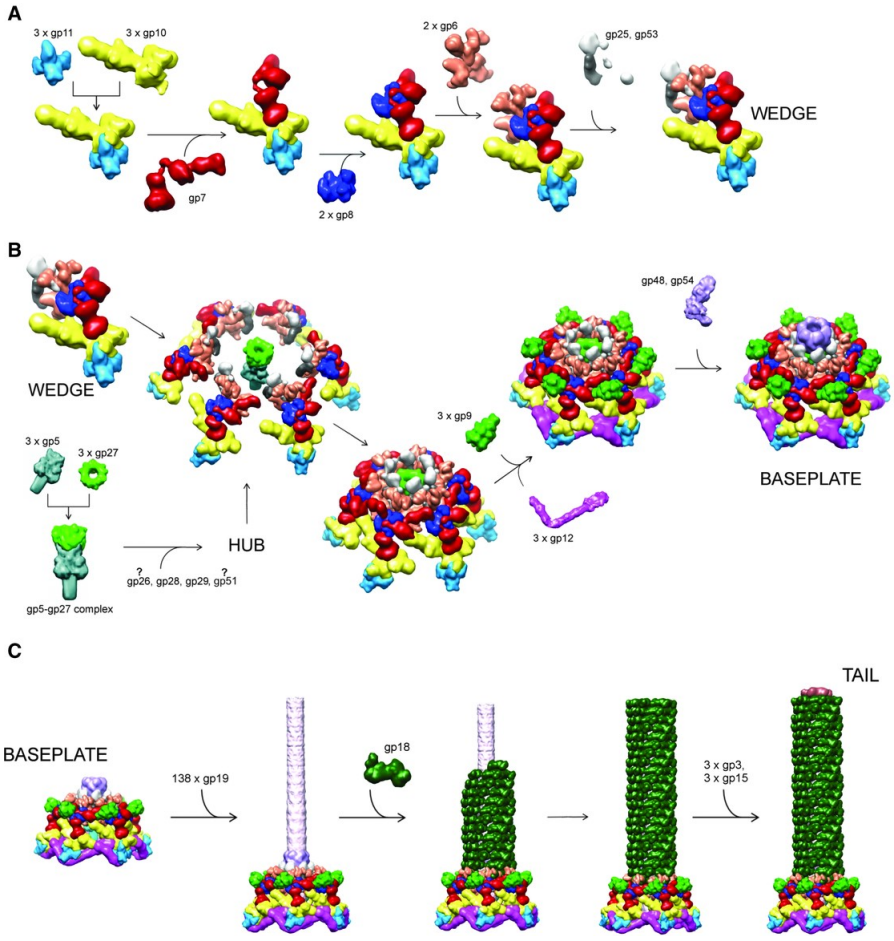

FIGURE 21.7 **Assembly of the T4 tail**. Assembly of the wedge **(A)**, the baseplate **(B)**, and the tail tube **(C)** with the sheath. (Reprinted from Leiman PG, Arisaka F, van Raaij MJ, et al. Morphogenesis of the T4 tail and tail fibers. *Virol J*. 2010;7:355. http://creativecommons.org/licenses/by/2.0.)

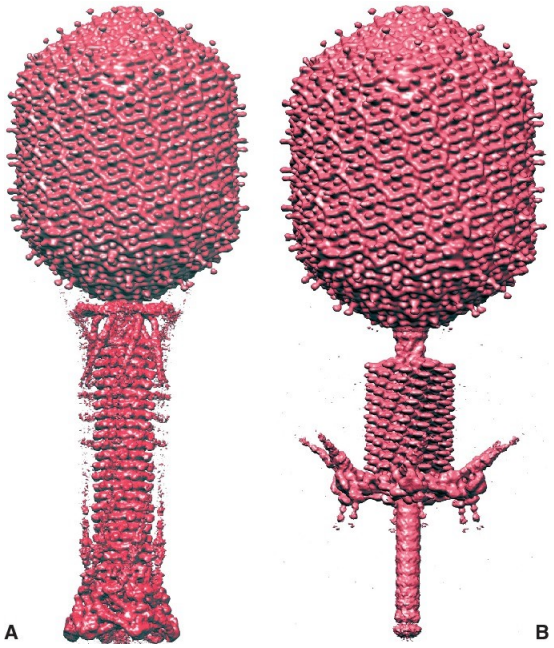

FIGURE 21.8 Cryoelectron microscopy (cryo-EM)-derived model of the T4 phage particle prior to **(A)** and upon **(B)** host cell attachment. Tail fibers are disordered in the cryo-EM structures, as they represent the average of many particles each having the fibers in slightly different conformations.

Assembly begins with the baseplate wedge, which is composed of seven different polypeptides (Fig. 21.8). The hub is independently assembled from gp5, gp27, and gp29 (the tail tape measure protein), which then joins with gp12, gp9, gp48, gp54, and six preassembled wedge components to form the baseplate, along with its short tail fibers (gp12). The tail tube (composed of 138 copies of gp19) assembles onto the baseplate, gp18 forms the tail sheath around the tube, and gp3 and gp15 cap the top of the tail. The long tail fibers are bent rods composed of trimers of gp34, gp36, and gp37 and a hinge composed of gp35. They are made by a separate pathway from the rest of the tail with the aid of gp38 and gp57A chaperones. Tail fibers normally attach to the baseplate only after heads and tails are joined and attach to the gp9 socket protein on the baseplate. Both the Wac whiskers and gp63, a protein that is also an RNA ligase, have been found to accelerate tail fiber addition. As a general rule, the assembly of the individual components of tails and tail fibers follows a strict order (with a few exceptions), such that omission of one component or protein halts assembly at the stage when that component is required.

Adsorption of T4 to *E coli* involves recognition of the outer membrane–located OmpC receptor by the long tail fibers, specifically the C-terminal tip of gp37. This association results in a large conformational change in which the hexagon-shaped baseplate opens up into a star shape, the sheath contracts, and the internal tube is pushed through the baseplate and through the cell envelope, with the lysozyme action of gp5 facilitating passage through the peptidoglycan layer. The tape measure protein gp29 is presumed to exit the tube so that DNA can be released from the capsid, through the tube, and into the cytoplasm of the cell. In this process, the baseplate and sheath essentially adopt two alternative configurations: a hexagonal baseplate with an extended sheath, and a “star” baseplate configuration with a contracted sheath. The transition from one to the other involves numerous dynamic changes, with perhaps the most prominent being the rotation of more than 100° of the gp10-gp11 complex that attaches the side tail fibers to the baseplate. As a consequence, the short tail fibers unfold from under the baseplate and extend toward the cell surface. A movie of a reconstruction of the whole T4 injection process is available at http://www.youtube.com/watch?v=41aqxcxsX2w.

Antigen Display

Because Hoc and Soc are dispensable for the formation of mature virions, they provide an intriguing platform for display of antigens and other proteins on the outside of the head shell. Fusion proteins containing the gp23 association sequences of Hoc or Soc attached to an antigen of choice can be expressed during infection of a Hoc- and Soc-defective mutant of T4 to generate decorated particles.[201] Alternatively, purified fusion proteins can be assembled onto *hoc*$^{-}$ *soc*$^{-}$ mature virions *in vitro*. The ability to add a large number of epitopes—up to 1895—onto a single virion is a particularly attractive feature.[126] These approaches have been successfully demonstrated for antigens of a variety of pathogens including human immunodeficiency virus (HIV), poliovirus, swine fever virus, foot-and-mouth virus, and *Neisseria meningitides*.[172,186] Some of these show considerable promise as vaccine candidates, including for protection against anthrax and SARS-CoV-2.[157,229]

This approach for virion decoration has also been applied to the construction of small peptide libraries and using these to identify associating proteins. In one example, libraries of the T4 large terminase subunit were panned and a peptide identified that interacts with the late sigma factor, gp55, and subsequent analysis showed that gp55 plays a role in loading the terminase onto the viral genome.[131]

Other Tailed Phages

The *E coli* phages T4 and λ are the most extensively studied individual phages of the ~10^{31} on the planet, and they have shown the way over the past approximately seven decades to a remarkable number of fundamental insights into how viruses earn their livings and interact with their hosts, not to mention revealing some of the most basic aspects of molecular biology. However, another lesson from studies of tailed phages is that they are astonishingly diverse, both in their genetic content and in the genetic and biochemical mechanisms they have developed. Here we present a small selection of other well-studied tailed phages, emphasizing only features of their life cycles that are not found in λ or T4.

Bacteriophage HK97

Escherichia coli phage HK97 was a relatively unknown distant relative of phage λ, but it was selected for further study because it morphologically resembled λ but has a longer tail.[93] However, HK97 has become an important model system for capsid assembly and structure because of a relatively simple capsid assembly pathway that is experimentally amenable (Fig. 21.9A). HK97 requires only three proteins to direct capsid assembly of its T = 7 capsid: the portal protein, the protease, and the major capsid protein. Missing from this list is the scaffolding protein identified as a required assembly factor in all tailed phages studied previously. In HK97, the scaffolding protein role is played by an ~100 residue N-terminal extension of the major capsid protein called the delta domain. Like the scaffolding proteins of other phages, the delta domain is removed after assembly by the HK97 capsid maturation protease, and the digested pieces exit from the particle. This proteolysis makes the assembly essentially irreversible and results in a particle (prohead II) that is ready for DNA packaging; subsequent conformational changes lead to the expansion of the particle from the round prohead shape to the larger angular shape of the mature form, head II.[52]

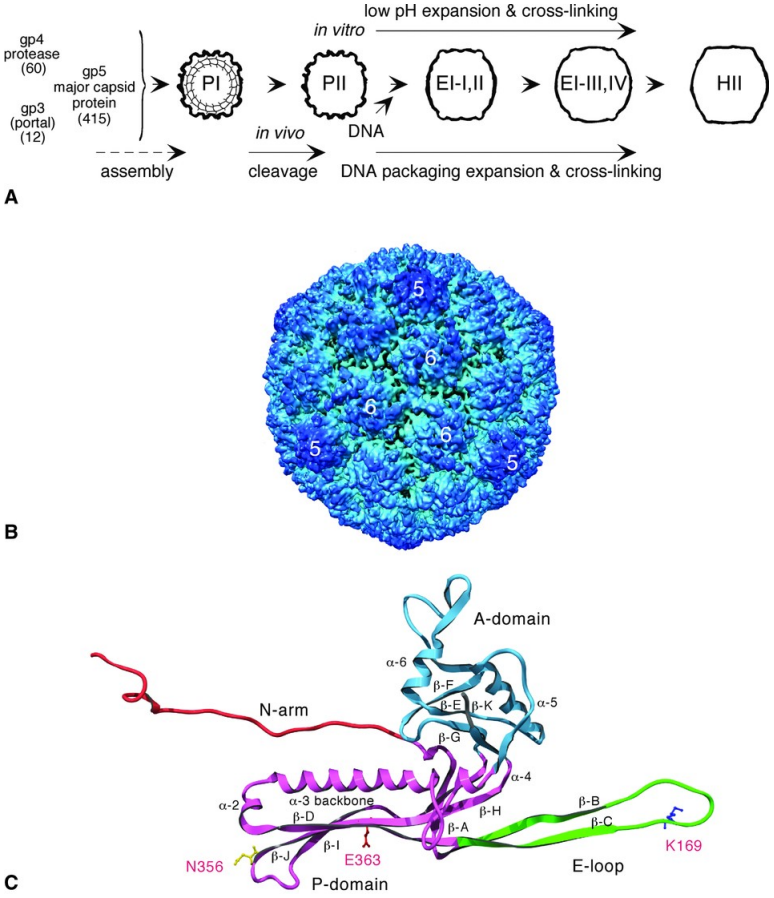

FIGURE 21.9 **Assembly of HK97**. **A**. PI is prohead I, the first intermediate, and PII is prohead II, which is the cleaved form after proteolysis. EI-I, EI-II, EI-III, and EI-IV are expansion intermediates, as detected in.[119] HII is the mature HK97 capsid containing fully cross-linked major capsid protein. Numbers in parentheses on the left are copy numbers of proteins used. **B**. Cryoelectron microscopy reconstruction of HK97 prohead I with three hexons labeled with a *6* and three pentons labeled with a *5*. (J. Conway, A. Steven, N. Cheng, R. Duda, and R. Hendrix, unpublished data.) **C**. Subunit F extracted from the head II structure (PDB ID 1OHG) showing major elements of the structure and the three residues involved in cross-link formation.

A particularly surprising aspect of HK97 virion assembly is how the mature capsid protein is stabilized, using covalent cross-links between the major capsid subunits.[217] This is in contrast to phages that use *decoration proteins*, such as λ and T4 (as described earlier), or phages such as P22 and T7, which achieve their stable mature forms by conformational changes alone. The covalent bonds in HK97 act like rivets between the inside and outside of the capsid, forming between a lysine—part of a secondary structure element on the outside of the capsid, the "E-loop"—and an asparagine on an inner part of a separate subunit. The reaction occurs during the conformational changes of maturation, which brings the two cross-link residues into a reaction center containing a third residue, glutamic acid, which is required to "catalyze" the reaction (Fig. 21.9C). There are 415 of these cross-links, which also change the overall topology of the capsid polypeptide chains into covalent circles that are interlocked in a way that resembles chain mail.[217] This results in an unusually stable capsid.

All of the capsid assembly intermediates illustrated in Figure 21.9 have had their structures determined by cryo-EM, so there is a wealth of information about the conformation changes that occur, at increasingly higher resolutions as techniques improve.[51,119] The very stable cross-linked HK97 mature capsid was the first of the tailed phage capsids to yield a structure by x-ray crystallography[217] (other HK97 intermediates have also yielded x-ray structures since). The fold of the subunits found in the HK97 capsid (Fig. 21.9C), dubbed the HK97 fold because it was unique among known tertiary structures at the time, has since been found in virtually all other tailed phage capsid proteins that have been studied so far, and also in the inner part of herpesvirus nucleocapsids. The x-ray models of HK97 combined with lower-resolution cryo-EM density maps have enabled a fairly complete description of the later stages of HK97 maturation,[93,119] and it is hoped that similar work on the earliest stages (Fig. 21.9B) will help complete the story and shed light on the mechanism of capsid size determination, which is still poorly understood.[66]

Bacteriophage T7

E coli phage T7 is one of the seven classical "type" virulent phages anointed by Max Delbrück as appropriate for study in the early days of phage molecular biology.[145] T7 is a strictly lytic phage with a short (~20-minute) life cycle; if T4 is the *Tyrannosaurus rex* of phages, T7 is the *Velociraptor*. The genomic DNA in the T7 virion is not permuted, and all the genes are transcribed in the same direction. Upon infection, only the first 7 kbp of the "left" end of the DNA, corresponding to the upstream end of transcription, enter the cell initially. This segment of DNA contains three strong, tandem promoters recognized by the host RNA polymerase, leading to transcription and expression of a small number of genes. These include a protein that inactivates restriction enzymes but, most importantly, includes the phage RNA polymerase. This is the highly efficient single-subunit RNA polymerase that has been used to drive expression in many plasmid protein expression vectors. For T7, its job is to transcribe the remainder of the phage genes, starting from a phage-specific promoter near the end of the short sequence of DNA that was initially injected into the cell. Remarkably, entry of the remaining 83% of the genomic DNA into the cell is driven by transcription by the phage RNA polymerase; as the polymerase transcribes in the direction of the DNA still in the phage capsid, its translocation along the template pulls the remainder of the DNA into the cell.[146]

In light of T7's long-standing reputation as a quintessentially lytic phage, it was a surprise when a T7-like prophage (!) was found in the genome of a *Pseudomonas putida* strain.[36] The prophage has an essentially complete inventory and arrangement of T7 family genes, with an extra ~4 kbp of DNA at the right end of the genome encoding an integrase and at least three additional proteins of unknown function. Unlike in the better-studied prophages, the gene order of the T7-like prophage is not circularly permuted relative to the gene order in the virion DNA. Like many other prophages, the T7-like prophage is integrated into the middle of a tRNA gene and appears to have restored an intact tRNA gene with a copy of the downstream half of the tRNA gene encoded at one end of the prophage.

Bacteriophage P22

The genetic diversity of the lambdoid phages is legendary among virologists, and nowhere is this more clearly demonstrated than in their head assembly genes. There are currently 12 types of lambdoid phages known whose head genes have diverged to the point where their major capsid protein amino acid sequences are not recognizably similar, and there are significant parallel variations in their head assembly mechanisms.[39] One of these types is exemplified by *Salmonella enterica* phage P22, a temperate phage with a 41 724-bp genome.[159] Its genes are organized and regulated like those of λ, but its virion has a very short tail (it is a member of the *Podoviridae* family; Table 21.1), and unlike λ it utilizes a headful packaging strategy. P22 was discovered at about the same time as λ, but it was immediately noticed that, unlike λ, P22 could transfer host genetic material from one *Salmonella* cell to another.[230] This process was called *generalized transduction* because any host gene could be transferred in this way. It is now known that the P22 DNA packaging apparatus occasionally makes a mistake and initiates packaging on the host chromosome instead of on its own phage DNA.[136] P22 is a headful packaging phage, and the headful nuclease that cuts the packaged DNA from the long packaging substrate DNA has little sequence specificity. So, when a head is full of host DNA, the headful nuclease cuts the packaged DNA from the host chromosome, normal tails assemble on these heads, and a "virion" is produced, which is in all respects identical to a genuine P22 virion except that it contains a single ~43-kbp molecule of host DNA instead of the phage chromosome. Such a "transducing virion" can, like an authentic P22 virion, inject its host DNA payload into a susceptible *Salmonella* cell, but this DNA cannot replicate and does not encode P22 proteins. This would be a dead end of no consequence, except that the injected host DNA can replace the parallel portion of the new host's chromosome by homologous recombination that is mediated by host cell proteins.[136] Because P22 does not inject any toxic proteins with its DNA, this recipient cell can survive the experience, and if there are genetic differences between the original donor host and the new recipient host, these differences can be transferred from the donor cell to the recipient cell by this transduction process. Geneticists studying *Salmonella* soon found this to be an extremely useful way of moving specific genetic alleles from one *Salmonella* strain to another, and small terminase subunit mutants of P22 were found that had error-prone DNA packaging machinery that made the process much more efficient.[37] Soon generalized transducing phages had been isolated to perform this function for many bacterial species. For wild-type generalized transducing phages, virions with host DNA typically make up 0.1%-2.0% of the total virions made during an infection, but the frequency of transduction of any given allele from one host to another is considerably lower than this, because only a small fraction (1%-3%) of the transducing virions carry host DNA that contains any particular host DNA sequence. In addition, the efficiency of recombination of the injected host DNA with its resident homolog is much <100%.[136] Nonetheless, successful transduction frequencies as low as one in a million recipient cells can be utilized in the laboratory, and transduction remains a common and powerful tool of bacterial genetics. Generalized transduction certainly also occurs in nature, where it is thought to be responsible for much of the genetic exchange that happens between bacteria in the wild.

P22 was also the first phage found to encode an *antirepressor* or protein that antagonizes its prophage repressor.[199] P22 antirepressor protein binds the P22 prophage repressor and stops it from binding to its operator. In this way the presence of antirepressor can initiate prophage induction or prevent establishment of lysogeny. Expression of the antirepressor gene is controlled by two other P22 transcriptional repressor genes (*mnt* and *arc*) and a small RNA gene (*sar*).[127] The Mnt repressor binds its operator, which overlaps the antirepressor gene's promoter, and keeps transcription from initiating there in the prophage state. However, if the Mnt repressor releases its operator, antirepressor protein is made, and it in turn inactivates the prophage repressor so that prophage induction ensues. The small *sar* RNA, which blocks translation of antirepressor mRNA, and both Mnt and Arc transcriptional repressors are all required to lower antirepressor synthesis to the very low level required for P22 to establish and maintain the lysogenic state. The *sar* RNA was one of the first untranslated regulatory RNAs to be discovered and characterized.[127] Antirepressors of several types are now known to be fairly commonly encoded by temperate phage genomes.

Some tailed phage virions utilize polysaccharide receptors to adsorb to the bacterial surface. P22 is such a phage, and it was instrumental in the discovery that such virion receptor-binding proteins (tailspikes) are usually also enzymes that cleave these surface polymers. P22 virions have 6 trimeric tailspikes and so have 18 polysaccharide binding/cleavage sites. The detailed role of this cleavage is not completely understood, but it appears to allow the virion to work its way down to the outer membrane surface.[41] Such tailspikes are very specific for the particular sugars that make up the polysaccharide chain, which means that these phages are very specific for particular bacterial subspecies, strains, or "serovars." P22, for example, only adsorbs to a small fraction of *Salmonella* cells, those whose O-antigen polysaccharides are built with a mannose-rhamnose-galactose repeat. This specificity of P22 tailspike binding can be used to identify its host bacterium, *S enterica* serovar Typhimurium.[202] Phages that infect *Enterobacteriales* bacteria (the order that includes *Escherichia*, *Shigella*, *Salmonella*, *Serratia*, etc.) are known that carry similar tailspikes with at least 51 different polysaccharide specificities.[42] All these phages are most likely similarly restricted to infecting a small subset of their host species, and the surface polysaccharide of their hosts could presumably be identified in a similar manner. Some phage virions carry more than one tailspike, and they can adsorb to and infect multiple hosts that have surface polysaccharides to which

their different tailspikes bind.[189]

The genetic diversity and mosaicism of the phage P22 virion assembly genes have been particularly well studied. These phages have been evolving for a very long time, and even in a phage group as narrowly defined as the P22-like lambdoid subgroup, the coat proteins have diverged *within* this group to the point that some pairs are <15% identical in amino acid sequence, apparently without genetic contact with coat genes from other tailed phage types.[156] Other proteins involved in recognition of DNA to be packaged and in receptor binding are even more variable (see earlier), and in these two cases there has been horizontal acquisition of some gene types from other more distantly related tailed phage groups.[42] In addition, there has been extensive genetic exchange among the various phages *within* the P22-like group, and in many cases parts of genes that encode protein domains rather than whole genes have been exchanged.[42]

Recently phages are being exploited for nanotechnology purposes, and P22 has been in the forefront of this research. The facile P22 genetic system has allowed P22 virion and procapsids to be specifically coated with and/or filled with foreign materials to create nanoparticles with various potential uses.[190,191] Particularly attractive is the use of controlled *in vitro* capsid assembly using cargo-fused scaffold protein for efficient and well-controlled encapsulation of both and small molecules.[191] This represents a potentially new nanoscale platform with multiple applications in biomedicine.

Bacteriophages P2 and P4

Bacteriophage P2 is the best-characterized member of a large family of temperate *Myoviridae* found in the genomes of γ-*Proteobacteria*.[152] It was isolated in 1951 by Bertani[20] from the oldest known lysogen, the Lisbonne and Carrère strain of *E coli*, along with phages P1 and P3. One hallmark of P2-related phages is their lack of ultraviolet (UV) inducibility; unlike the lambdoid phages, repressors of P2-related phages are not cleaved in the presence of activated RecA.

P2 is among the smallest *Myoviridae*, with a genome of 33 593 bp; the virion DNA is linear and double stranded, with 19-bp cohesive ends. DNA replication proceeds by a modified rolling circle mechanism reminiscent of that used by single-stranded DNA phages such as φX174, and like φX174, P2 depends on the host *rep* helicase.[152] Replication requires a *cis*-acting phage-encoded initiator protein, the A protein, that catalyzes cleavage at the origin and becomes covalently linked to the 5′ end of the cleaved strand. It acts again at the end of replication to cleave the newly synthesized origin and rejoin the displaced old strand. The resulting products are monomeric double-stranded circles, an unusual substrate for packaging of double-stranded phage DNA but one that is required for the P2 packaging reaction.[22]

All P2 transcription is carried out by the host RNA polymerase. As in other temperate phages, early transcription initiates from a pair of divergent promoters encoding the lysogeny and replication functions. The P2 immunity repressor, C, differs from the majority of phage repressors in that it recognizes nonpalindromic direct repeats of DNA, even though it is structurally similar to repressors that bind to inverted repeats. P2 C regulates its own promoter and blocks expression of the rightward operon encoding the replication genes and *cox*, which encodes the repressor of the lysogenic promoter. P2 Cox is unusual in that it functions not only as the repressor of the lysogenic promoter but also as the recombination directionality factor for prophage excision.[226]

Transcription of the P2 late genes requires the product of the phage *ogr* gene, a transcriptional activator that binds to a conserved sequence about 55 bp upstream of the initiation sites for the four P2 late promoters.[47] Ogr was the earliest example of a transcription factor that interacts with the α subunit(s) of *E coli* RNA polymerase. It is a small zinc-binding protein found almost exclusively among P2-related phages and their satellites, with a Cys_2Cys_2 motif essential for metal binding and activity.

Capsid assembly has been studied extensively in P2, largely in the context of its relationship as a helper phage for satellite phage P4, which is discussed in more detail later. P2 has also served as a model for bacteriophages with contractile tails. An exciting recent development was the demonstration that the bacterial membrane–penetrating protein, gpV, is an iron-binding spike.[24]

P4 was discovered in the early 1960s by Erich Six and was initially characterized as a satellite bacteriophage dependent upon a P2 helper phage for lytic growth. Subsequent work has shown that P4 may be more appropriately considered to be an integrative plasmid that acquired the ability to exploit a helper phage for highly specialized horizontal transfer.[152] In the absence of a helper genome, P4 can be maintained as an integrated prophage or as a multicopy plasmid. P4 replicates its DNA by θ mode both in the multicopy plasmid state and during the lytic cycle, and this replication is independent of helper phage functions. P4 immunity is regulated by a novel mechanism involving transcription termination caused by sequence-specific binding of a short stable immunity RNA. This immunity RNA is processed out of the same transcript that it regulates.

Exploitation of P2 by P4 can occur in several situations, including P4 infection of a P2 lysogen, P2 infection of a strain carrying P4 in either the immune-integrated or multicopy plasmid state, and co-infection by both phages. In each of these cases, P4 responds to the presence of the helper phage by activating functions that allow it to modify P2 gene expression appropriately. The nature and timing of the regulatory cross-talk depends on the infection conditions and appears to be designed to optimize P4 reproduction. One set of reciprocal regulatory interactions between P4 and P2 allows mutual derepression. The P4 Epsilon protein binds to the P2 immunity repressor and interferes directly with its function. Derepression of P4 by P2 requires a third activity of the P2 Cox protein, which stimulates transcription of the operon encoding the P4 replication functions from a promoter that bypasses the P4 immunity system. A second set of reciprocal interactions regulates late gene transcription. The two P4 late promoters are activated by P2 Ogr, the same protein required for P2 late transcription. One of the P4 late gene products, Delta, is an Ogr homolog that activates the same two P4 late promoters and the four P2 late promoters.[103] This mutual transactivation allows earlier expression of P4 late genes in the presence of a P2 helper. It also allows P4 to activate directly the transcription of the P2 morphogenetic genes required for packaging and lysis, bypassing their normal requirement for P2 replication.

The P4 lytic cycle requires all of the morphogenetic functions of the helper phage. A striking feature of the P2-P4 interaction is the redirection of the viral capsid assembly pathway. The 33-kb P2 genome is packaged into icosahedral, isometric T = 7 capsids with a 60-nm diameter. Satellite phage P4 packages its smaller (11 624 bp) genome into a T = 4 particle formed by the interaction of the P4-encoded size determination protein, Sid, with the P2 major capsid protein, gpN. The P2 scaffolding protein, gpO, is an internal scaffold required for assembly of the larger T = 7 P2 procapsids. Both P2 and P4 require gpO for capsid maturation; in addition to its role as a scaffold, it also acts as a protease for N-terminal processing of both gpN and itself. P4 Sid functions as an external scaffold, forming a size-restricting cage that influences the bending of the phage capsid protein at a flexible hinge region. Mature P4 virions have lost the external Sid scaffold but contain a P4-encoded decoration

protein, Psu, that helps to stabilize the smaller capsid. The smaller P4-induced capsid cannot accommodate the P2 genome, leading to interference with helper phage growth.[152]

Recently this phenomenon has been found to be much more prevalent than was previously thought, and numerous "satellite-helper" phage relationships have been discovered in which bacterial regions call pathogenicity islands (chromosomal regions that contain bacterial virulence genes) trick phages into packaging their genes into virions. This "molecular piracy" is an important mechanism for the spread of virulence genes.[65,74] Notable examples are the *Staphylococcus aureus* Pathogenicity Islands (SaPIs), a large family of chromosomal islands expressing toxins including the toxic shock syndrome toxin.[128]

Bacteriophage G

Bacillus megaterium phage G is perhaps the largest lytically growing phage known and among the nonphage viruses is exceeded in size only by the Mimiviruses. The G genome is 497 513 bp long, with nearly 700 predicted protein genes and 17 tRNA genes.[90] Fewer than one-third of the predicted protein sequences match any sequences in the databases. The sequences with good database matches include some virion structural proteins, DNA replication functions, and a wide variety of metabolic enzymes. Compared to phages with smaller genomes, phage G has an unusually large number of apparent transcription factors and even has some translation components, including the tRNAs and an apparent tRNA synthetase, features that have also been reported for the very large eukaryotic Mimiviruses. Metagenomic analyses have identified even larger phagelike sequences ("huge" phages) although these have yet to be propagated lytically.[6]

Bacteriophage Mu

Escherichia coli phage Mu (*Mu* is short for "Mutator" and is not the Greek letter) is a temperate phage that gets its name from the fact that the prophage integrates at essentially random positions around the host chromosome, often inactivating genes into which it inserts.[154] Mu is a transposon as well as a bacteriophage, and when it grows lytically it replicates its DNA by replicative transposition, resulting in ~200 copies of the phage genome inserted around the host chromosome. These phage genomes are excised from the host DNA and packaged into procapsids in such a way that some flanking host DNA is included in the DNA in the virion— 50-150 bp on the left end and 1-2 kbp on the right end. In this sense the Mu genome is always inserted between flanking host sequences, whether it be in the virion particle, as a prophage, or replicating lytically.

Another striking and unusual feature of Mu, shared with only a minority of the extensive family of Mu-like phages as well as with some members of the P1-like and P2-like phage families, that has been described is that it has two alternative types of tail fibers, which give it two alternative host ranges. It achieves this by having a 3-kb invertible segment of DNA (the "G segment") containing sequences that encode two alternative C-terminal halves of the tail fiber, one on each end of the G segment.[26] The orientation of the G segment in the genome determines which of these alternative C-terminal half-genes is fused to the half-gene located immediately adjacent to the upstream side of the G segment encoding the N-terminal half of the tail fiber. The N-terminal half of the tail fiber attaches the fiber to the phage tail and the C-terminal half contains the host cell receptor binding specificity, determining the host range. Inversion of the G segment is mediated by a DNA invertase, Gin, encoded within the G segment. Gin is a member of a family of invertases, including the Hin invertase of *Salmonella*, which is responsible for flagellar antigen switching.

