Preface

In the early 1980s, Bernie Fields originated the idea of a virology reference textbook that combined the molecular aspects of viral replication with the medical features of viral infections. This broad view of virology reflected Bernie's own research, which applied molecular and genetic analyses to the study of viral pathogenesis, providing an important part of the foundation for the field of molecular pathogenesis. Bernie led the publication of the first three editions of Virology, but he unfortunately died soon after the third edition went into production. The third edition became *Fields Virology* in his memory, and it is fitting that the book continues to carry his name. A number of changes and enhancements have now been introduced with the seventh edition of *Fields Virology*. The publication format of *Fields Virology* has been changed from a once every 5-6 years, two volume book to an annual publication that comprises approximately one-fourth of the chapters organized by category. The annual publication provides both a physical book volume and importantly an eBook with an improved platform. Using an eBook format, our expectation is that individual chapters can be easily updated when major advances, outbreaks, etc., occur. The editorial board organized the four-volume series for the seventh edition to consist of volumes on Emerging Viruses, DNA Viruses, RNA Viruses, and Fundamental Virology, to be published on an annual basis, with the expectation that the topics will cycle approximately every 4 years creating an annualized, up-to-date publication. Each volume contains approximately 20 chapters. The first three volumes of this seventh edition of *Fields Virology*, entitled Emerging Viruses, DNA Viruses, and RNA Viruses were published in 2020, 2021, and 2022, respectively. This fourth volume, Fundamental Virology, has been principally edited by L. W. Enquist, Peter M. Howley, and David M. Knipe with valuable input from all of the Associate Editors. We wish to thank Patrick Waters of Harvard Medical School and all of the editorial staff members of Wolters Kluwer for all their important contributions to the preparation of this book.

Introduction

Fundamental Virology is the fourth volume of the seventh edition of *Fields Virology*. The first three volumes, Emerging Viruses, DNA Viruses, and RNA Viruses were published in 2020, 2021, and 2022, respectively. There have been continued rapid advances in virology since the sixth edition that was published in 2013, and all the chapters in this Fundamental Virology volume are either completely new or have been significantly updated to reflect these advances. Major advances in basic virology since the last edition have been included in this volume.

This volume covers basic aspects of virology providing a historical context as well as fundamental principles, virus entry and uncoating, viral replication and assembly, and host immune responses to virology. There are chapters on viruses of insects, plants, bacteria, as well as chapters on prions as infectious agents. New chapters included in this seventh edition of *Fields Virology* are Metabolism and Viral Infection and Evolution of Viral Proteins. This Fundamental Virology volume is appropriate for use as a textbook for graduate students or advanced undergraduate students in virology courses, often when supplemented with individual virus chapters from Volumes 1-3 of this seventh edition.

We are grateful to L. W. Enquist, Jeff I. Cohen, Blossom Damania, Eric O. Freed, and Sean P. J. Whelan who joined us as the senior editors and participated in putting this volume together. We also are thankful to the chapter authors who have updated their chapters for this volume and to the new authors who have joined us in this continued endeavor to provide a comprehensive resource in basic virology.

CHAPTER 1

Virology: From Contagium Fluidum to Virome

L. W. Enquist • Vincent R. Racaniello

The concept of viruses as particulate infectious agents

The birth of virology

Pathogen discovery, 1886–1903

Plant viruses and the chemical period: 1929–1956

Bacteriophages

Early years: 1915–1940

Phages and the birth of molecular biology: 1938–1970

Developing the modern concept of virology

Animal viruses

Cell culture technology and discovery: 1898–1965

The molecular and cell biology Era of virology

The role of animal viruses in understanding eukaryotic gene regulation

Animal viruses and the recombinant DNA revolution

Animal viruses and oncology

Vaccines and antivirals

Virology and the birth of immunology

Emerging viruses

Epidemiology of viral infections

Host-virus interactions and viral pathogenesis

The COVID-19 pandemic

Lessons learned

Past is prolog

The future of virology

A role for systems biology in virology

Genomics and the predictive power of sequence analysis

The virome: how many viruses are there and where are they?

Pathogen discovery

Virology has had a remarkable history. Even though humans did not realize viruses existed until the late 1880s, viral infections have shaped the history and evolution of life on the planet. Viruses are likely to infect all living organisms, even though some have not yet been discovered. Not only do viral infections shape the evolution of their hosts but their hosts also influence the evolution of viruses. The consequences of viral infections not only altered human history but also have powerful effects on the entire ecosystem. As a result, virologists have gone to extraordinary lengths to study, understand, and in some cases attempt to eradicate these agents. It is noteworthy that just as the initial discovery of viruses required new technology (porcelain filters), uncovering the amazing biology underlying viral infections has gone hand in hand with new technology developments. Indeed, virologists have elucidated new principles of life processes and have been leaders in promoting new directions in science. For example, many of the concepts and tools of molecular and cell biology have been derived from the study of viruses and their host cells. This chapter is an attempt to review selected portions of this history as it relates to the development of new concepts in virology. A compendium of milestones in virology history is found in Table 1.1.

TABLE 1.1 Milestones in virology

Early observations and interventions

4000 BC: Visual evidence of rabies and polio in ancient art and artefacts
1796: Cowpox lesions used to vaccinate against smallpox (Jenner)
1885: Development of rabies vaccine (Pasteur, Roux)

The birth of virology

1882: Transmission of tobacco mosaic disease with cell-free extracts (Mayer)
1892: Description of filterable infectious agent (TMV) (Ivanovsky)
Discovery of virus neutralization (vaccinia) (Sternberg)
1898: Concept of the virus as a contagious element (TMV) (Beijerinck)
First animal virus (FMDV) (Loeffler, Frosch)
1901: First human virus (yellow fever virus) (Reed, Carroll, Agramonte, Lazear, Finlay)
1908: First leukemia-causing virus (Ellerman, Bang)
1909: Discovery of poliovirus (Landsteiner, Popper)
1911: First solid tumor virus (RSV) (Rous)
1913: Virus cultivation in tissue culture (VV) (Steinbault, Israeli, Lambert)
1915: Discovery of bacterial viruses (bacteriophages) (Twort, d'Hérelle)
1917: Development of the plaque assay and discovery of the particulate nature of viruses (bacteriophage) (d'Herelle)

1930–1950: Pathogen discovery and the birth of molecular biology

1931: Virus propagation in embryonated chicken eggs (Woodruff, Goodpasture)
Discovery of first influenza virus (swine influenza) (Shope)
1933: Discovery of human influenza virus (Smith)
1935: TMV crystallized (Stanley)
1936 TMV comprised of nucleoprotein and the nucleic acid is RNA (Bawden, Pirie)
1938: Yellow fever vaccine (Theiler)
Electron microscopy of viruses (TMV) (von Borries, Ruska, Ruska)
1939: One-step growth cycle (bacteriophage) (Ellis, Delbrück)
1941: First virus-associated enzymes (influenza virus) (Hirst)
1943: Genetic origins of mutations (bacteriophage) (Luria, Delbruck)
1948: Poliovirus replication in nonneuronal cell cultures (Enders, Weller, Robbins)
1949 Discovery of lysogeny and induction (bacteriophage) (Lwoff, Siminovitch, Kjeldgaard)

The remarkable 1950s

1951: Bacteriophage λ discovered (Lederberg)
1952: Animal virus plaque assay (poliovirus) (Dulbecco)
Discovery that viral genome is nucleic acid (Hershey, Chase)
Transduction of genetic information by bacteriophage (Zinder, Lederberg)
1953: Discovery of host-controlled restriction and modification (Luria, Bertani, Weigle)
1954: Development of polio vaccines (Salk, Sabin)
1955: Human cell culture (HeLa cells) (Gey)
In vitro assembly of infectious virus (TMV) (Fraenkel-Conrat, Williams)
1956: Discovery of mRNA in bacteriophage infection (Volkin, Astrachan, Brenner, Jacob, Meselson)
Virus particles composed of identical subunits (Watson, Crick)
RNA can carry genetic information (TMV) (Schramm, Fraenkel-Conrat, Williams)
1957: Discovery of interferon (Isaacs, Lindemann)
1958: Bacteriophage λ regulation paradigm (Pardee, Jacob, Monod, Lwoff)

The spectacular 1960s

1960: Discovery of SV40 (Sweet and Hilleman)
Triplet nature of the genetic code demonstrated (bacteriophage) (Crick)
Nonsense codons elucidated (bacteriophage) (Campbell, Epstein, Bernstein)
1962: Studies of virus structure (Klug, Caspar)
1964: Demonstration of the colinearity of gene with polypeptide chain (bacteriophage) (Brenner)
First human tumor virus (EBV) (Epstein, Barr, Burkitt)
1965: Autocatalytic *in vitro* synthesis of bacteriophage DNA (Spiegelman)
1967: Discovery of hepatitis B virus (Blumberg)
Isolation of bacteriophage λ repressor (Ptashne)
Discovery of viroids (Diener)
First virion-associated polymerase (VV) (McAuslan, Kates)
Discovery of the first filovirus (Marburg) (Siegert, Slenczka, Martini, Kissling, Robinson, Murphy, and others)

Ten highly productive years; the advance of recombinant DNA technology

1970: Discovery of retroviral reverse transcriptase (Temin, Baltimore)
1971: RNA polyadenylation (Darnell, Edmonds)
1972: First recombinant DNA molecules (phage λ, SV40) (Berg)
1973: First restriction map (SV40) (Nathans)
Major histocompatibility locus restriction of viral antigens (Doherty, Zinkernagel)
1974: First transgenic mouse (SV40) (Mintz)
Phage lambda vectors for recombinant DNA technology (Blattner, Davis, Enquist, Murray)

1975:	Discovery of mRNA capping (Shatkin, Moss)
1976:	First RNA virus genome sequenced (bacteriophage MS2) (Fiers)
	Demonstration that retroviral oncogenes are derived from cells (J. M. Bishop, Varmus)
1977:	First DNA virus genomes sequenced (ϕX174, SV40) (Sanger, Fiers, Weissman)
	RNA splicing discovered (adenovirus) (Roberts, Sharp)
	Discovery of tumor suppressor p53 (SV40) (Levine, Crawford)
	First virus crystal structure (TBSV) (Harrison)
1979:	World Health Organization declares smallpox eradicated
	First *in vitro* replication of viral DNA (adenovirus, SV40) (Kelly, Hurwitz, Stillman)
	First *in vitro* mRNA transcription system (adenovirus) (Roeder)
	First highly active template-specific RNA-dependent RNA polymerase from a eukaryotic source (BMV) (Hall)
	Discovery of tyrosine kinases (Hunter, Erikson, Eckhart)
The 1980s; major technology advances and four Nobel Prizes in 2 years	
1980:	First human retrovirus (HTLV-1) (Gallo)
1981:	First infectious molecular clones of an RNA virus (poliovirus) (Baltimore, Racaniello)
	Transcriptional enhancers discovered (Chambon, Khoury)
	Identification of mammalian transcription factors (MMTV, SV40) (Yamamoto, Tjian)
	Insertional activation of cellular oncogenes by retroviruses (Hayward, Astrin)
	Identification of polyadenylation signal (Shenk)
	Discovery of the Cre/lox recombination system in phage P1 (Sternberg)
	Structure of first viral envelope protein (Wiley, Skehel, Wilson)
1982:	Development of antiviral and other drugs (Elion, Hitchings)
	Definition of prions (Prusiner)
1982	Recombinant virus as vaccine for unrelated pathogens (Moss, Paoletti)
1983:	High-risk human papillomaviruses identified and linked to cervical cancer (zur Hausen)
	Discovery of AIDS virus (HIV) (Montagnier, Barre-Sinoussi, Gallo)
1984:	Discovery of nuclear localization signals (Smith, Butel)
	First infectious, multicomponent virus produced from cloned DNA (BMV) (Ahlquist)
1986:	First recombinant viral vaccine (HBV)
	Generation of transgenic virus-resistant plants (TMV) (Beachy)
	Discovery of hammerhead ribozymes (TRSV, ASV) (Bruening, Symons)
1988:	Discovery that DNA virus oncogenes products bind cellular tumor suppressor proteins (adenovirus, SV40, HPV) (Harlow, Weinberg, Livingston, Howley)
	First ribozyme with engineered specificity (Haseloff, Gerlach)
	Discovery of internal ribosome entry sites (poliovirus) (Wimmer, Sonenberg)
1989:	Discovery of hepatitis C virus (Houghton)
1990:	Transgenic mouse model for viral infection (poliovirus) (Ren and colleagues)
Technology and pathogen discovery as we enter the 21st century	
1990:	First human gene therapy with a retrovirus vector (Anderson, Blaese)
1991:	Discovery of viral antiapoptotic proteins (baculovirus) (Miller)
1994	Kaposi sarcoma herpesvirus discovered (HHV-8) (Moore, Chang)
1995:	Development of HAART treatment for AIDS
1998:	Gene silencing by double-stranded RNA, an antiviral response (Fire, Mello)
	Plant virion used for the synthesis of nanoparticles (Young)
	Discovery that plant viruses encode suppressors of RNAi (Vance, Baulcombe)
2002:	Severe acute respiratory syndrome (SARS) worldwide outbreak and containment
2003	Discovery of mimivirus (Raoult, Claverie)
2005:	Reconstruction and sequencing of the 1918 influenza virus genome (Palese, Garcia-Sastre, Tumpey, Taubenberger)
	Hepatitis C virus propagated in tissue culture (Chisari, Rice, Wakita)
2006:	Vaccine against human papillomavirus, the first vaccine designed to prevent human cancer
2008–2015:	Planned global eradication of poliomyelitis (WHO)
2010	Vertebrate genomes carry ancient viral genomes (Skalka, Bely; Taylor, Leach, Bruenn)
2011	Rinderpest virus declared eradicated
2012	Development of CRISPR technology for gene editing (Doudna, Chapentier, Zheng)
2013	Approval of telaprevir and boceprevir, first direct-acting antiviral drugs for hepatitis C virus
2017	Development of cryoelectron microscopy (Dubochet, Frank, Henderson)
2017	Delivery of CAR-T cells by retroviral vector approved by FDA
2017	Luxturna, an adenovirus-associated virus vector, approved by FDA for treatment of blindness
2020	WHO declares the COVID-19 pandemic
2020	First COVID-19 vaccines deployed after development in <1 year

Discoveries recognized by a Nobel Prize are highlighted in red.

Abbreviations: ASV, avocado sunblotch viroid; BMV, brome mosaic virus; HAART, highly active antiretroviral therapy; HIV, human immunodeficiency virus; HPV, human papillomavirus; TBSV, tomato bushy stunt virus; TMV, tobacco mosaic virus; TRSV tobacco ringspot virus; SV40, simian virus; FMDV, foot and mouth disease virus; WHO, World Health Organization; MHC, major histocompatibility complex; RSV, Rous sarcoma virus.

The Concept of Viruses as Particulate Infectious Agents

A diverse microbial world of bacteria, fungi, and protozoa had been widely accepted by the last half of the 19th century. An early proponent of the germ theory of disease was the noted German anatomist Jacob Henle of Gottingen (the discoverer of Henle loop in kidneys and the grandfather of 20th-century virologist Werner Henle). He hypothesized in 1840 that specific diseases were caused by infectious agents that were

too small to be observed with the light microscope. But he had no evidence for such entities, and consequently his ideas were not generally accepted. It would take the work of Louis Pasteur and Henle's student, Robert Koch, before it became evident that microbes could cause diseases.

As early as 1728, the term virus was used to describe an agent that causes infectious disease. Long before bacteria, fungi, and viruses were identified, it was known that some diseases could be transmitted from person to person. The nature of such agents was unknown, but because the word virus comes from the Latin meaning a poison, we can surmise that the agents were thought to be liquids.

In the 1800s, the work of Pasteur, Lister, and Koch founded the field of microbiology, leading to the germ theory of disease: microbes could cause infectious diseases. Louis Pasteur (1822–1895) studied fermentation by different microbial agents. From his work, he concluded that "different kinds of microbes are associated with different kinds of fermentations" and he soon extended this concept to diseases. In fact, Pasteur thought that all infectious diseases were caused by microbes, as suggested by his statement that "every virus is a microbe." Pasteur's reasoning strongly influenced Robert Koch (1843–1910), a student of Jacob Henle and a country doctor in a small German village. He developed solid media to isolate colonies of bacteria to produce pure cultures and stains to visualize the microorganisms. With these tools in hand, he identified the bacterium that causes anthrax (*Bacillus anthracis*, 1876) and tuberculosis (*Mycobacterium tuberculosis*, 1882). Joseph Lister (1827–1912), a professor of surgery in Glasgow, had heard about Pasteur's work and surmised that a sterile field should be maintained during surgery. Although many other scientists of that day contributed tools and concepts, it was principally Pasteur, Lister, and Koch who put together a new experimental approach for medical science.