Bacteriophages P1 and N15

Just as phage Mu is both a bacteriophage and a transposon, *E coli* phages P1 and N15 are both bacteriophages and plasmids. N15 is a temperate phage with a 46 363-bp genome that has many features in common with phage λ. P1 is a different type of temperate phage whose genome is considerably larger (93 601 bp). In the lysogenic state these two phages do not integrate their DNA into the host chromosome. The P1 and N15 prophages replicate as linear and circular plasmids, respectively.[171,224] P1 is a generalized transducing phage and a classical tool of *E coli* genetics,[136] and it also played a critical early role in the discovery of restriction endonucleases (the P1 genome encodes such an enzyme), which in turn was critical in the early development of genetic engineering.[49]

The P1 and N15 prophage plasmids are both present in low copy number close to the number of bacterial chromosomes in the cell, and the study of P1 was important in our current understanding of how bacterial plasmids are partitioned into the two daughter cells during cell division.[68] Both phages encode two proteins, ParA and ParB, that are responsible for accurate plasmid segregation. ParB molecules bind to a centromerelike site(s) on the phage DNA to form a large macromolecular structure, and ParA protein is an ATPase that can form filaments and binds to ParB. The precise mechanism of control of plasmid partitioning by these proteins is not yet known, but it has been speculated that polymerization of ParA into filaments acts to push or pull the plasmid DNAs into the daughter cells.[68] In spite of the fact that P1 does not integrate its prophage into the host chromosome, it encodes a site-specific DNA recombinase, Cre protein, that performs several roles for P1, including aiding prophage plasmid segregation by resolving dimer circles (that form by homologous recombination between two monomers) into two monomer circles.[224] The Cre/*lox* recombination system has been applied to the genetic engineering of higher organisms with great success, where it is used to cause gene targeting or deletion to occur in response to a specific environmental signal or to occur only in a specific tissue.[187]

Most bacterial DNAs are circular, so the fact that the N15 prophage plasmid is a linear dsDNA molecule is unusual. At the ends of this plasmid the two strands are joined covalently to form a closed hairpin at each end. The mechanism by which the N15 plasmid prophage is formed is interestingly analogous to the mechanism of λ prophage integration. The DNA in the N15 virion, like λ virion DNA, is linear dsDNA with 12 base ssDNA cohesive ends that join upon DNA injection to circularize the molecule. When the phage enters the lysogenic cycle, this circular form of the DNA is converted into the linear prophage form by integrase in the case of λ and by a phage-encoded enzyme known as protelomerase ("prokaryotic telomerase") in the case of N15.[170] Protelomerase binds to a *tel* site adjacent to its gene, analogous to λ's *attP*, and cuts both strands of the DNA. But instead of joining the cut ends to host DNA, it joins the 5′ end of each strand to the 3′ end of its complementary strand, thus forming the hairpin ends of the linear prophage plasmid.[99] Replication of the linear N15 plasmid then proceeds as normal semiconservative duplication by separation of the two parental strands and synthesis of the complementary strand without breaking the parental DNA chain. This converts the linear molecule into a dsDNA head-to-head dimer circle, which is in turn resolved into two hairpin-ended

linear molecules by action of the protelomerase at the two *tel* sites in the dimer circle.[170]

Bacteriophage ø29

The *Bacillus subtilis* bacteriophage ø29 is a small, dsDNA lytic virus of the *Podoviridae* family. Although λ and T4 were being investigated intensively in the mid-1960s, ø29 was chosen for study because it is small (~20 genes) yet shares some of the complexities of other larger phages, including a prolate (elongated) head and a complex, noncontractile tail.[7] From the start, the study of ø29 held the promise of understanding the function of every gene and of isolating and characterizing every intermediate of the assembly pathway. The system was deemed well suited to investigate complex questions such as the mechanism of form determination, the regulation of assembly *via* sequential protein and DNA conformational changes, and the mechanism of DNA packaging. ø29 has since proven to be a rich model system, especially for the study of DNA replication and the DNA packaging phase of viral assembly.

The genome of ø29 is a linear, unit-length (ie, nonconcatemeric) chromosome of ~19.3 kbp.[140,182] The ø29 chromosome is unusual in that a phage terminal protein, gp3, is covalently bound to each 5′ end of the DNA via a phosphoester bond. Terminal proteins are also found in the chromosomes of some other phages, such as PRD1 and the eukaryotic adenoviruses. These proteins are essential for DNA replication, which proceeds by a protein-primed mechanism. In ø29, a specific serine residue of gp3 provides the free 3′-OH needed to initiate DNA replication. Replication is bidirectional, with the viral-encoded polymerase, gp2, forming a complex with a free gp3 at both ends of the DNA and then catalyzing covalent attachment of a 3′-deoxy-adenosine monophosphate (dAMP) to the terminal protein. The complex “slides back” to the first nucleotide, and DNA synthesis proceeds from this single priming event. This mechanism allows ø29 to overcome the challenge of replicating the ends of linear DNA without loss of genetic information. The monomeric phage-encoded DNA polymerase is notable in that it has been shown to have exceptionally high processivity, and it is capable of both polymerization and template-strand displacement, precluding the need for a helicase to unwind the template DNA.

During dsDNA phage virion assembly, the genomic DNA is packaged into a preformed protein shell (prohead or procapsid).[168] This process is driven by an ATP-dependent molecular motor that transiently assembles at the unique portal vertex of the head. In most phages, the motor consists of the connector and a terminase complex composed of large and small subunits that house the ATPase/nuclease and DNA recognition functions, respectively. In ø29, the covalently bound terminal proteins are also essential for packaging,[147] likely providing the role of the small terminase subunit. The ø29 packaging ATPase is smaller (~60%) than other phage large terminase subunits, in part due to the lack of a required nuclease function as the packaging substrate is already unit length. Additionally, ø29 is unique in that a small noncoding RNA is also an essential component of the motor. This 174 nucleotide prohead RNA (termed pRNA) forms a novel pentameric ring via intermolecular base pairing.[147] The pRNA ring serves to bridge the connector and the ATPase rings in the packaging motor.[64,80] Because all the dsDNA phages are thought to employ similar packaging mechanisms, the functions of pRNA likely reside in subdomains of the larger motor proteins of other phages[168] (Fig. 21.10). Movement of DNA into the head is driven by the ATPase gp16. Like the analogous large terminase enzymes of other dsDNA phages, this ATPase ring is related to a large class of cellular ring ATPases that perform many substrate translocating functions.[28]

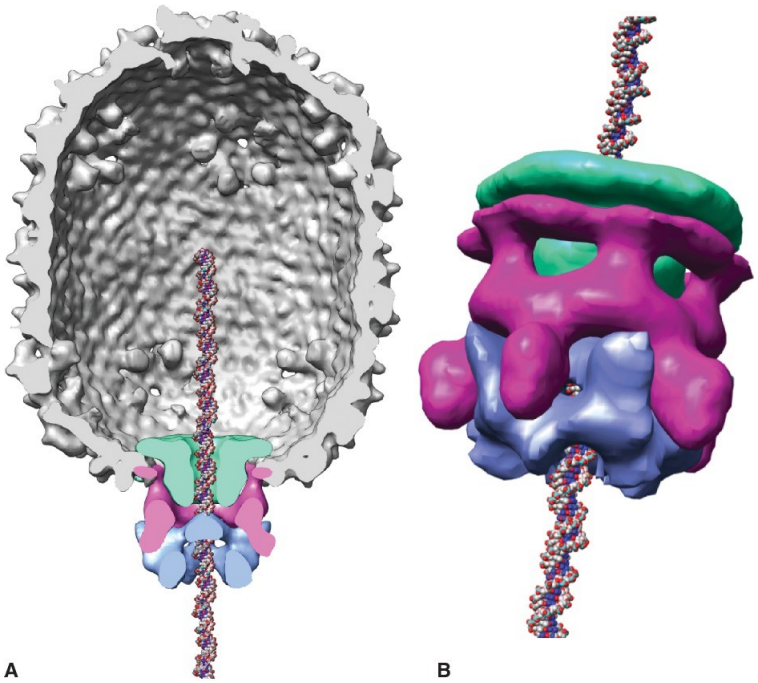

FIGURE 21.10 **Packaging of φ29 DNA**. The φ29 DNA packaging motor. **A**. Cutaway view of cryoelectron microscopy reconstruction of the prohead/motor complex showing the molecular envelopes of the motor components.[128] Gray is the capsid, green is the head-tail connector, magenta is the prohead RNA (pRNA) ring, and blue is the packaging ring adenosine triphosphatase (ATPase) gp16. A DNA model has been placed in the channel for reference. (Courtesy of Marc Morais. **A** reprinted from Grimes S, Ma S, Gao J, et al. Role of φ29 connector channel loops in late-stage DNA packaging. *J Mol Biol*. 2011;410(1):50-59. Copyright © 2011 Elsevier, with permission.) **B**. Close-up of the motor components. Structure and assembly of the essential RNA ring component of a viral DNA packaging motor. *Proc Natl Acad Sci U S A*. 2011;108(18):7357-7362.)

A ring motor can work using a mechanism where each subunit works independently, or alternatively, two or more motor subunits can work together via a more complex and coordinated mechanism. Single-molecule laser-tweezers studies indicate that DNA translocation subunits are

coordinated such that the ring loads with ATP while holding the DNA during a “dwell” phase, then hydrolyzes these ATPs to drive a “burst” of 10 base pairs into the head that is coupled to the release of inorganic phosphate from the motor. This high degree of coordination requires communication between motor components, possibly mediated through adjacent ATPase subunits, the pRNA ring to which it is bound, and/or the DNA substrate itself.

Studies of ø29 and other phage motors have revealed that the packaging motor is powerful when compared to other biological molecular motors, generating forces over 65 piconewtons, which is approximately an order of magnitude stronger that skeletal myosin.[168,192] In part this high-force-generating capacity is required to overcome the resistance encountered when compacting the highly charged and relatively stiff DNA to near-crystalline density inside the head.

Insights from other Phage Families

Tectiviridae: dsDNA, Linear, With Proteins on 5′ Ends

Tectiviruses, typified by *E coli* phage PRD1, share with the tailed phages (*Caudovirales*) a linear dsDNA genome in the virion as well as a few general features of their infection strategy, but in many ways they are quite distinct. Perhaps the most prominent difference is that the tailless PRD1 virion contains a lipid membrane, located inside an icosahedral protein capsid and surrounding the viral DNA[79] (Fig. 21.11). Its linear DNA is 14 927 bp long, not permuted, with inverted terminal repeats at the ends. Thirty-seven genes have been identified that are arranged in five operons. Promoters for the two early operons are in the terminal repeats, pointing toward the middle of the DNA, and the three late transcripts fill the center of the map, all oriented in the same direction.[79] The 5′ ends of the two DNA strands are covalently joined to a phage-coded protein that serves as the primer for DNA replication by a phage-coded polymerase.

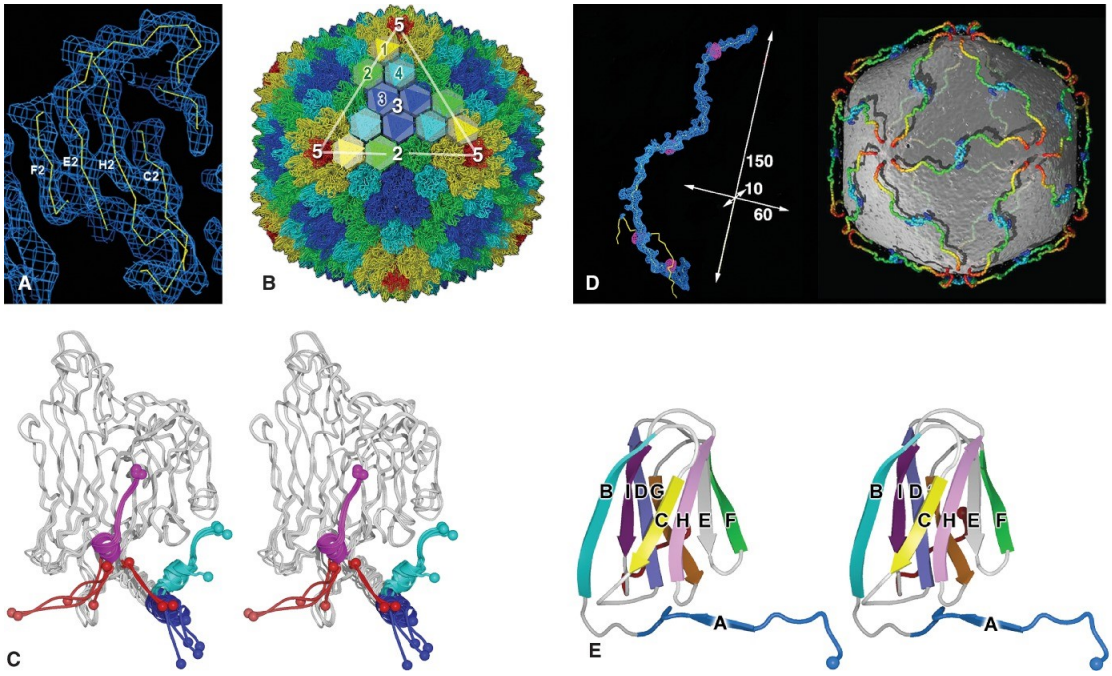

FIGURE 21.11 **Architecture and structural components of bacteriophage PRD1**. PRD1 is composed of four protein subunits P3, P16, P30, and P31, surrounding a membrane. P30 is a linearly extended protein that nucleates the formation of the icosahedral facets (composed of trimers of the major capsid protein, P3) and acts as a molecular tape measure, defining the size of the virus and cementing the facets together. Pentamers of P31 form the vertex base, interlocking with subunits of P3 and interacting with the membrane protein P16. **A**. Strands of the second of two jelly-roll domains in the PRD1 capsid subunit, P3. **B**. The building blocks of a facet (the triangular area defined by white lines). The icosahedral asymmetric unit contains 12 P3 subunits arranged as four trimers, with orientations represented by triangles labeled 1-4 and colored yellow, green, blue, and cyan, respectively (the underlying gray hexagons show the trimer morphology; numbers and symbols follow the adenovirus convention). P3 trimers outside the marked facet are colored similarly and shown as coil, as is protein P31, drawn in red. **C**. Stereo Cα traces of the superposed 12 unique copies of major capsid subunit P3, showing switching at the N (*blue* and *cyan*) and C (*red* and *magenta*) termini. **D**. Protein P30 is shown on the left in *royal blue*, with the SeMet differences in magenta. Part of a twofold related P30 subunit is shown in *yellow*. Dimensions are in angstroms. On the right, 60 copies of P30 (colored *blue* through *green* to *red* from the N-terminus to the C-terminus) wrap around the electron density of the membrane. The small holes in the membrane close to the fivefold axes are the transmembrane helices of protein P16. **E**. Stereo view of P31. Jelly-roll strands are labeled B-G; the β-strand at the N-terminus is labeled A. N-terminal and C-terminal segments are colored blue and red, respectively. (Adapted by permission from Nature: Abrescia NG, Cockburn JJ, Grimes JM, et al. Insights into assembly from structural analysis of bacteriophage PRD1. *Nature*. 2004;432(7013):68-74. Copyright © 2004 Springer Nature.)

The high resolution x-ray structure available of the entire virion reveals several noteworthy features of PRD1 structure.[2] The major capsid protein, also known as P3 or hexon protein, has two β-barrel domains, each structurally similar to the single β-barrel domains that are found in many virus capsids. P3 trimerizes into a “hexon” that has a nearly sixfold symmetric arrangement of β-barrel domains and occupies the position in the capsid lattice that would be occupied by a hexamer in a canonical Caspar-Klug icosahedral structure. A different protein occupies the icosahedral vertices as a pentamer. These hexons and pentons are arranged in a pseudo T = 25 structure. There are two additional proteins forming the spike structure at the fivefold symmetry position but displaying symmetry mismatch. The spikes are involved in receptor recognition. One of the 12 vertices is a portal for the DNA packaging process where the DNA enters an empty procapsid through the protein and

membrane layers of the virion.[195] The virus release utilizes similar mechanisms to those operating in tailed bacterial viruses where a holin protein makes an opening to the plasma membrane and a lytic enzyme digests the peptidoglycan layer leading to cell disruption and virus release.

Microviridae: ssDNA, Circular

The *Microviridae* are small viruses with icosahedral capsids that contain the genome in the form of a circular ssDNA molecule. They are typified by the *E coli* phage φX174, genome size 5386 nucleotides, with which most of the experimental work with this group has been done.[71] A few tens of rather close relatives of φX174 have been isolated on enterobacterial hosts, and these have been used in comparative experimental studies with φX174 as well as in evolution studies.[216] A second small group of isolates infects hosts of the *Chlamydia*, *Bdellovibrio*, and *Spiroplasma* genera of bacterial hosts. This group of viruses shares general features with the φX174 group but differs in details of gene content and organization and of virion morphology; they are accordingly classified as a separate subfamily of the *Microviridae* family. Little has been known until recently about the abundance of the *Microviridae* in the environment. However, metagenomic studies of environmental samples have shown (when the sequencing technology employed can detect ssDNA) that *Microviridae* sequences are a significant component of the sequences in these samples that are recognizably of viral origin.[204]

Infection by φX174 begins with binding of the virion to the surface of the *E coli* host, and electron micrographs of infecting virions show them at locations where the inner membrane and the cell wall of the host are closely apposed. The initial receptor on the host is a portion of the lipopolysaccharide, recognized by a glucose-binding site on the virion surface. Host range mutants of the phage map to a different part of the virion surface, suggesting that there is at least one more host receptor molecule. It is not known how the virion DNA crosses the cell envelope to enter the cytoplasm, but it appears that the virion proteins remain outside the cell.

The virion ssDNA is of the plus sense, so transcription to produce mRNA cannot start until replication of the DNA has produced the minus-strand template. In fact, the first stage of DNA replication, which converts the single-stranded circular virion DNA into a double-stranded circle, is carried out entirely by host replication proteins. The resulting double-stranded circle, called RF I (replicative form I), can serve as the template for transcription but also serves as the template for the second stage of replication, in which the dsDNA RF I circles are amplified to make more dsDNA circles, now called RF II.[196] In addition to the host replication proteins required for converting virion DNA to RF I, this second stage of replication requires a phage-coded protein, the A protein, and an additional host protein, the *rep* helicase. The A protein binds to the replication origin, cuts the plus strand, and attaches the 5′ end of the plus strand to itself by an ester bond. The *rep* helicase then unwinds the 5′ end and replication proceeds by elongation of the free 3′ end of the plus strand. This is the classical rolling circle form of DNA replication, first identified in this phage. When the free single-stranded plus strand reaches unit length, the A protein cuts again and ligates the ends of the ssDNA to form an ssDNA circle. This ssDNA circle is identical to the virion DNA, and it is converted to the dsDNA circle, RF II, by the same host replication proteins that converted virion DNA to RF I.

The final stage of replication also uses a rolling circle mechanism initiated by the action of the phage-coded A protein, and the ssDNA plus-strand circles are produced as described for the second stage of replication. However, in this stage, replication takes place in a complex with the newly assembled procapsids. Formation of this complex is mediated by the phage-coded C protein. The ssDNA is apparently inserted into the procapsid as it is displaced from the rolling circle, with the packaging driven by the energy of replication (Fig. 21.12). Lysis involves a mechanism that alters the host MraY protein to interfere with cell wall synthesis.[17]

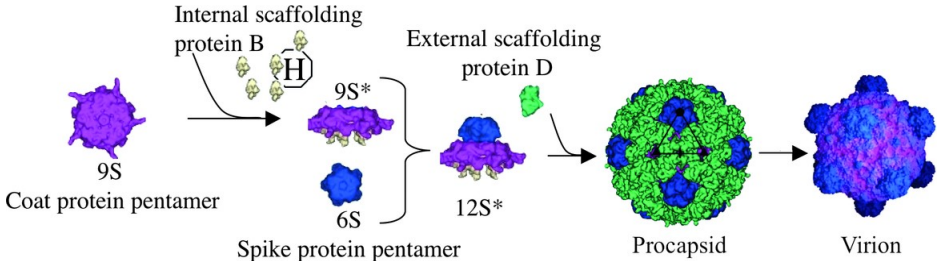

FIGURE 21.12 **Assembly of φX174 particles**. The first identifiable assembly intermediates are pentamers of the viral coat F and major spike G proteins, the 9S and 6S particles, respectively, which can form in the absence of both scaffolding proteins. Five internal scaffolding B proteins bind to the underside of the 9S particle, yielding the 9S* intermediate. This interaction induces a conformational change that allows 9S*-6S particle associations, forming the 12S* intermediate. The internal scaffolding protein also facilitates the incorporation of the DNA pilot protein H. Two hundred and forty copies of the external scaffolding D proteins, most likely in the form of 60 tetramers, associate 12 12S* particles into the procapsid, a DNA-less particle. Both scaffolding proteins are removed from the procapsid when particles are filled with single-stranded DNA (ssDNA) during the last stages of the maturation.

Inoviridae: ssDNA, Filamentous

Filamentous phages have striking morphologies, flexible long rods up to several micrometers in length, and diameters of only ~7 nm. These phages were first detected by Loeb[129] with phage f1, and later, M13 and fd were isolated, all of which are closely related and use *E coli* as their host. Several other *Inoviridae* have been described with host bacteria other than *E coli*,[212] but we will focus here on M13, perhaps the best studied of these phages.

M13 particles consist of a 6407-base single-stranded DNA molecule that is helically coated by about 2800 copies of a small (50 amino acids) major coat protein, gp8. The C-terminal sequence of gp8 is positively charged and interacts with the phosphate backbone of the DNA, stabilizing the phage particle. The tip of the phage has five copies each of gp7 and gp9, two minor coat proteins, whereas the base of the phage is made up of five copies each of gp3 and gp6 that are involved in adsorption to the host.

M13 adsorption to its host is quite distinct, is male specific, and uses *E coli* F pili for attachment. The N2 domain of gp3 binds to the tip of the F pilus and induces a retraction signal in the pilus similar to that induced by a contact with a female cell in bacterial conjugation. The F pilus

retracts by sequential disassembly into the bacterial inner membrane[29] along with the phage that effectively extends the tip of the pilus. During this process, the N1 domain of gp3 interacts with the periplasmic domain of the host TolA protein.[130] As the coat proteins partition into the membrane bilayer upon pilus retraction, the single-stranded DNA is released into the cytoplasm where it is converted into double-stranded DNA by the host DNA polymerase.

Only 11 gene products are encoded by the M13 genome, most of which are involved in assembly of the virion. The major coat protein gp8 is synthesized as a "procoat" with a cleavable signal sequence and inserted into the inner membrane of *E coli*. It is not a substrate of the signal recognition particle (SRP) and the Sec-translocase, but instead it requires the membrane insertase YidC for membrane localization.[183] After insertion, the procoat protein is converted to mature coat protein by the leader peptidase of *E coli*.[115] YidC is also involved in the membrane insertion of gp9.[163] All the virion minor proteins, gp3, gp6, gp7, and gp9, are membrane proteins, as are gp1 and gp11.[83]

Replication of M13 DNA proceeds by the rolling circle mechanism.[97] The endonuclease gp2 creates the free 5′ ends that are required to form new single-stranded circles. These are first converted to dsDNA to increase the numbers of rolling circles, and later in infection, when the structural phage proteins are synthesized, the newly replicated ssDNA is covered by the phage-encoded ssDNA binding protein, gp5.

As early as 9 minutes postinfection, the first progeny are released from the host cells without lysis (Fig. 21.13). Virion assembly takes place at the host membrane, initiating with gp7 and gp9 to form the tip of the prospective virion. This likely occurs within a transmembrane complex containing the membrane proteins gp1, gp11, and thioredoxin.[169] The ssDNA is then introduced into the assembly process by binding to the "packaging signal" in the M13 genome.[181] Oligomers of the major coat are then added to form a fivefold helical structure around the ssDNA that grows out from the cell surface.[151] During this elongation process ssDNA moves through the membrane and is simultaneously covered by major coat protein subunits, replacing the bound gp5 molecules. Passage through the outer membrane is facilitated by a porinlike structure containing gp4.[180] Finally, the assembly process is terminated by attachment of gp3 and gp6 to the end of the phage. Thus, the length of the virion filament is determined by the length of the ssDNA genome.

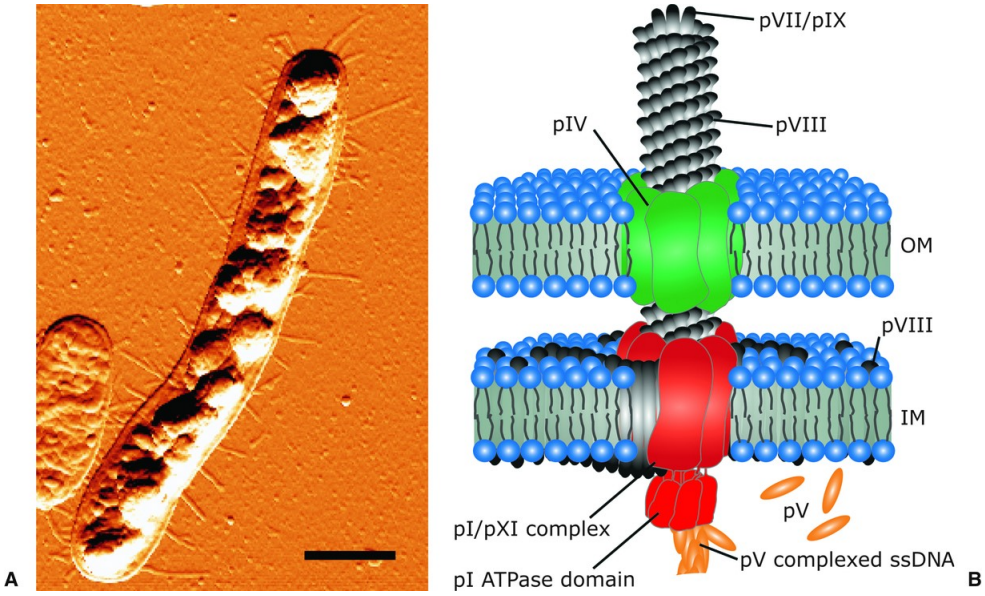

FIGURE 21.13 **Secretion of M13**. **A**. M13 phage secreted from *Escherichia coli* cells 9 minutes postinfection by atomic force microscopy. The bar represents 1 μm. **B**. Schematic model of M13 passing the inner membrane (IM) and outer membrane (OM) of the host envelope.

The rate of phage production is constant with about six particles released per cell per minute,[162] but because the particles are secreted, no host lysis occurs, and cell division continues, albeit at a reduced rate. Phage production ceases, however, as the cells enter the stationary phase. During an infection, a single cell can produce about 1000 phage virions in 2 hours.

M13 has been of considerable biotechnical use, first for DNA sequencing and later in "phage display."[193] Phage-display technology uses short peptides inserted into gp3 that are exposed on the surface of the phage and can be used as affinity probes. If a random sequence encoding the peptide is inserted into gene *3*, the affinity of the best binding phages for a ligand can be selected. Applications in nanotechnology, in surface chemistry, and for medical and material science have shown the broad utility of this phage display technology.

The filamentous phage CTXφ phage of *Vibrio cholerae* is of considerable interest as it encodes the cholera toxin genes.[210] CTXφ phage encodes homologs of all M13 genes, except gene *4*, which is replaced by the toxin genes *ctxA* and *ctxB*. Consequently, CTXφ phage uses the secretin EpsD in the outer membrane of *V cholera* for traversing the outer membrane. To infect new host cells CTXφ phage uses a type IV pilus, the toxin co-regulated pilus (TCP), as a receptor. The pilus genes are localized in a pathogenicity island, which resembles elements of another filamentous prophage, VPI phage.[105] CTXφ integrates into the chromosome of its host and CTXφ expression is regulated by the phage repressor, RstR. A second integrated filamentous satellite phage, called RS1, is involved in inducing CTXφ replication by binding of its antirepressor RstC to RtsR.[58] The pathogenicity of *V cholerae* is thus the consequence of a complex interplay between different filamentous phages.

Leviviridae: +ssRNA

The *Leviviridae* are among the smallest of the known phages and the only ones with ssRNA in their virions.[209] The virion RNA is of the positive

(ie, mRNA) sense and encodes four genes, with functions that are described later. There are two slightly different varieties of these phages that have been well studied, one typified by phages MS2, R17, and others, with a genome length of ~3500 bases, and a second typified by phage Qβ, with a genome length of ~4200 bases. These best-studied examples of this family of phages infect *E coli*, but similar phages have been identified that infect a variety of other hosts, including Gram-positive hosts, and virions of this family appear to be quite abundant in the environment.

The virion is a T = 3 icosahedral structure with 180 molecules of the "coat" protein and one copy of the "maturation" protein. The RNA is inside, and although it does not have the icosahedral symmetry of the protein capsid, a significant amount of RNA interacting with coat protein can be visualized in icosahedrally averaged cryo-EM structures of virions.[111] This indicates that there is significant order to the RNA within the virion. The coat protein has a fold that has not been seen in any other viruses, consisting of a β-sheet and a large α-helix. The subunits associate as dimers in which the α-helices are passed across the dimer twofold axis to link the two subunits by their α-helical "arms." The dimer is the functional unit that assembles into the capsid.

Infection starts when the virion binds, through its maturation protein, to the side of the F pilus. The maturation protein becomes proteolytically cleaved and the RNA is released into an RNase-sensitive form, which transits to the cytoplasm of the cell. How this last step is accomplished is not clear, but it may involve retraction of the pilus. The maturation protein may have a role in guiding the RNA into the cytoplasm, but once it is there the RNA alone is sufficient to initiate the infectious cycle, as demonstrated by the fact that naked RNA can be electroporated into the cell to successfully initiate infection. The virion RNA and copies of it that are made subsequently serve as the mRNA for the virus. No subgenomic mRNA is made, yet there is substantial temporal and quantitative regulation of expression from the four genes. This is accomplished by a complex interaction of the extensive and dynamic secondary structure of the RNA with ribosomes and with the replicase.

The genes are arranged on the RNA in the order 5′–[maturation]–[coat]–[replicase]–3′. In MS2-type phages a fourth gene, the lysis gene, overlaps both the end of the coat gene and the beginning of the replicase gene.[73] When the RNA first enters the cell, its secondary structure allows productive binding of ribosomes only at the start of the coat gene. As ribosomes proceed through the coat gene they disrupt RNA secondary structure that is sequestering the start of the replicase gene, allowing other ribosomes to make replicase protein with delayed kinetics relative to coat. The phage-encoded replicase protein joins with three host proteins—translation factors EF-Tu and EF-Ts, and ribosomal protein S1—to constitute the four-subunit polymerase complex that copies the RNA. Replication is a conceptually simple synthesis of a (−) strand from a (+) strand template followed by synthesis of a (+) strand from a (−) strand template. Synthesis of (+) strands is more efficient than synthesis of (−) strands, in part because the polymerase has to compete with ribosomes for access to the (+) strands through a mechanism that prevents polymerase from synthesizing RNA in the 3′-5′ direction on the (+) strand template at the same time that ribosomes are synthesizing protein in the 5′-3′ direction. The translational start site for the maturation protein is always sequestered from ribosomes except for a brief period after that part of the mRNA is synthesized, before the secondary structure that hides the ribosome binding site forms. There is time for only about one ribosome to get on the mRNA before the secondary structure forms and the site is obscured; this means there is roughly one maturation protein made for every (+) strand RNA synthesized—just the ratio that is found in virions.

Progeny virions are assembled from 90 dimers of the coat protein, one molecule of the maturation protein, and one (+) strand RNA. Neither the coat protein nor the RNA will achieve their assembled configuration in the absence of the other. It has been shown that protein and RNA each interact with the other in ways that influence its conformation and assembly capabilities, in an intricate *pas de quatre-vingt-douze* leading to a mature infectious virion.[15] In phage MS2, the protein responsible for lysis is encoded by a gene that starts within the coding sequence of the coat gene, in a different reading frame. Ribosomes do not directly enter the start of the lysis gene; rather, the ribosomes that terminate at the coat gene termination codon remain associated with the mRNA, and a small fraction of them drift back by several nucleotides and initiate synthesis of the lysis protein.[225] Cell lysis occurs when the lysis protein has accumulated to a sufficient level, but the mechanism of lysis is unknown. In phage Qβ the genes are organized slightly differently and there is no explicit lysis gene. Rather, lysis is caused by a portion of the maturation protein. In this case it has been shown that lysis is caused by inhibition of an enzyme in the cell wall synthesis pathway, MurA.[18] This is similar to what is described earlier for the φX174 E (lysis) protein, except that it targets a different step in the cell wall synthesis pathway.