These observations led Robert Koch to formalize some of Jacob Henle's original ideas for defining whether a microorganism is the causative agent of a disease. Koch's postulates state that (1) the organism must be regularly found in the lesions of the disease, (2) the organism must be isolated in pure culture, (3) inoculation of such a pure culture of organisms into a host should initiate the disease, and (4) the organism must be recovered once again from the lesions of the host. By the end of the 19th century, these concepts outlined an experimental method that became the dominant paradigm of medical microbiology. It was only when these rules broke down and failed to yield a causative agent that the concept of a virus as an infectious particle was born.

A key point in the history of virology was the development in 1884 by Charles Chamberland, an associate of Pasteur, of a porcelain filter that could retain bacteria. The filters were initially used to provide bacteria-free water for the laboratory. Pasteur, working on the agent of rabies, found that it could pass through such filters and thought it to be unusually small.

Later Ivanovsky and Beijerinck showed that the agent of tobacco mosaic disease to be small enough to pass through filters. Beijerinck had the important insight that the pathogen could only be propagated in plants not in broth as was known for bacteria. He called it a "contagious living fluid." After this work, many similar agents were found and the name "filterable virus" was applied to distinguish them from infectious agents that were retained on the filter.

At this point, the distinctions between bacteria and viruses were on the basis of filterability and reproduction in broth. The exact nature of "filterable viruses" was obscure. Four subsequent observations were essential in leading to our current concept of viruses.

Bacteriophages were discovered in 1917 and found to cause clear spots, or plaques, on lawns of bacteria growing on agar plates. Such behavior did not fit in with the previously "fluid" nature of viruses. Bacteriophages were visualized by the electron microscope for the first time in 1939, proving beyond all doubt that they were particulate.

Crystals of the tobacco mosaic disease agent were produced by Stanley in 1935, which to chemists proved that filterable viruses were not only chemicals but could be made pure and homogeneous. To Stanley, this observation meant that filterable viruses were "infectious proteins," a conclusion he reached by ignoring the small amounts of phosphate present in his crystals. He was wrong about tobacco mosaic virus (TMV), whose RNA was later shown to be infectious, but many years later infectious proteins (prions) were discovered.

The last important observation on the road to virus was the development of the one-step growth curve of bacteriophages by Ellis and Delbruck in 1939. They noted that when viruses were added to bacteria, there was initially a lag phase during which no new infectious viruses were produced. This lag phase contrasted with observations made with bacteria: when added to broth, they immediately began to divide. This result showed that viruses were not simply miniature bacteria. We now know that the lag phase is a period during which new viral components are being synthesized, which are later assembled to form infectious particles. Bacteria reproduce by binary fission, and viruses reproduce by making new parts and assembling them.

As a consequence of these observations, the word "filterable" was dropped and these agents became simply "viruses" as their distinction from bacteria and other infectious agents became clear. And that is how we came to today's definition of virus, which began as a catchall for all agents of infectious diseases.

The Birth of Virology

Pathogen Discovery, 1886–1903

Adolf Mayer (1843–1942) was a German agricultural chemist and director of the Agricultural Experiment Station at Wageningen in The Netherlands when he was asked to investigate a disease of tobacco. He named the affliction tobacco mosaic disease after the dark and light spots that appeared on infected leaves (Fig. 1.1). To investigate the nature of the disease, Mayer inoculated healthy plants with the juice extracted from diseased plants by grinding up the infected leaves in water. Mayer reported that, "in nine cases out of ten (of inoculated plants), one will be successful in making the healthy plant . . . heavily diseased".[122] Although these studies established the infectious nature of the tobacco mosaic disease, neither a bacterial nor a fungal agent could consistently be cultured or detected in these extracts, so Koch's postulates could not be satisfied. In a preliminary communication in 1882,[121] Mayer speculated that the cause could be a "soluble, possibly enzymelike contagium, although almost any analogy for such a supposition is failing in science." Later Mayer concluded that the mosaic disease "is bacterial, but that the infectious forms have not yet been isolated, nor are their forms and mode of life known".[122]

FIGURE 1.1 **Lesions on a tobacco leaf infected with tobacco mosaic virus**. Adolph Mayer was the first to describe the pattern of *light* and *dark green areas* on infected leaves in 1886. Mayer showed that lesions could be transmitted from one plant to another using extracts produced from an infected leaf.

A few years later, Dimitri Ivanofsky (1864–1920), a Russian scientist working in St. Petersburg, was commissioned by the Russian Department of Agriculture to investigate the cause of a tobacco disease on plantations in Bassarabia, Ukraine, and the Crimea. Ivanofsky repeated Mayer's observations by showing that the sap of infected plants contained an agent that could transmit the disease to healthy plants. But he added an important step—before the inoculation step, he passed the infected sap through a Chamberland filter (Fig. 1.2). This device, made of unglazed porcelain and perfected by Charles Chamberland, one of Pasteur's collaborators, contained pores small enough to retard most bacteria. Ivanofsky reported to the Academy of Sciences of St. Petersburg on February 12, 1892 that "the sap of leaves infected with tobacco mosaic disease retains its infectious properties even after filtration through Chamberland filter candles".[90]

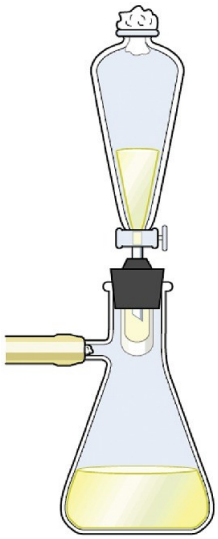

FIGURE 1.2 **Chamberland filter**. These filters, first used to demonstrate the filterable nature of viruses, are made of diatomaceous earth pressed into the form of a hollow candle. The fluid to be filtered is placed into the opening at the top using a funnel, and the filtrate, containing viruses, is collected in the flask.

Ivanofsky, like Mayer before him, failed to culture an organism from the filtered sap and could not satisfy Koch's postulates. Consequently, he suggested that a toxin (not a living, reproducing substance) might pass through the filter and cause the disease. As late as 1903, when Ivanofsky published his thesis,[91] he still believed that he had been unable to culture the bacteria that caused this disease. Bound by the dogma of Koch's postulates, Ivanofsky could not make a conceptual leap. It is, therefore, not surprising that Pasteur, who worked on the rabies vaccine[135] at the same time (1885), never investigated the unique nature of the infectious agent.

The conceptual leap was provided by Martinus Beijerinck (1851–1931), a Dutch soil microbiologist who collaborated with Adolf Mayer at Wageningen. Unaware of Ivanofsky's work, in 1898, he independently found that the sap of infected tobacco plants could retain its infectivity after passage through a Chamberland filter. But he also showed that the filtered sap could be diluted and regain its "strength" after replication in living, growing tissue of the plant. This observation showed that the agent could reproduce (therefore, it was not a toxin) but only in living tissue, not in the cell-free sap of the plant. Suddenly it became clear why others could not culture the pathogen outside its host. Beijerinck called this agent a contagium vivum fluidum,[10] or a contagious living liquid. He sparked a 25-year debate, summarized above, about whether these novel agents were liquids or particles. This conflict was resolved when d'Herelle developed the plaque assay in 1917[33] and when the first electron micrographs were taken of TMV in 1939.[99]

Mayer, Ivanofsky, and Beijerinck each contributed to the development of a new concept: a novel organism smaller than bacteria—an agent defined by the pore size of the Chamberland filter—which could not be seen in the light microscope and could multiply only in living cells or tissue. The term virus (from the Latin for slimy liquid or poison[85]) was at that time used interchangeably for any infectious agent, and so the agent of tobacco mosaic disease was called tobacco mosaic virus, TMV. The literature of the first decades of the 20th century often referred to these infectious entities as filterable agents, and this was indeed the operational definition of viruses. Sometime later, the term virus became restricted in use to those agents that fulfilled the criteria developed by Mayer, Ivanofsky, and Beijerinck.

Shortly after this pioneering work on TMV, the first filterable agent from animals was identified by Loeffler and Frosch—foot and mouth disease virus.[113] The first human virus discovered was yellow fever virus (1901), by Walter Reed and his team in Cuba.[144]

Plant Viruses and the Chemical Period: 1929–1956

For the next 50 years, TMV played a central role in research that explored the nature and properties of viruses. With the development of techniques to purify proteins in the first decades of the 20th century came the appreciation that the infectious material that passed through filters was proteins and so could be purified in the same way. Working at the Boyce Thompson Institute in Philadelphia, Vinson and Petre (1927–1931) precipitated infectious TMV (using an infectivity assay developed by Holmes[84]) from the crude sap of infected plants using selected salts, acetone, or ethyl alcohol.[178] They showed that the infectious material could move in an electric field, just as proteins did. At the same time, H. A. Purdy-Beale, also at the Boyce Thompson Institute, produced antibodies in rabbits that were directed against TMV and could neutralize the infectivity of this agent.[140] This observation was taken as further proof of the protein nature of viruses, although it was later realized that antibodies recognize chemicals other than proteins. With the advent of purification procedures for viruses, both physical and chemical measurements became possible. The strong flow birefringence of purified preparations of TMV was interpreted (correctly) to show an asymmetric particle or rod-shaped particle.[165] Max Schlesinger,[152] working on purified preparations of bacteriophages in Frankfurt, Germany, showed that the infectious particles were composed of proteins and also contained phosphorus and ribonucleic acid. This observation led to the first suggestion that virus particles were composed of nucleoproteins. The crystallization of TMV in 1935 by Wendell Stanley,[158] working at the Rockefeller Institute branch in Princeton, New Jersey, brought this infectious agent into the world of the chemists. Within a year, Bawden and Pirie[8,9] had demonstrated that crystals of TMV contained 0.5% phosphorus and 5% RNA. The first "view" of a virus came from x-ray crystallography using these crystals to show rods of a constant diameter aligned in hexagonal arrays containing RNA and protein.[16] The first electron micrographs of any virus were of TMV, and they confirmed that the virus particle is shaped like a rod[99] (Fig. 1.3).

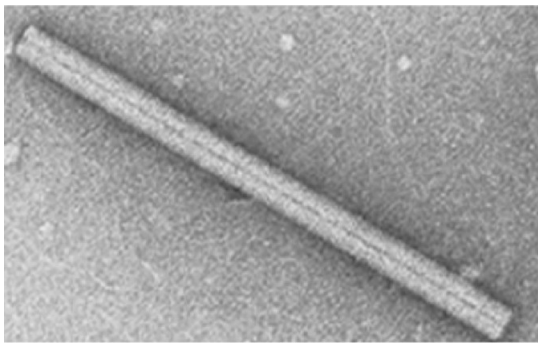

FIGURE 1.3 **Electron micrograph of the tobacco mosaic virus particle**. The virion is composed of a naked, helical nucleocapsid composed of multiple copies of a single viral protein complexed with the viral RNA genome.

The x-ray diffraction patterns[16] suggested that TMV was built from repeating subunits. These data and other considerations led Crick and Watson[32] to realize that most simple virus particles had to consist of one or a few species of identical protein subunits. By 1954–1955, techniques had been developed to dissociate TMV protein subunits, allowing reconstitution of infectious TMV from its RNA and protein subunits[63] and leading to an understanding of the principles of virus self-assembly.[25]

The concept that virus particles contained genetic information emerged as early as 1926, when H. H. McKinney reported the isolation of "variants" of TMV with a different plaque morphology that bred true and could be isolated from several geographic locations.[123,124] Seven years later, Jensen confirmed McKinney's observations[96] and showed that the plaque morphology phenotype could revert. Avery's DNA transformation experiments with pneumococcus[96] and the Hershey-Chase experiment with bacteriophages[80] both demonstrated that DNA was genetic material. TMV had been shown to contain RNA, not DNA, and in 1956, this nucleic acid was shown to be infectious. RNA, therefore, comprised the genetic material of the virus and was the first demonstration that RNA could be a genetic material.[63,70] Studies on the nucleotide sequence of TMV RNA confirmed codon assignments for the genetic code, adding clear evidence for the universality of the genetic code. These studies helped to elucidate the mechanisms of mutation by diverse agents.[62] Research on TMV and related plant viruses has contributed significantly to both the origins of virology and its development as a science.

Bacteriophages

Early Years: 1915–1940

Frederick W. Twort was superintendent of the Brown Institution in London when he discovered viruses of bacteria in 1915. In his research, Twort was searching for variants of vaccinia virus (the smallpox vaccine virus) that would replicate in simple defined media outside living cells. In one of his experiments, he inoculated nutrient agar with an aliquot of the smallpox vaccine (which essentially was lymph fluid from vaccinia pustules). The virus failed to replicate, but bacterial contaminants flourished on the agar medium. Twort noticed that some of these bacterial colonies changed visibly with time and became "watery looking" (ie, more transparent). The bacteria within these colonies were apparently dead, as they could no longer form new colonies on fresh agar plates. He called this phenomenon "glassy transformation." Simply adding the glassy transforming principle could rapidly kill a colony of bacteria. It readily passed through a porcelain filter, could be diluted a million-fold, and when placed upon fresh bacteria would regain its strength, or titer.[173–175]

Twort published these observations in a short note[173] in which he suggested that a virus of bacteria could explain glassy transformation. He then went off to serve in World War I, and when he returned to London, he did not continue this research.

While Twort was puzzled by glassy transformation, Felix d'Herelle, a Canadian medical bacteriologist, was working at the Pasteur Institute in Paris. When a *Shigella* dysentery infection devastated a cavalry squadron of French soldiers just outside of Paris in August 1915, D'Herelle readily isolated and cultured the dysentery bacillus from filtered fecal emulsions. The bacteria multiplied and covered the surface of his agar plates, but occasionally d'Herelle observed clear circular spots devoid of growth. He called these areas taches vierges, or plaques. He followed the course of an infection in a single patient, noting when the bacteria were most plentiful and when the plaques appeared.[33,34] Plaques appeared on the fourth day after infection and killed the bacteria in the culture dish, after which the patient's condition began to improve.

D'Herelle found that a filterable agent, which he called a bacteriophage, was killing the *Shigella* bacillus. In the ensuing years, he developed fundamental techniques in virology that are utilized to this day, such as the use of limiting dilutions to determine the virus titer by plaque assay. He reasoned that the appearance of plaques showed that the virus was particulate, or "corpuscular," and not a liquid as Beijerinck had insisted. D'Herelle also found that if infectious material was mixed with a host cell and then subjected to centrifugation, the infectious material was no longer present in the supernatant fluid. He interpreted this to mean that the first step of a virus infection is attachment, or adsorption, of virus particles to the host cell. Furthermore, particle attachment occurred only when bacteria sensitive to infection were used, demonstrating that host specificity can be conferred at a very early step in infection. Lysis of cells and the release of infectious particles were also described in startlingly modern terms. D'Herelle clearly established many of the principles of modern virology.[34,35]

Although D'Herelle's bacteriophages lysed their host cells, by 1921 it had become apparent that under certain situations the bacteriophage and cell existed peacefully—a condition called lysogeny. In some experiments, it became impossible to separate the virus from its host. This condundrum led Jules Bordet of the Pasteur Institute in Brussels to suggest that the transmissible agent described by d'Herelle was nothing more than a bacterial enzyme that stimulates its own production.[22] Although incorrect, the hypothesis has remarkable similarities to modern ideas about prion structure and replication (see Chapter 22).

During the 1920s and 1930s, d'Herelle sought ways to use bacteriophages for medical applications, but he never succeeded. Interestingly, phage therapy (the use of bacteriophages to treat patients with bacterial infections) has seen renewed interest. To complicate matters, the basic research of the era was dominated by the interpretations of scientists with the strongest personalities. Although it was clear that there were many diverse bacteriophages, and that some were lytic while some were lysogenic, their interrelationships remained ill defined and contentious. The highlight of this period was the demonstration by Max Schlesinger that purified phages had a maximum linear dimension of 0.1 micron and a mass of about 4×10^{-16} g, and that they were composed of protein and DNA in roughly equal proportions.[151,152] In 1936, no one quite knew what to make of that observation, but over the next 20 years, it would begin to make a great deal of sense.