At the time of the early studies of these phages, their virion RNA was the only prokaryotic mRNA available in pure, homogeneous form. As a result, it allowed the first view of what a translation start site looks like, as well as showing that some parts of an mRNA might not encode protein. In the time since, these viruses have provided extremely fruitful models for understanding how the structure and structural dynamics of RNA can influence and regulate biological processes of general importance, such as gene expression and virion assembly.

Cystoviridae: dsRNA, Segmented

Cystoviruses are unique phages that have a segmented genome composed of dsRNA and an envelope enclosing a viral nucleocapsid composed of two concentric protein shells and the genome.[12] The viral envelope fuses with the outer membrane of the Gram-negative host bacterium after receptor binding. The type member of the family *Cystoviridae* is *Pseudomonas* phage φ6, but other similar viruses have been isolated, all infecting Gram-negative hosts, mainly in the *Pseudomonas* genus. The genome consists of three linear dsRNA molecules, 2948, 4063, and 6374 bp in size, that encode 11 viral structural proteins and two nonstructural ones. The genes are clustered on the three genome segments according to their functions.[166] During the replication cycle the genome segments are converted into full-length polycistronic transcripts, each encoding four to five viral proteins. Noncoding regions at the 3′ and 5′ termini of the ssRNA molecules, flanking the internally located coding sequences, are ~370 and 310 nucleotides long, respectively. The sequence at the 5′ end displays only limited homology (17 nucleotides identity) between the segments, while the untranslated regions at the 3′ end are more similar to one another.[144]

The innermost protein shell in the virion, the polymerase complex, is composed of four protein subunits. The major capsid protein P1 is arranged on an icosahedral T = 1 lattice so that a dimer of P1 occupies the asymmetric unit. Such capsid organization is also characteristic for the dsRNA viruses infecting eukaryotic hosts.[165] Hexamers of the packaging nucleoside triphosphatase (NTPase) occupy the fivefold symmetry positions, exterior to the P1 shell. The assembly co-factor P7 and the RNA-dependent RNA polymerase P2 are located within the interior of the P1 shell. The first detectable assembly intermediate formed during phage φ6 infection is an empty polymerase complex, procapsid.[166] The three genome segments are packaged into these capsids in single-stranded form. RNA encapsidation is dependent on the segment-specific packaging signals at the 5′ termini of the viral ssRNA molecules and the activity of the packaging NTPase; it proceeds in an orderly fashion from the smallest to the largest genome segment.[144] The encapsidated ssRNA molecules are replicated within the polymerase complex into dsRNA form by the P2 polymerase utilizing a *de novo* initiation mechanism.[208] Efficient replication is dependent on 3′ terminal replication signals. Following replication the polymerase produces new single-stranded mRNA molecules from these dsRNA segments using a semiconservative strand displacement mechanism. During the encapsidation of the dsRNA genome, the polymerase complex particle undergoes substantial

conformation changes expanding the internal volume and making the particles compatible for nucleocapsid surface shell assembly.[166] The nucleocapsid surface shell follows T = 13 icosahedral symmetry and is made mainly of protein P8, which is essential during the virion entry to assist the polymerase complex particles through the host plasma membrane. The viral envelope containing four phage-encoded integral membrane proteins is derived from the host plasma membrane in a process that is dependent on the viral nonstructural protein P12. As a last step of the virion maturation, receptor-binding spike protein associates with the fusogenic protein embedded in the envelope.[166] The progeny virions are released from the infected cell by phage-induced host cell lysis.

Corticoviridae: dsDNA, Circular

Bacteriophage PM2 is the sole described member, and therefore the type organism, of the family *Corticoviridae*.[10] The virion is icosahedral, with triangulation number 21. Its coat protein has the double β-barrel fold similar to that found in PRD1 (*Tectiviridae*). Consequently, also the virion architecture resembles that of PRD1 with an internal membrane.[3] The genome is represented in a tightly supercoiled circular dsDNA molecule of 10 079 bp, inside the membrane.[133] Ten phage-encoded proteins have been identified as components of the virion: one making up the capsid shell and one forming spikes on the vertices of the capsid, and most of the others are membrane proteins. The lipids of the virion membrane are derived from the plasma membrane of the host cell, but curiously the relative amounts of the different lipids are significantly different from the average lipid composition of the host.[120]

The host of PM2 is a marine bacterium of the genus *Pseudoaltermonas*. Infection begins when the virion binds to a receptor on the cell surface leading to the release of the major coat protein and most possibly the virion membrane fuses with the host one.[108] Twenty-one protein-coding genes are inferred from the genome sequence, and the encoded proteins have been identified for 15 of them. The genes are organized into three operons. The *immediate early* operon has just three genes, is transcribed in the opposite direction to transcription of the other genes, and has sequence similarity to a region of a plasmid found in some *Pseudoaltermonas* strains. The *early* operon encodes an apparent replication initiation protein and two transcription factors necessary for transcription of the *late* operon, which encodes the virion structural components. DNA replication is thought to occur by the rolling circle mechanism, based on EM views of replication intermediates, and this interpretation is bolstered by the similarity of the replication initiation protein to the corresponding protein of phages such as φX174 (*Microviridae*), which is known to replicate its DNA by this mechanism. The mechanism of virion assembly is not well understood, but structures that appear to be membrane-enclosed DNA are seen associated with the cell membrane late in infection, and it is surmised that these are assembly intermediates around which the protein capsid assembles. In laboratory growth in rich medium, about 300 progeny virions/cell are released after a 60- to 70-minute life cycle. The particles exit from the host utilizing a novel mechanism.[114] There is a new type of holinlike protein to permeabilize the plasma membrane, and PM2 seems to use a host-derived lytic enzyme to digest the peptidoglycan. There is also a viral protein that disrupts the outer membrane of the host, a function not described previously in phage release.

PM2 was the first bacteriophage shown to have a lipid membrane as part of the virion. It is noteworthy that PM2 was isolated in the mid-1960s, yet no other examples of the family have been reported in the more than 40 years since. Very recently PM2-like sequences, which may be prophages, have been detected in the genomes of many marine bacteria.[113] This may mean that they are not that rare in the environment, and perhaps more plausibly it could mean that methods usually employed for isolating new phages fail to capture this group efficiently. This raises the question of how many novel groups of phages still await discovery.

Plasmaviridae: Circular dsDNA

The *Plasmaviridae* are a small family of phages in which the few known examples infect members of the bacterial genus *Acholeplasma*, a member of the mycoplasma. Most of the work on the group has been done with phage L2. The genome of L2 is found in the virion as an 11 965-bp circular, supercoiled dsDNA molecule.[132] Fifteen protein-coding genes have been deduced from the sequence, including at least four that encode components of the virion and one that encodes an integrase. The virions are small, quasispherical, somewhat pleomorphic structures, consisting of a membrane envelope surrounding the DNA. The locations of the viral proteins in the structure are not known.

Phage L2 has an unusual life cycle in which, instead of making a decision between lytic and lysogenic modes of growth, it does both every time it infects. That is, the first part of the life cycle is productive, producing virions that leave the infected cell by budding, without killing the cell. This is followed by the lysogenic phase in which virion production ceases and the phage DNA integrates into the host chromosome by a site-specific recombination event, apparently catalyzed by the phage integrase. Prophage-containing cells are immune to infection by homologous but not heterologous phages of the family, and lytic growth of the prophage can be induced by UV or mitomycin treatment. These observations are suggestive of a phage-encoded repressor analogous to those of phages like λ.

Evolution of Phages

Genome Mosaicism

How phages evolve has been a long-term interest in the field, and the scope and specificity of what can be learned have expanded greatly with the availability of high-throughput DNA sequencing. To somewhat oversimplify, phages have been used in two ways in evolutionary studies. In the first, phages are put into a controlled environment in the laboratory and followed by genome sequencing through various selections, competitions, population bottlenecks, and so forth. This approach has allowed rigorous testing of a number of different aspects of evolutionary theory and made it possible to elucidate specific pathways of adaptation, typically at the single nucleotide level, and in this way to illustrate individual evolutionary events that must take place in natural phage evolution. This work has been very valuable but has not necessarily represented most of the enormous and chaotic complexity of the natural environments where phages evolve nor the extraordinarily long times over which phage evolution is thought to have occurred.[27,155] The goal of understanding the mechanisms of evolution as actually practiced by phages in the wild has been more closely approached by isolating phages from the environment and sequencing and comparing their genomes.[85] This approach has the limitation that the sampling of the population is extremely sparse and almost certainly biased, but it has nevertheless yielded a wealth of information about the structures of the genomes produced by phage evolution, and this has allowed inferences about the mechanisms by which they got there. In thinking about phage evolution it is helpful to keep in mind the numbers cited in the first paragraph of this chapter. For example, there are ~10^{24} infections per second on a global scale for the tailed phages alone (see earlier), and each of those infections is an opportunity for genetic rearrangement. As we describe later, there is reason to believe that this has been going on for something

like the past 10^{17} seconds. Most of the discussion given later relates to the tailed phages, for which the most information is available; there is also some comparable work available for the *Microviridae*, which has produced similar but not identical conclusions about mechanisms in this different group of phages.

If the genomes of a closely related group of tailed phages are compared, they are seen to be genetic mosaics with respect to each other. That is, the sequences of two genomes may be nearly identical over the length of a few genes and then abruptly change so that they match less well or not at all.[38,94] These sites are the "fossils" of nonhomologous recombination (ie, recombination between two DNA sequences that are different from each other) in the ancestry of one of the phages, creating a "novel joint" in the genome such that two sequences are placed adjacent to each other that were not adjacent in either parental sequence.[158] This is the mechanism by which these phages are thought to achieve horizontal exchange of DNA sequences, and horizontal exchange is a central feature of the evolution of these phages. The locations of the novel joints are informative; in most cases they have recombined between genes or at gene boundaries. This was initially thought to suggest that recombination events occurred preferentially at gene boundaries.[199] However, closer examination of the data argues that nonhomologous recombination occurs promiscuously across the entire genome without site specificity, but that the vast majority of recombinants are eliminated by natural selection. The recombinants that survive are those that do not disrupt function, and most of these are at gene boundaries, or in other words, not within protein-coding regions. The exceptions that prove the rule are novel joints that fall within protein-coding regions but at positions corresponding to functional domains of the protein. The tyrosine integrases, tail fibers and tailspikes, and DNA packaging proteins provide good examples of this. Opportunities for recombination between different phage genomes arise when a cell is infected simultaneously by two phages; however, a more frequent opportunity for recombination occurs when the infected cell carries one or more prophages, as is likely true for a great majority of cells.[36]

Homologous recombination (ie, between identical sequences) also certainly has a significant role in the reassortment of genes among genomes in that homologous recombination between identical sequences on different genomes can reassort the novel joints and dissimilar genes that flank the identical sequences. These identical sequences may be identical protein-coding sequences. In addition, there are scattered examples of identical stretches of sequence shared between intergenic regions, and more generally, intergenic regions may share more than random sequence similarity due to shared occurrence of transcription and translation signals, and this may bias recombination toward these locations.[48]

There are apparent constraints beyond those described earlier on where recombination between genomes can occur (and survive natural selection to be seen by us). Thus, in the smaller tailed phages like λ and its relatives, there is little or no mosaicism seen within the group of procapsid assembly genes and usually also little mosaicism within the group of tail tip assembly genes. Similarly, genes for DNA binding proteins, for example, the λ *cI* repressor gene, "travel through evolution" together with the DNA sites their encoded protein binds. Such cases are thought to be explained by shared function of the genes that show this behavior. Thus, the proteins encoded by the head genes of a phage like λ must each interact intimately with the other head proteins during head assembly and in the assembled structure, and they have co-evolved over time to maintain productive interactions among the group. Substitution of a homologous gene or genes from a phage that had followed a different path of mutation and co-evolution would in almost all cases be expected to produce a nonfunctional set of head genes and be counterselected, even though all the genes would be functional in their home genomes. A notable exception to such co-evolution is the parts of tail fiber and tailspike genes that bind bacterial receptors. They appear to have been horizontally exchanged many times among even very different phages. For example, there are members of the *Podoviridae*, *Siphoviridae*, and *Myoviridae* that, in spite of having very different life cycles, have nearly identical tailspikes that utilize the same host receptors, and it is unlikely these arose through convergent evolution. It seems that sometimes when a phage manages to obtain a new host specificity in this way, it can have an advantage, because it can enter an evolutionarily naive cell that is not prepared to defend itself against a phage that it has not "seen" before.

Common Ancestry of Archaeal and Eukaryal Viruses With Phages

Homology (shared ancestry) among viral genes can be inferred from similarity of their encoded amino acid sequences, as is done routinely, for example, for genes of mammalian genomes. However, this approach has turned out to be quite limited for viral sequences because the sequences of viral proteins that are thought on other grounds to be homologs have often diverged to the point that they can no longer be recognized as similar. This has meant that, while it is possible to construct phylogenetic trees based on protein sequences from closely related viruses, there is little hope of inferring the deep evolutionary history of viral proteins or their associated viruses based on sequence comparisons alone. Happily, this situation has changed somewhat with the advent of structural information about viral proteins—mostly virion structural proteins—in recent years.

The capsid *hexons* of bacteriophage PRD1 (*Tectiviridae*) are homotrimers of a protein subunit that has two domains, each of which is a β-barrel of the *jelly-roll* type.[11] Each of the jelly-rolls occupies a position in the capsid lattice that would be occupied by a single capsid protein subunit in a classical Caspar-Klug structure. The high-resolution structure of the PRD1 hexon was a surprise when it was first determined because the aforementioned description applies equally well to the hexons of adenovirus.[16] The similarity extends to the protein folds of the two hexon proteins, and this has led to the inference that these two proteins may share common ancestry, despite the fact that their amino acid sequences no longer share any detectable similarity. The same double jelly-roll fold has been found subsequently in eukaryal viruses PBCV1 (*Phycodnaviridae*) and Mimivirus (*Mimiviridae*); Sulfolobus turreted icosahedral virus (STIV; *Rudiviridae*), which infects the hyperthermophilic archaeon *Sulfolobus;* and bacteriophage PM2, arguing that this diverse and sequence-dissimilar group of capsid proteins also shares in the PRD1 and adenovirus ancestry.

The tailed phages (*Caudovirales*) have a capsid protein with a very different fold, typified by that of *E coli* phage HK97.[217] Evidence to date indicates that this fold is shared across most of the tailed phages, including those that infect archaeal hosts, often in the absence of detectable sequence similarity. It also appears that this same "HK97 fold" makes up the shell-forming domain of the herpesvirus capsid protein, arguing for a common ancestry with the tailed phage capsid proteins for the herpesvirus protein as well.[102] The case for common ancestry between tailed phage and herpesvirus capsid proteins is bolstered by shared mechanisms of capsid assembly and DNA packaging, including faint but convincing sequence similarity between the DNA-packaging proteins of phage T4 and herpes simplex virus. A third capsid protein fold reaching across host domains includes phage φ6 (*Cystoviridae*) and the reoviruses of plant and animal hosts. These viruses have double protein shells; the inner shell has the noncanonical T = 2 structure with a novel protein fold and the outer shell is a T = 13 shell of single jelly-rolls.[165] Together these observations lead to the view that these viruses define at least three viral lineages, or perhaps more properly three viral capsid lineages, whose hosts span all three domains of cellular life (Fig. 21.14). A simple (but not yet firmly established) interpretation is that viruses with the basic capsid characteristics of these contemporary viral lineages had already evolved by the time of the last common cellular ancestor of the cellular domains of life. There are of course viruses with icosahedral capsids but without any of the capsid protein folds of these three lineages,

for example, the *Leviviridae* (small ssRNA genomes) among phages. The capsid protein folds associated with these other viruses are thus far associated only with hosts within one cellular domain, and it will be interesting to see how that situation changes as more viruses are identified and characterized. There are also other examples of virion protein structural similarities among very different virus types. For example, fibers that protrude from the icosahedral vertices of adenoviruses and tectiviruses, as well as fibers that extend from some phage tails, have knobs at the distal tips. The polypeptide folds of these three knobs are sufficiently similar to suggest a possible common ancestry.[21]

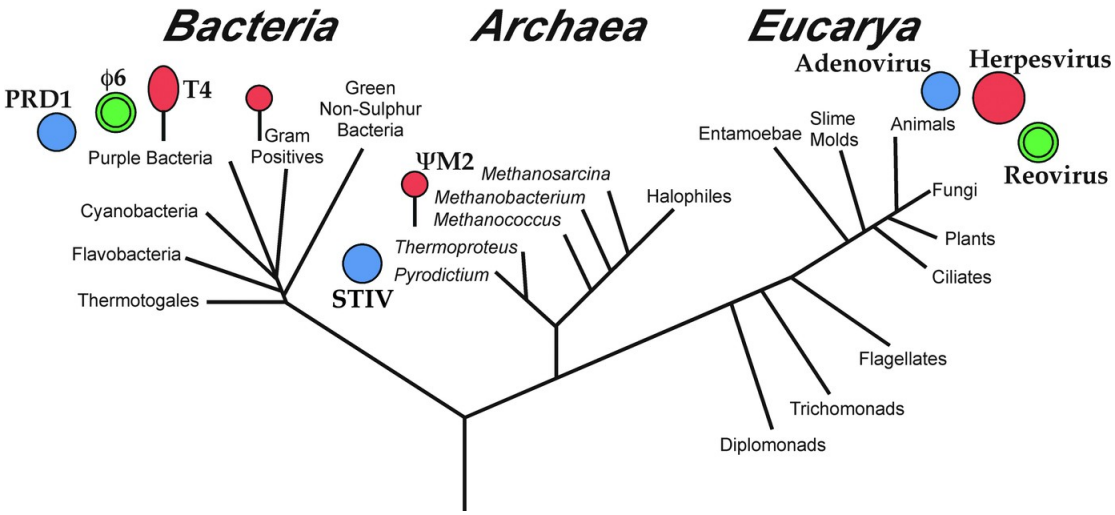

FIGURE 21.14 **Deep evolutionary connections among viruses**. The tree represents the tree of cellular life. The colored symbols represent the indicated viruses, placed near their cellular hosts. Shared color indicates shared "viral lineage," as deduced from shared structural features of the virions.

Phage Parts in other Contexts

Structures are occasionally found in bacterial or archaeal cells that bear a structural resemblance to virions—or parts of virions—of the tailed phages. For the examples given here, examination of the polypeptide folds of the components of the structures, and in most cases, comparisons of their amino acid sequences, makes a strong case for common ancestry shared by the virions of tailed phages and these "cellular" structures.

Pyocins

The pyocins are a class of high-molecular-weight bacteriocins encoded in the genomes of some *Pseudomonas* strains.[142] They have the morphology of phage tails, either contractile or not, and they kill sensitive cells after they are released from the cell that encodes them, apparently by making holes in the cell envelope and causing collapse of the cellular membrane potential. The genes encoding the pyocins have close sequence similarity to the tail gene operons of well-studied phages—*E coli* phages P2 (contractile tail) and λ (noncontractile tail), respectively—in the well-characterized cases of the R2 and F2 pyocins of *P aeruginosa*.[142] The high sequence similarity between the respective pyocin and phage tail operons bespeaks an evolutionarily recent common ancestry.

Gene Transfer Agents

Gene transfer agents, or GTAs, were discovered as a generalized transducing activity in cultures of *Rhodobacter capsulatus*.[124] They were subsequently shown to be small particles with the morphology of a tailed phage that package short (4.5-kbp) pieces of DNA derived from apparently random locations around the *R capsulatus* genome. GTA-like particles with similar properties have been identified in several other bacterial and archaeal species, but the *R capsulatus* GTAs are the best characterized. The GTA particles are encoded by a ~14-kb-long operon of genes in the *R capsulatus* genome. In both gene organization and sequence similarity, the genes of this operon strongly resemble the head and tail genes of a tailed phage with a noncontractile tail. The GTA operon bears some resemblance to a prophage, and it may well have derived from one, but it is not a conventional prophage that has suffered deletion of its nonvirion assembly genes for at least two reasons. First, the heads of the particles can only package the equivalent of about one-quarter of the genes that encode the particle. Second, expression of the GTA genes is under the control of a cellular two-component system that senses conditions outside the cell. It appears that the cell may have co-opted the GTA genes to serve its own purpose. What that purpose might be is not known, but a plausible possibility is that the GTA particles are genetic repair kits, sent from one cell to other cells in the population, to save the population from the ravages of Müller's ratchet.

Encapsulins

The encapsulins are a recently described group of subcellular shells found in both bacteria and archaea.[52] In cases where their function has been inferred, they enclose and sequester biochemical reactions that produce potentially harmful reactive intermediates. The shells are icosahedral structures, T = 1 or T = 3, made of protein subunits that bear clear homology to the phage HK97 family of capsid proteins, based both on close structural similarity and on a low but unequivocal level of amino acid sequence similarity. The genes encoding the encapsulin subunits are not associated with any other phagelike genes in the cellular genome.

Type VI Secretion Systems

Recent structural studies of the proteins of the needles of the *Pseudomonas* and *Edwardsiella* type VI secretion systems (T6SS) show that the

major subunits of the needles have the same polypeptide fold as the tail tube protein of phage T4 (gp19), despite a lack of recognizable shared sequence.[101] This is taken to suggest a common ancestry for the two proteins and, by extension, possible common ancestry for the phage tail and the T6SS apparatus.[14] A parallel study with the phage λ tail tube subunit, gpV, shows that it shares the gp19 fold, arguing that the common ancestry inferred for the tail tube of a contractile tailed phage and the T6SS needle extends to the noncontractile phage tails as well.[160] Recent structural studies have identified a long contractile structure, resembling an exceptionally long contractile phage tail, in cells indulging in type VI secretion[122] (Fig. 21.15). This structure assembles in the bacterial cell as it is preparing for secretion and disassembles after. It appears to drive the T6SS needle into the target cell by contraction of the sheath, just as a contractile phage tail drives the tail tube through the envelope of a target bacterium.[35]

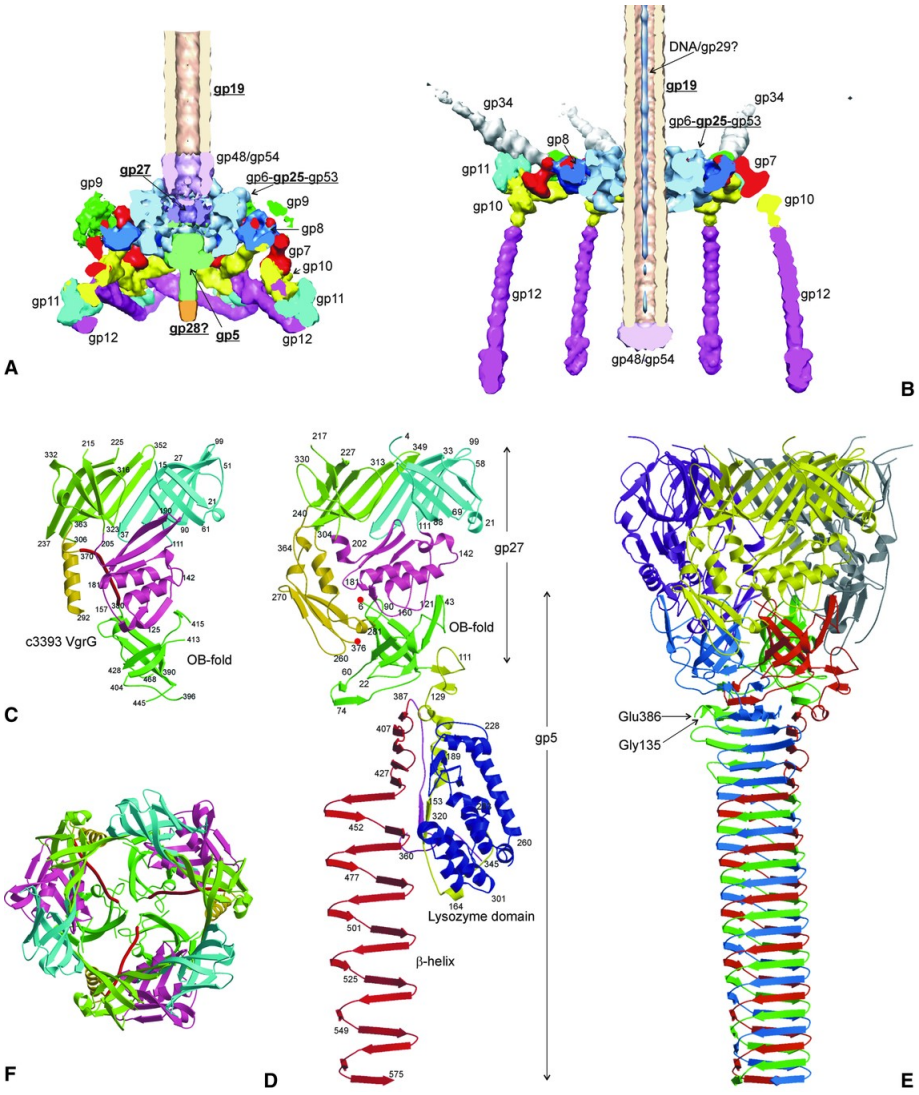

FIGURE 21.15 **Structure of the bacteriophage T4 baseplate and comparison of the *Escherichia coli* CFT073 c3393 VgrG with its T4 homologs, gp5 and gp27**. Cryoelectron microscopy (cryo-EM) reconstructions of the T4 baseplate before **(A)** and after **(B)** attachment to the host cell. Component proteins are labeled with their respective gene numbers. The T6SS protein homologs are highlighted in bold and underlined. **C**. The crystal structure of the c3393 VgrG. Different domains are colored in distinct colors. The gp27 tube domains are colored cyan and light green. The fragment of the polypeptide chain connecting the gp27 and gp5 modules is shown as a thick red tube. **D**. The structures of gp5 and gp27 monomers extracted from the (gp5)3-(gp27)3 complex. The terminal ends of the gp5 and gp27 polypeptide chains, which become fused in the VgrG structure, are highlighted with *red dots*. **E**. A model of the prototypical VgrG is created from the entire (gp5)3-(gp27)3 complex by removing the lysozyme domain. **F**. End-on view of the crystal structure of the c3393 VgrG trimer. (Reprinted with permission from Leiman PG, Basler M, Ramagopal UA, et al. Type VI secretion apparatus and phage tail-associated protein complexes share a common evolutionary origin. *Proc Natl Acad Sci U S A*. 2009;106(11):4154-4159.)

In all of these cases, there seems little doubt that the structural proteins of phages and the corresponding proteins of phagelike structures in bacterial and archaeal cells share common ancestry. A simple and generally accepted explanation for this relationship is that a group of phage genes has been captured by the host cell, possibly from a resident prophage, and placed under a regulatory scheme that benefits the host. In this view, such acquisition of phage virion structural genes is simply an example of the more general phenomenon of cells acquiring “phage” genes and converting them over time into “cellular” genes. The difference in the case of the structural genes is that they are more easily recognized as being of phage origin, even after mutational drift has eliminated any detectable sequence similarity. However, despite the plausibility of tailed phages as the progenitors of the cellular structures enumerated earlier, there is no formal proof that the arrow might not go in the other direction—that is, that T6SS needles, for example, might be the ancestors of phage tails!

Host Interactions

The essence of being a virus is interacting with the host, and these interactions influence both virus and host. We will consider some examples of interactions between phages and bacteria in three somewhat artificial and overlapping categories.

Parasitic Interactions

Phages hijack their hosts' biochemical machinery, usually to the detriment of the host, and as in other areas of virology, understanding how these interactions work often tells as much about the cell as about the virus. The ways these interactions are carried out are as varied as the phages doing them; we give examples here of some of the better-studied cases.

DNA Replication

Some phages such as phage T4 encode all the proteins needed to replicate the phage genome. These form a complex that replicates the phage DNA with a preference for the modified cytosine nucleoside that T4 uses in place of cytosine. At the same time other phage-encoded enzymes are degrading the host DNA and recycling the nucleotides (in conjunction with some host nucleotide metabolism enzymes) for use by the phage replication machine. *Bacillus* tailed phage SPO1 has at least nine genes required for phage DNA replication but appears to be lacking some of the complete set of replication genes that a phage like T4 has.[194] SPO1 uses hydroxymethyl uracil in its DNA in place of thymine, and the phage encodes several enzymes with roles in depleting thymine pools and synthesizing hmU, and the phage-encoded DNA polymerase has an extra domain that is proposed to help it recognize the hmU-containing template. Many phages use the complete host replication machinery, synthesizing only the proteins needed to recruit the replication complex to the phage DNA template. An example is phage λ, which makes two replication-specific proteins, one of which (gpO) binds the phage replication origin and one (gpP) that recruits the host replication helicase, and through it the rest of the host replication complex, to the phage origin.[203] Unlike T4, λ does not degrade the host DNA, presumably because doing so would preclude the possibility of forming a lysogen. Phage φX174 also uses the host replication machinery. However, unlike the host and unlike most other phages, it uses the host transcription RNA polymerase to lay down the RNA primers at the start of new DNA chains, rather than primase, the specialized RNA polymerase that usually carries out the priming function. For technical reasons, this peculiarity of φX174 facilitated the original discovery that RNA primers have a role in DNA replication. The ssRNA phage MS2 encodes a replicase protein, but to replicate the RNA it co-opts the activities of three cellular proteins (EF-Tu, EF-Ts, S1) that normally interact with RNA but to very different ends.

Transcription

Most DNA phages use the host RNA polymerase for some or all of their transcription. They often achieve temporal separation of different classes of transcripts by successive modifications of the host polymerase. For phage λ the transition from *immediate early* to *early* transcription is mediated by the immediate early antitermination protein gpN, which interacts with the nascent RNA transcript and the RNA polymerase to render the polymerase able to read through termination signals.[175] The transition from *early* to *late* transcription is mediated by another antitermination protein gpQ, acting by a different mechanism. Phage T4 makes covalent modifications to the host polymerase early in infection and adds a phage-specific sigma factor to the polymerase to effect the transition to late transcription.[96] Phage T7 transcribes its early genes with the host RNA polymerase, but one of these genes encodes the phage RNA polymerase, which is responsible for subsequent transcription of phage genes. Another early gene of T7 encodes a kinase that inactivates host transcription by phosphorylation of the host RNA polymerase.[141] A phage that flouts all the normal conventions for organizing transcription is *E coli* phage N4. N4 packages a few copies of a *virion RNA polymerase* in the virion with the DNA, and they are injected into the cell along with the DNA.[60] The virion RNA polymerase transcribes the early genes, some of which encode a second (phage-encoded) RNA polymerase that transcribes the middle genes. The middle genes include genes supporting phage DNA replication and also an ssDNA binding protein, which interacts with the late promoters in such a way that they can be read by the unmodified *E coli* $\sigma(^{70})$-RNA polymerase!

Translation

All phages, like all viruses, use the host translation apparatus to make their proteins. For the most part the phages appear to use it in unaltered form, though they do make use of some of the "special abilities" that ribosomes have beyond the textbook descriptions of translation. These include programmed translational frameshifts (many phages), a 50-nt ribosomal "hop" (phage T4), a few examples of regulation of gene expression at the level of translation (phage T4), and the extensive examples of regulation of translation described earlier in the section on the *Leviviridae* (the ssRNA phages).[98,223] For many tailed phages, particularly (but not exclusively) those with larger genomes, there is suggestive evidence that they also make specific alterations to the host translation apparatus. The most frequently encountered support for this assertion is in the form of phage-encoded tRNAs. Although the majority of characterized phages do not encode any tRNAs, there are many that do. The numbers of apparent tRNAs per genome in this group range from 1 to >30, with their genes usually arranged in one or more clusters on the genome. Some of these putative tRNAs give high scores in tRNA search programs trained on cellular tRNAs and some do not, and in only a few cases have they been tested and shown that they can actually function as tRNAs. It has been suggested that the purpose of the phage-encoded tRNAs is to adjust the tRNA pools in the infected cell to better serve the needs of phage translation, but they may have other roles that are not yet identified. Several phages have been found to carry a copy of a transfer-messenger RNA (tmRNA), the RNA found in prokaryotes with features of both tRNA and mRNA and a role in releasing stalled ribosomes from mRNA. Finally, phage G of *Bacillus megaterium*, the phage with the largest genome known at 498 kb, has one aminoacyl tRNA synthetase.[90] This last feature is reminiscent of the very large Mimiviruses, which also carry aminoacyl tRNA synthetases for which the biological role also is not known.[50] These observations taken together make a strong case that some phages modify the host translation machinery, but there is as yet little specific information about how or to what end they might actually do this.

Other Cellular Machinery

Phages rely on their hosts for energy metabolism. They also typically use the cellular biosynthetic machinery to make precursors for macromolecular synthesis, but a number of phages encode enzymes with roles in nucleotide metabolism. When these are present, they typically act in conjunction with cellular enzymes of nucleotide metabolism. Two of the most easily recognized and frequently found nucleotide metabolism genes in phages encode ribonucleotide reductase and thymidylate synthetase. To date, there is no evidence of phages participating in amino acid biosynthesis, nor of phages incorporating noncanonical amino acids into their proteins. For phages with lipid membranes in their

virions, the lipids appear in all cases to be derived from the cellular membrane.[3]

Phages also make use of host chaperone proteins, and in fact some of the most important of these were discovered because of their roles in the life cycles of phages λ and T4. The *E coli* DnaK and DnaJ proteins (also known as Hsp70 and Hsp40) were found to be required for λ DNA replication, where they partially disassemble the replication initiation complex and allow the replication machinery to leave the origin and begin synthesis. GroEL and GroES (Cpn60 and Cpn10) are required for accurate assembly of phage λ heads, now understood as a consequence of their role in mediating correct folding of some of the head proteins. GroEL is also required for phage T4 head assembly because of its role in folding the major capsid protein gp23. The gp23 subunit is apparently slightly too big to fit into the GroE folding cavity with the GroES "lid" in place, and T4 encodes its own homolog of GroES, gp31, which leaves enough more space in the cavity for successful folding of gp23. We note that these two chaperones, now known as the hsp70 (DnaK) and hsp60 (groE) systems and known to be very important and present in virtually all organisms, were originally discovered in work designed to understand the molecular nature of these phage infections.

Phages interact in significant ways with cellular structures, particularly the cell wall and membranes, during cell entry and exit. The *Leviviridae* (ssRNA, icosahedral) and *Inoviridae* (ssDNA, filamentous) of *E coli* bind to the sides and tip, respectively, of the F pilus, and they are thought to be brought to the surface of the cell for further interactions by retraction of the pilus. The tailed phages Cb13 and CbK of *Caulobacter crescentus* have helical tail fibers that wrap around the shaft of the bacterial flagellum.[82] This makes an interaction that is apparently able to slide along the helical flagellum, and when the flagellum rotates in the appropriate direction the phage is screwed down to the surface of the cell where it interacts with a cell surface receptor.

Antagonistic Interactions

Phages and their bacterial hosts engage in ongoing "biological warfare" in which mutations arise in the bacterium that block successful lytic growth by the phage, which in turn creates a selective advantage for phages with mutations that overcome the block. The best-known examples are mutational changes that affect the binding between the virion and its receptor on the surface of the cell. In the tailed phages, a single amino acid change in the tail fiber protein can be sufficient to restore binding to a recalcitrant cellular receptor, but bigger changes occur as well. The parts of tail fiber genes that encode the receptor-binding part of the tail fiber often show evidence of recent horizontal exchange, and in some phages rapid changes of sequence, specifically in tail fibers, are programmed into the phage genome, as in the examples of phage Mu and phage BPP-1.[137,184] The biological warfare continues after the phage has successfully gotten its genomic DNA or RNA into the cell. Many examples could be given; a particularly piquant example comes from the *prrC* gene of *E coli*. The product, PrrC, is a nuclease that cuts in the anticodon loop of the cellular $tRNA^{Lys}$, inactivating it and so inhibiting protein synthesis in the cell.[207] PrrC is ordinarily held in an inhibited form, but infection by phage T4 causes its release in active form, whereupon it cleaves this tRNA. The "purpose" of the cleavage is evidently to prevent the phage from making virions that could infect other cells in the population. However, T4 encodes two enzymes, polynucleotide kinase and RNA ligase, that counter this host defense by repairing the tRNA. Relatives of T4 that lack the repair enzymes are unable to grow on *E coli* strains that carry *prrC*. A more widely distributed host defense is the CRISPR system, sometimes referred to as bacterial (and archaeal) adaptive immunity.[62] Cells with a CRISPR system have a mechanism to collect an array of short (~25-bp) DNA sequences derived from phages of past infections (which the ancestral cells evidently survived). When a phage that has an exact match to one of the sequences in the CRISPR array infects, it is inactivated by a mechanism that may have some features in common with the eukaryotic small interfering RNA (siRNA) mechanism. Phages can escape CRISPR surveillance if they acquire as little as a single nucleotide change in the sequence being recognized.

Symbiotic Interactions

When a phage enters the lysogenic cycle and becomes a prophage, most of the genes are repressed by the repressor protein. However, some phage-encoded proteins continue to be made from the repressed prophage—most obviously the repressor protein itself—and the list of other proteins expressed from an otherwise repressed prophage is growing.[25] These proteins all have the potential to cause lysogenic conversion of their host cell, that is, a change in cell phenotype as a consequence of the protein's expression. In many cases, the biological function of these lysogenic conversion genes is not known, but when it is, it can typically be construed as providing a selective benefit to the host cell in which the prophage resides. Thus, the phage λ prophage expresses the repressor and three other proteins, SieB, RexA, and RexB, each of which protects the cell from infection by certain other phages, and it also expresses two proteins, Bor and Lom, which are thought to make the lysogenic cell better able to parasitize a mammalian host.[13] Other such proteins are described later. It has been suggested that these lysogenic conversion genes do not provide a selective benefit to the phage directly but instead provide a selective benefit indirectly by providing a direct benefit to the lysogenic cell in which the prophage is being replicated. In other words, the lysogenic conversion protein is the rent the prophage pays to its host. It may also be that lysogeny provides a rather efficient pathway for the bacterium to acquire novel beneficial genetic functions. That is, as random deletions occur over time in the bacterial chromosome, any that remove one of the beneficial lysogenic conversion genes will be counterselected, whereas deletions that remove other parts of the prophage will be either neutral or selected. Over time, only the beneficial genes will remain as part of the bacterial genome.

One of the best-studied groups of lysogenic conversion genes is the group of prophage genes known to encode toxins produced by bacterial pathogens.[34] The toxins of the human diseases botulism, diphtheria, cholera, and hemolytic uremic syndrome (HUS), among others, and the animal disease ovine foot rot, are encoded by prophage genes. The Shiga-like toxin encoded by *E coli* 0157:H7, the causative agent of HUS, is of particular interest. This toxin is expressed at low levels from its own promoter, but the higher levels of toxin required to produce severe disease are only made when the prophage is induced and the toxin is produced under the control of the phage's strong late promoter.[206] Some antibiotics cause induction of this prophage, and for this reason antibiotic treatment is contraindicated for this infection. The cholera toxin case is also noteworthy in that the toxin is carried on a prophage of a filamentous ssDNA phage of the *Inoviridae* family.[59] All the other known examples involve prophages of the tailed dsDNA phages of the *Caudovirales* order.

Because studies of lysogenic conversion have been carried out by human biologists, it is not surprising that some of the best-studied examples of lysogenic conversion involve toxins of human pathogens. However, it is unquestionably true that there are prophages supplying selectively beneficial functions to their host bacteria (and host archaea) in virtually all of the ecological situations where these cells find themselves.

Phage Communities and Ecology

Every gram of soil and sediment, every milliliter of water, and the surfaces and insides of plants and animals are hosts to extensive and diverse

phage and bacterial communities. We now know that these environmental phage communities contain most of the uncharacterized genetic diversity on Earth. And because of their rapid killing of large numbers of bacteria, they strongly influence the flow of carbon, phosphorus, and other elements within the biosphere.

Metagenomic analyses of viral communities, also called viromes, have shown that 1 kg of marine sediment may contain over a million different phage genotypes (roughly equivalent to a species).[23] Similarly, there are hundreds of thousands of viral species in the ocean and soils.[72] Viromes from stool samples show that most of the genomic differences between individual humans are gut-associated phages.[173] There are even phages in our blood.[76]

Phage could potentially protect against pathogens by killing them, but phage may actually be the causes in others. For example, many bacterial pathogens are actually lysogens and their prophages carry the disease-causing genes. For example, the common mouth microbe *Streptococcus mitis* carries the prophage SM1. When induced, the phage SM1 virions carry modified tail fibers known as pblA and pblB, which "glue" *S mitis* cells together and to platelets. If this happens in the blood, say, after tooth cleaning, then the phage-platelet-microbe blob can cause endocarditis. Scarily, the phage SM1 is induced by soy sauce and other more commonly ingested substances; eat up[220]!

Bacterial communities in the environment are often controlled in a top-down manner; that is, there is more food available than the microbes use.[56,218] This occurs because they are killed off by phage and other predators like unicellular protists. The continuous predation by phage leads to "kill the winner" dynamics, where one phage kills so much of a particular bacterial strain that another strain grows up in the unoccupied niche. This means that the dominant bacterial strain within an ecosystem will be constantly changing. Recent work has shown that kill-the-winner dynamics does not change the species of bacteria; rather, it causes cycling of different strains.[177]

Our understanding of phages in the environment is in its infancy. At this point we know that there are almost unimaginable numbers of them, and they contain most of the uncharacterized genomic diversity on the planet. It is clear that to maintain the observed steady state, phages are influencing both the types and replication of bacteria, and it is also clear that there is an amazing, essentially unexplored world of phage diversity to be studied.

Prospects for Therapeutic Uses of Phages

The idea of using phages to control human bacterial infections was recognized by d'Herelle soon after their discovery around 1917. Only 30 years earlier the germ theory of disease was becoming accepted, and the rules for etiology established by Koch. A vigorous search for cures based on killing bacterial pathogens began in the late 19th century, and there were numerous false claims of success, including Koch's assertion of tuberculin as a cure for consumption.[221] Thus, the possibility of using d'Herelle's newly discovered phages therapeutically would have been a welcome and timely discovery, coming still several years prior to Fleming's penicillin (1928) or Schatz and Waksman's streptomycin (1943), and the widespread introduction of antibiotic therapies in the 1940's.

Nonetheless, the therapeutic use of bacteriophages ("phage therapy") has been a turbulent subject for the past 100 years. D'Herelle's research, together with that of George Eliava, in Tbilisi, Georgia prompted broad use of phage therapy in the former Soviet Union, although it was not adopted early in the United States and Europe, and became largely ignored with the widespread use of antibiotics.[197] Phage therapies were likely successful for at least some infections in the early days in the USSR, although the literature is sparse and mostly in Russian; double-blinded randomized clinical trials are rare or not easily accessible. After several hiatuses phages are still provided for treating infections in Tbilisi, in Poland, and elsewhere.[227] Some of the most important lessons emerging from these experiences are that "success" often depends on isolating and propagating phages on a specific pathogenic strain.

General interest in the therapeutic use of phages has cycled over the past 30 years, partly in response to the growing limitations of antibiotic control of bacterial infections balanced against the challenges in advancing phage therapeutic use.[84] Over the past 5 years, there has been more intense interest in light of the growing severity of antibiotic resistance and some successful case studies. In addition, innovations in the biotechnology community supporting intellectual property protections and promoting financial investment are fueling new approaches towards therapeutic success. Nonetheless, the future of phage therapy remains unclear, with considerable uncertainty over its broad applicability but some confidence that phage treatments have important roles to play.

Three recent examples of successful therapeutic use of phages illustrate notable advances. First is the use of phage cocktails to treat a highly antibiotic resistant disseminated infection of *Acinetobacter baumannii*.[188] The case is notable because of personalization of the phages for specificity against the particular bacterial isolate, the use of multiple cocktails to counter resistance, the likely interaction between the phages and ongoing antibiotic therapy, and safe intravenous administration. The patient was sufficiently sick and antibiotics sufficiently inept that he would have surely died without phage intervention. Enthusiasm should be tempered before concluding that phage therapies are a general treatment for *A baumannii* infections, but it suggests strongly that phages may be an important component of treatment options. Although there were no adverse reactions to the phage treatment in this case, it was essential that the level of contaminating lipopolysaccharide endotoxin be reduced to avoid severe complications following IV administration.

The second case is the use of phages to treat a highly antibiotic-resistant *Mycobacterium abscessus* infection in a pediatric cystic fibrosis patient who was immunosuppressed following a bilateral lung transplant.[61] This was the first successful use for treating any *Mycobacterium* infection with phages and has implications not only for the treatment of nontuberculous *Mycobacterium* (NTM) infections but potentially for human tuberculosis, a disease that afflicts many millions of people across the globe.[81] In this case it was also necessary to personalize the phage cocktail to the patient's isolate, and the phages were administered intravenously without adverse reactions. This case is also notable as it was the first therapeutic use of engineered phages. Most of the phages infecting *Mycobacterium* pathogens are temperate and thus unsuitable for therapy. However, tools for efficient engineering of mycobacteriophages have been developed[134,215] facilitating precise removal of the repressor and integrase genes, converting these to lytic phages with therapeutic utility.

In the third case, phages were used to treat an aortic arch prosthesis with a severe *Pseudomonas aeruginosa* infection that was unresponsive to antibiotics.[45,46] This case is notable because the phage used (OMKO1) was chosen as it binds to an outer-membrane efflux system, and loss of the efflux system contributes to phage resistance, while sensitizing the bacteria to several antibiotics. The phage also disrupted *P aeruginosa* biofilms on the implant surface. Treatment was successful, and the implant remained sterile after cessation of phage and antibiotic treatments.

These examples are among many suggesting that bacteriophage treatments have a role to play in the control of bacterial infections. What that role is remains unclear, although it will almost certainly differ for different infections and different pathogens.[1,84] If it restricted to personalized treatments of last resort it will be relatively expensive and challenging to bring to the marketplace. A broader utility—working together with antibiotics and helping to minimize the emergence of antibiotic resistance—is likely achievable for at least some infections but will require an understanding and management of phage host range and the bacterial mechanisms of phage sensitivity and resistance.

Acknowledgments

This work is a revised version of that written previously by my colleague Roger Hendrix, who died unexpectedly in 2017. Much of the text was written by Roger and has been only modestly revised. I am very grateful to our colleagues who contributed to the prior version, and who have continued in this one: Dennis Bamford (*Tectiviridae* and *Corticoviridae*), Sherwood Casjens (P22, P1, and N15), Gail Christie (P2 and P4), Eric Miller (T4), Bob Duda (HK97), Paul Jardine and Shelley Grimes (ø29), Andreas Kuhn (*Inoviruses*), Minna Poranen (*Cystoviridae*), and Forest Rohwer (communities and ecology). Sankar Adhya, Anastasia Aksyuk, Nicola Ambrescia, Ben Fane, Andrey Fokin, Burton Guttman, Betty Kutter, Petr Leiman, and Dale Lewis assisted with figures. I am also grateful to Sherwood Casjens for comments on the manuscript.

Prions Are Alternative, Transmissible States of Proteins

Prions are protein-based infectious or transmissible agents that, unlike viruses and other pathogens, lack a specific nucleic acid genome.[312] Prominent examples of prion diseases in mammals include Creutzfeldt-Jakob disease (CJD) in humans, bovine spongiform encephalopathy (BSE) in cattle, scrapie in sheep and goats, and chronic wasting disease (CWD) in cervids such as deer and elk. Usually, prions are nonnative forms of host proteins that replicate themselves by converting their normal counterpart to the prion state. As has been described in fungi, prions also include epigenetic elements of inheritance comprising altered forms of host proteins that, when transferred to a new host, can replicate and cause a heritable phenotypic change in the recipient (see Chapter 20).[408] Most prions cause disease in the host, but some have physiological roles.[409] Although prions do not carry any nucleic acid code for themselves, a susceptible host must make the normal precursor protein from which the infectious prions are made. Many proteins can refold and/or assemble into ordered aggregates that can seed further growth under certain natural or experimental conditions, whether *in vivo* or *in vitro*.[94] Indeed, many normal macromolecular assemblies within organisms grow by such mechanisms. However, most such protein assemblies are not, strictly speaking, prions because the prion concept implies that the altered state of the protein can propagate between individuals, or at least from cell-to-cell within a multicellular host. In this chapter, we review many aspects of mammalian prion structure and biology but, given space limitations, we have only been able to include representative primary references or reviews of the literature.

Evolution of the Prion Concept

Perhaps the earliest descriptions of a prion disease were in the 1700s when scrapie was observed as a peculiar fatal affliction of sheep.[54] An obvious manifestation of scrapie was a desire to scrape against abrasive objects, presumably due to itching in the skin. Later studies early in the 20th century indicated that scrapie is transmissible and can remain contagious in vacant pastures for years. Scrapie infectivity was found to be unusually resistant to treatments that destroy other types of pathogens, leading to proposals in the 1960s that it may be an abnormal self-replicating form of a protein or membrane that lacks its own nucleic acid genome.[7,161,305] In 1957, Vincent Zigas and D. Carleton Gajdusek travelled to Papua New Guinea to study a rapidly fatal neurodegenerative disease affecting the Foré people. This disease was called "kuru," which means "to shiver," as the symptoms included startle myoclonus. It was primarily affecting women and children, and the cause was unknown. A neuropathology exhibit on brains from kuru patients was presented in London in 1959, where William Hadlow, a veterinarian pathologist, attended. Hadlow had experience with the transmissible spongiform encephalopathy "scrapie," which affects sheep, and he noted the similarity between the spongiform changes seen in kuru brains and those seen in scrapie. He proposed that kuru might also be transmissible.[164] This was subsequently proven for both kuru[141] and CJD.[152] It was then determined that the transmission of kuru was through funeral cannibalistic practices, with higher titer tissues (brain) being preferentially given to women and children, hence the higher incidence in these groups.[229] These observations earned Gajdusek a Nobel Prize in 1976. Complicating epidemiological studies of kuru and other prion diseases are the long incubation periods between the initial infection and the appearance of clinical signs, which, in humans, can exceed four decades. Such prolonged incubation times, together with the small minimum size of the infectious particles, led many in the field at the time to refer initially to these agents as "slow viruses."

In 1981, Patricia Merz and colleagues identified abnormal scrapie-associated fibrils (SAF) in subfractions of brain from scrapie-infected animals.[273] Soon thereafter, Stanley Prusiner and colleagues identified a protease-resistant protein ("PRP") that turned out to be the main component of both SAF and scrapie infectivity,[47,315] which Prusiner dubbed *prions*.[47,311,315] PRP then became PrP, an abbreviation for prion protein. The Prusiner, Charles Weissmann, and Bruce Chesebro laboratories cloned the PrP gene (*Prnp*) from hamsters and mice and showed that it was present in both infected and uninfected rodents.[88,235,289] PrP was then shown to undergo a posttranslational conversion in infected hosts from a detergent-soluble, mainly monomeric, protease-sensitive, and α-helical form (named PrP^{C} for "cellular PrP," details to follow) into a usually aggregated, insoluble, and partially protease-resistant state that is high in β-sheet structure (named PrP^{Sc} for "PrP-scrapie") (Fig. 22.1).[49,79,82,300] Additional studies identified many mammalian homologs of PrP that are the main components of abnormal aggregates associated with other transmissible scrapielike neurodegenerative disorders of humans and other animals.[267] These diseases are now known as prion diseases or, with reference to the frequently observed spongelike neuropathological lesions, transmissible spongiform encephalopathies (TSEs).

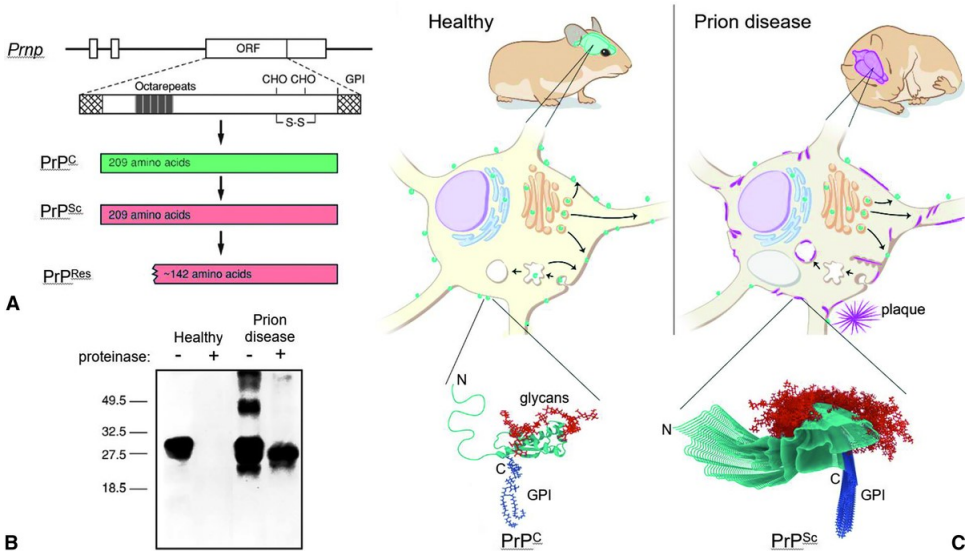

FIGURE 22.1 **Prion protein isoforms**. **A**. Diagram of the Syrian hamster PrP (prion protein) gene (*Prnp*) that encodes a protein of 254 amino acid residues. After biosynthetic processing of the N- and C-termini, both PrP^{C} (PrP-cellular) and PrP^{Sc} (PrP-scrapie) consist of 209 residues. Among the basic features of mammalian PrP molecules are a series of octapeptide repeats (octarepeats), a disulfide bond (S-S), two N-linked glycosylation sites (CHO), and a C-terminal glycophosphatidylinositol (GPI) anchor. After limited proteolysis of PrP^{Sc}, a core of ~142 residues (PrP^{Res}) remains. **B**. Immunoblot of brain homogenates from healthy and prion-diseased hamsters with and without prior proteinase K treatment. PrP^{C} was completely degraded as shown in the healthy homogenate, whereas only ~67 residues were removed from the N-terminus of PrP^{Sc}. Molecular weight markers (kD) are located on the *left*. **C**. In healthy mammals, PrP^{C} (*aqua*) is usually a membrane-bound monomer expressed in many cell types but particularly abundant in neurons. It has a flexible N-terminal domain (drawn shorter than actual scale relative to rest of molecule) and a folded C-terminal domain with three helices, up to two glycans (*red*), and a GPI membrane anchor (*blue*) on the end. In diseased mammals, monomeric PrP^{C} is converted to PrP^{Sc} (*magenta* in the cell cartoon), which is usually found as membrane-bound multimers (see later sections) but can sometimes escape the membrane environment to form extracellular plaques. (**A** and **B** adapted from Figure 76.1A and B in Prusiner SB. Prions. In: Knipe DM, Howley P, eds. *Fields Virology*. Vol 2. 6th ed. High-resolution structure and strain comparison of infectious mammalian prions. *Mol Cell*. 2021;81(21):4540-4551. e6. Copyright © 2021 Elsevier, with permission.)

Prion Replication and Strains

The evidence for PrP being fundamental to prion disease continued to build, with Weissmann and others showing that PrP is an essential susceptibility factor for prion diseases.[60] Prusiner won a Nobel Prize in 1997 for his contributions. In addition, human familial prion diseases were linked to expression of various mutant PrPs (see below). Yet the fact that prion diseases could present with distinct phenotypes, neuropathologies and incubation periods led to the recognition of distinct prion strains.[58,197] Furthermore, the consistent propagation of divergent prion strains in hosts with the same PrP sequence raised the question of what "encodes" prion strain characteristics when the gene involved is invariant.

Early in the 1990s, Richard Bessen and Richard Marsh reported evidence that abnormal PrP aggregates that accumulated in hamsters infected with different prion strains had different conformations, providing a potential basis for prion strain variation.[44] Concurrently, the Byron Caughey and Peter Lansbury laboratories found collaboratively that disease-associated aggregated forms of PrP could themselves induce the conversion of normal PrP molecules to abnormal forms *in vitro*.[74,204] These findings provided direct biochemical evidence of the self-replicating activity of the prions. Such prion-induced conversion reactions also exhibited profound biochemical specificities that suggested molecular mechanisms for known prion strain characteristics and transmission barriers between different host species.[43,205,324] However, the yields of the initial cell-free PrP conversion reactions were substoichiometric, and the subsequent development of continuous cell-free prion amplification or *de novo* prion formation reactions, primarily by the Claudio Soto, Surachai Supattapone, and Prusiner laboratories in the 2000s, was crucial to prove unequivocally that prions were composed of refolded PrP aggregates without any requirement for prion-specific, coding nucleic acids.[71,98,118,223,334] There are now many lines of evidence that support the hypothesis that faithful propagation of distinct PrP^{Sc} conformers underpins the existence of prion strains within a given type of host.[33,122,212,352] There is also evidence that nonprotein cofactors, for example, nonspecific nucleic acids, sulfated glycosaminoglycans, or phospholipids, can influence PrP conformational conversions[80,117,140,169,371,402,417,419] and modulate host susceptibilities or disease phenotypes. Notably, Suehiro Sakaguchi and colleagues have reported that infection of murine neuroblastoma cells with a neurotropic H5N1 avian influenza A virus can instigate the formation of PrP^{Sc} that can then propagate continuously on its own and be transmissible to mice.[169]

Extension of the Prion Paradigm to Fungi

Although the name "prion" was initially given to the agents of the TSEs as described above, the first clear evidence that transmissible protein states exist in biology came from Reed Wickner's demonstration that unexplained epigenetic elements of yeast were prions.[407] These prions were not composed of a yeast homolog of PrP but of entirely distinct proteins (see Chapter 20).

Extension to Other Mammalian Protein Misfolding Diseases

Analogous to PrP-based prion disorders, many diseases of mammals involve the formation and prionlike spreading of specific protein aggregates within the host. Prominent examples in humans include Alzheimer disease (Aβ peptide and tau protein); Parkinson disease (α-synuclein), chronic traumatic encephalopathy (tau), type 2 diabetes (islet amyloid polypeptide), and amyotrophic lateral sclerosis (TAR DNA-binding protein-43, superoxide dismutase 1, and fused in sarcoma).[94,211,262,361,398] Studies of several of these proteinopathies have shown that extracts of human patients can induce, or at least accelerate, related pathogenesis in experimental animals. Such findings have fueled concerns that, like TSEs, these diseases might be transmissible and therefore are examples of prion, or prionlike, diseases. The extent to which transmitted etiologies of these various protein aggregation diseases might be clinically significant is currently under debate[18] (see Perspectives section). However, at present, it appears that the vast majority of cases of such human proteinopathies are of sporadic or genetic, rather than acquired, origin.[181]

OVERVIEW OF PrP PRIONS

This chapter will focus primarily on PrP-based TSE prions where a host's normal PrP is converted to aberrant conformers that are typically aggregated.[73,211] Terminology in the prion field is evolving and variably applied (Table 22.1), but here, we will use the term prion, by itself, to refer to the infectious agents of prion diseases; PrP^{Sc}, generically, for forms of PrP that are known to be infectious; and PrP^{Res} to designate protease-resistant forms of PrP^{Sc}. Otherwise, we will use the term PrP^{d} to refer to any disease-associated form of PrP[189] and PrP^{C} for the normal, cellular, nonprion, form.[61]

TABLE 22.1 Prion-related glossary

Term	Description
Prion	A proteinaceous infectious particle that lacks a self-coding nucleic acid and can self-propagate
PrP	Prion protein (any isoform of *PRNP* or *Prnp*-encoded polypeptide)
PrP^{Sc}	Abnormal, pathogenic isoform of PrP that causes illness (PrP-scrapie); the key protein component of transmissible agent of the PrP-based prion diseases or transmissible spongiform encephalopathies
PrP^{C}	Normal cellular isoform of PrP
PrP^{d}	Disease-associated form of PrP, whether transmissible, pathogenic, or not
PrP^{Res}	Partially protease-resistant form of PrP^{Sc}
PrP^{Sen}	Protease-sensitive form of PrP
PRNP	Human PrP gene located on chromosome 20
Prnp	Mouse PrP gene located on syntenic chromosome 2
PIRIBS	Parallel in-register intermolecular β-sheet
Amyloid fibril	Filamentous polypeptide assembly with high cross-β-sheet secondary structure that typically stains with amyloid-sensitive dyes such as Congo red, thioflavin T, and thioflavin S
Amyloid plaque	Localized deposit of many amyloid fibrils in tissue
Prion strain	Prion isolate causing consistent combination of clinical signs, pathological lesions, and PrP^{Res} subtype after inoculation into a given type of host. Incubation periods can be highly predictable and strain-dependent with defined doses and routes of inoculation
GPI	Glycophosphatidylinositol

PrP Prion Structures

A variety of aberrant forms of PrP have been observed *in vivo* and *in vitro*, and a major challenge is to understand which forms are relevant to

disease. Histological staining of infected brain tissue with PrP antibodies has revealed that PrP^d deposits can range from small, diffuse deposits to large extracellular amyloid plaques (Fig. 22.2A and B). The relative amounts and distributions of PrP^d deposits can vary systematically with prion strain and host type.[33,87,90,149,189] Immunogold labeling with transmission electron microscopy has shown that PrP^d can often accumulate in forms that are not visibly fibrillar,[73,189] with the close association of PrP^d with cellular membranes obscuring visualization of PrP^d morphology (Fig. 22.2C-G).