Phages and the Birth of Molecular Biology: 1938–1970

Max Delbrück was trained as a physicist at the University of Göttingen, and his first position was at the Kaiser Wilhelm Institute for Chemistry in Berlin. There he joined a diverse group of individuals actively discussing how quantum physics related to an understanding of heredity. Delbrück's interest in this area led him to develop a quantum mechanical model of the gene, and in 1937, he moved to the Biology Division at the California Institute of Technology to study genetics of Drosophila. Once there, he became interested in bacteria and their viruses and teamed up with another research fellow, Emory Ellis,[50] who was working with the T-even group of bacteriophages, T2, T4, and T6. Delbrück soon appreciated that these viruses were ideal for the study of how genes replicated and how genetic information could determine the structure and function of an organism. They replicated rapidly and offered simple quantitative assays. Delbruck brought the rigor of quantitative, well-defined experiments to virology. Bacteriophages were also viewed as model systems for understanding cancer viruses or even for understanding how a sperm fertilizes an egg and a new organism develops. Together with Ellis, Delbrück showed that when infections were synchronized, new virus particles were produced in one step (a burst),[51] in contrast to the multiplication of other organisms by binary fission. The elegant one-step growth curve experiment showed that a single infected bacterium liberates hundreds of phages synchronously after a half hour period during which viral infectivity was lost (Fig. 1.4). The one-step growth curve became the experimental paradigm of the phage group.

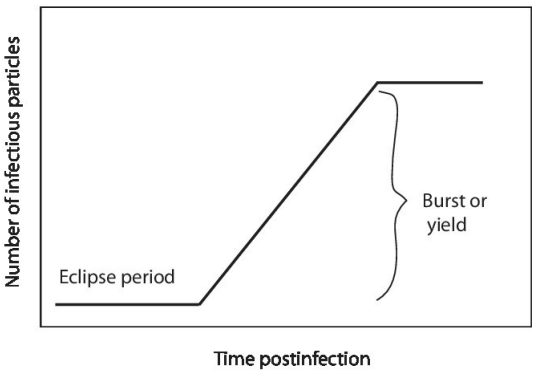

FIGURE 1.4 **One-step growth curve of bacteriophage**. The conclusion of Ellis and Delbrück that viruses reproduced in one step was drawn from the one-step growth curve experiment, in which an infected bacterium liberates phages synchronously after a half hour period (eclipse) during which viral infectivity is lost.

When World War II erupted, Delbrück remained in the United States (at Vanderbilt University) and met an Italian refugee, Salvador E. Luria, who had fled to America and was working at Columbia University in New York (on bacteriophages T1 and T2). After their encounter at a meeting in Philadelphia on December 28, 1940, they went to Luria's laboratory at Columbia where they spent 48 hours doing experiments with bacteriophages. These two scientists eventually established the "phage group," a community of researchers focused on using bacterial viruses as a model for understanding life processes. Luria and Delbrück were invited to spend the summer of 1941 at Cold Spring Harbor Laboratory, where they pursued research on phages. It is remarkable that a German physicist and an Italian geneticist joined forces during the war years to travel throughout the United States and recruit a new generation of biologists (Fig. 1.5).

FIGURE 1.5 **Max Delbrück and Salvador Luria at Cold Spring Harbor Laboratory**. Photograph taken during the 1953 Cold Spring Harbor Symposium on Quantitative Biology organized by Milislav Demerec. (From http://profiles.nlm.nih.gov/ps/retrieve/ResourceMetadata/QLBBJF. Courtesy of the Cold Spring Harbor Laboratory Archives, NY.)

When Tom Anderson, an electron microscopist at the RCA Laboratories in Princeton, New Jersey, met Delbrück, the result was the first clear pictures of bacteriophages.[117] At the same time, the first phage mutants were isolated and characterized.[115] By 1946, the first phage course was being taught at Cold Spring Harbor, and in March 1947, the first phage meeting attracted eight people. From these humble beginnings, the field of molecular biology emerged, which focused on the bacterial host and its viruses.

Developing the Modern Concept of Virology

The next 25 years (1950–1975) was an intensely productive period of bacteriophage research. Hundreds of virologists produced thousands of publications that covered three major areas: (1) lytic infection of *Escherichia coli* with the T-even phages; (2) the nature of lysogeny, using lambda phage; and (3) the replication and properties of several unique phages such as ϕX174 (single-stranded circular DNA), the RNA phages, and T7. This work set the foundations for modern molecular virology and biology.

The idea of examining, at the biochemical level, the events occurring in phage-infected cells during the latent period had come into its own by 1947–1948. Impetus for this work came from Seymour Cohen, who had trained first with Erwin Chargaff at Columbia University, studying lipids and nucleic acids, and then with Wendell Stanley working on TMV RNA. His research direction was established after taking Delbrück's 1946 phage course at Cold Spring Harbor, Cohen examined the effects of phage infection on DNA and RNA levels in infected cells using a colorimetric analysis.[30] The results showed a dramatic alteration of macromolecular synthesis in infected cells. This included cessation of RNA accumulation, which later formed the basis for detecting a rapidly turning over species of RNA and the first demonstration of messenger RNA (mRNA).[4] DNA synthesis also halted, but only for 7 minutes, followed by resumption at a 5- to 10-fold increased rate. At the same time, Monod and Wollman showed that the synthesis of a cellular enzyme, the inducible β-galactosidase, was inhibited after phage infection.[125] Based on these observations, the viral eclipse period (when infectivity was lost immediately after infection) was divided into an early phase, prior to DNA synthesis, and a late phase. More importantly, these results demonstrated that virus infection could redirect cellular macromolecular synthetic processes in infected cells.[31]

By the end of 1952, two experiments had a critical effect on virology. First, Hershey and Chase asked whether bacteriophage genetic information is DNA or protein. They differentially labeled viral proteins (with 35SO4) and nucleic acids (with 32PO4) and allowed the radioactive "tagged" particles to attach to bacteria. When they sheared the viral protein coats from the bacteria using a Waring blender, only DNA was associated with the infected cells.[80] This result proved that DNA had all the information needed to reproduce new virus particles. A year later, the structure of DNA was elucidated by Watson and Crick, a discovery that permitted full appreciation of the Hershey-Chase experiment.[180] The results of these two experiments formed a cornerstone of the molecular biology revolution.

While these blockbuster experiments were being carried out, G. R. Wyatt and S. S. Cohen were quietly making another seminal finding.[191] They identified a new base, hydroxymethylcytosine, in the DNA of T-even phages, which replaced cytosine. This began a 10-year study of how deoxyribonucleotides were synthesized in bacteria and phage-infected cells and led to the critical observation that bacteriophage infection introduces genetic information for a new enzyme.[59] By 1964, Mathews and colleagues had proved that hydroxymethylase does not exist in uninfected cells and must be encoded by the virus genetic material.[31] These experiments introduced the concept of early enzymes, utilized in deoxypyrimidine biosynthesis and DNA replication,[102] and provided biochemical proof that viral genomes encoded new information expressed as proteins in an infected cell. At the same time, phage genetics became extremely sophisticated, allowing mapping of the genes encoding these viral proteins. Perhaps the best example of genetic fine structure was done by Seymour Benzer, who carried out a genetic analysis of the rII A and B cistrons of T-even phages with a resolution of a single nucleotide (without doing any DNA sequencing!).[13] Studies on viral DNA synthesis, using phage mutants and cell extracts to complement and purify enzyme activities *in vitro*, contributed a great deal to our understanding of DNA replication.[1] A detailed genetic analysis of phage assembly, utilizing the complementation of phage assembly mutants *in vitro*, revealed

how complex structures are built using the principles of self-assembly.[45] The genetic and biochemical analysis of phage lysozyme helped to elucidate the molecular nature of mutations,[161] and the isolation of phage nonsense mutations (first called "amber" mutations) provided a clear way to study second-site suppressor mutations at the molecular level.[14] The circular genetic map of the T-even phages[161] was explained by the circularly permuted, terminally redundant conformation of these DNAs (giving rise to phage heterozygotes).[171]

The remarkable reprogramming of viral and cellular protein synthesis in phage-infected cells was dramatically visualized by an early use of electrophoresis and sodium dodecyl sulfate (SDS)-polyacrylamide gels.[104] These studies showed that viral proteins are made in a specific sequence of events. The underlying mechanism of this temporal regulation led to the discovery of proteins (sigma factors) that modified RNA polymerase and conferred specificity to gene expression.[73] The study of gene regulation at almost every level (transcription, RNA stability, protein synthesis, protein processing) was revealed from a set of original contributions derived from an analysis of phage infections.

Although this remarkable progress had begun with the lytic phages, no one knew quite what to make of the lysogenic phages. This situation changed in 1949 when André Lwoff began his studies at the Pasteur Institute with Bacillus megaterium and its lysogenic phages. By using a micromanipulator, Lwoff could show that single lysogenic bacteria divided up to 19 times before liberating infectious particles. No virions were detected when lysogenic bacteria were broken open by the investigator. But from time to time, a lysogenic bacterium spontaneously lysed and produced many infectious particles.[119] Many potential inducing agents were investigated, but ultraviolet light was very efficient. Indeed, exposing lysogenic bacteria to ultraviolet light efficiently induced production of infectious particles. This experiment began[120] to outline this curious relationship between a virus and its host. By 1954, Jacob and Wollman[93,94] at the Pasteur Institute had made the important observation that a genetic cross between a male, lysogenic bacterial strain (Hfr, lambda) and a nonlysogenic female recipient resulted in the induction of infectious particles after conjugation, a process they called zygotic induction. In fact, the position of the lysogenic phage (also called prophage) in the chromosome of its host *E coli* could be mapped by interrupting mating between two strains.[94] This experiment was crucial for our understanding of lysogenic viruses because it showed that the provirus behaved like a bacterial gene on a chromosome in a bacterium. It also was one of the first experimental results suggesting that the prophage genetic material was kept quiescent by negative regulation, which was lost as the chromosome passed from the lysogenic donor bacteria to the nonlysogenic recipient host. This conclusion helped Jacob and Monod to realize as early as 1954 that the "induction of enzyme synthesis and of phage development are the expression of one and the same phenomenon".[119] These experiments laid the foundation for the operon model and[180] the nature of coordinate gene regulation.

Although the structure of DNA was elucidated in 1953 and zygotic induction was described in 1954, the physical interaction between the bacterial chromosome and the viral genetic material in lysogeny was not clear. It often was referred to as the "attachment site" and literally thought of in those terms. The close relationship between a virus and its host was appreciated only when Campbell proposed the model for physical integration of lambda DNA into the bacterial chromosome,[26] based on the fact that the sequence of phage markers was different in the integrated state than in the replicative or vegetative state. The idea was that a circular lambda DNA molecule integrated by recombination between a specific site on the phage DNA with a specific site on the bacterial DNA. This integrated DNA was the prophage, which was transcriptionally silent. This model led to the isolation of the negative regulator or repressor of lambda, the understanding of why lysogens could not be infected by related bacteriophages (so-called immunity), and one of the early examples coordinated gene regulation.[139] The genetic analysis of the lambda bacteriophage life cycle is one of the great intellectual adventures in microbial genetics.[79] It deserves to be reviewed in detail by all students of molecular virology and biology. Other lysogenic *E coli* phages offered different paradigms that did not involve integration of viral DNA into host DNA. Bacteriophage P1 has a circular genome that is maintained in the cytoplasm as an episome and maintains stable inheritance by repressors and cytoplasmic replication.

The lysogenic phages[193] of *Salmonella typhimurium* such as P22 provided the first example of generalized transduction, whereas lambda provided the first example of specialized transduction.[128] The finding that virus particles could not only carry cellular genes but transfer those genes from one cell to another provided not only a method for fine genetic mapping but also a new concept in virology. As the genetic elements of bacteria were studied in more detail, it became clear that there was a remarkable continuum from lysogenic phages to episomes, transposons and retrotransposons, insertion elements, retroviruses, hepadnaviruses, viroids, and prions. Genetic information moves between viruses and their hosts to the point where definitions and classifications begin to blur.

The genetic and biochemical concepts that emerged from the study of bacteriophages stimulated the next phase of virology. The lessons of the lytic and lysogenic phages were often relearned and modified as the animal viruses were studied.

Animal Viruses

Cell Culture Technology and Discovery: 1898–1965

Once the concept took hold that viruses were particulate filterable agents, many diseased animal tissues were subjected to filtration to determine if a virus were involved. Filterable agents were found that were invisible in a light microscope and replicated only in living animal tissue. There were some surprises, such as the transmission of yellow fever virus by a mosquito vector,[144] specific visible pathologic inclusion bodies (virions and subviral particles) in infected tissue,[91,133] and even viral agents that can "cause cancer."[49,146] Throughout this early period (1900–1930), a wide variety of particulate animal infectious agents were found (see Table 1.1) and characterized with regard to their size (using the different pore sizes of filters), resistance to chemical or physical agents (eg, alcohol, ether), and pathogenic effects. Just based on these properties, it became clear that viruses were a very diverse group. Some were even observable in the light microscope (vaccinia in dark-field optics). Some were inactivated by ether, whereas others were not. Infectious agents that replicated in every tissue type were identified. Some were specific for a particular tissue. They could cause chronic or acute disease; they were persistent agents or recurred in a periodic fashion. Some caused cellular destruction or induced cellular proliferation. Some changed the morphology of the cells they infected. For the early virologists, unable to see their agents in a light microscope and often confused by this great diversity, many studies certainly required an element of faith. In 1912, S. B. Wolbach, an American pathologist, remarked, "It is quite possible that when our knowledge of filterable viruses is more complete, our conception of living matter will change considerably, and that we shall cease to attempt to classify the filterable viruses as animal or plant".[188]

The first way out of this early confusion was led by the plant virologists and the development of techniques to purify viruses and characterize both the chemical and physical properties of these agents (see previous section, The Plant Viruses and the Chemical Period: 1929–1956). The second path came from the studies with bacteriophages, where single cells infected with viruses in culture were much more amenable to experimental manipulation than were virus infections of whole animals. Whereas the plant virologists of that day were tethered to their

greenhouses, and the animal virologists were bound to their animal facilities, the viruses of bacteria were studied in Petri dishes and test tubes. Nevertheless, progress was made in the study of animal viruses one step at a time; from studying animals in the wild, to laboratory animals, such as the mouse[64] or embryonated chicken eggs,[189] to the culture of tissue, and then to single cells. Between 1948 and 1955, a critical transition converting animal virology into a laboratory science came in four important steps: Sanford and colleagues at the National Institutes of Health (NIH) overcame the difficulty of culturing single cells[149]; George Gey at Johns Hopkins Medical School cultured and passaged human cells for the first time and developed a line of immortal cells (HeLa) from a cervical carcinoma[69]; and Harry Eagle at the NIH developed an optimal medium for the culture of single cells.[44] In a demonstration of the utility of all these methods, Enders and his colleagues showed that poliovirus could replicate in a nonneuronal human explant of embryonic tissues.[53]

These ideas, technical achievements, and experimental advances had immediate effects on the field of virology. One of these was the development of the polio vaccine, the first ever produced in cell culture. From 1798 to 1949, all the vaccines in use (smallpox, rabies, yellow fever, influenza) had been grown in animals or embryonated chicken eggs. Poliovirus was grown in monkey kidney cells propagated in flasks.[81,110] The modern era of molecular virology began with the exploitation of cell culture. The first plaque assay for an animal virus in culture was done with poliovirus,[41] and it led to an analysis of poliovirus every bit as detailed and important as the contemporary work with bacteriophages. The simplest way to document this statement is for the reader to compare the first edition of General Virology by S. E. Luria in 1953[116] to the second edition by Luria and J. E. Darnell in 1967[118] and to examine the experimental descriptions of poliovirus infection of cells. The modern era of virology had arrived, and it would continue to be full of surprises.

The Molecular and Cell Biology Era of Virology

The history of virology has so far been presented chronologically or according to separate virus groups (plant viruses, bacteriophages, and animal viruses), which reflects the historical separation of these fields. In this section, the format changes as the motivation for studying viruses began to change. Virologists began to use viruses to probe questions central to understanding all life processes. Because viruses replicate in and are dependent on their host cells, they must use the rules, signals, and regulatory pathways of the host. By using viruses to probe these processes, virologists began to make contributions to all facets of biology. This approach began with the phage group and was continued by the animal virologists. The recombinant DNA revolution also took place during this period (1970 to the present), and both bacteriophages and animal viruses played a critical and central role in this revolution. For these reasons, the organization of this section focuses on the advances in cellular and molecular biology made possible by experiments with viruses. Some of the landmarks in virology since 1970 are listed in Table 1.1.

The Role of Animal Viruses in Understanding Eukaryotic Gene Regulation

Viral genetic material can be DNA or RNA, single stranded or double stranded.[156] How these forms of nucleic acid are replicated, how gene products are produced, and how they are packaged into infectious particles were and still are fundamental questions. The closed circular and superhelical nature of polyoma virus DNA was elucidated by Dulbecco and Vogt[42] and Weil and Vinograd.[181] The reason why the viral genome adopted this structure was first shown to be related to the packaging of simian vacuolating virus 40 (SV40) DNA into virus particles. The viral DNA is wound around nucleosomes during replication and is packaged into particles.[68] When the histones are removed, a DNA superhelix results. The structure of polyoma viral DNA served as an excellent model for the *E coli* genome[190] and mammalian chromosomes.[105,106]

Many elements of the eukaryotic transcription machinery have been elucidated with viruses. The first transcriptional enhancer element (acts in an orientation- and distance-independent fashion) was described in the SV40 genome,[74] as was a distance- and orientation-dependent promoter element.[108] The transcription factors that bind to the promoter, SP-1,[43] or to the enhancer element, such as AP-1 and AP-2, and which are essential to promote transcription along with the basal factors, were first described with SV40. AP-1 is composed of fos and jun family member proteins, demonstrating the role of transcription factors as oncogenes.[21] Indeed, the great majority of experimental data obtained for basal and accessory transcription factors come from *in vitro* transcription systems using the adenovirus major late promoter or the SV40 early enhancer-promoter.[182] Our present-day understanding of RNA polymerase III promoter recognition comes, in part, from an analysis of the adenovirus VA gene transcribed by this polymerase.[61]

Almost everything we know about the steps of mRNA processing began with observations made with viruses. The list is long but here are a few highlights: RNA splicing of new transcripts was first described in adenovirus-infected cells[15,28]; polyadenylation of mRNA was first observed with poxviruses,[97] the first viruses shown to have a DNA-dependent RNA polymerase in the virion[98]; the signal for polyadenylation of mRNA was identified using SV40[58]; the methylated cap structure found at the 5'-end of most mRNAs was first discovered on reovirus mRNAs[65]; and a remarkable discrimination for transport of viral and cellular mRNAs out of the nucleus was shown by the adenovirus E1B-55Kd protein.[137]

Our early understanding of translational regulation came from studies of virus infected cells. Recruitment of ribosomes to mRNAs was shown to be directed by the 5'-cap structure first discovered on reovirus mRNAs. The nature of the protein complex that allows ribosomes to bind the 5'-cap was elucidated in poliovirus-infected cells, because viral infection leads to cleavage of one of the components, eIF4G. Internal initiation of translation was discovered in cells infected with picornaviruses (poliovirus and encephalomyocarditis virus).[95,136] Interferon, discovered as a set of proteins that inhibited influenza virus replication, was subsequently found to induce the synthesis of many antiviral gene products that act on translational regulatory processes.[88] Similarly, the viral defenses against interferon by the adenovirus VA RNA provided unique insight to the role of eIF-2 phosphorylation events.[101] Mechanisms for producing more than one protein from a eukaryotic mRNA (there is no "one mRNA one protein" rule as described for bacteria) were discovered in virus-infected cells, including polyprotein synthesis, ribosomal frameshifting, and leaky scanning. Posttranslational processing of proteins by proteases, carbohydrate addition to proteins in the Golgi apparatus, phosphorylation by a wide variety of important cellular protein kinases, or the addition of fatty acids to membrane-associated proteins have all been profitably studied using viruses. Indeed, a good deal of our present-day knowledge of how protein trafficking occurs and is regulated in cells comes from the use of virus-infected cell systems. The field of gene regulation has derived many of its central tenets from the study of viruses.

Animal Viruses and the Recombinant DNA Revolution

The discovery of the enzyme reverse transcriptase[5,170] not only elucidated the replication cycle of retroviruses but also provided an essential

tool to convert RNA molecules to DNA, which could then be cloned and manipulated. The first restriction enzyme map of a chromosome was done with SV40 DNA, using the restriction enzymes HindII plus HindIII DNA.[36,37] The first demonstration of restriction enzyme specificity was carried out with the same viral DNA cleaved with EcoRI.[127,129] Some of the earliest DNA cloning experiments involved insertion of SV40 DNA into bacteriophage lambda DNA, or human β-hemoglobin genes into SV40 DNA, yielding the first mammalian expression vectors.[92] A debate about whether these very experiments were potentially dangerous led to a temporary moratorium on all such recombinant experiments following the scientist-organized Asilomar Conference. From the earliest experiments in the field of recombinant DNA, several animal viruses had been developed into expression vectors to carry foreign genes, including SV40,[72] retroviruses,[183] adenoviruses,[67] and adeno-associated virus.[148] Modern day strategies of gene therapy rely on some of these recombinant viruses. The gene for beta hemoglobin was first cloned using lambda vectors. The elusive hepatitis virus C (previously known as non-A, non-B) viral genome was cloned from serum using recombinant DNA techniques, reverse transcriptase, and lambda phage vectors.[27]

The study of RNA viruses was accelerated by recombinant DNA technology, particularly in the construction of "infectious clones." The RNA virus genome was converted into DNA by reverse transcriptase and the resulting DNA was cloned into appropriate vectors. When introduced into cells, the DNA was copied into RNA that was infectious.[142,168]

Animal Viruses and Oncology

Much of our present understanding of the origins of human cancers is a consequence of work on two major groups of animal viruses, retroviruses, and DNA tumor viruses (see Chapter 11). The first oncogene discovered was from the genome of Rous sarcoma virus. Remarkably, the virus had picked up a host gene that was involved in growth control.[159] Since those seminal studies, virologists have identified a wide variety of oncogenes that have been captured by retroviruses (see Chapter 8). Additional cellular oncogenes were identified when they were activated by insertion of retroviral proviral DNA in or near the gene.[75] When activated, these oncogenes are dominant and activate cell growth. The second group of genes that contribute to the origins of human cancers is the tumor suppressor genes that stop cell growth.[109] Two such genes (*p53* and *pRB*) are intimately associated with the so-called DNA tumor viruses that must replicate their DNA in cells that are not replicating. Genetic alterations at the p53 locus are the single most common mutations known to occur in human cancers—they are found in 50%-80% of all cancers.[111] The p53 protein was first discovered in association with the SV40 large T-antigen, a viral gene essential for viral DNA replication.[107,112] SV40, the human adenoviruses, and the human papillomaviruses all encode proteins that interact with and inactivate the functions of the retinoblastoma susceptibility gene product (Rb) and p53.[39,43,107,112,150,184,185] Our understanding of the roles of cellular oncogenes and the tumor suppressor genes in human cancers would be far less significant without the insight provided by studies with these viruses.

Viruses associated with cancers have provided some of the most extraordinary episodes in modern animal virology.[126] The recognition of a new disease and the unique geographic distribution of Burkitt lymphomas in Africa[17] (see Chapter 11) set off a search for viral agents that cause cancers in humans. From D. Burkitt[24] to Epstein, Achong, and Barr[56] to W. Henle and G. Henle,[78] the story of the Epstein-Barr virus and its role in several cancers, as well as in infectious mononucleosis, is a science detective story without rival. Similarly, the identification of adult T-cell leukemia, a new pathologic disease, in Japan by K. Takatsuki[176] led to the isolation of human T-cell leukemia virus (HTLV-1) by I. Miyoshi and Y. Hinuma.[138] It was soon realized that this virus had been identified previously by Gallo and his colleagues. Even with the virus in hand, there is still no satisfactory explanation of how this virus contributes to adult T-cell leukemia.

An equally interesting detective story concerns hepatocellular carcinoma and the discovery of hepatitis B virus. By 1967, S. Krugman and his colleagues[103] had strong evidence indicating the existence of distinct hepatitis A and B viruses, and in the same year B. Blumberg[20] had identified an unusual protein called the Australia antigen. Through a tortuous path, it eventually became clear that the Australia antigen was the coat protein of hepatitis B virus. Its detection was a predictable indictor for the presence of hepatitis B virus. Although this discovery ultimately freed the blood supply of this dangerous virus, Hilleman at Merck, Sharp, and Dohme and the Chiron Corporation (which later isolated the hepatitis C virus) went on to produce the first human vaccine that prevents hepatitis B infections and very likely hepatocellular carcinomas associated with chronic virus infections (see Chapter 15). The idea that a viral vaccine could prevent cancer (first proven with the Marek disease virus and T-cell lymphomas in chickens)[18,47] came some 82-85 years after the first discoveries of tumor viruses by Ellerman, Bang, and Rous.

Vaccines and Antivirals

Among the most remarkable achievements of the 20th century is the eradication of smallpox, a disease with a >2000-year-old history.[76] In 1966, the World Health Organization began a program to immunize all individuals who had encountered an infected person. This strategy was adopted because it simply was not possible to immunize entire populations. In October 1977, Ali Maolin of Somalia was the last person in the world to have a naturally occurring case of smallpox (barring laboratory accidents). Because smallpox has no animal reservoir and requires person-to-person contact for its spread, most scientists agree that we are free of this disease as a natural infection.[76] Consequently, most populations have not maintained immunity to the virus and the world's populations are becoming susceptible to infection. Many governments now fear the use of smallpox virus as a weapon of bioterrorism, and the debate continues over whether to destroy the two known stocks of smallpox virus in the United States and Russia.[77] As a consequence, the development of new, more effective vaccines and safe anti–smallpox virus drugs has risen high on the list of priorities for some countries and have already been stockpiled in the United States. It is paradoxical that humankind's most triumphant medical accomplishment is now tarnished by the specter of biowarfare.

The Salk and Sabin poliovirus vaccines were the first products to benefit from the cell culture revolution. In the early 1950s in the United States, just before the introduction of the Salk vaccine, about 21,000 cases of poliomyelitis were reported annually. Today, thanks to aggressive immunization programs, polio has been eradicated from most of the world (see Chapter 11).[132] However, complete eradication has proven to be difficult in some countries due to economic and political issues. With the substantial financial support of the Gates Foundation, there is hope that global immunization campaigns can lead to eradication of poliomyelitis from the planet.

The first viral vaccines deployed included infectious but attenuated viruses, inactivated virus preparations, and subunit vaccines comprising viral proteins and no viral nucleic acid. Both the Salk inactivated virus vaccine and the recombinant hepatitis B virus subunit vaccine were products of the modern era of virology. Today many new vaccine technologies are either in use or are being tested for future deployment.[3,23,153]

These include recombinant subunit vaccines, viruslike particle vaccines, viral antigens delivered in viral vectors comprising vaccinia virus or adenovirus, DNA plasmids that express viral proteins from strong promoters, and mRNA vaccines. Therapeutic vaccines boost the immune system using specific cytokines or hormones in combination with new adjuvants to stimulate immunity at specific locations in the host or to tailor the production of immune effector cells and antibodies. The first vaccines for smallpox were reported in the Chinese literature of the 10th century,[57] but up until a few years ago, progress and new approaches had been slow.

Although vaccines have been extraordinarily successful in preventing specific diseases, up until the 1960s, few natural products or chemotherapeutic agents that cured or reduced viral infections were known. That situation changed dramatically with the development of Symmetrel (amantadine) by Dupont in the 1960s as a specific influenza A virus drug. Soon after, acyclovir, an inhibitor of herpesviruses, was developed by Burroughs-Wellcome. Acylovir achieves its remarkable specificity because to be active, it must be phosphorylated by the viral enzyme thymidine kinase before it can be incorporated into viral DNA by the viral DNA polymerase. This drug blocks HSV-1 and HSV-2 replication after reactivation from latency and stopped a growing epidemic in the 1970s and 1980s (Chapter 14). The development of other nucleoside analogs that inhibit viral replication has led to many compounds effective against DNA viruses. Until the HIV epidemic, few drugs effective against RNA viruses other than the influenza A virus were known. That issue has changed dramatically in the past 10 years as many new antivirals effective against different RNA viruses, particularly HIV and HCV, have been discovered.

As natural products, the interferons are used successfully in the clinic for hepatitis B and C infections, cancer therapy, and multiple sclerosis. The interferons, novel cytokines, produced by infected cells were found while studying virus interference.[23,88,89] They modulate the immune response and continue to play an increasing role in the treatment of many clinical syndromes.

Virology and the Birth of Immunology

Edward Jenner was a British surgeon who is credited with making the first smallpox vaccine in 1796 and has also been called the "father of immunology." Jenner began a long tradition of virology providing seminal discoveries about the immune response. Two examples will serve to illustrate this pattern.

Alick Issacs and Jean Lindenmann, while working at the National Institute for Medical Research in London, found that addition of heat-inactivated influenza virus to the chorioallantoic membrane of chicken eggs interfered with the replication of influenza virus. When they published this observation in 1957, they coined the term "interferon".[88] In the 1970s, the protein was purified from cells by Sidney Pestka and Alan Waldman,[147] and subsequently the genes encoding the proteins were cloned.[71] This achievement allowed formal proof that IFN—by that time known to comprise a variety of different proteins—could interfere with viral replication. Extensive work with viruses showed that IFNs bind to cell surface receptors, and through the JAK-STAT signal transduction pathway, induce the synthesis of over 1000 mRNAs whose products establish an antiviral state in that cell.[38] Interferons protect against both viral and bacterial infections and also play a role in tumor clearance.

While working at the John Curtin School of Medical Research in Australia, Rolf Zinkernagel and Peter Doherty provided seminal insight on how cytotoxic T cells (CTLs) recognize virus-infected cells. They were studying mice infected with lymphocytic choriomeningitis virus (LCMV). Because this virus is noncytopathic, they hypothesized that brain damage in infected mice was a consequence of CTLs attacking virus-infected cells. They saw that CTLs isolated from LCMV-infected mice lysed virus-infected target cells *in vitro* only if both cell types had the same MHC haplotype. This requirement was termed MHC restriction.[194] In other words, a CTL must recognize two components on a virus-infected cell, one virus-specific, and one from the host. Subsequent research revealed that CTLs recognize a short viral peptide bound to MHC class I proteins on the surface of target cells. These observations revolutionized our understanding of T-cell mediated killing, establishing a foundation for understanding the general mechanisms used by the immune system to recognize both foreign microorganisms and self-molecules. The results have had wide implications for clinical medicine, not only in infection but also in areas such as cancer and autoimmune reactions in inflammatory diseases.

Emerging Viruses

In general, emerging viruses cause human infections that have not been seen or reported before (see Volume 1). They usually attract the public's attention, often by media sound bites like "killer viruses emerge from the jungle." The fact is that spread of infections through different hosts is well known in virology. Most so-called emerging infections represent zoonotic infections: infection of humans by a virus that normally exists in an animal population in nature.[172] Typically, these viruses have RNA genomes and some are spread to humans by insect vectors.

Perhaps the most infamous emerging virus infection of the 20th century is the human immunodeficiency virus, HIV-1, a retrovirus.[82] Progenitor HIV viruses exist in primates and we now believe they infected humans as a result of hunting and slaughter for food.[155] HIV was first recognized as a new disease entity by clinicians and epidemiologists in the early 1980s, and they rapidly tracked down the venereal mode of virus transmission. The virus was detected in blood products and transplant tissue. The immune system of HIV-infected individuals is severely compromised, which results in a variety of infections by usually benign microbes. The first published report of acquired immunodeficiency syndrome (AIDS) was in June 1981. Possible causative agents were first suggested in 1983[7] and then 1984.[66] Had this pandemic occurred in 1961 instead of 1981, neither the nature of retroviruses nor the existence of its host cell (CD-4 helper T-cell) would have been understood. HIV is a lentivirus (lenti is Latin for slow), and despite its recent appearance in humans, lentiviruses have been around for a long time. In fact, one of the first animal viruses to be identified in 1904 was the lentivirus that causes infectious equine anemia.