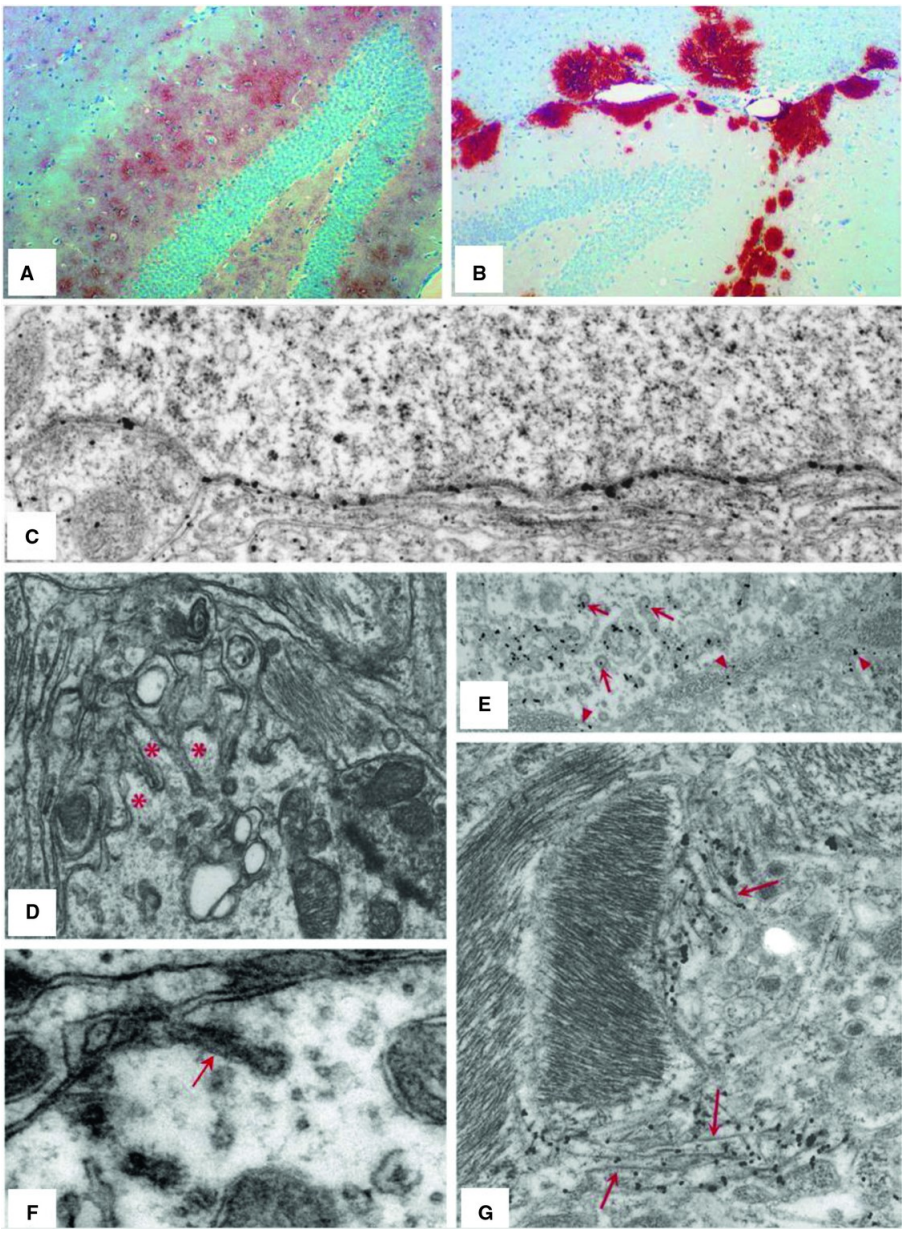

FIGURE 22.2 **Abnormal PrP^d deposition in prion-infected brain tissue**. **A**. Immunohistochemical staining for PrP^d (*red*) in scrapie-infected wild-type mice (diffuse staining) and **(B)** mice expressing only GPI-anchorless PrP (amyloid plaques). **C**. Immunogold labeling of PrP^d accumulation *without* membrane distortions on the surface on neurons and astrocytes in scrapie-infected sheep brain tissue. **D**. Dendritic membrane distortions (microfolding labeled with *asterisks*), not immunolabeled. **E**. Upon extraction from tissues with detergents, PrP^d most often is found in the form of amyloid fibrils.[273] However two-dimensional, sheetlike crystalline arrays and other nonfibrillar or subfibrillar oligomeric ultrastructures have also been observed (Fig. 22.3).[106,356,393,413] Both

fibrillar and smaller oligomeric forms have been linked to prion infectivity,[106,337,356,386,393] but the relative pathological roles of various prion ultrastructures remain to be determined. Here, we will focus primarily on the structures of fibrillar forms of PrP, including PrP^{Sc}/PrP^{Res}, because those are the only forms for which high-resolution structural data are available.

The properties of prions have prevented determination of their detailed structures by solid state nuclear magnetic resonance (ssNMR) spectroscopy or conventional x-ray or electron diffraction techniques. Nonetheless, fiber diffraction data from infectious brain-derived prion fibrils have revealed regular ~4.9 Å spacings of polypeptide strands perpendicular to the fibril axis; this spacing is characteristic of amyloid fibrils formed by stacked β-strands.[35] Electron paramagnetic resonance (EPR) and ssNMR studies of the protease-resistant cores of synthetic recombinant PrP fibrils have also demonstrated that PrP molecules, or fragments thereof, can form fibrils in which monomers are stacked parallel and in-register (ie, residues of one monomer are aligned with the corresponding residues of the adjacent monomers)[97,162,380,385] (Fig. 22.4A). This alignment, together with the ~4.9 Å spacing, showed that these synthetic PrP fibrils have parallel in-register intermolecular β-sheet/stack (PIRIBS) architectures. These and many other empirically derived, but relatively low-resolution, conformational constraints on PrP fibrils underpinned initial proposals of PIRIBS-based molecular models of prion fibrils.[162]

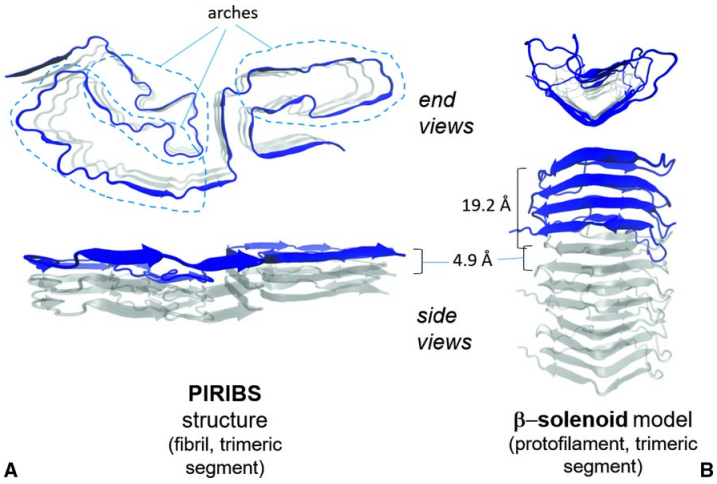

FIGURE 22.4 **Parallel in-register intermolecular β-sheet/stack (PIRIBS) vs 4-rung β-solenoid (4RβS) architectures for prion fibrils**. **A**. Short segment (trimer) of PIRIBS-based architecture as shown by high-resolution cryo-EM analysis of 263K prions.[212] **B**. Segment (trimer) of 4RβS protofilament model more speculatively based on low-resolution cryo-EM data for GPI-anchorless RML prion.[362] *Top* models show cross-sectional views. *Bottom* models show lateral views. A single monomeric unit within each segment is highlighted in *blue*. These models were each drawn using publicly available PDB coordinates as specified in Refs.[212,362] (Figure assembled from modeling by Efrosini Artikis. Adapted from Artikis E, Kraus A, Caughey B. Structural biology of ex vivo mammalian prions. *J Biol Chem*. 2022;298(8):102181. Copyright ©2022 Elsevier, with permission.)

An alternative model arose from brain-derived prion fiber diffraction patterns and low-resolution cryo-electron microscopy (cryo-EM) data that have been interpreted by some groups to indicate a 4-rung β-solenoid (4RβS)-based architecture.[362,395] Among the salient clues was evidence of repeated spacing along the fibril axis of 19.2 Å in addition to the ~4.9 Å spacing between strands within β-sheets. In the proposed 4RβS architectures, each PrP molecule provides four adjacent rungs along the protofilament axis (Fig. 22.4B).

Recent cryo-EM studies have further characterized the types of structural motifs that can be formed by PrP fragments within synthetic PIRIBS fibrils. These fibrils contained two closely packed symmetrical protofilaments, each with a β-arch (a hairpinlike loop of residues with PIRIBS structures on its flanks) at its core.[142,156,401] Analogous hairpinlike motifs in various PrP fibrils may not meet all formal β-arch criteria, so we have taken to simply calling them arches. While these synthetic fibrils are likely to be noninfectious, or at least orders of magnitude less infectious than many natural prions,[75,163,213,226] studies of their distinct modes of assembly within the PIRIBS framework set the stage for the most recent structural analyses of infectious fibrils.

Near-Atomic Structures of Infectious Tissue-Derived Prion Fibrils

Three near-atomic cryo-EM–based structures for fully infectious tissue-derived prion fibrils are available as of this writing, each of which have PIRIBS-based architectures. The first to be solved was PrP^{Res} fibrils of the hamster-adapted scrapie strain 263K[212] (Fig. 22.5), which contain not only the full complement of glycans and GPI-anchors of most natural prions but also ~10^9 50% lethal doses (LD_{50}) per mg protein.

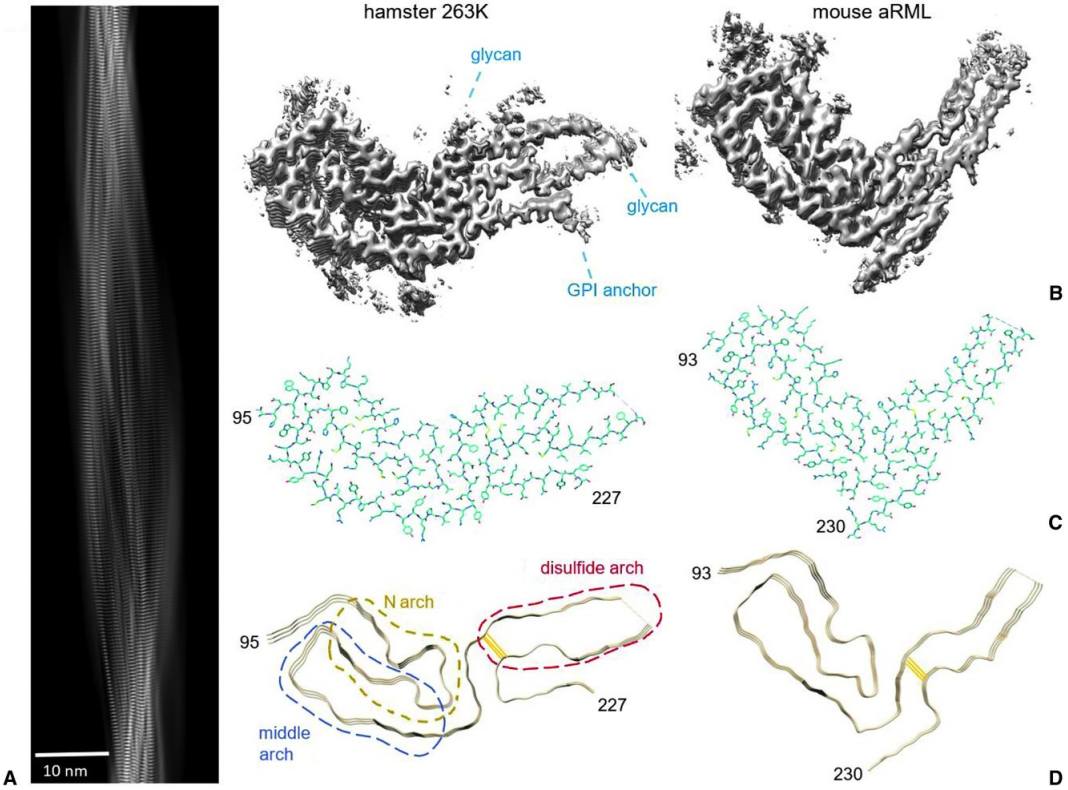

FIGURE 22.5 **Cryo-EM–based structures of two strains of brain-derived scrapie prion fibrils.**[178,212] **A**. Magnified end-on (cross-sectional) views density maps of hamster 263K and mouse aRML prion fibrils. The attachment sites of the mostly unresolved N-linked glycans and GPI anchor are indicated on the 263K map. **C**. Stick depictions of monomeric units of atomic models. **D**. Ribbon diagrams of stacks of three monomers with structural motifs circumscribed in the 263K model that are similar, but not identical, in aRML. *Dashed lines* indicate poorly resolved tips of the disulfide arches. (Panel **A** adapted from Figure 1E of Kraus A, Hoyt F, Schwartz CL, et al. High-resolution structure and strain comparison of infectious mammalian prions. *Mol Cell*. 2021;81(21):4540-4551. e6. Copyright © 2021 Elsevier, with permission.)

The core of the hamster 263K prion fibrils contains arches that partially overlap those seen in the synthetic PrP fibrils,[142,156,401] namely an N-proximal (N) arch spanning residues ~95-144 and a disulfide arch of residues ~170-229 (Fig. 22.5B-D).[212] A major difference is that the much larger 263K core contains both of these types of arches rather than just one or the other. Also, the detailed conformations of these arches in the 263K prion fibril differ markedly from those of the synthetic fibrils. A third major arch not seen in the synthetic protofilaments, named the middle arch (residues ~125-168), shares its N-terminal flank with the N arch. The tip of the middle arch forms a steric zipper with residues 96-100 to immobilize the N-terminus of the fibril core, the folding of which can strongly modulate infectivity.[286] Steric zippers are frequent features of amyloid fibrils[126] and can be important mediators of PrP fibril stability.[96] Whereas the synthetic fibrils have two-protofilament cross sections, the 263K fibril cross section is spanned by a single PrP monomer. The N-linked glycans and GPI anchors can be inferred to project outward from the core, but these posttranslational modifications are too heterogeneous to be resolved by cryo-EM.

The two additional near-atomic prion structures are of the highly infectious mouse-adapted RML scrapie strain in both its wild-type (wtRML)[253] and GPI-anchorless (aRML)[178] forms. The core structures of wtRML and aRML PrP^{Sc} are similar to each other but distinct from hamster 263K fibrils in both amino acid sequence (at eight positions within their ordered cores) and conformation (Fig. 22.5B-D). aRML differs additionally from 263K and wtRML in lacking GPI anchors, being severely underglycosylated, and accumulating predominantly in extracellular amyloid plaques rather than more diffuse membrane-associated deposits (Fig. 22.2A and B). Like 263K, aRML and wtRML prion fibrils have a PIRIBS architecture with N, middle, and disulfide arches, but the specific conformations and relative orientations of these arches and other structural features of these two prion strains differ markedly[178,253] (Fig. 22.5B-D).

PrP Fibril Structures and Transmissibility

Although the number of available high-resolution structures of PrP assemblies is limited, themes are emerging regarding features that influence relative prion infectivity: (1) Highly infectious PrP fibrils have larger tightly packed cores than marginally infectious, or noninfectious, fibrils.[163,213,286,360] Indeed, even small differences in the extent and structure of the core can profoundly affect infectivity[399] (Fig. 22.6). (2) Although glycans and GPI anchors strongly affect prion disease susceptibilities and phenotypes,[63,64,87,90,247,348,416] they are not required for infectivity[90,98,118,195,223,248,400] (see below). These high-resolution structures also allow the study of conversion of PrP^{C} to PrP^{Sc}, using molecular dynamic simulations, providing possible mechanisms for the species barrier between mice and hamsters (Fig. 22.7).

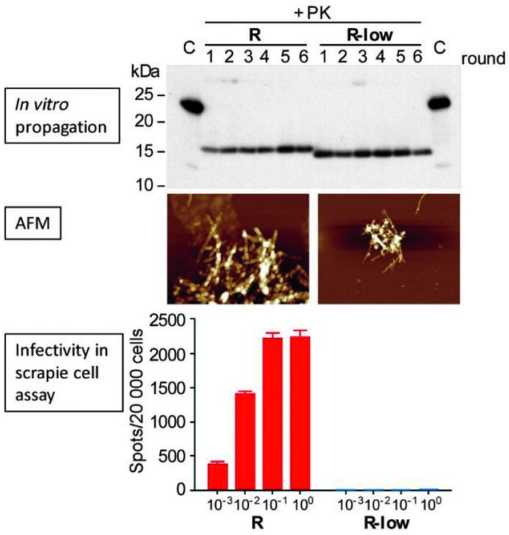

FIGURE 22.6 **Two conformers of murine PrP fibrils (R and R-low) formed and propagated under similar conditions *in vitro* differ markedly in infectivity.**[399] **Top**: The "R" and "R-low" fibrils maintain a ~1 kDa difference in their proteinase K (PK)-resistant cores through 6 rounds of *in vitro* amplification. "R" refers to the RNA cofactor that was included in the propagation of both types of fibrils. **Middle**: Atomic force microscopy (AFM) images of the "R" (*left*) and "R-low" (*right*) preparations indicate that both have fibrillar ultrastructures. **Bottom**: A live-cell–based assay of infectivity measured on across four 10-fold dilutions, indicating a difference in infectivity of at least 10 000-fold. THE NORMAL, NONPRION ISOFORM OF PrP (PrP^C)

As the obligate precursor of PrP^{Sc}, PrP^C figures prominently in PrP prion disease pathogenesis. PrP^C and homologs thereof are found in many mammals and other vertebrates.[404] Although the overarching physiological function(s) of PrP^C remain unclear,[72,341,352] the structures from different species show a degree of conservation that suggests retention of a significant function through evolution.[313] Interactions of PrP^C with multiple ligands,[341,352] as well as effects on processes such as cellular differentiation, signaling, adhesion, and stress tolerance,[45] suggest a cell-surface scaffolding function that organizes and mediates a variety of physiological functions.[231]

Given that refolding of PrP^C molecules is fundamental to prion propagation, much attention has focused on their structures. Mammalian PrP^C molecules share the features summarized in Figure 22.1. The most abundant forms of PrP^C contain asparagine-linked glycans at one or both consensus glycosylation sites[170] as well as a GPI anchor[364] that targets PrP^C to lipid raft domains of membranes.[283] However, minor subsets of PrP^C lack glycans and/or GPI anchors.[363] PrP^C can be found in many cell types and tissues but is particularly abundant in neurons. As a glycoprotein, it is found along the secretory pathway, at the cell surface, and in endocytic and other membrane-bound transport vesicles (Fig. 22.1C).[78] PrP^C is also found in the inner mitochondrial membrane.[130] Cleavage near the C-terminus by ADAM 10 protease can release PrP^C molecules into extracellular spaces, a process that can be stimulated by events such as ligand binding.[232,376] An internal cleavage of PrP^C under physiological conditions can generate N- and C-terminal fragments, which can influence cellular functions.[65,103,227,252]

Although *Prnp* knockout mice are resistant to prion disease,[60] they are viable and healthy under controlled laboratory conditions.[61] Partially or wholly, PrP-deficient humans,[274,275] goats,[39] and cattle[329] are also generally healthy, suggesting that either PrP^C deficiency can be largely compensated by backup mechanisms or that PrP^C's function is not crucial for viability. However, there are studies indicating roles of PrP^C in many physiological processes such as circadian rhythm,[383] lymphocyte activation,[69] axonal myelination,[214] development,[254,365] neuronal signaling; synapse formation, neurite outgrowth,[8,340] cell adhesion,[343] metal ion homeostasis,[53] neuroprotection,[41,119] alcohol sensitivity,[306] and meditation of the neurotoxicity of oligomers of other proteins such as Aβ, α-synuclein, and tau.[40,72,104,133,220,231, 291,299,328,352,381] A note of caution is that some studies using PrP-deficient experimental models may be confounded by uncontrolled influences of flanking genes, overexpression, or ectopic expression.[121,366,369]

Prion Disease Pathogenesis

Given that organisms have quality control (proteostatic) mechanisms to counter the accumulation of abnormally folded proteins, a fundamental feature of proteinopathies is a kinetic race between aggregate replication/accumulation and clearance. Direct comparisons in prion-infected cell cultures have shown that PrP^{Sc} has a much slower turnover rate than PrP^C,[49,79] but studies have indicated that hosts have some ability to clear PrP^{Sc}.[309,336] Even so, with inoculation of a sufficient quantity of prions, for example, as little as few femtograms of PrP^{Sc}, the kinetic race is always won by prion replication, resulting in the demise of a susceptible host. This pathogenic process can be highly reproducible with death occurring months after inoculation and rodents of similar genetic background dying within days of each other. A primary factor controlling prion incubation periods is the level of PrP^C expression in the host. For example, whereas mice expressing wild-type levels of PrP^C can have scrapie incubation periods of <165 days when inoculated with a given dose and prion strain by a given route, hemizygous knockout mice can have incubation periods of 400-465 days when given the same challenge.[314]

Prion Growth

The detailed step-by-step mechanism of PrP^{Sc}-induced conversion of PrP^C to new PrP^{Sc} is unclear. Nonetheless, the respective conformations of PrP^C and PrP^{Sc} indicate that major events in this conversion process are the peeling of the first helix away from the other two helices, as well as a straightening of each of the helices into extended chains or loops that form intermolecular β-sheets and other linkages to the corresponding residues in the templating monomer at the ends of the fibrils (Fig. 22.8A).[212] It is not certain whether PrP^{Sc} interacts directly with individual PrP^C monomers or partially unfolded oligomers, but the net effect is that each incoming monomer usually assumes the conformation of the PrP^{Sc} template.[43,335,351,377] As the prion assembly grows, fragmentation must generate more prion particles *in vivo*[271] via a poorly understood mechanism.

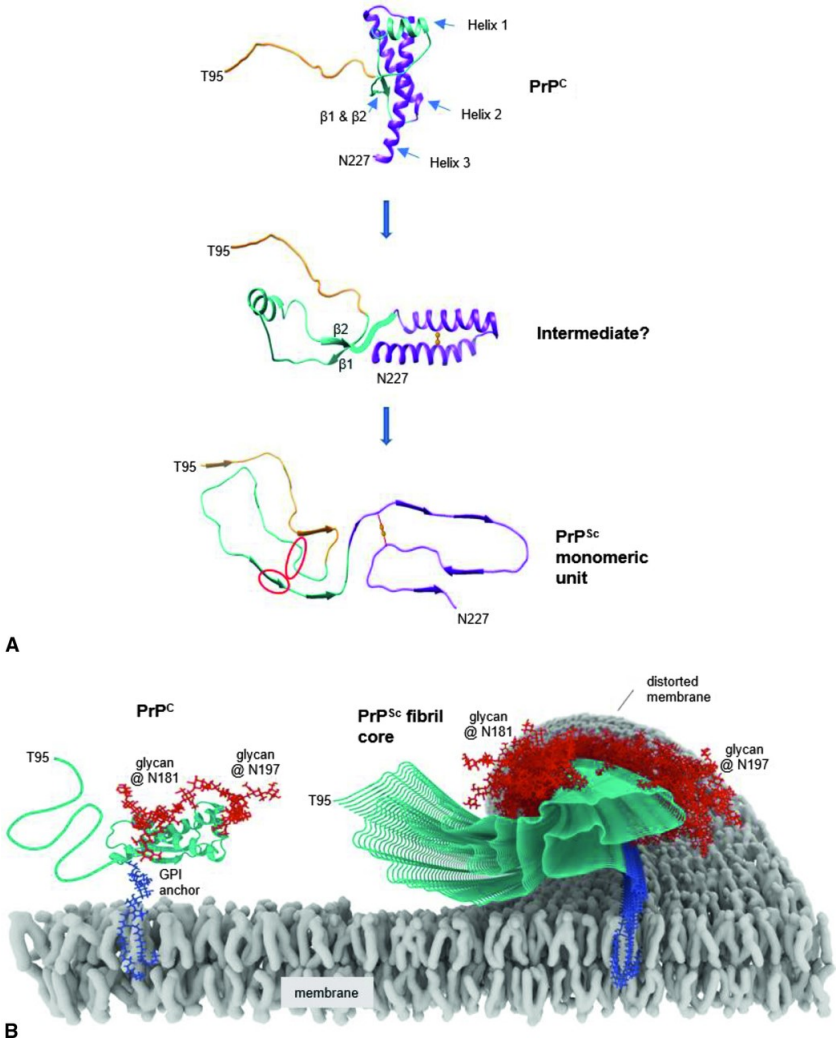

FIGURE 22.8 **Surmised conversion of PrP^C to PrP^{Sc} formation**. **A**. Hamster PrP residues 95-227 spanning the ordered core of the 263K prion fibril (*bottom*)[212] are depicted on top as PrP^C with the conformation of residues 125-227 as determined by NMR[182] and remaining residues 95-124 (*orange*) as an arbitrary flexible chain. A hypothetical intermediate in the middle illustrates the need for the β1-helix 1-β2 loop (*turquoise*) of PrP^C to separate from helices 2 and 3 (*purple*). The β1-β2 sheet of PrP^C must break to form intermolecular bonds in PrP^{Sc} (new positions encircled in *red*). **B**. Depictions of residues 95-231(*turquoise*) of PrP^C (monomer) and PrP^{Sc} (multimer) bound to a membrane with representative glycans (*red*) and GPI anchors (*blue*). The curl of the membrane (*gray*) is shown hypothetically to follow the axial twist of the GPI anchors. (Adapted from Figure 4 of Kraus A, Hoyt F, Schwartz CL, et al. High-resolution structure and strain comparison of infectious mammalian prions. *Mol Cell*. 2021;81(21):4540-4551. e6. Copyright © 2021 Elsevier, with permission.)

Prion Spreading Within Hosts

In sporadic CJD (sCJD), which represents a preponderance of human prion disease cases, the origin of the pathogenic PrP aggregation process is difficult to ascertain. In experimental animals, highly localized inoculations into sites as distal as the foot pad[155] have shown that prions can spread from remote areas into the brain.[33,155,243,352] Most studies have indicated that prion spreading occurs most efficiently via neural circuitry[199,349] and is dependent on levels of membrane-bound PrP^C in those neurons.[51,155,200] However, other, even hematogenous, routes also appear to be possible.[25,27,387] Nonneuronal spreading can also be important in, for example, the initial spread of infection from the gut to the peripheral nervous system.[70,243] In this scenario, key players in prion transport to the nervous system are follicular dendritic cells of secondary lymphoid organs. The extent to which other nonneuronal modes of spread might also be significant in ferrying prions to the brain is not clear. Chronic lymphocytic inflammation in the host can extend the tissue distribution of prions,[172] and *in vitro* studies indicate that the intercellular spread of prions and other proteopathic seeds can be enhanced by viral coinfections.[222,233] Even without experimental induction of systemic inflammation, prions have been detected in many tissues of infected hosts, including lymphoid tissues, skin, eyes, blood, and muscle[9,123,124,172,295-297,333] (see later sections); however, the apparent prion titers in such peripheral tissues are usually much lower than those of the brain.

Cellular and Molecular Pathogenesis

When neuronal cell lines are exposed to exogenous prions, they can internalize the prions into late endosomes and lysosomes and transport them along neuritic processes to points of contact with other cells (Fig. 22.9A).[245,309] The initial uptake has been reported to be facilitated by the presence of heparan sulfate on the cell surface,[176] but another study has suggested that sulfated glycosaminoglycans are dispensable for prion uptake.[417] The internalization pathways can vary with prion strain.[132] Establishment of persistent infection appears to involve transport from late endosomes or lysosomes into the endocytic recycling pathway.[256,421] In persistently infected cell cultures, PrP^{Sc} is formed posttranslationally from mature PrP^C molecules after they have been transported to the cell surface.[49,79] In most such cells, PrP^{Sc} can then be endocytosed and N-terminally truncated by endo-lysosomal proteases.[81,374] The initial site of conversion is either on the plasma membrane or in endocytic vesicles[50,81,159,256,422] and is most efficient when the two isoforms are in the same membrane.[29] Strikingly, nascent PrP^{Sc} can be visualized on the cell surface in patches, strings, or webs that resist endocytosis for hours and appear to be membrane-anchored PrP^{Sc} amyloids.[331,405] Spreading between cells[309] can be enhanced by cell-to-cell contact,[192] tunneling nanotubes,[160] and extracellular vesicles[394] (Fig. 22.9B and C).

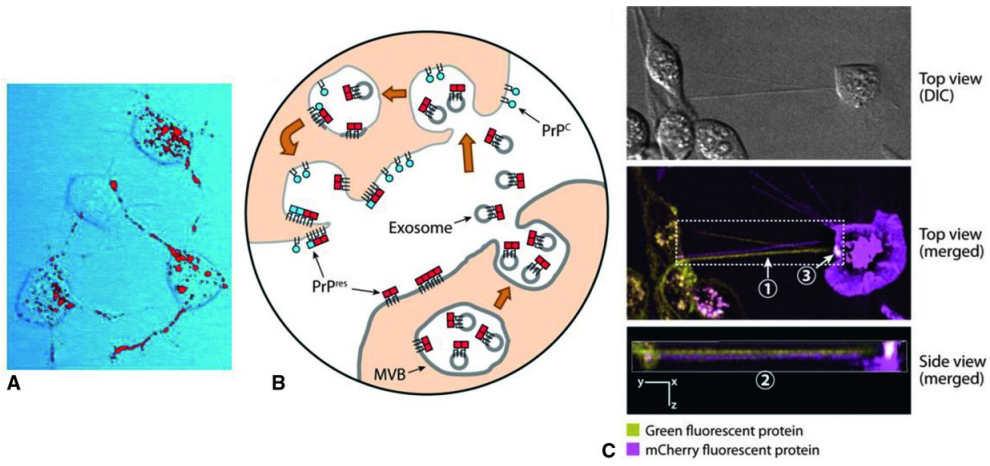

FIGURE 22.9 **Movement of prions within and between cells**. **A**. Pseudo-colored fluorescence microscopy image of neuronally derived SN56 tissue culture cells showing internalization and neuritic transport of exogenenously added fluorescently tagged PrP^{Sc} (*red*) to points of contact with other cells. **B**. Diagram of intercellular spread of PrP^{Sc} via exosomes, which form within multivesicular bodies (MVB) and can then be released into extracellular spaces and internalized by other cells. **C**. Differential interference contrast (DIC) and fluorescence images of threadlike tunneling nanotubes (*1* and *2*) between cocultured cells expressing GPI-anchored proteins tagged with either green fluorescent protein (GFP) or mCherry fluorescent protein. Number *3* points to a site where a tunneling nanotube from a GFP expressing cell has transferred a GFP-tagged protein onto a cell expressing a GPI-linked mCherry-tagged protein. (**A** is courtesy of Dr. Kil Sun Lee while at NIAID and B and C adapted with permission from Figure 7 of Caughey B, Baron GS, Chesebro B, et al. Getting a grip on prions: oligomers, amyloids, anchors and pathological membrane interactions. *Annu Rev Biochem*. 2009;78:177-204. Copyright © 2009 by Annual Reviews, http://www.annualreviews.org.)

In cultured cells that express various human genetic prion disease–linked PrP^C mutants, early misfolding and aggregation may in some cases

occur in the endoplasmic reticulum, along with incomplete maturation of glycans and delayed transport to the cell surface.[19,85,125] Such aberrant structures are nonetheless transported to post-ER components of the secretory pathway, where they are transferred to acidic lysosomal compartments for degradation.[19] A recent study has further described post-Golgi pathways for misfolded mutant PrP in neurons.[85] One pathway resembles the rapid ER stress-induced export (RESET) mechanism that is observed in nonneuronal cells in which the mutants are transported to lysosomes for immediate degradation. Another newly described pathway, dubbed *a*xonal *r*apid *e*ndosomal *s*orting and *t*ransport-dependent *a*ggregation (ARESTA), involves post-Golgi sorting to late endosomal structures called endoggresomes that are then subjected to anterograde transport into axons where they can fuse, aggregate, impair calcium transport, and hasten cell death.[85]

In the brain, nascent PrP^{Sc} has been detected near the outer basement membrane of blood vessels early after microinjection of scrapie brain homogenate (Fig. 22.10)[89] and then in neuronal plasma membranes and in both axons and dendrites.[158] Interestingly, injection of normal brain homogenate leads to dense aggregation of PrP^{C} near the needle track, but such aggregates are soon cleared.[89,402] These and multiple other studies are consistent with a role of PrP^{C} in response to tissue injuries and stresses.[264] Among the early deficits seen after prion infections is established in the brain are synaptic and mitochondrial dysfunction followed by axon terminal degeneration, dendritic atrophy, unfolded protein response, translational repression, and reactive gliosis.[66,113,139,157,187,188,255,280,373] Despite conflicting initial reports, microglial responses now appear to be protective against multiple strains of prions in mice.[66] Of likely relevance is a recent description of microglial networks picking up prionlike α-synuclein fibrils from neurons and either degrading them if they can, or, if not, passing them on to adjacent, less-burdened microglia.[342] Also protective in prion disease is the presence of SARM1, a factor that under other circumstances can promote axonal degeneration.[427] Ultimately, prion infections can lead to cell death, autophagy, and spongiform change.[354,414] The sequence of PrP^{Sc} accumulation and its neurotoxic effects has been particularly well visualized in the retinas of infected mice where photoreceptor degeneration begins with PrP^{Sc} deposition at the cilia and ribbon synapses of cones[370] (Fig. 22.11).