Many other examples of emerging viruses have attracted global concern and an exceptional rapid response of scientists and health officials.[172] The SARS and West Nile virus epidemics revealed the presence of a new human corona virus (SARS-CoV 1), identified with unprecedented speed, and the invasion of an Old World virus into the western hemisphere (West Nile virus).[86,131] In 2006, Chikungunya virus (an endemic virus infection in Africa) spread explosively to several countries where it was hitherto unknown.[154] On Reunion Island, more than 40% of the population of 800,000 people was infected. Other emerging infectious agents include Ebola virus, Lassa fever virus, Zika virus, and many mosquito-borne viruses. The first appearance of avian H5N1 virus in humans in 1999 produced fears of a pandemic of serious proportions since humans had no immunological history of infection by this avian strain.[167] Soon thereafter, the emergence of the pandemic H1N1 influenza virus in 2009 produced similar worries because of the relationship of the virus to the deadly 1918 influenza epidemic.[169] The mobilization of world health networks, public health officials, vaccine producers, veterinarians, clinicians, and molecular virologists marked a new chapter in dealing with emerging diseases. As the COVID-19 pandemic revealed, emerging viruses are and will be ongoing features of viral infections. There will

always be another potential pandemic in our future.

Epidemiology of Viral Infections

The study of the incidence, distribution, and control of disease in a population is an integral part of virology. The technology advancements of the last 50 years have provided epidemiology with a terrific boost. The discovery of specific molecular reagents (eg, recombinant DNA technology, antibodies, polymerase chain reaction [PCR], rapid diagnostic tests, high volume DNA and RNA sequencing) now enables detection of virions, proteins, and nucleic acids in body fluids, tissue samples, or in the environment. Moreover, we now can compare and classify viral isolates rapidly, determine the relationships between virus strains, and track the spread of infections around the world. The marriage of behavioral, geographic, and molecular epidemiology made this a most powerful science.[48]

The understanding of epidemics and pandemics of our most common viral infections such as influenza requires the perspective of ecology, population biology, and molecular biology.[100,167,169] G. Hirst and his colleagues (1941–1950) developed the diagnostic tools that permitted both the typing of the hemagglutinin (HA protein) of influenza A strains and the monitoring of the antibody response to this antigen in patients (see Chapters 42 and 43). These observations have been expanded, with more and more sophisticated molecular approaches, to prove the existence of animal reservoirs for influenza viruses, the reassortment of viral genome segments between human and animal virus strains (antigenic shift), and a high rate of mutation (antigenic drift) caused by RNA-dependent RNA synthesis with no known RNA editing or corrective mechanisms.[143] These molecular events that lead to episodic local epidemics and worldwide pandemics are understood in broad outline. Many viruses such as SARS CoV-2 are now known to evolve at high rates following basic darwinian principles in a time frame shorter than that of any other organism. Indeed, we now understand that RNA virus populations exist as a quasispecies or a swarm of individual viral genomes where every member is unique. Influenza viruses are successful because they have evolved to carry the very engines of evolution: mechanisms of mutation and recombination (reassortment). Influenza A virus has not been eliminated even with effective vaccines and antiviral drugs. Variants always arise that escape effective immune responses thorough high mutation (drift) and when coinfection occurs with viruses spreading from nonhuman hosts, new reassortants regularly arise. These new combinations of viral genes can change the pattern of infection from local to pandemic via an antigenic shift of its HA and NA subunit genes. These studies reveal an extraordinary lifestyle that reverberates around the planet in birds, farm animals, and humans. The study of the mechanisms of viral pathogenesis and modulation of the immune system has led to new insights in the virus-host relationship.

New technology discovered and developed over the past 35 years is changing the way viral infections are studied in the lab and in the field and is changing our appreciation of epidemiology and virus ecology.[166] Amplification technologies such as PCR permit rapid sampling of viral nucleic acids without growth in culture or plaque purification. Microarray technology where discriminatory DNA sequences from all sequenced viral genomes are put on a single array enables rapid classification of PCR amplified nucleic acids.[179] Rapid genome sequencing has revealed hitherto described viral genomes, relationships among viruses, and sequence heterogeneity within a virus population.[114] Mutations can be detected rapidly, documented, and localized in the viral genome. Importantly, the biological consequences can be monitored quickly. For example, in the late 1970s, viral epidemiologists were confronted with a highly transmissible, lethal infection of puppies.[134] In record time, scientists found that just two mutations in the capsid gene of feline parvovirus altered the host range such that the mutant could infect dogs. In less than a year, a completely new, highly pathogenic virus called canine parvovirus spread all around the world. Its evolution has continued to be monitored and a highly effective vaccine was developed. A similar type of molecular archeology enabled scientists to analyze serum samples collected from patients in the 1950s in efforts to understand the origins of HIV.[82] Sequence analysis of the HIV genome from one sample (ZR 1959) suggested that the virus may have emerged in the 1940s to 1950s. Field studies in Africa of viruses present in primate feces indicated that HIV most likely derived from a chimpanzee lentivirus in Africa.[155] After the initial human infection, rapid mutation and selection established the first human variants of this lentivirus that replicated and continued to evolve as they spread through their new human hosts.

We cannot forget the considerable impact of veterinary virus epidemiology on our understanding of complicated human diseases. For example, careful epidemiological work by Sigurdsson and colleagues on unusual diseases of sheep[160] provided the first understanding of slow infections in sheep (Visna-Maedi virus; a lentivirus) and infectious proteins (prions), which cause spongiform encephalopathies (Chapter 22).

As we will describe in the next section, molecular epidemiology is reaching new levels of sophistication, not only in detecting new viruses but also taking inventory of the viral ecosystem (the virome). Whether the next human epidemic will result from a novel variant of Ebola virus, coronavirus, or Norwalk virus or the more likely possibility of a new pandemic variant of influenza virus remains to be seen. The new technologies also enable analysis of virus populations in natural communities of nonhuman animals.[143] What is abundantly clear, however, is that the demographics of the human population on earth are changing at unprecedented rates (see Table 1.2). Even as birth rates slow, our planet will house 8-10 billion people by 2050–2100. For the first time, there will be three to four times more people above the age of 60 than below 3-4 years of age. Not only are we an aging population but we also are moving to urban environments with more than 20-30 cities containing more than 10 million people. Clearly, patterns of human behavior (increased population density, increased travel, increased ages of the population, income disparity, food shortages, and climate change) will provide the environment for the selection of emerging viruses and the challenges to the new field of molecular epidemiology.

TABLE 1.2 Advances and Challenges

Vaccines	Yellow fever virus vaccine, live attenuated Salk and Sabin vaccines for poliovirus, killed and live attenuated Recombinant hepatitis B vaccine, subunit Vaccinia virus vaccine to eradicate natural smallpox virus from the planet Influenza virus vaccines, inactivated and live attenuated Varicella-zoster virus vaccines, live attenuated Rotavirus vaccines, live attenuated Measles vaccines, live attenuated Recombinant human papillomavirus vaccine; subunit; prevents cancers and virus infections SARS CoV 2 mRNA vaccines, attenuated vaccines, adenovirus vectored vaccines, passive immunity with monoclonal antibodies
Antiviral Drugs	Acyclovir against herpes simplex type 1 and type 2 Combination therapy: protease, reverse transcriptase, and integrase inhibitors against HIV Interferon therapy for hepatitis B and C Amantadine against influenza virus A Neuraminidase inhibitors against influenza virus HCV replication inhibitors
Epidemiological advances	Understanding the molecular basis of antigenic shift and drift in influenza viruses Identification of the cause of AIDS and SARS Prion diseases recognized and mechanisms elucidated Deep sequencing, genome analysis, pathogen discovery, uncovering the molecular nature of epidemic and pandemic infections Recognition of the role of zoonotic infections in the emergence of new viral diseases Recognition of specific viruses as causative agents in human cancers Elucidation of the concept of viral quasispecies and the molecular biology of viral populations
Viral pathogenesis	Identification of viral virulence genes Identification of host genes affecting virus replication and spread Identification of the molecular bases for antiviral immune defenses (adaptive immunity) Identification of the molecular basis of front-line cellular defenses (intrinsic and innate immunity) including apoptosis and induction of defensive cytokines Understanding of the molecular basis for viral tropism Elucidation of the mechanisms involved in viral quiescence and persistence
The challenges (societal) The challenges (scientific)	Population explosion: more people now live on the planet than at any time in our existence (predicted to be 8-10 billion in the next few decades) Population concentration: world populations are concentrating in large urban centers of 10-20 million people or more Population demographics: for the first time, there are more people over the age of 60 than under the age of 4 Population interactions: world populations interact physically at rates and extents never before possible Acceptance of public health mitigation measures (social distancing, masks, vaccines, quarantine) Pandemic viral diseases and bioterrorism provide continuing challenges for human survival Research costs money: how do we alleviate the pressures on funding and support of fundamental research Discoveries cannot be predicted: how to balance true discovery research with applied (translational) research Public support: how do we develop support and advocacy for virology research and public health measures Policy makers must understand virology: more engagement of scientists with lawmakers and the general public Public education about vaccination and other public health issues Discovering an effective vaccine against HIV Developing vaccines against persistent viruses Discovering and developing new antiviral drugs Development of rapid viral diagnostic and identification strategies Coupling new technology with established procedures Balancing risks and benefits of dangerous pathogen research Developing surrogates for Koch's postulates in modern pathogen discovery programs Defining and understanding the composition and interplay of microbial communities inside and outside hosts (natural vs unnatural flora)

Host-Virus Interactions and Viral Pathogenesis

The technologies that contributed most to the modern era of virology (1960 to present) were advances in cell culture and molecular biology.[54] Virologists described the replicative cycles of viruses in great detail under well-defined conditions and demonstrated the elaborate interactions between viral genomes, viral proteins, and the host cellular machinery. As indicated previously, these advances resulted in an extraordinary inquiry into the functions of infected or uninfected host cells using the tools of both molecular and cell biology. As this approach matured, it became more reductionist in nature, and the questions became more detailed. However, some virologists used the new knowledge to move back to more complicated *in vivo* systems to study previously difficult problems in host-virus interactions involving the natural host or animal models of infection. Chief among these new questions was, how does a virus cause disease processes in the animal? How do we quantitate viral virulence and what is the genetic basis of an attenuated virus? How is a viral infection transmitted? These studies have identified, in selected viruses, a set of genes and functions that broadly impact our understanding of pathogenesis.

The COVID-19 Pandemic

(Section adapted from Ref.[40])

The world-wide spread of SARS-CoV-2 was devastating on a scale that few could have imagined. While there have been multiple viral pandemics in the last century, two stand out for their impact: the 1918 influenza pandemic and acquired immune deficiency syndrome (AIDS). Both killed millions of people and have had broad social and economic impacts. At this writing in January 2022, there are more than 400 million documented cases of COVID-19 worldwide and over 6 million deaths. Given the difficulties in testing massive numbers of people, the true prevalence of infection and death is undoubtedly much higher. The explosive spread of SARS-CoV-2 in late 2019 and early 2020 caught most of the world unprepared in many ways. Initially, there were few ways to control the spread except by old-fashioned quarantine methods: most of the world's population locked down, suspended travel, closed borders, and limited or stopped interactions of large groups of people. As a result, the medical disaster was compounded with social disruption and economic devastation.

The COVID-19 causative agent was isolated rapidly, identified as a coronavirus, and named SARS-CoV-2. While a new member of the *Coronaviridae*, it was not a "new" virus because coronaviruses are well known. Indeed, the first human coronavirus was described in 1964 by June Almeida in London. There are at least four known human coronaviruses that cause mild respiratory infections, including the common cold. Other animals can be infected with particular coronaviruses such as mouse hepatitis virus, infectious bronchitis virus of chickens, and transmissible gastroenteritis virus of swine. SARS-CoV-2 joins severe acute respiratory syndrome (SARS) and Middle East respiratory syndrome (MERS) coronaviruses, which emerged in 2002 and 2012, respectively, that cause severe human disease. SARS and MERS share some features with COVID-19 but each also has unique aspects. The SARS-CoV epidemic ended after ~8000 documented infections and that virus has not been since isolated from humans. MERS-CoV continues to infect several humans each month, mainly in the Arabian Peninsula.

Like most emerging viruses, SARS-CoV-2 most likely existed in an animal reservoir before it entered the human population. When and where SARS-CoV-2 entered humans has not been determined, although all evidence points to a bat origin: multiple SARS-CoV-2–related viruses have been identified from bats in China, Japan, Thailand, and Laos.

The genome sequence of some of the first virus isolates in China was widely disseminated to the research community. Within a few weeks, a global army of investigators was mobilized to study this new agent. This intense, scientific effort led to the rapid characterization of the SARS-CoV-2 attachment/fusion protein and the cell surface receptor was identified as the human enzyme ACE2, the same receptor used by SARS-CoV, the cause of SARS. Remarkably, the structure of the viral attachment protein (also called the spike protein) was determined at atomic-level resolution within a few months. Even more astounding was the development of new vaccines for production of the spike protein: mRNA vaccines, adenovirus vectored vaccines, and protein vaccines. Testing these vaccines for safety and efficacy was achieved faster than any other vaccine. The efficacy of these vaccines is nothing less than amazing. Nevertheless, the challenges of manufacturing, distributing, and public acceptance have been substantial.

Lessons Learned

(Section adapted from Ref.[40])

The most important lesson is that future pandemics are inevitable, and we must be ready for them. If we learned anything by being caught by surprise by the explosive spread of SARS-CoV-2, it is that rapid methods of surveillance and data sharing are essential. One challenge is how to recognize potential pandemics early and inform the public to allow prompt public health interventions. The world must have coordinated plans for action, to avoid confusion and inadequate responses. A second challenge is that we must identify and stockpile antiviral compounds and vaccines that can inhibit replication by a wide range of coronaviruses. Such therapeutics must have been tested for safety in humans so that at the first signs of a new outbreak they could be rapidly deployed.

We learned that transmission of infection can be slowed by physical distancing, wearing masks, washing hands, and staying home when ill. These efforts are classical public health procedures that we must not forget. An important lesson is that research in basic virology, cell biology, immunology, biochemistry, and other relevant areas is essential. These studies provide the necessary head start to meet new viruses before they overtake us and our health system, economy, and society. The fruits of such research enabled the rapid development of diagnostic tests, the use of DNA sequencing methods to characterize millions of genomes, and of course novel vaccines that are changing the face of the pandemic.

While these lessons are obvious, a more difficult challenge has emerged. COVID-19 has revealed deficiencies in how different societies operate and communicate as well as how politics can color public health responses. Since we live in a world of instant communication, dissemination of information, without regard to accuracy, is fast and seemingly uncontrollable. Moreover, the unwillingness of some institutional and political leaders as well as some members of the public to follow science-based guidelines and protocols is a serious problem that will continue long after the COVID-19 pandemic eases. More education is essential because much of the public and many of our public officials barely had any concept of viruses as infectious agents and their potential to upend our world. Until the public has some basic understanding of virology, history will repeat itself.

Past is Prolog

(Section adapted from Ref.[55])

The COVID-19 pandemic not only changed the world but also changed the study of virology as well. In general, virology has always been shaped by technology. When a virologist wants to answer a question, and current methods are inadequate, the virologist invents, borrows, or repurposes to develop a new technique. Many techniques and methods deployed to study SARS-CoV-2 and COVID-19 were not available just a few years ago. Moreover, the integration of new technology with public health measures to detect viral genomes and proteins as well as the immune response to infections has been revolutionary. New vaccine technology has enabled discovery, production, and mobilization of vaccines with remarkable efficacy.

Deep, high-throughput sequencing, the relatively unbiased methods to determine the entire genome sequence of viruses both known and unknown, has revolutionized virology because it enables characterization of millions of genomes in a short time. Molecular epidemiology, learning about the transmission of infections in real time, and the study of virus evolution have been changed forever by this new technology. At the molecular level, structural biology has been changed dramatically by cryoelectron microscopy. The atomic structure of individual viral proteins or intact virus particles, which used to take many years dominated by trial and error, can be determined in less than a month. Artificial

intelligence programs have revolutionized the prediction of protein structures. Antiviral drug discoveries that relied on painstaking work to identify potential molecular targets followed by tedious screens are relics of the past. With new genetics technology, imaging, and powerful chemistry methods, potential cellular targets for antivirals can be identified in weeks.