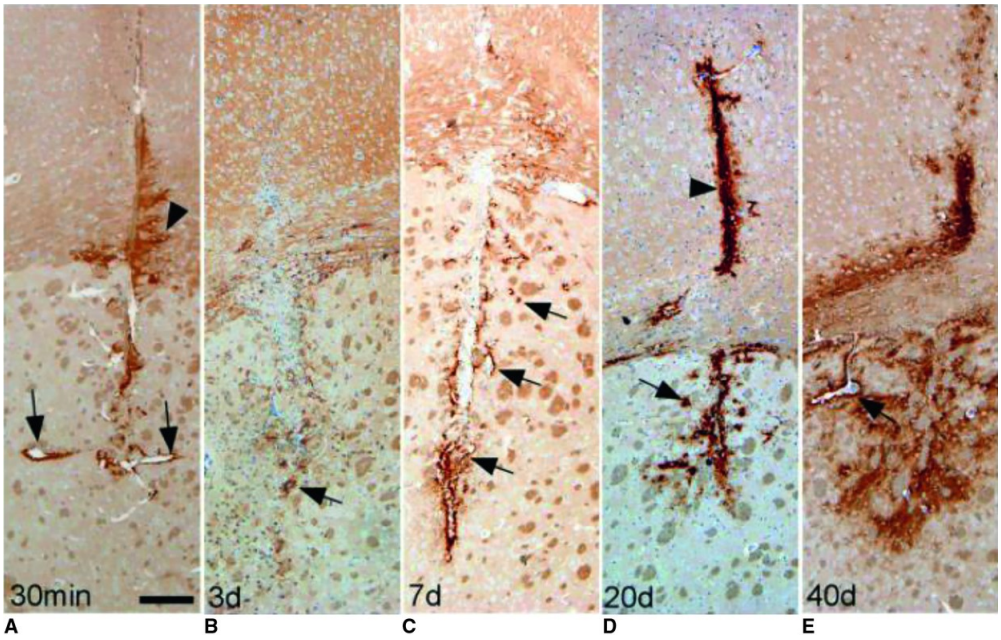

FIGURE 22.10 **Time course of immunostaining of PrP^{d} (darker brown against lighter, more diffuse staining of PrP^{C}) after intracerebral microinjection of scrapie strain 22L into wild-type mice**. **A**. At 30 minutes, staining of the inoculum is seen around blood vessels (*arrows*) in the striatum and along the needle track in the corpus callosum and cortex (*arrowhead*). **B**. Reduced staining at 3 days suggests initial clearance of inoculum. *Arrow* indicates blood vessel–associated staining. **C-E**. Subsequent increase in staining from 7 to 40 days. *Arrows* and *arrowheads* mark blood vessel and wound-associated staining respectively. PrP (*pink*) is located below cone pedicle (cp) containing ribbon synapses (rs). OS, outer segment; IS, inner segment; ONL, outer nuclear layer; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer, cc; connecting cilium, m; mitochondria, n; nucleus, cp; cone pedicle, rs; ribbon synapse. **B**. Cone photoreceptor inner segments (*yellow arrow*) and pedicles (*green arrow*) are stained with cone arrestin (*green*) in uninfected mouse. *Pink arrows* indicate PrP. **C**. At 67 days post infection (dpi), staining pattern is similar to uninfected mouse. **D**. At 104 dpi, small irregular PrP^{d} deposits associated with cones become apparent (*yellow arrows*). **E**. At 118 dpi, PrP^{d} accumulation is more extensive in IS and OPL, cone numbers are reduced (*green*), cone pedicles have disappeared from the OPL, and remaining cones are dystrophic (*yellow arrow*). **F**. At 131 dpi, few cones remain, and pedicles (*yellow arrow*) are smaller and associated with PrP^{d} (*arrowhead*). **G**. Cones are no longer detected and the ONL is thinner, indicating loss of photoreceptors. *Yellow arrow* marks a macrophage or microglial cell containing PrP^{d}. *Bright pink* in OS is autofluorescence. Scale bar in **A** = 20 µm. (Adapted from Figure 5A and 6 of Striebel JF, Race B, Leung JM, et al. Prion-induced photoreceptor degeneration begins with misfolded prion protein accumulation in cones at two distinct sites: cilia and ribbon synapses. *Acta Neuropathol Commun*. 2021;9(1):17. http://creativecommons.org/licenses/by/4.0/.)

Mechanisms of PrP^{Sc} Toxicity

The mechanisms of PrP^{Sc} toxicity, whether direct or indirect, are not well understood. Several aspects of neuronal proteostasis can be perturbed by prion infections in ways that might be deleterious to neurons.[352] These include the disturbances of the ubiquitin/proteasome system,[263] autophagy and lysosomal pathways,[1,420] the unfolded protein response,[280] stress protective signaling,[323] and mitochondrial function.[5,95,130,225] Direct association of PrP^{Sc} with membranes results in deformed membrane structures (Fig. 22.2C-G).[73,185,186,212] Such deformities seem likely to affect a variety of cellular functions, including those involving intracellular transport[127,128] and neuronal receptor signaling.[92,345] Major aspects of PrP^{Sc} toxicity also appear to be mediated through interactions with cell surface PrP^{C}.[51,87,221,249] Moreover, as infectivity plateaus prior to onset of symptomatic prion disease, PrP^{C} levels drop along with an increase in oligomeric forms of PrP^{Sc} that may be particularly neurotoxic.[261] However, loss of PrP^{C} function does not appear to be the sole reason for prion disease pathology because hosts with depleted PrP^{C} alone do not develop prion disease.[61,249,326]

Implications of GPI-Anchoring and Glycans of PrP^{Sc}

For at least some prion strains, the GPI anchors and N-linked glycans do not appear to markedly affect the core β-sheet structure,[28,178,253] and serial passages from wild-type mice through anchorless PrP transgenic mice and back again do not alter the fundamental prion strain characteristics.[87] However, the outward display of the N-linked glycans and GPI anchors, when present, is likely to have major implications in pathogenesis.[212] Comparison of prion strains in mice expressing PrP^{C} with or without GPI-anchors and/or N-linked glycans have shown profound phenotypic differences.[64,87,90,200,247,320,348,416] For example, as noted above, PrP^{d} in anchorless mice is found not in diffuse, cell-associated deposits, but in extracellular amyloid plaques (Fig. 22.2B) reminiscent of those seen in human Gerstmann-Sträussler-Scheinker

syndrome (GSS)[149] and kuru.[230]

The cryo-EM structure of hamster strain 263K suggests that the presence of, and variations in, glycans and GPI anchor modifications could strongly modulate the interactions of prions with their tissue environments. As depicted in Figure 22.8B, the glycans and GPI-mediated membrane tethering should severely restrict access of other macromolecules to at least the C-terminal half of the 263K fibril core whether they might be cofactors for prion growth or proteostatic factors involved in prion recognition and clearance. Also, several pathognomonic PrP^{d}-associated membrane distortions have been described in prion-diseased brains that might be attributable to tight tethering of membranes to PrP^{Sc} fibrils via the linear array of GPI anchors as they follow the twist of the fibril (Fig. 22.8B),[212] including invaginations, protrusions, and spiral membrane inclusions (Figs. 22.1C and 22.2D-G).[73,185,228] Membrane associations might also be expected to help mediate cell-to-cell spreading of prions via membranous structures such as exosomes and tunneling nanotubes (Fig. 22.9B and C).[73,160,394] Nonetheless, although disease phenotypes are affected dramatically by GPI anchors and glycans, PrP^{Sc} accumulation can be fatal and highly transmissible either with or without these posttranslational modifications on either PrP^{C} or PrP^{Sc}.[87,90,200,320]

Human Prion Diseases: Epidemiology and History

Human prion diseases are rare TSEs affecting 0.3-1.7 people per million population per year, with a peak incidence in the seventh decade of life.[217,389] They can be classified as sporadic, genetic, or acquired. Sporadic cases represent 85% of all cases, with the remaining 15% being genetic and <1% acquired.

The history of human prion diseases is one of misclassification and serendipity. The most common type is sporadic Creutzfeldt-Jakob disease (sCJD). The name derives from one case report by Hans Gerhard Creutzfeldt and five case reports by Alfons Maria Jakob in 1920-1923, that described patients with rapidly progressive motor, speech, and cognitive deficits that were ultimately fatal.[194] Of note, it was Jakob who proposed that Creutzfeldt's case could be one of the same syndromes he reported, but a more recent analysis of brain samples from these cases has revealed that Creutzfeldt's case was actually not a prion disease, nor were all of Jakob's initial cases.[194] Nonetheless, the eponym remains and is used to refer to the most common types of human prion disease.

Sporadic Human Prion Diseases (85%)

Patients with CJD typically present with a rapidly progressive neurodegenerative syndrome, but there is considerable variability in the presence and timing of symptoms, including ataxia, visual disturbances, parkinsonism, dementia, and myoclonus. Even disease duration can vary from weeks to a few years.

Before the identification of PrP, distinct clinical presentations of CJD were categorized by phenotype. The Heidenhain variant referred to patients with prominent visual symptoms, including hallucinations, distortions, cortical blindness, and/or Anton syndrome,[171] and the Brownell-Oppenheimer variant was used to describe patients with predominantly ataxia.[57] Today, six subtypes are recognized, based on patient *PRNP* codon 129 status, PrP electrophoretic mobilities after proteinase K digestion, and neuropathological patterns of PrP deposition (diffuse synaptic or more plaquelike) and spongiform change[303,358,425] (Fig. 22.12, Table 22.2).

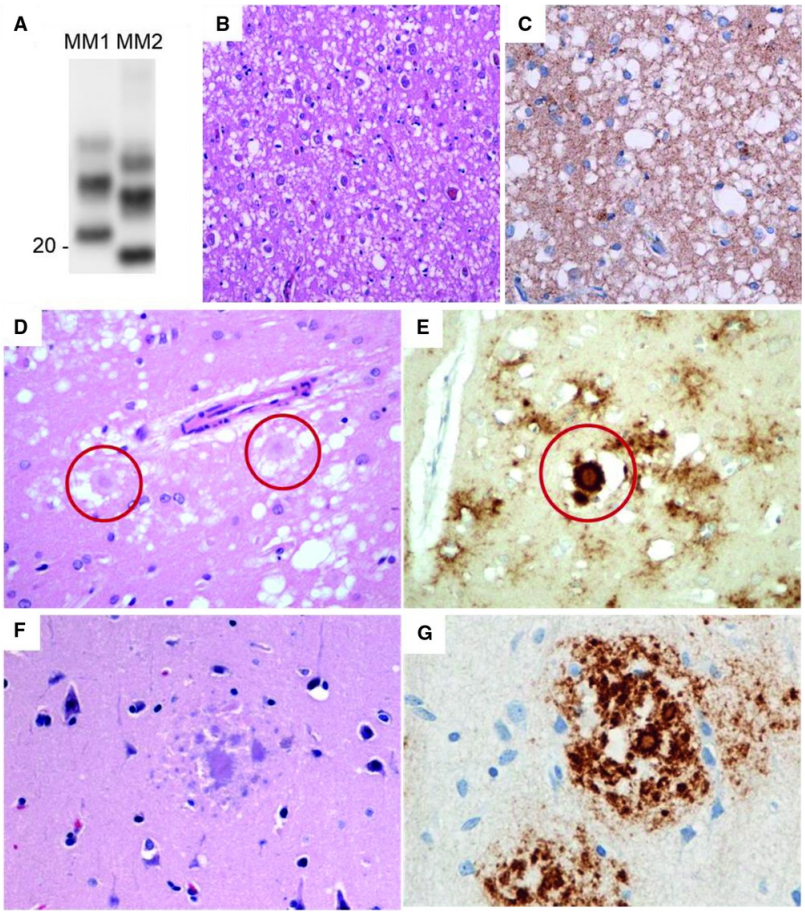

FIGURE 22.12 **Pathological findings in human prion disease**. **A**. Immunoblot comparing PK-digested banding profiles of CJD subtypes MM1 and MM2 (3F4 antibody). Type 1 has a lower band of 21 kDa; type 2 is 19 kDa. **B**. Sporadic Creutzfeldt-Jakob disease (sCJD) brain: Hematoxylin and eosin stain showing typical spongiform change. **C**. sCJD brain: Immunostaining for prion protein (12F10 antibody) showing diffuse synaptic pattern (*brown*). **D**. Variant Creutzfeldt-Jakob disease (vCJD): Periodic acid-Schiff stain showing typical florid plaque surrounded by vacuoles (*red circles*). **E**. vCJD: Immunostaining for prion protein (12F10 antibody) showing a florid plaque (*red circle*). **F**. GSS: Hematoxylin and eosin stain showing a typical multicentric plaque. **G**. GSS: Immunostaining for prion protein (12F10 antibody) showing multicentric plaques. TABLE 22.2 Subtypes of sporadic Creutzfeldt-Jakob disease

Molecular Type[a]	Onset: Years (Range)	Duration: Months (Range)	Clinical Presentation	Diagnostics	Neuropathology
M(M/V)1 MM1 and MV1 are considered the same subtype	68 (31-86)	4 (1-24)	Rapid dementia Myoclonus 50% ataxia at onset 30% visual impairment	MRI: basal ganglia and cortex EEG positive	Neocortex (predominantly occipital), striatum, thalamus, and cerebellum; "synaptic" PrP
VV2	64 (40-83)	6.5 (3-18)	Ataxia at onset Dementia later	MRI: basal ganglia and thalamus EEG negative	Prominent in cerebellum and subcortical, late cortical involvement; plaquelike and perineuronal PrP
MV2K (K for Kuru plaques)	65 (36-83)	17 (4-48)	Dementia Ataxia Extrapyramidal signs	MRI: basal ganglia and thalamus EEG negative	Amyloid kuru plaques in the cerebellum; plaquelike focal PrP deposits
MM2C (C for cortical)	64 (49-77)	16 (9-36)	Dementia Myoclonus Pyramidal signs Less frequent ataxia	MRI: cortex EEG negative	Spongiosis with large confluent vacuoles in cortex; perivacuolar PrP
MM2T (T for thalamus) May be sporadic FI	52 (26-71)	16 (8-36)	Psychiatric features Depression Psychosis Parkinsonism	MRI: thalamic gliosis EEG negative	Atrophy of the thalamus and inferior olive, focal spongiosis limited to the cerebral cortex
VV1	39 (24-49)	15 (14-16)	Dementia at onset Late ataxia Late extrapyramidal	MRI: cortex EEG negative	Severe pathology in the cerebral cortex and striatum with sparing of brainstem nuclei and cerebellum

Subtypes are listed in order of decreasing frequency.

[a]Polymorphism at codon 129 of the *PRNP* gene (M, methionine or V, valine) as well as the PrP^{Res} classification (1 or 2) with additional pathological phenotypes as defined in parentheses. MRI findings specifically refer to typical areas of hyperintensity on FLAIR (fluid-attenuated inversion recovery) or DWI (diffusion-weighted imaging). A positive or negative EEG refers to the presence or absence of generalized discharges. See section on diagnosis for more details.

Factors Influencing Creutzfeldt-Jakob Disease Susceptibility and Phenotype

PRNP Gene Polymorphisms

In humans, *PRNP* polymorphisms at codons 127, 129, and 219 are genetic risk factors or modifiers of disease phenotype[267] (Fig. 22.13). The polymorphism at codon 129 encodes either methionine (M) or valine (V), with homozygosity of the M allele being a susceptibility factor for variant CJD and homozygosity of either allele enhancing risk of developing sporadic CJD.[268,302] Heterozygosity is associated with longer survival time.[308]

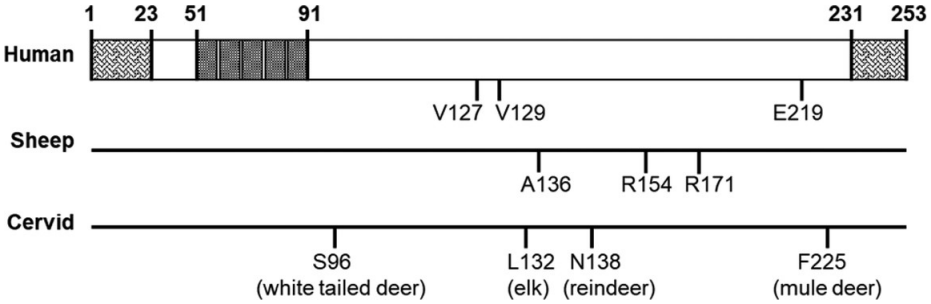

FIGURE 22.13 ***PRNP* polymorphisms known to modify disease in humans and other mammals**. Polymorphisms with resistance or protective effects are shown. (Adapted from Figure 76.11 of Prusiner SB. Prions. In: Knipe DM, Howley P, eds. *Fields Virology*. Vol 2. 6th ed. Wolters Kluwer Health/Lippincott Williams & Wilkins; 2013.)

The geographically localized variant, V127, is associated with resistance to kuru in New Guinea[269] and can render transgenic mice expressing human PrP V127 completely resistant to multiple prion strains.[17] The E219K polymorphism found in Japan is likely to be protective against sCJD.[350]

Non-PRNP Single Nucleotide Polymorphisms

A recent genome-wide association study identified two non-*PRNP* loci associated with increased risk of sCJD, specifically missense mutations in GAL3ST1 and a variant causing increased expression of STX6.[191] GAL3ST1 encodes galactose-3-*O*-sulfotransferase 1, an enzyme involved in sphingolipid metabolism, whereas STX6 encodes syntaxin-6, which is involved in endosomal recycling. The increased risk is modest at best, and given the rarity of CJD, the presence of two copies of both alleles only confers a lifetime risk of CJD of 1 in 3000.[390] Nevertheless, the discovery of these associations has opened new possibilities for studying disease pathogenesis and therapeutic design.

Other Sporadic Forms of Human Prion Disease

Variably Protease-Sensitive Prionopathy

A newer form of sporadic prion disease, variably protease-sensitive prionopathy (VPSPr), was identified in 2008[143] and is thought to account for 0.7%-1.7% of all sporadic prion diseases.[288] It fulfills the criteria of a prion disease in that it has been transmitted to animals.[288] Interestingly, while all codon 129 genotypes can be affected, the majority (65%) are VV, unlike sCJD, where the majority are MM. The phenotype involves more psychiatric presentations and speech/language impairment, before cognitive decline, and the neuropathology includes spongiform change and PrP amyloid miniplaques. The name derives from the atypical electrophoretic profile of five to seven PrP bands that are variably protease-resistant.[288] Diagnosis requires a high level of suspicion, because the MRI is usually normal, electroencephalography (EEG) is rarely abnormal, and often patients are older with longer disease durations, often 2 years. VPSPr has phenotypic and biochemical similarities to the V180I PrP gene mutation,[288] suggesting that it may reflect the sporadic form of this inherited disease (see Genetic Prion Diseases below).

Sporadic Fatal Insomnia

A thalamic form of sCJD, specifically categorized as MM2T, may represent a sporadic form of fatal insomnia (sFI), but sFI has more heterogeneity. For example, insomnia, while present in 29% of sFI patients at presentation, is a less prominent finding than in fatal familial insomnia (FFI), and atypical parkinsonism is more often present in sFI than in FFI.[110,279,316]

Genetic Prion Diseases (15%)

For any patient presenting with prion disease symptoms, it is prudent to perform *PRNP* sequencing, as the clinical presentation of sporadic cases and genetic forms can overlap. Furthermore, patients with heritable forms of prion disease may not always have a family history of the same.[209] Mutations include deletions, insertions, missense, nonsense, and splice site variants (Fig. 22.14). To date, all inherited prion diseases are associated with mutations in the *PRNP* gene itself, but some mutations are less penetrant.[275]

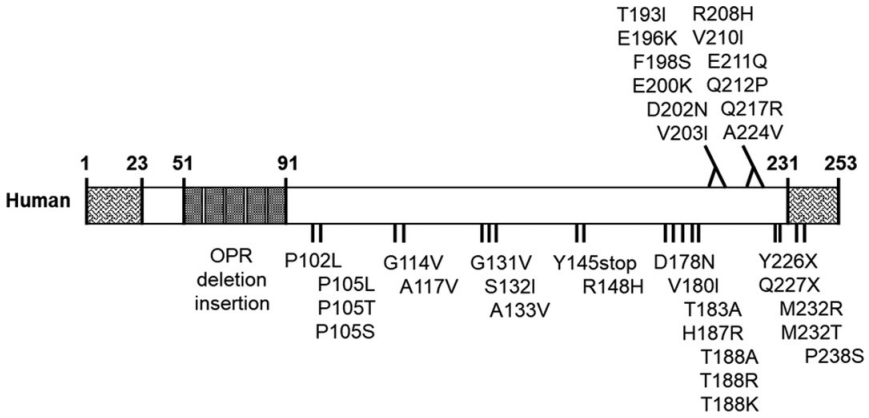

FIGURE 22.14 **Human *PRNP* mutations associated with prion disease**.

Historically, patients with inherited prion disease were categorized based on three clinical/neuropathological phenotypes: fatal familial insomnia (FFI), Gerstmann-Sträussler-Scheinker syndrome (GSS), and familial CJD. As we learn more about the PrP features underlying these diseases, and their overlapping clinical presentations, it may become more appropriate to classify these diseases based on their neuropathological profiles, with thalamic degeneration and PrP amyloidosis replacing FFI and GSS, respectively.

Thalamic Degeneration (Fatal Familial Insomnia)

In 1986, Lugaresi et al. first coined the phrase “fatal familial insomnia (FFI)” to describe a heritable neurodegenerative syndrome of progressive sleep disturbance, autonomic changes including pyrexia and diaphoresis, tremor, dysarthria, ataxia, myoclonus with cognitive decline progressing to akinetic mutism within a year of onset.[239] Pathological findings revealed severe atrophy of the thalamus, without marked spongiform change or amyloidosis. The association with a mutation in *PRNP* was identified in 1992.[251,270] In 1995, FFI was proven to be a transmissible prion disease.[101,375]

The *PRNP* mutation that gives rise to the FFI is D178N when it occurs *in cis* with a methionine at codon 129. Interestingly, if D178N occurs *in cis* with valine at codon 129, a phenotype of familial CJD occurs, which is indistinguishable from sporadic CJD. In patients who are heterozygous for the codon 129 allele, disease duration, clinical phenotype, and neuropathology are modified. 129MM patients have a shorter disease duration (11 ± 4 months) compared with 129MV patients (23 ± 9 months).[144] Homozygous patients typically present with sleep disturbances, with more prominent myoclonus, autonomic dysfunction, spatial disorientation, hallucinations, and weight loss, whereas heterozygotes often have early visual symptoms and ataxia, followed by dysarthria, seizures, and bulbar symptoms.[144,210]

Diagnosing FFI is challenging. MRI is less often abnormal, possibly because there is less spongiform change or PrP^d burden, and EEG reveals loss of sleep architecture but not the classic periodic discharges.[109] The real time-quaking-induced conversion (RT-QuIC) assay, which has high sensitivity and specificity for many types of human prion disease (see below), also has reduced sensitivity for FFI, reaching only 83% sensitivity at best.[339] Fluorodeoxyglucose positron emission tomography (FDG-PET) or single photon emission computed tomography (SPECT) may be helpful, in that it can reveal hypometabolism in the thalamus that spreads to other areas as the disease progresses,[298] but ultimately, the proof is the detection of the *PRNP* mutation.

PrP Amyloidosis (Gerstmann-Sträussler-Scheinker)

The history behind GSS is more complicated.[150] It was initially identified as a heritable neurodegenerative syndrome in an Austrian family in 1912,[145] where patients presented at a younger age (early 50s) with early ataxia, late cognitive decline, and often pyramidal and extrapyramidal features. The progression of disease was also much longer, often lasting 6 years. All patients had a characteristic neuropathology with multicentric amyloid plaques. Subsequent studies have identified these plaques as being composed of PrP^d.[151] GSS has also been shown to be transmissible to mice expressing human PrP with the P102L mutation.[16]

Over the following decades, at least 24 mutations in *PRNP* have been linked with GSS neuropathologies of cerebral amyloidosis (Fig. 22.14),[150] with the majority having P102L *in cis* with methionine at codon 129, as seen in the original GSS kindreds.[179] It is really the pathology that defines this group of cerebral amyloidoses more than the clinical phenotypes, because unlike FFI, GSS phenotypes overlap with different mutations, and there are now four recognized clinical phenotypes associated with the P102L mutation alone, including the typical GSS described originally, GSS with areflexia and paresthesia, pure dementia GSS, and CJD-like GSS.[379] At least some of this variability appears to relate to the relative levels of PrP^d generated from the mutant vs wild-type PrP allele in a given individual.[301,307]

A separate type of prion amyloidosis has also been identified as a cerebral amyloid angiopathy (CAA) in which PrP amyloid accumulates in the cerebral blood vessels. This is often associated with nonsense mutations causing truncated versions of PrP and can coexist with tau aggregates.[150]

In keeping with the distinct pathologies of these cerebral amyloidoses, a neuropathological classification has been proposed: (1) parenchymal PrP amyloid and prominent spongiform changes; (2) parenchymal PrP amyloid and minimal or no spongiform changes; (3) parenchymal PrP amyloid coexisting with severe tau neurofibrillary pathology, and absent or minimal spongiform changes; and (4) vascular PrP-CAA coexisting with severe neurofibrillary pathology.[150]

Systemically, there are also PrP amyloidoses that affect the gut and peripheral nervous system, causing syndromes associated with diarrhea and peripheral or autonomic neuropathy. To date, these have been linked to the nonsense mutations Q160X[136] and Y163X.[266]

Implications of Genetic Prion Diseases

The detection of a mutation in *PRNP* has implications for diagnosis, genetic counseling, and access to surgical procedures for asymptomatic carriers. Several mutations are considered 100% penetrant, including E200K, which causes genetic CJD; A117V and P102L, which cause GSS; and D178N, which causes either FFI if *in cis* with methionine at codon 129, or genetic CJD if *in cis* with valine at codon 129. However, sometimes patients with progressive dementia have *PRNP* mutations that are not causal or have low penetrance, so care must be taken before counseling family members of patients. For example, the penetrance of M232R, V180I, and V210I are low, with lifetime risks estimated to be 0.1%, 1%, and 10%, respectively.[275] Interestingly, the mutation sometimes influences the clinical phenotype; patients with E200K and V210I present similarly, with symptoms indistinguishable from sporadic CJD,[426] whereas V180I is associated with a later onset of slowly progressive dementia without many of the other motor or visual manifestations seen in CJD.[317]

Another important feature of genetic prion diseases is that the age of onset can vary greatly and cannot be predicted by age of onset in family members.[276] This makes it challenging both to counsel patients and to recruit patients into prophylactic treatment trials. In the future, predictive biomarkers, such as neurofilament light chain levels,[382] may help identify patients who are close to the clinical stage of disease.

Patients with a risk of inheriting a *PRNP* mutation, or who already know they are an asymptomatic carrier, can face challenges in access to health care. No cases of iatrogenic transmission from asymptomatic genetic carriers of *PRNP* mutations have been reported, so the risk remains theoretical. Tissues considered to have high infectivity are the same as those seen in sporadic CJD (Table 22.3). Most guidelines recommend that any surgical procedure involving higher-risk tissues requires that equipment go through additional sterilization procedures and that single-use tools be used whenever possible. Routine reprocessing procedures can be used for surgeries involving low-risk tissues. No cases of disease transmission by blood transfusion from sporadic or genetic CJD patients have been identified, but patients with a family history of CJD or a genetic carrier of CJD are generally not accepted as blood donors.

TABLE 22.3 Sporadic Creutzfeldt-Jakob tissue infectivity

Infectivity Titer	Tissue/Secretion
High	Brain, spinal cord, dura mater, pituitary gland, posterior segment of the eye (posterior hyaloid membrane, retina, retinal pigment epithelium, choroid, subretinal fluid, optic nerve)[56]
Low (case transmission to human/partial transmission to primate)	Cornea (1 definite and 1 probable iatrogenic human case following transplant) Cerebrospinal fluid, spleen, lymph nodes, lung, liver, kidney (partial transmission in primate studies[56])
Low (transmission to TgHuPrP mice)	Nasal olfactory mucosa,[325] blood,[124] bone marrow,[180] skin,[297] skeletal muscle, adrenal glands, thyroid, pancreas, salivary gland, heart, thymus, tonsil[123]
Detected only with ultrasensitive tests like RT-QuIC or PMCA	Blood vessels, peripheral nerves, urine,[240] placenta,[241] anterior parts of eye[295]
Below detection limits	Sweat, tears, nasal mucous, gingival tissue, feces, semen, GI tract, ovaries, uterus, adipose, bone[56]

Compilation of data based on iatrogenic human cases, animal transmission, and ultra-sensitive PrP^{Sc} detection studies.

RT-QuIC, real-time quaking–induced conversion; PMCA, protein misfolding cyclic amplification; TgHuPrP mice, transgenic mice expressing only human PrP.

Acquired Human Prion Diseases

Less than 1% of human prion disease cases are acquired. They can be iatrogenic or result from zoonotic exposure. In general, the incidence of acquired prion disease has decreased with the awareness of high-risk tissues (Table 22.3), improved surgical protocols, the cessation of using cadavers as source material for growth hormone and dura mater, and the decline in BSE, which caused variant CJD (vCJD) in humans.

Iatrogenic Cases

Patients have acquired CJD after exposure to corneal transplant, stereotactic EEG electrodes, neurosurgical instruments, cadaveric dura mater, pituitary-derived growth hormone, and blood transfusion from vCJD patients.[42,55] Of these, dura mater and human growth hormone recipients make up the vast majority, with at least 228 and 226 cases, respectively (Table 22.4). Incubation periods have ranged from 1 to 42 years after exposure.[55]

TABLE 22.4 Iatrogenic CJD

Source	Number of Cases	Incubation: Years (Range)
Dura mater graft	228	12 (1.3-30)
Neurosurgical instruments	4	1.4 (1-2.3)
Stereotactic EEG needles	2	1.3, 1.7
Cornea	2 (1 definite after graft; 1 probable after keratoplasty)	1.5, 27
Growth hormone	226	17 (5-42)
Gonadotropin	4	13.5 (12-16)
Packed red blood cells	3 (1 other died prior to symptom onset)	6.5, 7.8, 8.3

Adapted from Table 2 of Brown P, Brandel JP, Sato T, et al. Iatrogenic Creutzfeldt-Jakob disease, final assessment. *Emerg Infect Dis*. 2012;18(6):901-907.

A causal relationship between prior non-CNS surgery and risk of CJD has not been proven, but the quality of evidence available for assessing these associations is low, with prolonged incubation periods complicating associations and statistical significance depending largely on how the control group is selected.[116,237] In some studies, the timing of procedures may overlap symptom onset, and the majority of studies have found associations between procedures such as lumbar punctures, which are often done to investigate early clinical symptoms of CJD, and insertion of gastrostomy tubes, which are often provided to patients with inability to swallow, a finding that usually develops in later CJD.[112] In these situations, the link is clearly not causal as the procedures occur after symptom onset.