The COVID-19 pandemic mobilized powerful technology leading to rapid applied and fundamental progress. The drive to develop therapeutics and vaccines as well as to discover how viruses work was remarkable and productive. The testing and Food and Drug Administration emergency use authorization of two vaccines within less than a year of the first genome sequence being posted—and more remarkably, both based on a vaccine platform that had not been previously used at any scale in humans for vaccine purposes—is without precedent. The kinetics and scale of molecular epidemiology is remarkable. With millions of SARS-CoV-2 genome sequences, we know almost as much about the evolution of this virus as any other.

Fortunately, the pace of work and depth of analysis are applicable to many viruses, not just coronaviruses or the next pandemic virus. These technological advances move all of biology forward. In the midst of this worldwide calamity, the new revolution in virology brings hope for the future. There will be another pandemic, and lessons learned from this one will help us with the next.

The Future of Virology

The future of virology is unpredictable but is guaranteed to be exciting. Who knows what discoveries remain? Certainly, the number of astounding and groundbreaking developments in biology over the past 60 years is remarkable.[54] Most could not have been predicted or even imagined, prior to their discovery. That virologists participated in making many of these discoveries is no accident: viral gene products have evolved to engage all the key nodes of biology ranging from the atomic to the organismal. We only must be smart enough to figure out how to identify these nodes. The forces that will drive our field are technology development, public health, information processing, and, of course, personal curiosity. Indeed, new life science technologies invariably will give rise to new, unexpected insights in virology to meet our current challenges. That has been and continues to be the future of virology (see Table 1.2).

A Role for Systems Biology in Virology

Not too long ago, molecular virology was limited to studies of one virus and one gene or gene product at a time. More complex studies often were seen as “descriptive.” Times have changed! New technology enables virologists to interrogate simultaneously many viruses and large groups of genes or gene products in ever expanding environments and biological networks. In this context, a network is defined as the interconnected intracellular processes that control everything within a cell: for example, DNA replication, processes of gene expression, organelle biogenesis, and metabolism to name a few.[130] The definition also encompasses networks of intercellular communication at the tissue, organ, and whole-organism level. Virologists are beginning to embrace a tenet of systems biology where information flows through these networks and disease arises when these networks are perturbed. Viral gene products cause changes in network architecture and thereby alter the dynamics of information flow. Future studies of viral pathogenesis are likely to involve identification and understanding of specific viral signatures of network imbalance that do not affect just one pathway but alter the fundamental homeostatic balance.[19,54,141,164]

Genomics and the Predictive Power of Sequence Analysis

The development of technological advances in biology often drives new approaches and permits one to ask novel questions that could not even be framed in the past. In the last decade of the 20th century, rapid and inexpensive DNA sequencing methods opened the way to sequence the genomes of many viruses and their hosts. This created large databases containing information about the variation of DNA or RNA sequences within a single virus (eg, HIV, influenza, coronaviruses) and permitted predictions about the nature of the mutations driving selective changes, mutation frequencies of different viruses, and evolutionary changes from isolates around the world. The correlations of these sequence variations with drug and vaccine resistance, changes in the genetic background of the host, and virulence have been informative.

Host genomes contain an amazing number of viral or viral-related sequences.[11,12] More than 50% of the DNA sequences found in the human genome were derived from retroviruses, retrotransposons, DNA transposons and randomly amplified sequences of genes (SINES and the 7S RNA gene), pseudogenes, and repetitive DNA sequences.[106,177] Viruses certainly have left a major mark upon the evolution of their host’s genomes in addition to the selective pressures they exert via virus infections and deaths. During the evolution of humans from their ancestral line, retroviruses and retrotransposons (the LINE-1 elements) have entered the germ line, amplified their copy numbers, and integrated at various sites in the genome. This process introduces mutations, alters patterns of gene expression, and creates new interactions of viruses with their hosts. This is clearly one of the drivers of host evolution. Over time, these retroviruses (human endogenous retroviruses or HERVs) accumulate mutations in their genes, and some recombine out of the genome leaving only the LTRs as a remnant marking their past insertion. While humans no longer contain viable HERVs, the multiple copies of HERV-H or HERV-K viruses when transcribed in cells produce functional viral proteins from different copies of these viruses, and the viral particles that are produced are defective and very poorly transmitted. Cellular transcription factors regulate the expression of the HERVs, and the p53 transcription factor, activated by stress and DNA damage, transcribes the HERV H genome and produces particles in response to such stress.[192] Similarly, the LINE-1 retrotransposons, which have about 300 viable and movable elements in the human genome today, are responsible for about 1% of the mutations found in each generation. Line-1 transposons also contain p53 DNA response elements[83] and are also regulated by stress responses recorded by the host. While it is clear that retroviruses and transposons can shape the host genome, it is equally clear that the host genome is a place for new viral genomes to evolve, recombine with exogenous viral genomes and possibly produce a new agent optimized for replication in its host. Understanding the dynamics of these vestiges of viruses that reside in our genome is a challenge for the future.

With many host genome sequences representing all kingdoms of life in the databases, it has been possible to do some rather eye-opening analyses. For example, the resurrection of endogenous retroviruses from inactive sequences in host DNA has allowed the investigation of interactions between extinct pathogens called paleoviruses and their hosts that occurred millions of years ago.[52] By cloning these sequences, it has been possible to identify the cellular receptor of these extinct retroviruses.[157] Perhaps more amazing is that similar “viral genome fossils” representing DNA copies of filoviruses and bornaviruses as well as parvoviruses and circoviruses have been found in a variety of host genomes.[11,12] When the evolutionary history of various host genomes harboring these viral sequences were compared, it was possible to deduce that ancestors of modern viruses were in existence millions of years ago. What is even more curious is that these genome insertion events seemed to happen around the same time in a wide variety of mammals. What global event could have stimulated such activities?

The Virome: How Many Viruses Are There and Where Are They?

Virus ecology, as a result of modern virus discovery technology, is posing many questions.[100,166] In 1977, when Fred Sanger sequenced the DNA genome of coliphage phiX174, many virologists were impressed with the wealth of information contained in a "simple" DNA sequence and the congruence of genetic and biochemical data with the genome structure. The recent discovery of "giant viruses" that infect amoeba revealed that the time-honored definition of viruses as small filterable agents no longer holds (Chapter 17).

In <25 years, sampling, sequencing, and computer technology now provide the wherewithal to identify and sequence entire viral communities from their natural environment without the intervention of time-held techniques of isolation and characterization of individual viruses.[46,162,179] In early 2003, a novel viral DNA microarray was used to reveal and partially sequence a previously uncharacterized coronavirus in a viral isolate cultured from a SARS patient. This chip technology has advanced to the point that essentially all the known viral genomes can be represented on a single microarray. The technology may be obsolete already. The SARS-CoV-2 virus was identified quickly by high throughput sequencing technology. New techniques for discovery and analysis of viral populations are certain to be found. As can be expected in this "omics" era, the identification and study of an entire community of viruses in their natural habitat has been called metagenomics.[2,145,186] The diversity of viruses in the environment was unknown as we were limited to studying only those viruses that are easy to work with in the laboratory or those that have major impact on human health. The first metagenomic studies on viruses have revealed stunning diversity of genes and gene products that remain to be understood even in principle.[162,187] The combination of host and bacteriophage genome sequencing in the bacteria has proven to be an exceptional window on genome evolution and gene transfer. The practical value of identifying new gene products with novel functions cannot be overestimated. The repertoire of tactics for gene control and regulation is far more extensive than any of us imagined before the era of metagenomics. We can only expect that as the metagenomics of animal and plant viruses advances, the impact of knowing everything that is out there and the resulting knowledge of the dynamics of host-parasite interactions will be mind-boggling.[163]

Pathogen Discovery

With the plethora of viruses found in and on every living thing, defining new pathogens is challenging. Perhaps of fundamental importance is that proof of causation can no longer rely on the time honored Koch's postulates.[87] This assertion is made not only because it may be difficult to propagate new viruses and find models to test their pathogenicity but it also is likely that many diseases will involve the interaction of multiple microbial communities (viruses, bacteria, fungi) that will be difficult to reproduce in the laboratory. Pathogen discovery will require new biomarkers of health and disease, methods to improve sampling and stability of samples, and technology to record relevant data and capacity to associate all these data with the sample. In the past, pathogen identification methods were slow and tedious and working with multiple samples was difficult if not impossible. It is now possible to collect and analyze serial samples over time as patients move from health to disease. Assembling data, maintaining data bases, and providing access for analysis will also involve advances in software and bioinformatics. In the end, the fundamental challenge will be how one moves from correlation of the presence of an agent or agents in disease to proof of causation.

Whether or not viruses are living has been debated since their discovery. The virus particle is certainly not alive as it is a collection of chemicals that is inert unless it enters a cell to deliver its nucleic acid genome. However, the infected cell displays all the qualities of life, including energy generation and evolution. Hence, when considering this question, we must distinguish between the virus particle and the virus-infected cell.

The idea that the virus particle and the infected cell are distinct was first proposed by Bandea in 1983.[6] He suggested that a virus is an organism without a cohesive morphological structure, with subsystems that are not in structural continuity:

Viruses are presented as organisms which pass in their ontogenetic cycle through two distinctive phenotypic phases: (1) the vegetative phase and (2) the phase of viral particle or nucleic acid. In the vegetative phase, considered herein to be the ontogenetically mature phase of viruses, their component molecules are dispersed within the host cell. In this phase, the virus shows the major physiological properties of other organisms: metabolism, growth, and reproduction.

According to Bandea's hypothesis, the infected cell is the virus, while the virus particles are "spores" or reproductive forms. His theory was largely ignored until the discovery of the giant mimivirus: its DNA genome replicates and new virions are produced in the cytoplasm within complex viral "factories." Claverie suggested that the viral factory corresponds to the organism, whereas the virus particle is used to spread from cell to cell. He wrote that "to confuse the virion with the virus would be the same as to confuse a sperm cell with a human being".[29]

If we accept that the virus is the infected cell, then it becomes clear that most virologists have confused the virus particle and the virus. This situation is probably a consequence of the fact that modern virology is rooted in the study of bacteriophages that began in the 1940s. These viruses were not found to induce cellular factories and disappear (the eclipse phase) early after cell entry. Contemporary examples of such confusion include the production by structural virologists of virus crystals, and the observation that viruses are the most abundant entities in the seas. In both cases, it is the virus particle that is being studied. But virologists are not the only ones at fault—the media writes about the AIDS virus or COVID-19 while showing illustrations of the virus particle.

Forterre[60] writes that those who consider the virus to be the infected cell also believe that viruses are alive:

...one can conclude that infected eukaryotic cells in which viral factories have taken control of the cellular machinery became viruses themselves, the viral factory being in that case the equivalent of the nucleus. By adopting this viewpoint, one should finally consider viruses as cellular organisms. They are of course a particular form of cellular organism, since they do not encode their own ribosomes and cell membranes but borrow those from the cells in which they live.

This argument leads to the assumption that viruses—not virus particles—are living, according to the classical definition of living organisms as cellular organisms. In other words, a virus is an organism with two phases, the virus particle (which is not living) and the infected cell (which is living).

CHAPTER 2

Principles of Virology

Julie K. Pfeiffer • Richard C. Condit • John W. Schoggins

Virus taxonomy

History and rationale

Current taxonomy

Nomenclature

Informal groupings and alternate classification schemes

Virus cultivation and assay

Initial detection and isolation

Hosts for virus cultivation

Recognition of viral growth in culture

Virus cultivation

Quantitative assay of viruses

Quantitative considerations in virus assay, cultivation, and experimentation

One-step growth experiment

Modern viral assays and approaches

Virus genetics

Fundamental genetic concepts

Study of mutations and mutants

Reverse genetics

Defective interfering particles

Phenotypic mixing and pseudotypes

Viruses are unique in nature. They are the smallest of all self-replicating organisms, historically characterized by their ability to pass through filters that retain even the smallest bacteria. In their most basic form, viruses consist solely of a small segment of nucleic acid encased in a simple protein shell. Viruses have no metabolism of their own but rather are obliged to invade cells and parasitize subcellular machinery. Many have argued that viruses are not even living.[166]

The apparent simplicity of viruses is deceptive. The truth is that as a group, viruses infect virtually every organism in nature, they display a dizzying diversity of structures and lifestyles, and they embody a profound complexity of function.

The study of viruses—virology—must accommodate both the uniqueness and the complexity of these organisms. The singular nature of viruses has spawned novel methods of classification and experimentation entirely peculiar to the discipline of virology. The complexity of viruses is constantly challenging scientists to adjust their thinking and their research to describe and understand some new twist in the central dogma revealed in a *simple* virus infection.

This chapter explores several concepts fundamental to virology as a whole, including virus taxonomy, virus cultivation and assay, and virus genetics. The chapter is not intended as a comprehensive or encyclopedic treatment of these topics, but rather as a relatively concise overview with sufficient documentation for more in-depth study. In addition to primary resources and practical experience, the presentation draws heavily on previous editions of *Fields Virology*[46-48,87-89] for the taxonomy and genetics material, plus several excellent texts for material on virus cultivation and assay.[28,45,52,76,93,100,106] It is hoped that this chapter will be of value to anyone learning virology at any stage: a novice trying to understand basic principles for the first time, an intermediate student of virology trying to understand the technical subtleties of virological protocols in the literature, or a bewildered scientist in the laboratory wondering why the host-range virus mutant received from a colleague does not seem to manifest the described host range.

Virus Taxonomy

A coherent and workable system of classification—a taxonomy—is a critical component of the discipline of virology. However, the unique nature of viruses has defied the strict application of many of the traditional tools of taxonomy used in other areas of biology. Thus, scientists who concern themselves with global taxonomy of organisms have traditionally either ignored viruses completely as nonliving entities or left them

scattered throughout the major kingdoms, reasoning that viruses have more in common with their individual hosts than they do with each other.[107,112] By contrast, for practical reasons at least, virologists agree that viruses should be considered together as a separate group of organisms regardless of host, be it plant, animal, fungus, protist, or bacterium. This philosophy is justified by the observation that, in several cases, viruses now classified in the same family—for example, family *Reoviridae*—infect hosts from different kingdoms. Interestingly, the discipline of virus taxonomy brings out thought-provoking and philosophical discussions about the nature of viruses, probably because the decisions that must be made to distinguish one virus from another require deep thought about the nature of viruses and virus evolution. In the end, all of nature is a continuum, and the business of taxonomy has the unfortunate obligation of drawing boundaries within this continuum, an artificial task but necessary nevertheless. The execution of this obligation results today in a free-standing virus taxonomy, overseen by the International Committee on Taxonomy of Viruses (ICTV), with rules and tools unique to the discipline of virology. The process of virus taxonomy that has evolved uses some of the hierarchical nomenclature of traditional taxonomy. However, to cope with both the uniqueness and diversity of viruses as a group, the classification process has been deliberately nonsystematic and thus is "based upon the opinionated usage of data."[114]

Most importantly, the virus taxonomy that has been developed and refined works well. For the trained virologist, the mention of a virus family or genus name, such as "family *Herpesviridae*" or "genus *Rotavirus*" immediately conjures a set of characteristics that form the basis for further description. Virus taxonomy serves an important practical purpose as well, in that the identification of a limited number of biological characteristics, such as virion morphology, genome structure, or antigenic properties, quickly provides a focus for identification of an unknown agent for the clinician or epidemiologist and can significantly impact treatment or prevention of a virus disease. Virus taxonomy is an evolving field, and what follows is a summary of the state of the art, including important historical landmarks that influenced the present system of virus taxonomy and major changes in viral classification over the past 5 years.

History and Rationale

Virology as a discipline is scarcely 100 years old, and thus, the discipline of virus taxonomy is relatively young. In the early 1900s, viruses were initially classified as distinct from other organisms simply by their ability to pass through unglazed porcelain filters known to retain the smallest of bacteria. As increasing numbers of filterable agents became recognized, they were distinguished from each other by the only measurable properties available, namely the disease caused in an infected organism. Therefore, animal viruses that caused liver pathology were grouped together as hepatitis viruses, and viruses that caused mottling in plants were grouped together as mosaic viruses. In the 1930s, an explosion of technology spawned a description of the physical properties of many viruses, providing numerous new characteristics for distinguishing viruses one from another. The technologies included procedures for purification of viruses, biochemical characterization of purified virions, serology, and perhaps most importantly, electron microscopy, which permitted detailed descriptions of virion morphology. In the 1950s, these characterizations led to the distinction of three major animal virus groups, the myxoviruses, the herpesviruses, and the poxviruses.