There has also been concern about eye surgeries, given the two cases of transmission via corneal transplant and the fact that the posterior component of the eye is considered high titer (Table 22.3). A confounding factor is the fact that the age of onset for CJD overlaps with the age of developing cataracts, and CJD patients may first present with visual symptoms to an ophthalmologist. Cataract surgery, which involves the anterior compartment of the eye, is not infrequently performed on CJD patients early in disease course. Studies assessing the risk of eye surgery on developing CJD are conflicting,[102,332,392] although separating out ophthalmic surgeries involving retina or optic nerve revealed a small association with CJD patients in one analysis.[115]

In the end, while iatrogenesis is difficult to prove, it is important to acknowledge that prions do exist in peripheral tissues of patients with sCJD (Table 22.3). Since the first large-scale nonhuman primate study of prion infectious titers in peripheral tissues from CJD patients,[56] studies using Met129 human PrP-expressing mice and sensitive detection assays have identified more infectivity than previously demonstrated.[123] As such, iatrogenic risk from non-CNS surgeries remains a theoretical possibility that cannot be ignored.

Patients with iatrogenic disease, when sCJD is the source, present with symptoms that are indistinguishable from sCJD, although patients exposed to contaminated dura mater have been reported to have kuru-like plaques on neuropathology.[202] *PRNP* variant 129MM is overrepresented in iatrogenic cases, analogous to sCJD cases, and heterozygous patients usually have longer incubation periods.[55]

Human-to-human transmission has also occurred orally and through blood transfusion. Oral infection occurred through the cannibalistic rituals of the Fore people in Papua New Guinea, where kuru was spread (see Evolution of the Prion Concept section). Three cases of clinical vCJD transmission from blood transfusion have been reported, although none of sporadic or genetic CJD[111,388] (https://www.cjd.ed.ac.uk/projects/transfusion-medicine-epidemiology-review-tmer). Of note, one patient who received a blood transfusion from a vCJD-infected donor died from a nonneurological disorder 5 years after transfusion but had PrP^d detectable in the spleen (not the brain). Whether this patient would have gone on to develop clinical vCJD is unknown but is probable. The three patients with clinical vCJD developed symptoms on average 7.5 ± 1 years after red cell transfusion. Interestingly, the donors were asymptomatic at the time of blood donation but developed vCJD symptoms 21-41 months after donation. There have been no reports of vertical transmission in CJD pregnancies, despite evidence for low-level PrP^d detection in gestational tissues.[120,218,241,372]

Zoonotic Transmission: Bovine Spongiform Encephalopathy and Variant Creutzfeldt-Jakob Disease

The only known zoonotic transmission of prion disease to humans has been from BSE, which gave rise to vCJD.[411] Classical BSE (C-BSE) was first identified as a prion disease in the mid-1980s in the United Kingdom,[406] and it is estimated that over 1 million infected cattle entered the human food system (https://www.who.int/csr/resources/publications/bse/en/BSEthreat.pdf). Prior to being discovered in humans, a novel prion disease was discovered in cats (feline spongiform encephalopathy; FSE), and C-BSE was shown to be transmissible to marmosets.[6,24] Then, in 1995, the first cases of vCJD were identified in humans.[36,52,411] Clinical features differed from sporadic CJD in that patients were younger, had longer disease duration, and more often presented with behavioral changes or painful paresthesias.[411] Brain isolates from C-BSE, FSE, and vCJD all produced the same clinical and neuropathological profile when transmitted to mice, proving the zoonotic link.[59] Cases of vCJD peaked in 2001-2002, with a total of 231 definite or probable cases worldwide to date.[177] While there have been no new cases since 2016, presumably due to a decline in BSE and restrictions on use of certain bovine tissues for human consumption, it is important to learn from the history of vCJD, so that we can be best prepared for any new zoonoses that may arise.

Once again, the *PRNP* 129 codon influenced the risk of vCJD, with almost all cases being MM, save for one MV case presenting in 2008[193] and one other MV patient who did not go on to autopsy confirmation. While these MV cases raised concern for a second wave of heterozygous patients with longer incubation periods, to date that has not occurred.

There is also the real potential of asymptomatic carriers. Given that vCJD is largely acquired orally, there is accumulation of PrP^d in extraneural tissues, such as the gut and lymphoid system. PrP^d is detectable in tonsils of vCJD patients, allowing diagnosis to be confirmed premortem by tonsil biopsy.[174] To survey the burden of PrP^d among people who would have been exposed to C-BSE during the epidemic, two studies were conducted in which researchers examined 45115 removed appendices or tonsils, looking for PrP^d by immunohistochemistry. Nineteen samples were positive,[153,175] giving a 1 in 2000 estimate of PrP^d carriers in the United Kingdom. Whether this really reflects infection or is a nonpathological accumulation of PrP is not clear. One difference between symptomatic vCJD cases and the asymptomatic cases associated with PrP^d deposition is that so-called carriers were represented by all codon 129 genotypes. A third appendix study examined 29516 tissues collected before the C-BSE epidemic (1962-1979) and from people born after 1996 who had appendices removed between 2000 and 2014. This study also revealed PrP^d deposits in 7 cases, raising two possibilities: (1) C-BSE exposure has occurred over a longer than expected timeframe or (2) abnormal PrP may accumulate in lymphoid tissues at a low background rate independent of BSE exposure.[154] The epidemiological consequence of these PrP^d deposition findings, with respect to clinical cases of vCJD and iatrogenic surgical risk, remains uncertain.

Since the C-BSE epidemic, other apparently sporadic but transmissible forms of BSE with different strain characteristics (eg, H-type BSE [H-BSE] and L-type BSE [L-BSE] or bovine amyloidotic spongiform encephalopathy [BASE]) have been identified.[30,68] Multiple studies of the transmissibility of L-BSE, H-BSE, and C-BSE in transgenic mice expressing human PrP^C have suggested that their relative zoonotic potentials are L-BSE > C-BSE > H-BSE.[215] However, no transmissions of atypical BSE strains to humans have been documented.

Potential Future Prion Zoonoses

No other zoonotic transmissions of prions have been reported to date, but CWD of cervids, including deer and elk, is increasing in prevalence, particularly in Canada and the United States (see Animal Prion Diseases section). However, there is ongoing human exposure, largely through consumption, raising concern that CWD could cross the species barrier and cause a new prion disease in humans. *In vitro* studies using protein misfolding cyclic amplification (PMCA) or RT-QuIC have demonstrated the production of human PrP aggregates after seeding with CWD prions.[31,114] *In vivo* experiments have been less convincing, with no transmission to mice expressing human PrP[206,319,338] and no transmission to macaques.[321] There was transmission to squirrel monkeys,[259,318] but these animals are less related to humans when compared with macaques. An important caveat with these studies is that there are several different CWD strains, and it is possible that some strains will be better able to cross the species barrier than others. New strains may also be generated through interspecies transmission to other mammals.[34,196,258] At the time of writing, the authors are aware of human PrP mouse and macaque *in vivo* experiments where preliminary data have suggested possible transmission, so the implications of CWD on human health remain unresolved. Finally, the recent discovery of prion disease in camels in Algeria has raised concerns of zoonotic risk from that species as well.[23]

Human Prion Disease: Diagnosis

In humans, prion disease diagnosis is based on a combination of clinical presentation, supporting diagnostic tests, and the absence of other explanations for a rapidly progressive dementia. Importantly, many tests and investigations are normal. Although prion diseases are infectious by definition, they do not induce the typical adaptive (humoral or cell-mediated) immune responses seen in infections caused by viruses, bacteria, fungi, parasites, etc., so there are usually no signs of inflammation on routine blood tests or cerebrospinal fluid (CSF) examination. This lack of response is due in large part to the fact that the disease is caused by an altered conformation of an endogenous protein, PrP, so it does not activate this type of immune response. There is, however, a considerable innate immune response in the form of astrocytosis and microglial activation in the brain,[244] which can be seen on pathology. For a definitive diagnosis, pathological confirmation is required, but brain biopsies are rarely done and can be falsely negative or nondiagnostic. Fortunately, there are specific tests that can help support a probable or possible diagnosis antemortem (Table 22.5).

TABLE 22.5 Human prion disease diagnostic criteria

Diagnostic Category	Criteria
Definite	Pathological confirmation: brain sample showing neuronal loss, spongiform change, astrocytosis, deposition of protease-resistant PrP; the presence of PrP^{Sc} may also be confirmed by immunoblot, where digestion and glycoform profiling help determine strain type
Probable	1. Neuropsychiatric disorder plus positive RT-QuIC (CSF or other tissue) **OR** 2. Rapidly progressive dementia; plus at least two of: • Myoclonus • Visual or cerebellar signs • Pyramidal/extrapyramidal signs • Akinetic mutism **AND** Positive result on at least one of the following: • EEG (electroencephalogram) periodic sharp wave complexes • 14-3-3 CSF assay in patients with a disease duration of <2 years • High signal in caudate/putamen on magnetic resonance imaging (MRI) brain scan or at least two cortical regions (temporal, parietal, occipital) either on diffusion-weighted imaging (DWI) or fluid-attenuated inversion recovery (FLAIR)
Possible	Progressive dementia **AND** at least two of the following: • Myoclonus • Visual or cerebellar signs • Pyramidal/extrapyramidal signs • Akinetic mutism **AND** duration of illness <2 years

Adapted from 2018 CDC guidelines. For both probable and possible disease, routine investigations must also exclude any alternate diagnosis.

Pathology

A diagnosis of definite prion disease requires tissue confirmation of protease-resistant PrP. For most forms of human prion disease, this requires postmortem brain autopsy. Antemortem brain biopsy can also confirm the diagnosis but is rarely used in suspect cases because of the challenges of decontaminating surgical instruments, and false negative or nondiagnostic sampling can occur. The classic neuropathological hallmarks of prion disease are neuronal loss, astrocytosis, spongiform change, and PrP^{d} deposition. Regional differences in pathology and PrP^{d} deposition patterns are seen depending on prion disease type (Fig. 22.12).

An exception to antemortem biopsy is vCJD, where tonsillar biopsy can provide a definite diagnosis. While the peak incidence of this disease has long passed, and the vast majority of human prion cases that clinicians will encounter will be sporadic, genetic, or other iatrogenic forms, it is theoretically possible that tonsillar biopsy could help diagnose future orally acquired prion zoonoses. For example, the cervid prion disease CWD (see section on Animal Prion Diseases), if able to cross the species barrier into humans, is likely to invade extra-CNS tissues, making tonsillar biopsies useful again.

Other tissues that have been used premortem for CJD diagnosis include skin biopsy[250,297] and nasal brushings,[292] but in these cases, it is not tissue pathology that is assessed, but rather the ability for prions in the tissue to trigger amplification of PrP misfolding in the RT-QuIC assay.[22,410] These approaches have yet to become mainstream but are being studied in several clinical research centers. At present, CSF is the preferred sample to collect for RT-QuIC, in part because evaluation of CSF is usually indicated in the work-up of other causes of rapidly progressive dementia, and it can be analyzed for other markers of inflammation, infection, and neoplasm.

Imaging

Neuroimaging is critical in the investigation of any rapidly progressive dementia, and the most useful imaging for prion disease diagnosis is magnetic resonance imaging (MRI). Of note, it is diffusion-weighted imaging (DWI) that is most diagnostic, but this sequence is not always included in routine MRI scans. On DWI MRI, the presence of restricted diffusion in at least two cerebral cortical regions and/or both the putamen and caudate has 83% sensitivity and specificity for CJD.[397,424] These diffusion changes at least partially correlate with the degree of spongiform change and PrP^{d} burden in these brain areas.[147] Recent protocols that quantify diffusion changes in 12 brain regions have led to improved accuracy and may allow for discrimination of subtypes of CJD.[46,304] Unfortunately, detecting this pattern depends on the inclusion of DWI sequences during acquisition, and the findings can be subtle and not always recognized by nonspecialist radiologists.[67] As such, an MRI reported as normal in a patient with CJD-like symptoms should be scrutinized by someone with experience reading CJD MRIs. In addition, MRI is less often abnormal in the genetic syndromes of FFI[86] and GSS.[379] Cortical ribboning restricted diffusion can also occur during status epilepticus, often in a strictly unilateral pattern. False-positive MRI findings have also been observed in treatable inflammatory conditions, Alzheimer disease, and dementia with Lewy bodies.[84,148,424]

Ligand-specific positron emission tomography (PET) for the prion protein is not available, but FDG-PET is being used more to investigate causes of neurodegeneration. For the rare cases of FFI, FDG-PET or SPECT may show thalamic hypometabolism that spreads to other areas with disease progression,[298] but there is no pathognomonic finding for CJD. Hypermetabolism can be seen in the limbic system, and parietal hypometabolism is a common finding, the latter associated with neuropathological findings of neuronal loss, astrocytosis, and spongiosis.[272] Because parietal lobe hypometabolism can be seen in other more common syndromes, including Alzheimer disease,[91] this particular finding is not helpful for diagnosis *per se*, but a longitudinal 2-year study of seven asymptomatic carriers of the *PRNP* G114V mutation and six related

noncarriers demonstrated progressive parietal and temporal lobe hypometabolism in asymptomatic carriers.[238]

Interestingly, these same patients were also imaged with diffusion tensor imaging (DTI). Over 2 years, the asymptomatic carriers also developed increased mean diffusivity along several white matter tracts, including several areas seen affected in symptomatic CJD patients. These included the superior longitudinal fasciculi, anterior thalamic radiations, cingulate gyri, and the left uncinate fasciculus.[190]

Electroencephalography

Electroencephalography (EEG) can be helpful if it shows 1-2 Hz periodic generalized discharges, as this has very high specificity (91%) for CJD in the right clinical context.[367] However, the sensitivity is much lower, around 44%, in part because not all types of CJD are associated with this finding,[109,173,424] and the finding itself is often transient, appearing later in disease, and disappearing within weeks to be replaced by background slowing. As such, the absence of discharges does not rule out CJD.

Cerebrospinal Fluid Analysis

A lumbar puncture is usually performed on any patient presenting with a rapidly progressive dementia in order to look for treatable infectious, inflammatory, neoplastic, or paraneoplastic causes that can mimic the CJD phenotype.[146] In cases of CJD, the CSF is usually normal or may have a slightly elevated protein level. The presence of white blood cells should raise the possibility of nonprion causes. In the past 10 years, a highly sensitive and specific test for prion disease has been used to assist in prion disease diagnosis: the RT-QuIC assay.[22,410] This assay detects trace amounts of misfolded pathogenic prion protein in the CSF by measuring its ability to seed the aggregation of normal recombinant prion protein substrate under shaking conditions. The assay is performed in the presence of thioflavin T (ThT), which fluoresces in the presence of β-sheet aggregates. A positive result is defined by a significant increase in ThT fluorescence. CSF RT-QuIC has high sensitivity and specificity (90%-97% and 99%, respectively)[48,137,138,173,293] for the most common forms of CJD and is being incorporated into more diagnostic criteria worldwide (Table 22.5). However, the RT-QuIC tests can be falsely negative if the spinal tap is contaminated with red blood cells. It has also been reported to be less sensitive for certain rare subtypes of sCJD (VV1 and MM2), sFI, and some genetic forms of prion disease.[48,173,339]

A previously used biomarker of prion disease was elevated 14-3-3 protein in the CSF. However, the sensitivity and specificity of this assay for CJD varies depending on assay type (Western blot vs ELISA) and subtype of CJD. Current ELISA assays that detect the gamma isoform have the highest sensitivities of 88%-97%,[224,344] but it is important to remember that the protein itself is more a marker of acute neuronal injury so if it is applied to control groups with inflammatory or neoplastic CNS diseases, specificity may be only 82%-87%.[219,368] This is an important point for clinicians who must be thorough in looking for treatable causes of rapid dementias.

In a population of 1000 subacute encephalopathy patients, CSF total tau levels >976 pg/mL, as measured by ELISA, was superior to 14-3-3, giving a sensitivity and specificity for CJD of 91% and 88%, respectively.[108] However, elevated total tau in the CSF can be detected in a number of neurodegenerative diseases as well as inflammatory and neoplastic CNS diseases, and there are no agreed upon cutoff values; therefore, total tau elevation must be interpreted in context. Interestingly, the ratio of phospho-tau to total tau may have better diagnostic value for CJD.[234,330,359]

Neurofilament light chain is being studied as a biomarker in many neurodegenerative diseases.[20] It is released in response to axonal damage and is not specific to any one disease. Its specificity for CJD requires further study,[173] but it appears to have higher sensitivity than 14-3-3 and total tau in detecting MV2 and VV2 subtypes.[2] It may also have prognostic value for genetic CJD patients, as it can be detected within 2 years of symptom onset.[382]

Human Prion Disease: Therapeutics

At present, there are no disease-modifying or preventative treatments available for prion diseases in humans, livestock, or wildlife. For patients with prion disease, clinicians can only offer symptom management. Decades of research have been invested in different therapeutic approaches,[378,391] from small molecule chemotherapeutic strategies targeting prion conversion,[357] to immunotherapy strategies[242] and newer approaches to neuroprotection based on stem cells.[327] These efforts started with demonstrations that certain polyanionic compounds could protect against scrapie infections in animals.[131,198] Extensive further screens have identified many classes of compounds that inhibit PrP^{Sc} formation in infected cells.[77,83,203,357,378] Many have been shown to increase survival time if given early to animals challenged with peripheral inoculations of prions. Unfortunately, most such compounds have poor bioavailability to the CNS unless they are injected directly into the brain. Inhibitors with some bioavailability to the brain, or that have been delivered directly into CJD patients' brains, have not yielded clear therapeutic effects.[100,391] Indeed, doing human trials on rare diseases that are phenotypically heterogeneous and rapidly progressive presents its own challenges. A major impediment to treating sporadic prion diseases (by far the most common) is that much brain damage is done before the patient shows clinical signs and is properly diagnosed. One promising development is the demonstration of antisense oligonucleotides as an approach for suppressing PrP^{C} and markedly slowing disease progression in prion-infected animals even when treatment is initiated near the onset of clinical signs.[277,284,326] This treatment, coupled with an international database of patients at risk for developing genetic CJD (prionregistry.org), and the possibility that plasma levels of neurofilament light chain levels may increase within 2 years of symptoms onset,[382] may set the stage for new human trials. Such trials would target patients with rare genetic forms of prion disease. A treatment that will rescue patients who are already symptomatic may be much further down the road and require combination therapy that targets prion formation and clearance, as well as neuroprotection.

Animal Prion Diseases

Bovine Spongiform Encephalopathy

The origin of the C-BSE is uncertain, but the ensuing epidemic was amplified to nearly 200 000 diagnosed cases by recycling of bovine meat and bone meal into cattle feed.[105] The vast majority of cases were in the United Kingdom, but some were seen in dozens of other counties.[177]

Fortunately, ruminant feed bans and other measures have now virtually eliminated C-BSE. However, H- and L-BSE cases continue to arise sporadically and, although rare and most prevalent in older cattle (>8 years old), they raise the possibility that without mitigation, further agriculturally mediated outbreaks of BSE or transmissions to other species might occur.

The feed-mediated amplification of C-BSE implies that most cases were due to oral exposures. Oral dosing experiments indicated that transmission of C-BSE to cattle can require as little as 1 mg of infected brain tissue.[207] After oral exposure, infectivity can be detected early in the ileal Peyer patches and then progress primarily via the autonomic nervous system to the brain prior to the onset of symptomatic disease.[3,177] In later stages, the infection disseminates further to other tissues including muscles.[3,26,107] Accordingly, some countries have designated multiple tissues as specified risk materials (SRMs) that should be excluded from human food, pharmaceuticals, and animal feeds to reduce the risk of transmission.

The atypical forms of BSE were discovered during surveillance of healthy and fallen stock. The designations of H- and L-BSE (or BASE) are based on the relative sizes (higher vs lower) of protease-treated PrP^{Res} bands on immunoblots.[105,107,177] Although the causes of these atypical types of BSE remain uncertain, the rarity and age-dependence of their incidence are consistent with spontaneous, rather than acquired, etiologies. Both L- and H-BSE are transmissible as distinct prion strains via intracerebral inoculation,[30,62,208,236] but transmission of H-BSE to mice expressing bovine PrP has sometimes produced a C-BSE-like strain.[384] Oral transmission of L-BSE to cattle has been inefficient, with a low clinical attack rate.[290] L- and H-BSE PrP^{d} are found most abundantly in the central and peripheral nervous systems with little accumulation in lymphoid organs (reviewed in Refs.[107,177,215]).

Scrapie in Small Ruminants

As with BSE, scrapie strains in sheep have been described as “classical” or “atypical” with the latter referring to the Nor98 strain.[38,70,177,257] The occurrence of scrapie in small ruminants extends to many parts of the world, including 25 countries in the EU, with a prevalence of 9 and 6 cases per 10 000 tested animals for typical and atypical scrapie, respectively.[177] Interestingly, atypical scrapie also has been detected in Australia and New Zealand, countries that have been regarded as free of classical scrapie. The prevalence of classical scrapie varies within countries and over time, consistent with contagion between infected animals being the main etiology. In contrast, the prevalence of atypical scrapie is more consistent, regardless of exposure. Such findings support the notion that although atypical scrapie is experimentally transmissible, it is not as naturally contagious as classical scrapie and may be largely spontaneous.

Differences in the tissue distributions of classical and atypical scrapie PrP^{Sc} may help to explain the apparent differences in the natural contagiousness of these strains.[70,177] In classical scrapie, the infection is usually contracted orally within the first weeks of life. The infection enters gut-associated lymphoid tissue such as the Peyer patches and then spreads to other lymphoid organs, and on to the spinal cord and brain via the autonomic nervous system. Eventually, the infection spreads centrifugally to other tissues such as the peripheral nervous system, muscle, and blood. Pregnant ewes can accumulate infectivity in their placentas, which is shed into the environment as the afterbirth. Infectivity is also found in colostrum and milk. As a result, perinatal exposures contribute significantly to the natural spread of classical scrapie within flocks.

The distribution of atypical scrapie prions is more restricted to the central nervous system, presumably limiting the potential for environment shedding or transmission via casual contact,[177] but atypical scrapie can be transmitted experimentally via the oral route, raising the possibility that this might occur naturally to some extent.

Sheep have polymorphisms at *PRNP* codons 136, 154, and 171 that can influence susceptibility to scrapie (Fig. 22.13), with those homozygous for the A136, R154, R171 (ARR) allele being particularly resistant to scrapie.[70,177] Indeed, the resistance of this sheep genotype to classical scrapie has been used as justification for breeding programs aimed at generating scrapie-resistant flocks. Such programs have markedly reduced the prevalence of scrapie in Europe[15] and the United States.[12] However, a note of caution is that carriers of the ARR allele are susceptible to atypical Nor98 scrapie.[38] Also of concern is the emergence of a C-BSE–like prion strain in asymptomatic pigs inoculated with atypical (Nor98) sheep scrapie.[258] Such findings emphasize that resistance of host genotypes to prions can be strain dependent and that transmissions into intermediate species can alter prion strain characteristics and, perhaps, zoonotic potential.

Chronic Wasting Disease

Chronic wasting disease (CWD) is a prion disease of cervids that was first identified in 1967 in a captive mule deer in Colorado.[415] Since that time, it has steadily spread, both through transport of infected captive deer and elk and through wild animal migration, to at least 26 U.S. states, 3 Canadian provinces, and has affected cervids in Finland, Norway, Sweden, and South Korea (https://www.cdc.gov/prions/cwd/occurrence.html). The cervids affected include deer, elk, moose, and reindeer. CWD is the most efficiently transmitted prion disease and is now the most prevalent prion disease, with cases continuing to rise. Up to 30% of animals are infected in some free-ranging herds, and rates approach 100% in some captive deer herds. Management has proven difficult because CWD is being spread throughout the extensive geographic ranges of wild deer and elk, and CWD prions cannot be easily cleared from the environment, where they avidly bind soil and likely remain infectious for years.[216]

As with typical scrapie, CWD transmission is largely by the oral route. Prions can be found in many tissues of CWD-affected cervids, including the central nervous system, lymphoid tissues, spleen and pancreas, peripheral nerves, muscle, blood, and antler velvet.[129] Prions are shed into the environment through saliva, feces, urine, placenta, and carcasses, leading to environmental contamination and horizontal transmission.[260] There is also evidence for vertical transmission.[282,347] The fact that CWD prions are present in muscle[10] and elk velvet,[11] raise particular concern for human exposure and potential zoonotic transmission.

Several polymorphisms in the cervid *PRNP* gene have been linked to reduced CWD susceptibility, delayed disease onset, altered disease course, and/or pathology (Fig. 22.13).[13,14,278,285] These include alleles encoding leucine (L) at residue 132 in North American elk, asparagine (N) at residue 138 in reindeer or caribou, phenylalanine (F) at residue 225 in mule deer, and serine (S) at residue 96 in whitetail deer. Early results from a breeding strategy to reduce the frequency of the highly susceptible 96G (glycine at residue 96) *PRNP* variant in farmed whitetail deer have been promising with respect to CWD prevalence.[165]

Camel Prion Disease

Recently, prion disease has been discovered in three dromedary camels (>8 years of age) brought to a slaughterhouse in Algeria.[23] These animals had pathognomonic neurodegeneration and PrP^d in brain tissue. The origin of camel prion disease is unknown, but detection of PrP^d in lymphoid tissue increases the chances of horizontal spreading among individuals. A retrospective analysis indicated that 3.1% of camels coming to the slaughterhouse in 2015-2016 had neurological signs suggesting prion disease.

Other Mammalian Prion Diseases

Prion diseases of humans, cattle, sheep, and cervids have been transmitted experimentally or inadvertently to a wide range of additional mammalian species including nonhuman primates, mink (transmissible mink encephalopathy), cats (feline spongiform encephalopathy), pigs, rodents, and exotic ungulates.[4,353] Of note, some species are susceptible to an unusually broad range of prion strains, that is, bank voles[287,403] and squirrel monkeys,[56,259,321] while others are largely resistant, for example, dogs.[281,396] However, it is not clear whether these additional species naturally harbor their own prion disorders. Gianluigi Zanusso and colleagues revealed an intriguing situation in which a man and his cat had simultaneous prion diseases, with the man's disease like sCJD and the cat's being distinct from the feline spongiform encephalopathy resulting from BSE infections.[423] However, the origin(s) of these two cases remains unknown.

Given the diversity of prion strains in mammals, practical concerns include the extent to which interspecies exposures to prion-infected materials might generate prion strains with new transmission and virulence characteristics. Examples of such shifts in prion strain characteristics upon interspecies transmission are well documented.[34,196,258] A related concern is whether CWD is transmissible from cervids into predators, scavengers, other wildlife, or domesticated species. This appears not to be the case for mountain lions at least.[418] However, mountain lions, crows, and coyotes can shed prions that they have consumed in their feces for a few days, potentially contributing to environmental dissemination.[37] On a positive note, the prion seeding activity shed from mountain lions is only ~3% of that consumed, indicating an ability to either degrade or sequester ingested CWD prions.

Detection of Prions

The detection of prions, or surrogates thereof, is important in many facets of prion disease management, including surveillance, risk reduction, diagnosis, therapeutics, and fundamental research. Historically, prions have been detected by animal bioassays taking months to years. Much more rapid immunoassays, such as ELISA, Western blot, or immunohistochemistry, can now be used for prion (or PrP^d) detection in specimens with high prion loads, such as nervous or lymphoid tissues.[265] However, up to 10 million-fold higher sensitivities, even exceeding those of animal bioassays, can be obtained with cell-free prion seed amplification assays such as PMCA,[334] amyloid seeding assay,[99] or RT-QuIC.[22,135,265,410] Certain murine prions can also be assayed with high sensitivity using scrapie cell assays[201] that involve prion amplification through multiple *in vitro* passages followed by *in situ* immune detection of infected cells.

Many adaptations of cell-free amplification assays have been developed for most mammalian prion strains.[135,294] Although amplification assays are more time-consuming and technically demanding than ELISA assays, they provide the sensitivity necessary for detecting low levels of prion seeds in diagnostic specimens that can be collected from live individuals or released into the environment. As noted above, the most commonly used amplification assay platform for human diagnostics is RT-QuIC. *Antemortem* diagnostics for animal prion diseases are under development[70,134,166,167] and, if sufficiently practical and validated, may become particularly important in the determination of prion infection status in cervids and sheep as part of surveillance and prion-free certification programs. One approach to testing for CWD in live cervids has been to analyze rectoanal mucosal lymphoid–associated tissue (RAMALT) biopsied from anesthetized animals.[167] Several studies have demonstrated markedly improved diagnostic sensitivity when RAMALT biopsies are tested with RT-QuIC vs immunohistochemistry.[166] Another promising but as yet unvalidated approach is RT-QuIC testing of outer ear punches.[134]

Antemortem diagnosis has not only been difficult historically for PrP-based prion diseases but also for many of the other human proteinopathies. Accordingly, RT-QuIC–like seed amplification assays are being developed for many of these other diseases as well.[135]

Inactivation of Prions

Prions are often more resistant to inactivation than typical microbes and may resist decontamination procedures that are routine in clinical, agricultural, or mortuary settings. However, certain chemical treatments, prolonged high temperature autoclaving, and thorough incineration, alone or in combination, can be effective in decontaminating contaminated materials and surfaces. The reader is referred to the Biosafety in Microbiological and Biomedical Laboratories 6th edition for details and recommended handling protocols.[76]

Perspectives

Major challenges remain to be tackled in the prion diseases field. We currently have three near-atomic structures of two rodent prion strains, but there are dozens more to be determined to fully understand prion diversity. Research into the pathogenesis of prions has been rich and multifaceted. However, it remains unclear how to prioritize the many ways that prions can be neurotoxic, and how to translate such information into practical therapeutics. Although prion disease diagnostics in living human patients have improved markedly in recent years, much remains to be done to make *antemortem* diagnostics in other mammals accurate and practical enough for routine applications in agriculture and wildlife. Further study is also required to understand the extent to which prionlike mechanisms contribute to the etiology and pathogenesis of the many proteinopathies that involve the abnormal assembly of proteins other than PrP.

In assessing the clinical significance of prionlike characteristics of various protein aggregates, a key issue is not only transmissibility but also pathogenicity; that is, do replicating and spreading aggregates necessarily cause disease in the new host[75,93]? This issue is analogous to the distinction between virulent vs nonvirulent viral or bacterial infections. When transmitting TSE prions from one species to another, or when inoculating synthetic PrP aggregates, the inocula can sometimes initiate extensive conversion of the host's endogenous PrP molecules without causing clinical disease or, even TSE-associated neuropathological lesions, within the lifespan of the host.[32,75,163,213,246,322] Indeed, different

wild-type hamster PrP amyloid fibrils have been shown to range in lethality across many orders of magnitude and have varying abilities to replicate and/or cause neuropathology (Fig. 22.15). Also, some neuropathogenic mutant forms of PrP can accumulate in the host without being transmissible to other hosts.[93]

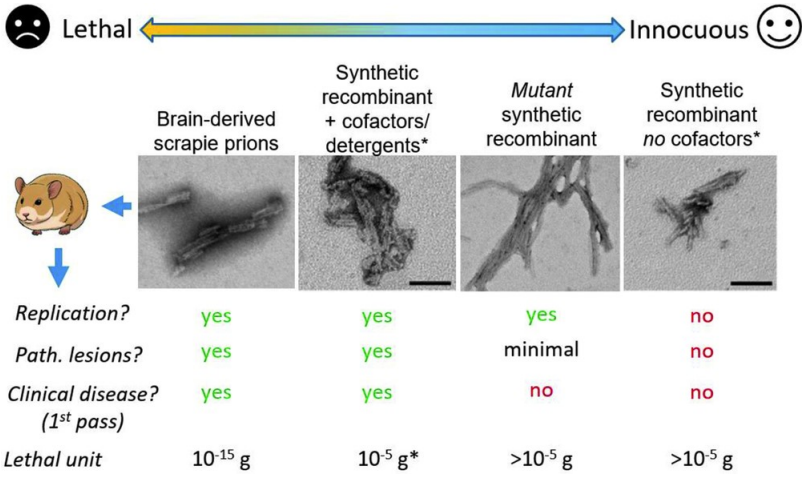

FIGURE 22.15 **Range of transmissibility and pathogenicity of hamster PrP amyloid fibrils**. Although all of the depicted amyloid fibrils are capable of continuous propagation either *in vivo* or *in vitro*, they differ dramatically in their infectious properties when inoculated intracerebrally into hamsters. Negatively stained transmission electron micrographs show fibrillar ultrastructures (bar = 100 nm). Although the fibrils depicted in the second panel from left were prepared with detergent and only barely lethal,[195] it is important to note that other synthetic recombinant prions prepared with cofactors can be orders of magnitude more lethal per unit protein (lethal unit of ~10^{-10} g).[400]

(Adapted from Figure 1 of Caughey B, Kraus A. Transmissibility versus pathogenicity of self-propagating protein aggregates. *Viruses*. 2019;11(11):1044. http://creativecommons.org/licenses/by/4.0/.)