By the 1960s, because of the profusion of data describing numerous different viruses, it became clear that an organized effort was required to classify and name viruses, and thus the ICTV (originally the International Committee on Nomenclature of Viruses [ICNV]) was established in 1966. The ICTV functions today as a large, international group of virologists organized into appropriate study groups, who develop rules for the classification and naming of viruses and coordinate implementation of these rules. The ICTV is a committee of the Virology Division of the International Union of Microbiological Societies. The objectives of the ICTV are to develop an internationally agreed taxonomy and nomenclature for viruses, to maintain an index of virus names, and to communicate the proceedings of the committee to the international community of virologists. The ICTV publishes an update of the taxonomy at ~3-year intervals. Since 2017, the ICTV Taxonomy Report is freely available online at http://www.ictvonline.org/Report.

Early in its history, the ICTV wrestled with the fundamental problem of developing a taxonomic system for classification and naming of viruses that would accommodate the unique properties of viruses as a group and that could anticipate advancements in the identification and characterization of viruses. Perhaps the most critical issue was whether the classification of viruses should consider virus properties in a monothetical or polythetical fashion. A *monothetic* system of classification is defined as a system based on a single characteristic or a series of single characteristics. *Polythetic* is defined as sharing several common characteristics without any one of these characteristics being essential for membership in the group. Thus, a monothetical classification, modeled after the Linnaean system used for classification of plants and animals, would rank individual virus properties, such as genome structure or virion symmetry, as being more or less important relative to each other and use these individual characteristics to sort viruses.[103] Although the hierarchical ordering of viruses is desirable, a strictly monothetical approach was problematic because both the identification of individual properties and the assignment of a hierarchy to individual properties seemed too arbitrary. A polythetic approach to classification would group viruses by comparing simultaneously numerous properties of individual viruses without assigning a universal priority to any one property. Thus, using the polythetic approach, a given virus grouping is defined by a collection of properties. One argument against the polythetic approach is that a truly systematic and comprehensive comparison of dozens of individual properties would be difficult if not impossible. However, this problem could be avoided by the adoption of a nonsystematic approach, using study groups of virologists within the ICTV to consider together numerous characteristics of a virus and make as rational an assignment to a group as possible. Therefore, the system that is currently being used is a nonsystematic, polythetical, hierarchical system. This system differs from any other taxonomic system in use for bacteria or other organisms; however, it is effective and useful.[113] As new techniques for identification and characterization of viruses are developed, the methods used for taxonomy continue to evolve, as described below.

Taxonomy Prior to 2018

Due to their high mutation rates, limited number of genes, and relative lack of old/"fossil" records, it was originally thought that deep evolutionary relationships among viruses could not be determined. As a consequence, prior to 1990, the highest taxonomic rank for viruses was family, followed by subfamily, genera, and species. This original viral classification strategy was completely separate from the tree of cellular life and only included the lower levels of the classical hierarchy, omitting designations for kingdom, phylum, and class. In practice, this original taxonomy was filled initially from the middle of the hierarchy by assigning viruses to genera and then elaborating the taxonomy upward by grouping genera into families and, to a limited extent, families into orders. By 1970, the ICTV had established two virus families each containing 2 genera, 24 floating genera, and 16 plant *groups*.[174] A rigorous species definition was not approved by the ICTV until 1991 but was then applied to the entire taxonomy and became the primary level of classification for viruses.[165] By 2011, the ICTV recognized 6 orders, 87 families, 19 subfamilies, 348 genera, and 2290 species.

For most experimental virologists, the viral family and species designations are among the most useful and familiar because they describe a

given morphology and replication strategy (family) and they are part of the vernacular (species). For example, *West Nile virus* is a species within the *Flaviviridae* family, *Vaccinia virus* is a species within the *Poxviridae* family, and *Measles morbillivirus* is a species with the *Paramyxoviridae* family. Until changes enacted in 2018, viral family was the highest consistently used taxonomic grouping, and therefore carries a convenient generalized description of a given virus group, and as a result has become a benchmark of the taxonomic system. Most families have distinct virion morphology, genome structure, and/or replication strategy (see Table 2.1). A virus species is defined as "a polythetic class of viruses that constitutes a replicating lineage and occupies a particular ecological niche."[164] The formal definition of a polythetic class is "a class whose members always have several properties in common, although no single common attribute is present in all of its members."[165] Thus, no single property can be used to define a given species, and application of this formal definition of a polythetic class to species accounts nicely for the inherent variability found among members of a species. The qualification of a replicating lineage implies that members of a species experience evolution over time with consequent variation but that members share a common ancestor. The qualification of occupation of an ecological niche acknowledges that the biology of a virus, including such properties as host range, pathogenesis, transmission, and habitat, are fundamental components of the characterization of a virus. Taxonomic levels lower than species, such as clades, strains, and variants, are not officially considered by the ICTV but are left to specialty groups.

TABLE 2.1 Characteristics of a small subset of vertebrate virus families

Family	Virion Morphology	Envelope	Genome[a]
dsDNA viruses			
Adenoviridae	Icosahedral	No	1 ds linear
Herpesviridae	Spherical, tegument	Yes	1 ds linear
Papillomaviridae	Icosahedral	No	1 ds circular
Polyomaviridae	Icosahedral	No	1 ds circular
Poxviridae	Ovoid	Yes	1 ds linear
ssDNA viruses			
Anelloviridae	Icosahedral	No	1 (–) circular
Circoviridae	Icosahedral	No	1 (– or +/–) circular
Parvoviridae	Icosahedral	No	1 (+, –, or +/–) circular
dsDNA reverse-transcribing viruses			
Hepadnaviridae	Spherical	Yes	1 ds circular
ssRNA reverse-transcribing viruses			
Retroviridae	Spherical	Yes	1 (+) linear
dsRNA viruses			
Reoviridae	Icosahedral	No	10-12 ds linear
Negative-sense ssRNA viruses			
Filoviridae	Filamentous	Yes	1 (–) linear
Orthomyxoviridae	Pleomorphic, spherical	Yes	6-8 (–) linear
Paramyxoviridae	Pleomorphic spherical	Yes	1 (–) linear
Rhabdoviridae	Bullet shaped	Yes	1 (–) linear
Positive-sense ssRNA viruses			
Arteriviridae	Spherical	Yes	1 (+) linear
Astroviridae	Icosahedral	No	1 (+) linear
Caliciviridae	Icosahedral	No	1 (+) linear
Coronaviridae	Spherical	Yes	1 (+) linear
Flaviviridae	Spherical	Yes	1 (+) linear
Picornaviridae	Icosahedral	No	1 (+) linear
Togaviridae	Spherical	Yes	1 (+) linear
Ambisense ssRNA viruses			
Arenaviridae	Spherical	Yes	2 (+/–) linear
Bunyaviridae	Spherical	Yes	3 (– or +/–) linear

[a]Number of segments, polarity (ds, double stranded; +, mRNA-like; –, cRNA-like; +/–, ambisense), conformation.

Taxonomic levels higher than species are formally defined by the ICTV only in a relative sense, namely a genus is a group of species sharing certain common characters, a subfamily is a group of genera sharing certain common characters, a family is a group of genera or subfamilies sharing certain common characters, and so forth. As the virus taxonomy has evolved, these higher taxa have acquired some monothetic character. They remain polythetic in that they may be characterized by more than one virus property; however, they violate the formal definition of a polythetic class in that one or more defining properties may be required of all candidate viruses for membership in the taxon. Not all taxonomic levels need be used for a given grouping of viruses; thus, whereas most species are grouped into genera and genera into families, not all families contain subfamilies, and only a few families have been grouped into orders.

Historically, a *type species* was identified for each genus. The type species is not necessarily the best characterized or most representative species in a genus; rather, it is usually the virus that initially necessitated the creation of the genus and therefore best defines or identifies the genus. However, in 2021, the ICTV decided to abolish the notion of a type species because it was mainly historical and no longer served a clear purpose.[169]

Current Taxonomy

A major shift in virus taxonomy has occurred over the past few years. The strategic change is in part due to the explosion of newly discovered viruses through metagenomic approaches but also due to recognition that taxonomy can be extended to include shared origins and evolutionary relationships among even distantly related viruses. Now, rather than a five-rank structure at the lower rungs of the evolutionary hierarchy (order, family, subfamily, genera, species), current taxonomy uses a 15-rank structure that more closely parallels cell-based organisms (realm, subrealm, kingdom, subkingdom, phylum, subphylum, class, subclass, order, suborder, family, subfamily, genus, subgenus, species). An important distinction was made at the top of the viral hierarchy to distinguish it from a similar rung on the evolutionary tree of cell-based organisms. The ICTV designated "realms" for viruses that are analogous to "domains" for bacteria, archaea, and eukaryota. Unlike cell-based organisms, viruses do not share one common ancestor and therefore phylogenetic trees cannot be made. Thus, the ICTV invented realms to convey similarity of genes and proteins, even when members arose from different ancestors. As of 2020, there are six realms: *Riboviria*, *Duplodnaviria*, *Monodnaviria*, *Varidnaviria*, *Adnaviria*, and *Ribozyviria*. The realm names are usefully descriptive. *Riboviria* are RNA viruses that use an RNA-directed polymerase to replicate, *Duplodnaviria* are dsDNA viruses with a common HK97-fold capsid protein, *Monodnaviria* are ssDNA viruses with a common endonuclease, *Varidnaviria* are DNA viruses with a common jelly roll capsid protein, *Adnaviria* are filamentous viruses with A-form DNA that infect archaea, and *Ribozyviria* are unusual small RNA viruses. In addition to these 6 realms, in 2020, there were 10 kingdoms, 17 phyla, 2 subphyla, 39 classes, 59 orders, 8 suborders, 189 families, 136 subfamilies, 2224 genera, 70 subgenera, and 9110 species.

While the higher level ranks—realm, kingdom, phyla, and class—were created in 2018 and are therefore new, the lower level ranks—order, family, genera, and species—have remained fairly constant aside from addition of new members from metagenomic studies. Thus, genus and species designations for existing viral systems have not changed with the new taxonomy. As a consequence, many virologists working on established viral systems may be unaware of the changes in taxonomy. *West Nile virus* is still *West Nile virus*, it just has a new realm (*Riboviria*), kingdom (*Orthornavirae*), phylum (*Kitrinoviricota*), and class (*Flasuviricetes*).

To facilitate the management and distribution of virological data, the ICTV shares taxonomic and other information on their web site: https://talk.ictvonline.org/. Constructed from virus descriptions in the published reports of the ICTV, the database comprises searchable descriptions, updated taxonomy, and historical records. The complete virus taxonomy is far too extensive to relate here; however, Figure 2.1 shows the general scheme and one specific example, *Zaire ebolavirus*.

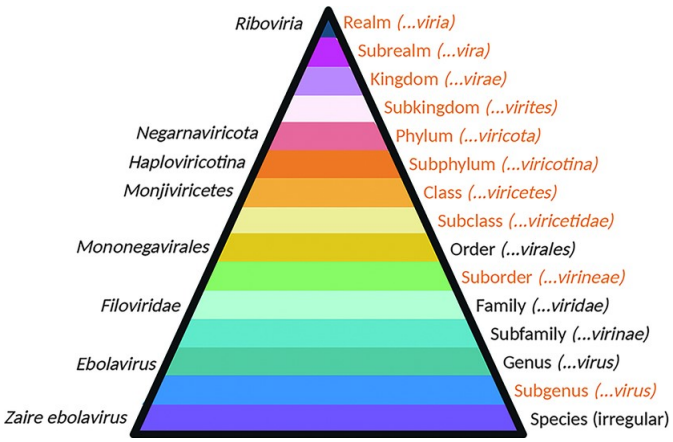

FIGURE 2.1 **Current taxonomy.** Viruses are grouped into 15 taxonomic ranks as shown on the *right side* of the diagram. Ranks indicated in *black text* were part of the prior scheme and ranks indicated in *orange text* were added in 2018. The width of the triangle indicates relative numbers within each rank, with 6 realms and over 9000 species in 2021. A specific example for one virus, *Zaire ebolavirus*, is shown on the *left*. (Created with BioRender.com.)

Metagenomics

Viral metagenomics is the study of genetic material collected directly from the environment, without the need to isolate or culture viruses, and it has dramatically expanded the known virosphere. Thousands of new viral genomes from diverse environmental sites can be sequenced quickly, and a method for taxonomic classification is needed. The ICTV accepts proposals to create taxa on the basis of genomic sequences alone—without the need for host information or other biological information—as long as there is evidence for accurate sequence assembly and the coding sequence is complete.[1,148] Additionally, it is possible to create species solely on the basis of sequencing data using the same hierarchy and nomenclature rules as traditionally described species. This has been particularly useful for an explosion of viral sequences from marine and intestinal environments.

Nomenclature

The ICTV has adopted a formal nomenclature for viruses, specifying suffixes for the various taxa, and rules for written descriptions of viruses. Names for each category must be single words ending with an appropriate suffix: realm (-viria), subrealm (-vira), kingdom (-virae), subkingdom (-virites), phylum (-viricota), subphylum (-viricotina), class (-viricetes), subclass (-viricetidae), order (-virales), suborder (-virinae), family (-viridae), subfamily (-virinae), genus (-virus), and subgenus (-virus). Species names may contain more than one word and have no specific

ending. In written usage, the formal virus taxonomic names are capitalized and written in italics, and preceded by the name of the taxon, which is neither capitalized nor italicized. For species names that contain more than one word, the first word plus any proper nouns are capitalized. As an example, the full formal written description of human immunodeficiency virus 1 is as follows: realm *Riboviria*, kingdom *Pararnavirae*, phylum *Artverviricota*, class *Revtraviricetes*, order *Ortervirales*, family *Retroviridae*, subfamily *Orthoretrovirinae*, genus *Lentivirus*, species *Human immunodeficiency virus 1*. The ICTV acknowledges that vernacular (informal) taxonomic names are widely used; however, they should not be italicized or capitalized except for proper names. For example, the vernacular name "herpesvirus" refers to a member of the family *Herpesviridae*.

While viral *taxa* are officially named by the ICTV, virus *names* are chosen by the virologists that discover and study them. In practice, the chosen names are valid only if they are accepted and used by the relevant virology community. Technically, there are no rules to govern virus names, but historically, viruses have been named after their properties, locations, hosts, diseases, or their discoverers. More recently, naming viruses after locations has been discouraged to avoid stigma associated with an outbreak. Thus, while existing virus names may refer to locations (Norwalk virus, Ebola virus, Japanese encephalitis virus, etc.), more newly discovered viruses are not named after locations (eg, SARS-CoV-2).

Informal Groupings and Alternate Classification Schemes

For convenience in presenting or tabulating the virus taxonomy, informal categorical groupings of taxa are often used. The criteria typically include nature of the viral genome (DNA or RNA), strandedness of the viral genome (single-stranded or double-stranded), polarity of the genome (positive sense, negative sense, or ambisense), and reverse transcription. Separate categories accommodate subviral agents (including viroids, satellites, and prions) and unassigned viruses. The Baltimore classification system, named after its creator David Baltimore, is a widely used scheme based on the nature of the genome packaged in virions and the pathway of nucleic acid synthesis that each group takes to accomplish messenger RNA (mRNA) synthesis.[3] This classification divides viruses into seven categories as depicted in Figure 2.2. Most usages of this system group ambisense virus families (family *Arenaviridae* and family *Bunyaviridae*) along with negative-sense single-stranded RNA (ssRNA) viruses. The families of vertebrate viruses listed in Table 2.1 have been grouped according to the Baltimore classification, with ambisense viruses split into an eighth genome category.