In humans, as noted above, concerns remain about the implications of finding abnormal PrP deposits in the appendices of 1 out of every 2000 Britons in an age cohort that could have been exposed to BSE prions. Related concerns about the potential transmissibility of Aβ amyloid have been raised recently based on the detection of Aβ pathology in patients with early-onset CAA or who had undergone prior neurosurgeries,[184] dura mater grafts,[168] or injections of cadaveric growth hormone.[183] However, an extensive analysis of a cohort of people in the latter category provided evidence that exposures to injected Aβ or α-synuclein amyloids were not epidemiologically significant causes of neurological disease.[18,181] These examples emphasize the epidemiological importance of considering not only prionlike spreading potential but also the clinical manifestations, if any, of accumulating self-propagating protein assemblies.

Acknowledgments

This work was supported in part by the Intramural Research Program of the NIAID. We thank Drs. Suzette Priola, Cathryn Haigh, Ankit Srivastava, Moses Leavens, James Carroll and Efrosini Artikis, and Kachi Isiofia for critiquing this manuscript. We thank James Striebel and Bruce Chesebro for assistance with Figures 22.10 and 22.11.

at plasma membrane, 154–155
viral glycoproteins in polarized epithelial cells, 156
Cellular protooncogenes, insertional activation, 294–295
Cellular responses, 405
Central nervous system neurons, 412
Cerebral amyloid angiopathy (CAA), 640

Cerebrospinal fluid analysis, 643–644

Cerebrospinal fluid serology, 461

Cervical intraepithelial neoplasia (CIN) grade 2, 423

cGAS virus recognition pathway, 229–230, 230*f*

cGAS-STING signaling pathways, 230

Chamberland, Charles, 4

Chamberland filter, 5, 5*f*

Chaperones

involvement in prion propagation, 581–582, 581*f*

ribosome-associated, 583

Chikungunya virus (CHIKV), 194

Chimeric live virus reassortant and recombinant vaccines, 428–429

Chimeric recombinant virus vectors, 427–429

Chinese hamster ovary (CHO) cells, 425

Chlorella, 467–468

Chloroviruses, 472

Cholesterol, 182–184, 183*f*

metabolism, 185

Cholesterol recognition/interaction amino acid consensus (CRAC), 507–509

Chronic infection, 192–193, 193*f*

vs acute, host response to, 193–194

serology in, 459

Chronic wasting disease (CWD), 624, 642, 645–646

Cidofovir, 366*f*–367*f*, 370, 388

Ciluprevir, 363–365, 364*f*

Circular genetic map, T-even phages, 8

Circulating vaccine-derived poliovirus type 2 (cVDPV2), 403

Citrate, 176–178

Class I fusion proteins, virus entry, structure biology of, 78–83

HIV-1 Env, 81, 82*f*

influenza A virus HA, 78–81, 79*f*, 80*f*, 81*f*

paramyxovirus and pneumovirus F, 81–83, 82*f*

Clathrin-mediated endocytic pathway, 101*f*, 102, 103*f*

Clinical Laboratory Improvement Amendments (CLIAs), 452

Clinical virus disease research, 199

Closteroviridae, 512

Cluster randomized trials, 336

Co-delivery vaccines, 435

Codon pair deoptimization, 420–421

Cohort studies, 335–336, 335*f*

Community (herd) immunity, 400–403
Complementary DNA (cDNA), 567
Conjugates, 435
Connector, in bacteriophages, 591–592
Contagious living fluid, 4
Contamination, nucleic acid amplification assays, 457
Continuous cell lines, 28
Copy number control (CNC), 560–561, 574–575
of 20S RNA and 23S RNA, 570
Coreceptors, 97, 358–360, 359*f*
Correlates of protection (CoPs), 404–405
Cortical actin network, 96
Cortical ribboning restricted diffusion, 642–643
Corticoviridae, 612–613
Cotesia congregata bracovirus (CcBV), 544
COVID-19 pandemic, 15–16, 101–102, 247–248
Coxsackie and adenovirus receptor (CAR), 97, 98*t*–99*t*
CpG 1018 adjuvant, 434
Creutzfeldt-Jakob disease (CJD), 624, 636
cerebrospinal fluid analysis for, 643–644
electroencephalography for, 643
imaging, 642–643
non-PRNP single nucleotide polymorphisms, 636–637
PRNP gene polymorphisms, 636, 639*f*
susceptibility and phenotype, 636–637
Crisis, 27
CRISPR effector complexes, 325–326
CRISPR gene editing, 203–204
CRISPR system, 618
CRISPR-based strategies, 35
Cryogenic electron microscopy (cryo-EM)
bovine papillomavirus, 51, 51*f*–53*f*
limitation, 51
Cryogenic electron tomography (cryo-ET)
herpes simplex virus type 1, 51, 52*f*
immature and mature HIV-1 particles, 51, 53*f*
Cryphonectria parasitica, 568
coding information and protein processing of, 569*f*
infectious cDNA *clones and biological control*, 570
mitochondrial RNA replicon NB631, 570

RNAi in, 568–569

Cryphonectria, reovirus of, 567–568

CTXϕ phage, 611

C-type lectin receptors (CLRs), 228, 233–234

Cultured cell types, 27*f*

Cydia pomonella granulovirus (CpGV), 531

Cystoviridae, 612, 614

Cytochrome oxidase subunit I (COX1) gene, 571

Cytokines, 432–433

and cytokine receptor homologs, 281

Cytolytic viruses, 194

Cytomegaloviruses, 179

Cytopathic effects, 25–26, 29

Cytoplasmic targeting/retention signal (CTRS), 149–150

Cytotoxic T lymphocytes (CTLs), 12, 412

D

Dane particle, 422–423

Danger-associated molecular patterns (DAMPs), 515

Dead end, 342

Decoration proteins, 600, 602

Deep mutational scanning, 46

Defective interfering (DI) particles, 46

Deglycosylated protein Ags, 409–410

Delbrück “type” phages, 596

Delivery vehicles, 434–435

cell-based carriers, 435

conjugates, 435

lipid-based carriers, 434

mechanical devices, 435

synthetic particles, 434–435

Dendritic cells (DCs), 228, 240, 240*f*, 435

activation/maturation, 259

direct infection, 259

inflammatory mediators, 259

T lymphocytes in secondary lymphoid organs, 258–259

uptake of virus, 259

Dengue virus (DENV), 408–411

replication, 180

DENV infection, 214

DENV-specific afucosylated IgG1, 214

Pithovirus, 484–487

genome structure and organization, 486

stages of replication, 486–487

virion structure, 484–486, 485*f*

PKR-like ER kinase (PERK), 185

Plant viral nanoparticles (VNPs), 520

Plant viruses, 494, 496*f*, 500–504
benefits of
and biotechnology, 520–521
delivery vehicles for siRNAs and proteins, 519
for hosts, 519
ecology of, 495–496
epidemics, 496–499, 497*t*–498*t*
epilogue, 521
Geminivirus, 502
infection cycle and interactions with host cell, 503*f*
genome expression strategies, 500
host responses in defense and immunity, 512–517
antiviral RNAi, 512–513
autophagy, 514
effector-triggered immunity (ETI), 515
pathogen-associated molecular pattern triggered immunity (PTI), 515–516, 516*f*
RNA silencing and associated pathways, 512
secondary sRNA production in antiviral RNAi, 513
SUMOlylation, 514–515
surveillance pathways of cellular mRNA metabolism, 514
ubiquitin proteasome system (UPS), 514–515
unfolded protein response (UPR), 516–517
VSRs with host pathways, 513
and insect vectors, 517–519
feeding on virus-infected plants, 517–518
metabolic modifications, benefit for vector, 518–519, 519*f*
nonpersistent and semipersistent transmission, of viruses by aphids, 517*f*–518*f*
plant metabolism, vector transmission, 518
Rice dwarf virus (RDV) in, 518*f*
movement of, 509–512
from cellular to whole plant levels, 510*f*
linkage between virus replication and intracellular movement to PD, 509–511
long-distance movement into and out of phloem, 511–512
negative-strand virus infection cycles, 504
nucleic acids in, 496
pandemic, 497*t*–498*t*
Potyvirus, 502–504
infection cycle and interaction with host cell, 505*f*
recombination in evolution
in Potyviridae, 499–500

in *Tombusviridae*, 499–500
(+)RNA virus replication, 507–509
(+)RNA virus translation, 504–507
cap-independent translation, 504–506, 506*f*
cap-independent translation enhancers, 506–507
internal ribosome entry sites, 504–506
taxonomic scheme of, 495*f*
viroids, 512
Plasma membrane, enveloped viruses, 154–155
Plasmacytoid dendritic cells, 241
Plasmaviridae, 613
Plasmodesmata (PD), 500, 507
linkage between virus replication and intracellular movement to, 509–511
P-loop enzymes, 319–320
PM2 bacteriophage, 612–613
Podospora anserina, 579*f*
Polio vaccine development, 406, 407*f*
Polioviruses, 57*f*, 419
eradication, requirements for, 348
pathogenesis, 205
transcription and assembly of, 158–159
transmission, 205
Poly lactic co-glycolic acid (PLGA), 434
Polydnaviridae, 529, 542–546
Polydnaviriformidae, 542–546
Polydnaviruses
classification and structure of, 542–544
contributions to host's life cycle, 545
genome organization, 544–545
modulation of larval responses during parasitization, 545–546
morphological features of, 544*f*
proviral DNA of, 545
transmission of, 543*f*
Polymerase chain reaction, 453–454
Polyomaviridae, 125*f*–128*f*
Polyprotein cleavage, inhibition, 362–365
Polyunsaturated fatty acids, 180–181
Porcine circovirus-1 (PCV-1), 436–437
Portal, in bacteriophages, 591–592
Portal rotation model, 599

Postassembly modifications and virus release
cell-associated and noncanonical spread of infection, 164–165
nascent particles, mechanisms, 163–164
nonproteolytic maturation events, 162
proteolytic cleavage and virus maturation, 161–162
viral and cellular proteins in membrane extrusion, 162–163
Postexposure prophylaxis, 400
Post-Golgi vesicle pH, influenza virus M2 protein, 159
Posttranslational modifications, 144–145
Potato mop-top virus (PMTV), 511
Potato virus X (PVX), 509–510
Potyviridae, recombination in, 499–500
Potyvirus, 502–504
infection cycle and interaction with host cell, 505*f*
Powderject, 435
Poxviridae, 23, 127*f*
Poxvirus Immune Evasion (PIE) domains, 326
Poxviruses, 380
acquisition of multiple membranes, 157–158
therapy, 389–390
vectors, 429, 432
PRD1 bacteriophage, 607–608, 608*f*
Premarket approval (PMA), 457
Presumption of inclusion, 416–417
Primary cell cultures, 27
Primary explant culture, 26
Primary mRNA synthesis
DNA viruses of animals, 119–120, 119*f*
RNA viruses of animals, 119–120, 119*f*
Prime-boost strategies, 436
Prion amyloids
structures of, 580*f*

monoclonal Ab isolation, 417–418

structural biology coupled with computational biology, 418

Subacute sclerosing panencephalitis (SSPE), 348

Subcellular localization of proteins, 147

Succinate, 178

SUMOlylation, 514–515

Superfamily 3 helicases, 316

Surface lattices, 55

Surveillance pathways of cellular mRNA metabolism, 514

Susceptibility, 338

SYBR Green, 453

Synthetic biology, 191, 200

Synthetic particles, 434–435

Synthetic peptides, immunogens, 426

Synthetic self-assembling polypeptides, 435

T

T and B lymphocytes

properties, 249, 249*t*

in secondary lymphoid organs, 259–261, 260*f*

T4 bacteriophage, 596–601

antigen display, 600–601, 602*f*

assembly of tail, 601*f*–602*f*

capsid, 600

core genome, 597

DNA packaging, 599

DNA replication, 599

gene expression and regulation, 597–599

genome, 596, 597*f*

internal proteins, 600

promoters, 598*f*

virion structure and assembly, 599–600

T7 bacteriophages, 602–603

T cells, effector activities of

CD8+ effector mechanisms, 273–274

CD8+ T-cell exhaustion/dysfunction, 275

CD4+ TE effector mechanisms, 274–275

regulatory T-cell function, antiviral adaptive immune responses, 275–276

T lymphocyte development and selection in thymus, 251, 251*f*

Tape measure protein, 593

Taq polymerase, 454

Taqman assay, 453

Target amplification, 453–457

T-cell activation, 261

T-cell memory, 278

T-cell receptor

coreceptor, 257

costimulatory genes and proteins, 257

T-cell response to viruses

antigen processing and presentation to T cells, 266

induction of T-cell responses to antigen, 269

by major histocompatibility complex class I pathway, 266–268, 266*t*

major histocompatibility complex class II pathway, 266*t*, 268–269

Tecovirimat, 380, 381*f*, 389–390

Tectiviridae, 607–608

Telaprevir, 362–363, 364*f*

Temperate phages, 591–592

Terminal hosts, 342

Terminase, 379

Tetrahedral symmetry, 52–54, 54*f*

Tetraviridae, 551–552

Tetraviruses

classification of, 551–552

genome organization, 552, 553*f*

replication, transmission, and pathology, 552

virion structure, 552

T-even phages, circular genetic map, 8

Thalamic degeneration, 638–639

Thioflavin T (ThT), 643–644

3D-correlative fluorescence light and electron microscopy (3D-CLEM), 110

Three-dimensional image reconstruction methods, 50–51

Tissue-resident lymphocytes, 239, 239*f*

Tissue-specific isoforms, induction, 171

Titer, 31

TLR3, 233

TLR7, 233

TLR8, 233

TLR9, 233

Tobacco mosaic virus (TMV), 4–6, 4*f*, 52, 509

Toll-interleukin-1-receptor (TIR) homology domain, 515

Toll-like receptors (TLRs), 228, 232–234, 232*f*, 406

TLR3, 233

TLR7, 233

TLR8, 233

TLR9, 233

Tomato brown rugose fruit tobamovirus (ToBRFV), 496–499

Tomato bushy stunt virus (TBSV), 52, 55, 507–509, 508*f*

Totivirus type species L-A of *S. cerevisiae*, 561–567

antiviral systems, 566

cap-snatching by Gag separates strands, 565–566

killer phenomenon of, 562*f*

L-A genome structure, 562–564

L-A virion structure, 561–562, 562*f*

N-acetylation of Gag protein by *mak3p*, 567

Nuc1 and Ski3 block viral lethality in meiosis, 566

positive-strand synthesis, 564–565

posttranslational modification, 566–567

replication (negative-strand synthesis), 567

ribosomal frameshifting, 565

60S subunits, 565

Ski2 antiviral system, 566

stages in replication cycle, 564, 564*f*

transcription reaction, 564–565

translation, 565–566

viral assembly, 567

Traditional thin-sectioning methods, 50–51

Transcription-based amplification, 454

Transcriptomic studies, 186

Transgenic mice, viral oncogenes, 287

Translocation, 143–144, 144*f*, 145*f*

Transmissible amyloidosis

of Sup35p, 578

of Ure2p, 577–578

Transmissible spongiform encephalopathies (TSEs), 576–577

Transmission ratio, 342–343

Transposable element D (TED), 542

Transpovirons, 477

Triacylglycerols (TAGs), 182

Triangulation number (T-number), 52–55, 55*f*

Tricarboxylic acid cycle (TCA), 176–178, 177*f*

Acetyl-CoA, 176–178

citrate, 176–178

intermediates, functions of, 178–179

reducing equivalents and oxidative phosphorylation, 177

Triple gene block (TGB), 509–510

Trofile, 462

Trojan horse strategy, 96

Tumor necrosis factor-alpha (TNFα), 236

Tumor suppressor pathways, inactivation, 296–297

Tumor virology

cancer and cell transformation, 286–287

cellular targets of, 289–291, 289*f*

DNA virus oncogene action, 295–298

history of, 287–289

in human, 298–302

and HIV, 302–306

RNA virus oncogene action, 291–295

tool development, revolutionized biology, 287–289

and viral oncogenes, discovery, 287

Tumorigenicity, 28

Turnip mosaic virus (TuMV), 496

Turnip yellow mosaic virus (TYMV), 52, 514

Ty elements, 560–561

expression of, 573–575

+1 ribosomal frameshifting, 573–574

chromosomal genes regulating Ty transcription, 573

control of transcription, 573

host limitations on Ty transposition efficiency, 575

insertion on cellular genes, 573

packaging and assembly, 574

phosphorylation, 574

proteolytic processing, 574

self-imposed copy number control, 574–575

genome structure and expression of, 573*f*

replication cycle of *Saccharomyces cerevisiae*, 571–573, 572*f*

integration, 572–573

reverse transcription, 572

stucture of, 571

Ty5 integration, 575

Type VI secretion systems (T6SS), 615–617, 616*f*

U

Ubiquitin proteasome system (UPS), 514–515

Umbravirus like RNAs, 499–500

recombination in evolution of, 501*f*

Umbraviruses, 499–500

Uncoating

genome, 108

program, 108

Unfolded protein response (UPR), 516–517

Universal protective vaccines, 436

URE3, 577–578, 580–581

genetic evidence, 577

Ure2p

domains of, 577–578

infectious amyloid of, 578

Ure2p

domains of, 577–578

infectious amyloid of, 578

recombinant, amyloid filaments of, 578*f*

transmissible amyloidosis of, 577–578

Uronema gigas, 467

V

Vaccines

sequential combination of, 436

Vaccination, 398, 424–426

enveloped viruslike particles, 424, 424*f*

eukaryotic cells, production of viral proteins in, 425

by gene delivery, 426–433

DNA vaccines, 427

gene-based vectors, limitations of, 432

mRNA vaccines, 427

nucleic acid vaccines, 426–427

replication-competent vectors, 427–430

replication-defective vectors, 430–432

viral vectors as vaccines, 432–433

immunogens, synthetic peptides as, 426

inactivated virus vaccines, 421–422

features of, 421–422

future considerations for, 422
live virus vaccines, 418–421
advantages of, 419
attenuation of live viruses, genetic basis for, 420–421
disadvantages of, 419–420
isolating attenuated strains, history of methods, 418–419
nonenveloped virus-like particles, 424
prokaryotic cells, production of viral proteins in, 425–426
with proteins/peptides, 425
protein purification, 426
sequential combination of, 436
types of, 418–433
virus-like particle vaccines, 422–423
advantages of, 423
disadvantages of, 423–424
future considerations for, 423–424
Vaccine hesitancy, 437–438
Vaccine manufacturing, modernization of, 436
Vaccine-induced cellular immunity, 413–415
CD4 T Cells, 414–415
CD8 T cells, 413–414
Vaccine-induced humoral immunity, 406–407, 407*f*
Vaccine-induced immunity
mechanisms of, 405–413
affinity, structural and biochemical features of antibodies, 408–409
antibodies active against virus-infected cells, 411
antibodies, adverse effects of, 413
antibodies *in vivo*, antiviral activity of, 412
antibody escape mechanisms, 411
antibody-mediated virus neutralization, 407–408
CDR3 loops, of antibody variable region, 409
classical in vitro neutralizing activity, inhibitory antibodies, 412
efficient antibody interactions, structural features of antigens critical, 409–410
host antigens, inadvertent induction of antibodies to, 411–412
humoral immune response, antigens recognized by, 410–411
isotype, role of, 409
mucosal antibodies, 412–413
vaccine-induced humoral immunity, 406–407, 407*f*
Vaccinia virus (VACV) protein E3, 23, 326
Vaccinology, origins of, 399–400, 399*f*

Variably protease-sensitive prionopathy (VPSPr), 637–638

Variant CJD (vCJD), 640–642

Varidnaviria, 23, 117

Vector-borne viral infections, 341

Velociraptor, 602

Venezuelan equine encephalitis virus (VEEV), 205–206, 431–432

Vermamoeba vermiformis, 484

Vesicle shuttle mechanism, 105–106, 106*f*

Vesicular stomatitis virus (VSV)

mouse model, 408–409

RNP and M, organization of, 70–71, 71*f*

Vestigial esterase domain, 407–408

Vibrio cholerae, 611

Viperin (gene *RSAD2*), 238

Viral adaptation, 207

Viral antigen recognition

B cells

antigenicity and immunogenicity, 262–263

B-cell activation by viral antigens, 264–265

B-cell epitopes, 262

primary B-cell repertoire generation, 263–264

by T cells

antigen processing and presentation to T cells, 266

induction of T-cell responses to antigen, 269

by major histocompatibility complex class I pathway, 266–268, 266*t*

major histocompatibility complex class II pathway, 266*t*, 268–269

Viral assembly/egress

inhibition of, 379–385

HIV protease inhibitors, 382

influenza virus neuraminidase inhibitors, 382–385

letermovir, 379–380

maribavir, 380

tecovirimat, 380, 381*f*

Viral carcinogens, principles of, 300

Viral clearance

and chronic viral infection, 215

tissue damage and disease, 215–216, 216*f*

Viral dynamics, modeling, 343

Viral emergence, 344, 344*f*

Viral entry

inhibition of, 356–360
bulevirtide, 356–357
enfuvirtide, 360
fostemsavir, 357–358, 359*f*
maraviroc, 358–360, 359*f*
Viral evasion of cellular (T-cell) immunity
cytokine functions, interference
cytokine and cytokine receptor homologs, 281
receptor binding and modulation of immune cell function, 281
subverting antigen processing and presentation
antigenic peptide generation, 280
class I or II major histocompatibility complex synthesis, 279–280
nontranscriptional inhibition of major histocompatibility complex class I cell surface expression, 280
peptide transport, 280
Viral gene expression
inhibition of, 361–365
baloxavir, 362, 363*f*
HCV NS3/4A protease inhibitors, 362–365
Viral genome fossils, 17
Viral genome replication
inhibition of, 365, 366*f*–367*f*
prospects for new inhibitors and targets, 379
Viral genomes
structures and organization of
DNA vs RNA genomes, 122
linear and circular genomes, 123
positive, negative, and ambisense genomes, 122–123
segmented and nonsegmented genomes, 123–124
single- and double-stranded genomes, 122
Viral glycoproteins in polarized epithelial cells, enveloped viruses, 156
Viral hepatitis therapy, 388–389
HBV therapy, 388
HCV therapy, 388–389
influenza therapy, 389
Viral infections
epidemiology of, 13–15, 14*t*
spatial patterns of, 338
Viral metagenomics, 24
Viral molecular clone technologies, 191, 199–200
Viral pathogenesis

abortive infection, 192
acute vs chronic infection, 192–193, 193*f*
host response, 193–194
age dependence of virus resistance, 209–210, 210*f*
biological sex, 210–211, 211*f*
clinical observations, 204–205
coinfection, 212
comorbidities on susceptibility, 212
description, 191
disease, 194
foundational principals, 191
genetic determinants, 207–208
integrated effects, viral and host properties, 208–212
invasiveness, 195
latent infection, 192
model systems for human disease, 191
permissive, 192
productive infection, 192
proviral and antiviral host factors, 195
quasispecies, 193
in research areas, 218
sequential stages in infection, 205–207, 205*f*
study of
animal models, 201–204
cell culture systems, 199
clinical research, 199
epidemiology, 197–199
functional genomics technologies, 200–201
viral molecular clone technologies, 199–200
susceptible, 192
treatments and vaccines, 191
tropism, 196
variation in host microbiome, 211–212
viral immune evasion, 195–196
viral interactions, host immune system, 212–217, 213*f*
virulence, 194–195
Viral replication complexes (VRCs), 507
antiviral drugs block various stages of, 356, 357*f*–358*f*
Viral replication cycle, 191
Viral replication strategies

cis-acting RNA signals and specificity, 124–125
DNA viral genomes
expression and replication, 125–128, 125*f*–128*f*
latent and persistent infections, 130
mechanisms of, 129–130
regulation of, 128–129
transcription, 129–130
viral oncogenes and neoplastic transformation, 130–131
genome diversity, 117, 118*t*
host cell components, 121–122
host response, 120–121
levels of segmentation, 121
RNA replication, 121
RNA viral genomes
compartmentalization of replication sites, 136
expression and replication, 131–132, 131*f*–132*f*
host cell factors, 135–136
mechanisms of, 136–137
regulation of, 132–135
structural and nonstructural proteins, 135
transcription, 136–137
subcellular sites, 120
unique biology of, 118–120
viral genomes
DNA vs RNA genomes, 122
linear and circular genomes, 123
positive, negative, and ambisense genomes, 122–123
segmented and nonsegmented genomes, 123–124
single- and double-stranded genomes, 122
Viral sensing, pattern recognition receptors, 228
Viral vaccines, licensed in United States, 401*t*–402*t*
Viral virulence, 344–345
Virgiaviridae, 511
Virion-associated nucleic acids (VANA), 496
Virions, 50, 54–55
Virology
birth of
of immunology, 12
pathogen discovery, 1886–1903, 4–5
plant viruses and chemical period, 5–6, 6*f*

future aspects
genomics and the predictive power of sequence analysis, 16–17
pathogen discovery, 17–18
systems biology, 16
virome, 17
history, 1, 2*t*–3*t*
host-virus interactions and viral pathogenesis, 15
modern concept, development, 7–9
Viromes, 619
Virosomes, 434
Virulence, 194–195
determinants, 196–197
and genes, noncoding promoters or elements, 197
of field isolates, myxoma virus, 1951-1981, 207, 208*t*
phages, 591–592
Virus assembly and maturation
intracellular targeting and assembly
complex interactions with secretory pathway, 156–158
of enveloped viruses, cellular membranes, 151–156
of enveloped viruses in nucleus, 148–149
intracytoplasmic transport and assembly of retroviral capsids, 149–151
modification of secretory pathway, 158–159
of nonenveloped viruses, nucleus, 147–148
nucleic acid genome, 159–161
post-assembly modifications and virus release, 161–165
cell-associated and noncanonical spread of infection, 164–165
nascent particles, mechanisms, 163–164
nonproteolytic maturation events, 162
proteolytic cleavage and virus maturation, 161–162
viral and cellular proteins in membrane extrusion, 162–163
protein partitioning within cell, 140–147, 141*f*
Virus capsid proteins, 317
double jelly roll capsid proteins, 317
HK97, 317
single jelly roll (SJR) capsid protein, 317
Virus cultivation and assay, 30
hosts for virus cultivation, 26–29
cell culture, 26–29
laboratory animals and embryonated chicken eggs, 26
initial detection and isolation, 25–26

modern viral assays and approaches, 34–36
one-step growth experiment, 34
quantitative assay of viruses, 30–33
quantitative considerations in virus assay, cultivation, and experimentation, 33–34, 33*t*
comparison of, 33
dose-response in plaque and focus assays, 33
multiplicity of infection, 33, 33*t*
recognition of viral growth in culture, 29–30, 30*f*
virus cultivation, 30
Virus discovery, 463–465
Virus ecology, 17
Virus entry, structure biology of
membrane fusion, 79*f*, 80*f*, 81*f*, 82*f*, 84*f*, 85–86, 85*f*, 86*f*
penetration by nonenveloped viruses, 86–88, 87*f*, 88*f*
receptors and coreceptors
bilayer fusion, 78, 78*f*
class I fusion proteins, 78–83, 79*f*, 80*f*, 81*f*, 82*f*
class II fusion proteins, 83, 84*f*
class III fusion proteins, 83–85, 85*f*
HIV-1 gp120 interaction, 75–76, 77*f*
neuraminidase, 85
viral fusion proteins, 78
Virus genetics
defective interfering particles, 46
fundamental genetic concepts, 36–37
essential and nonessential, 37
gain-of-function mutations, 37
genotype and phenotype, 36–37
loss-of-function mutations, 37
selection and screen, 37
wild type, mutations, and mutants, 36
phenotypic mixing and pseudotypes, 46
reverse genetics, 42–46
deep mutational scanning, 46
DNA viruses and reverse-transcribing viruses, 43–44, 43*f*–44*f*
mutation design, 45–46
RNA viruses, 44–45, 45*f*
study of mutations and mutants, 37–42
complementation, 41
double mutants and siblings, 38

induced mutation, 38
leakiness, 40–41
marker rescue, 42
mutant genotypes, 38
mutant phenotypes, 38–40
recombination and reassortment, 41–42
reversion, 40
spontaneous mutation, 37–38
Virus genome evolution, 312
Virus genome replication, 312
Virus hallmark proteins (VHPs), 312
family B DNA polymerases, 314–315
helicases and genome packaging NTPases, 316–317
and implications, origin, 318–319
palm/RRM domain, virus replication machinery, 316
reverse transcriptase, 314
RNA-dependent RNA polymerase, 314
rolling circle replication initiation endonuclease, 315, 315*f*
virus capsid proteins, 317
Virus pan-proteome organization, 328–329, 328*f*
Virus protein evolution
dark matter of virus proteomes, 326–327
knowable unknowns, 326–327
unknowable unknowns, 326–327
exaptation and recruitment of host proteins, 327–328
gene exchange, hosts, 312
lineage-specific virus proteins, core processes, 323–324
moderately conserved proteins, virus functions, 319–323
capping enzymes, 322–323, 323*f*
DNA-dependent RNA polymerases and transcription factors, 321–322
P-loop enzymes, 319–320
proteases, 320–321
virus hallmark proteins
family B DNA polymerases, 314–315
helicases and genome packaging NTPases, 316–317
and implications, origin, 318–319
palm/RRM domain, virus replication machinery, 316
reverse transcriptase, 314
RNA-dependent RNA polymerase, 314
rolling circle replication initiation endonuclease, 315, 315*f*

virus capsid proteins, 317

Virus-induced immunopathology, 194, 217
Virus-like particles (VLPs) vaccines, 153, 422–423
advantages of, 423
disadvantages of, 423–424
future considerations for, 423–424
Virus-receptor interactions, 76*f*
Virus-specific IgM assays, 460–461
Voxilaprevir, 364*f*
VSV glycoprotein, G (VSV-G), 84, 85*f*, 408–409
VZV therapy, 387
W
Wac protein, 600
Warburg effect, 175–176
Waring blender, 8
West Nile transmission cycle, 342
West Nile virus, 23, 410–411
replication, 180
Wheat soilborne mosaic virus (WSBMV), 512
Whole genome sequencing, 287

Wiskott-Aldrich syndrome (WASP)-like protein, 531

X

Xenophagy, 227

X-linked agammaglobulinemia, 412

X-ray diffraction patterns, 6

Y

Yadokari viruses, 570–571

Yeast prions, 577*t*

structures of, 579, 579*f*

Yellow fever vaccine virus (YFV), 428–429

Z

Zaire ebolavirus, 23

ZAP (gene *ZC3HAV1*), 238

Zidovudine (AZT), 366*f*–367*f*, 371–373

biochemical mechanism of, 371, 372*f*

Zika virus, 29, 344

fetal birth defects, 197–199

seropositivity, 197–199

“Zinc-knuckle” modules, 69

Zoonotic transmission, 641–642

Zygotic induction, 8–9