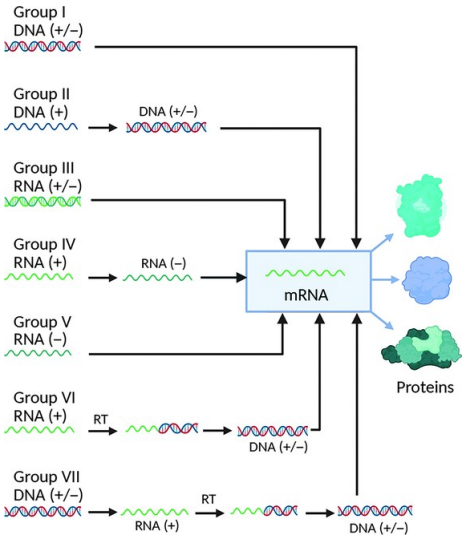

FIGURE 2.2 **The Baltimore classification system, a virus classification scheme based on the form of nucleic acid present in virion particles and the pathway for expression of the genetic material as messenger RNA.**[3] Viruses containing ambisense single-stranded RNA genomes are grouped under negative-sense single-stranded RNA viruses. +, sense strand; –, antisense strand; +/–, double-stranded; RT, reverse transcription. (Created with BioRender.com.)

Virus Cultivation and Assay

A genuine understanding of virology requires a clear understanding of virological methods. Some of these methods use techniques shared by other branches of biological science, whereas others are generally quite unique to the study of viruses. What follows is a summary of common techniques used in virology, presented as fundamental background for understanding the discipline.

Initial Detection and Isolation

The presence of a virus is typically assessed by examining effects on a host organism or, in the case of many animal viruses, by effects on cultured cells. Effects on animal hosts include a broad range of symptoms such as virus-induced lesions, behavioral changes, immune dysfunction tissue damage, organ failure, and death. Effects on cultured cells include a variety of morphological changes in infected cells, termed *cytopathic effects*, and described in detail later in this chapter. Both adenovirus[138] and the polyomavirus SV40[158] were discovered as cell culture contaminants before they were detected in their natural hosts.

Viruses can be isolated from an infected host by harvesting excreted or secreted material, blood, or tissue and testing for induction of the original symptoms in the identical host, or induction of some abnormal pathology in a substitute host or in cell culture. Historically, dogs, cats, rabbits, rats, guinea pigs, hamsters, mice, and chickens have all been found to be useful in laboratory investigations,[93] although most animal methods have now been replaced by cell culture methods.[106] There is also growing interest in identifying and isolating viruses from their natural hosts or from environmental samples (eg, sea water). Modern metagenomic sequencing techniques can be used to assess the repertoire of viral sequences in a given sample, also referred to as the "virome."[49]

Once the presence of a virus has been established, it is often desirable to prepare a genetically pure clone. This can be achieved by either limiting serial dilution or by plaque purification of a verified viral stock. Alternatively, many viral genomes, particularly RNA viruses, can be synthesized *de novo* using recombinant DNA technologies, as shown initially with poliovirus.[12]

Viruses that are cultivated in anything other than the natural host may adapt to the new host through acquisition of genetic alterations that provide a replication advantage in the new host. Such adaptive changes may be accompanied by a loss of fitness in the original host, most notably by a loss of virulence or pathogenicity. Whereas this adaptation and attenuation may present problems to the basic scientist interested in understanding the replication of the virus in its natural state, it also forms the basis of construction of attenuated viral vaccines.

Hosts for Virus Cultivation

Laboratory Animals and Embryonated Chicken Eggs

Prior to the advent of cell culture, animal viruses were propagated in whole animals or embryonated chicken eggs. Whole animals could include the natural host or laboratory animals such as rabbits, mice, rats, and hamsters. In the case of laboratory animals, newborn or suckling rodents often provide the best hosts. Today, laboratory animals are seldom used for routine cultivation of virus; however, they still play an essential role in studies of viral pathogenesis.

The use of embryonated chicken eggs was introduced to virology by Goodpasture et al.[56] in 1932 and developed subsequently by Beveridge and Burnet.[6] The developing chick embryo, 10-14 days after fertilization, provides a variety of differentiated tissues, including the amnion, allantois, chorion, and yolk sac, which serve as substrates for growth of a wide variety of viruses, including orthomyxoviruses, paramyxoviruses, rhabdoviruses, togaviruses, herpesviruses, and poxviruses.[93] These virus may replicate in several tissues of the developing egg, or replication may be confined to a single tissue. Some of them cause discrete and characteristic foci when introduced onto the chorioallantoic membrane of embryonated eggs, thus providing a method for identification of virus types or for quantifying virus stocks or assessing virus pathogenicity. Although embryonated eggs have been almost wholly replaced by cell culture techniques, they are still the most convenient method for growing high titer stocks of some viruses and thus continue to be used both in research laboratories and for vaccine production.

Cell Culture

The growth and maintenance of animal cells *in vitro*, described generally as tissue culture, can be divided into several different techniques: organ culture, primary explant culture, organoid culture, and cell culture. In *organ culture*, the original three-dimensional architecture of a tissue is preserved under culture conditions that provide a gas-liquid interface. In *primary explant culture*, minced pieces of tissue placed in liquid medium in a culture vessel provide a source for outgrowth of individual cells. *Organoid cultures* are a more recent addition to the repertoire of tissue culture and involve the formation of three-dimensional organlike structures from one or more stem cell types that differentiate to mimic the corresponding organ *in vivo*. In *cell culture*, tissue is disaggregated into individual cells prior to culturing. Cell culture and organoid culture will be discussed in more detail here, as they are the most commonly used tissue culture techniques in virology.

Cultured cells currently provide the most widely used and most powerful hosts for cultivation and assay of viruses. Cell cultures are of three basic types—primary cell cultures, cell strains, and cell lines—that may be derived from many animal species and that differ substantially in their characteristics. Viruses often behave differently on different types of cultured cells; in addition, each of the culture types possesses technical advantages and disadvantages. For these reasons, an appreciation of the use of cultured cells in animal virology requires an understanding of several fundamentals of cell culture itself. A detailed description of the theory and practice of cell and tissue culture is provided by Freshney,[52] and several additional texts provide excellent summaries of cell culture as it specifically applies to virology.[28,76]

Primary cell culture

A primary cell culture is defined as a culture of cells obtained from the original tissue that have been cultivated *in vitro* for the first time and that have not been subcultured. Primary cell cultures can be established from whole animal embryos or from selected tissues from embryos, newborn animals, or adult animals of almost any species. The most commonly used cell cultures in virology derive from primates, including humans and monkeys; rodents, including hamsters, rats, and mice; and birds, most notably chickens. Cells to be cultured are obtained by mincing tissue and dispersing individual cells by treatment with proteases and/or collagenase to disrupt cell-cell interactions and interactions of cells with the extracellular matrix. With the exception of cells from the hemopoietic system, normal vertebrate cells will grow and divide only when attached to a solid surface. Dispersed cells are therefore placed in a plastic flask or dish, the surface of which has been treated to promote cell attachment. The cells are incubated in a buffered nutrient medium in the presence of blood serum, which contains a complex mixture of hormones and factors required for the growth of normal cells. The blood serum may come from a variety of sources, although bovine serum is most commonly used. Under these conditions, cells will attach to the surface of the dish, and they will divide and migrate until the surface of the dish is covered with a single layer of cells, a monolayer, whereupon they will remain viable but cease to divide. If the cell monolayer is "wounded" by scraping cells from an isolated area, cells on the border of the wound will resume division and migration until the monolayer is reformed, whereupon cell division again ceases. These and other observations lead to the conclusion that the arrest of division observed when cells reach confluency results from cell-cell contact and therefore is called *contact inhibition*. Primary cultures may contain a mixture of cell types and retain the closest resemblance to the tissue of origin.

Subcultivation

Cells from a primary culture may be subcultured to obtain larger numbers of cells. Cells are removed from the culture dish and disaggregated by treating the primary cell monolayer with a chelating agent, usually EDTA, or a protease, usually trypsin, or both, giving rise to a single cell suspension. This suspension is then diluted to a fraction of the original monolayer cell density and placed in a culture dish with fresh growth medium, whereupon the cells attach to the surface of the dish and resume cell division until once again a monolayer is formed and cell division ceases. Cultures established in this fashion from primary cell cultures may be called *secondary cultures*. Subsequently, cells may be repeatedly subcultured in the same fashion. Each subculturing event is called a *passage*, and each passage may comprise several cell generations, depending on the dilution used during the passage. Most vertebrate cells divide at the rate of approximately one doubling every 24 hours at 37 °C. Thus, a passage performed with an eightfold dilution will require three cell doublings over 3 days before the cells regain confluency.

Cell strains

Normal vertebrate cells cannot be passaged indefinitely in culture. Instead, after a limited number of cell generations, usually 20-100 depending on the age and species of the original animal, cultured normal cells cease to divide, then degenerate and die, a phenomenon called *crisis* or *senescence*.[65] Starting with the establishment of a secondary culture and until cells either senesce or become transformed as described later, the culture is termed a *cell strain* to distinguish it from a primary culture on the one hand, or a transformed, immortal cell line on the other hand. During culture, cells in a strain retain their original karyotype and are thus called *euploid*; however, culturing induces profound changes in the composition and characteristics of the cell strain, which are manifested early during the passage history and may continue during passage. Whereas primary cell cultures may contain a mixture of cell types that survive the original plating of cells, only a few cell types survive subculturing; thus, by the second or third passage, typically only one cell type remains in the cell strain. Cell strains are usually composed of one of two basic cell types—fibroblast-like or epithelial-like—characterized based on their morphology and growth characteristics (Fig. 2.3). Fibroblasts have an elongated, spindle shape, whereas epithelial cells have a polygonal shape. Although after only a few passages only one cell type may remain in a cell strain, continued passage may select for faster-growing variants, such that the characteristics of a cell strain may change with increasing passage number. Despite the fact that normal cell strains experience senescence in culture, they may be maintained for many years by expanding the culture to a large number of cells early during the passage history and storing numerous small samples of low passage cells by freezing. Therefore, as a given strain approaches high passage number and senescence, low passage cells of the same strain may be thawed and cultured.

Cell lines

At any time during the culture of a cell strain, cells in the culture may become *transformed* such that they are no longer subject to crisis and senescence but can be passaged indefinitely. Transformation is a complex phenomenon, discussed in more detail later and in Chapter 11; however, in the context of cell culture, the most important characteristic of transformation is that the transformed cells become immortalized. Immortal cell cultures are called *cell lines*, or sometimes *continuous cell lines*, to distinguish them from primary cultures and cell strains. Immortalization can occur spontaneously during passage of a cell strain, or it can be induced by treatment with chemical mutagens, infection with tumorigenic viruses, or transfection with oncogenes. In addition, cells cultured from tumor tissue often establish immortal cell lines in culture. Spontaneous immortalization does not occur in cultured cells from all animal species. It has been observed frequently during culture of rodent cells (eg, in mouse and hamster cell strains), to a lesser extent in monkey kidney cells, and rarely, if at all, during the culture of chicken or human cells. Immortalization is typically accompanied by genetic changes such that cells become aneuploid, and the karyotype of each cell often differs across the culture.

As with the propagation of cell strains, continued culture of a cell line may result in selection of specific variants that outgrow other cells over time. With passage, the character of a cell line may change substantially, and cell lines of the same origin cultured in different laboratories over a period of years may have significantly different characteristics. It is prudent, therefore, to freeze stocks of cell lines having specific desirable properties so that these cells can be recovered if the properties disappear during culture. Likewise, it makes sense to obtain a cell line showing certain desired characteristics directly from the laboratory that described those characteristics, because cells from alternate sources may differ in character.

Transformation

Transformed cells are distinguished from normal cells by numerous properties that can be grouped into three fundamental types of changes: immortalization, aberrant growth control, and malignancy. *Immortalization* refers simply to the ability to be cultured indefinitely, as described previously. *Aberrant growth control* comprises a number of properties, several of which have relevance to experimental virology, including loss of contact inhibition, anchorage independence, and tumorigenicity. Loss of contact inhibition means that cells no longer cease to grow as soon as a monolayer is formed, and cells will now grow on top of one another. Anchorage independence means that the cells no longer need to attach to a solid surface to grow. Anchorage independence is often assayed as the ability to form colonies suspended in a semisolid medium such as agar, and a practical consequence of anchorage independence is the ability to grow in liquid suspension. Tumorigenicity refers to the ability of cells to form a tumor in an experimental animal, and *malignancy* refers to the ability to form an invasive tumor *in vivo*. While malignancy is obviously of vital importance as a phenomenon in its own right, it has limited application in virology except within the specific discipline of tumor virology (Chapter 11). Importantly, the many properties of transformed cells are not necessarily interdependent, and no one property is an absolute prerequisite for another. Thus, transformation is thought to be a multistep genetic phenomenon, and varying degrees of transformation are measurable. Tumorigenicity is often regarded as the most stringent assay for a fully transformed cell and is most closely correlated with

anchorage independence.

The fact that the various characteristics of transformed cells are not interdependent has important consequences for experimental virology, especially in the assay of tumor viruses. Specifically, a transformed cell line that is immortalized but still contact inhibited may be used in a viral transformation assay that measures the further transformation to loss of contact inhibition. When cells in a monolayer are transformed by a tumor virus and lose contact inhibition, they grow on top of a confluent monolayer, forming a *focus*, literally a pile of cells, which is readily distinguishable from the rest of the monolayer. This property forms the basis of a quantitative assay in which foci formed by tumor viruses can be stained and directly counted.[167]

Advantages and disadvantages of different cultured cell types

The various types of cultured cells described previously have specific application to different problems encountered in experimental virology. For most applications, an adherent cell line provides the most useful host cell. Cell lines are relatively easy to maintain because they can be passaged indefinitely, and adherence is a prerequisite for a plaque assay, described later. A distinct technical advantage of adherent cells is that the culture medium can easily be changed for the purposes of infection or metabolic labeling by simply aspirating and replacing fluid from a monolayer, a process that requires repeated centrifugations with suspension cells. By contrast, relative to adherent cell lines, suspension cell lines are easier to sample than adherent cells, and they produce large numbers of cells from a relatively small volume of medium in a single culture vessel, which has significant advantages for some high-volume applications in virology. Unfortunately, not all viruses will grow on a cell line, and often under these circumstances, a primary cell culture will suffice. This may reflect a requirement for a particular cell type found only under conditions of primary cell culture, or it may reflect a requirement for a state of metabolism or differentiation closely resembling the *in vivo* situation, which is more likely to exist in a primary culture than it is in a cell line.

Lastly, some viruses do not grow in standard cell culture at all. One example is the papillomaviruses, which cause warts. Although the viral nature of papillomatosis was demonstrated decades ago, progress studying these viruses was hampered because the viruses did not grow in culture. The inability to grow papillomavirus in culture results from a tight coupling of the regulation of viral gene expression with the differentiation state of the target epithelial cell, which in turn is tightly coupled to the three-dimensional architecture of the epidermis, which is lost in culture. Specialized tissue culture techniques have been developed that result in the faithful reconstruction of an epidermis by seeding primary keratinocytes on a “feeder” layer composed of an appropriate cell line and incubating these cells on a “raft” or grid at a liquid-air interface. On these raft cultures, the entire replication cycle of a papillomavirus can be reproduced *in vitro*, albeit with difficulty.[14] More recently, efficient infection of papillomavirus was achieved by prebinding viral particles to extracellular matrix components that were previously deposited by cells cultured in a plastic dish. After virus binding to the matrix, keratinocytes were overlayed and subsequently infected with higher efficiency than in previous models.[7] Notably, in the absence of these cultures, a large fraction of the genetics and biology of papillomaviruses was still able to be determined primarily through the use of recombinant DNA technology, without ever growing virus in culture.

A second and more contemporary example of a virus that has been difficult to culture in cells is human norovirus, a highly contagious foodborne virus that causes severe outbreaks of gastroenteritis worldwide. Human norovirus replicates in intestinal epithelial cells and certain immune cells, but standard culture of those various cell types does not support efficient norovirus replication. One study took advantage of human intestinal enteroid cultures (discussed below) derived from stem cells that are isolated from intestinal crypts from primary human tissue.[41,141] The enteroids supported replication of multiple strains of human norovirus, though certain strains required the presence of human bile for replication. Another group demonstrated that both human and murine norovirus could infect B cells, but that infection was uniquely dependent on the presence of enteric bacteria.[78] These two examples provide compelling support for the general concept that certain seemingly intractable viruses may simply require additional components to convert otherwise noninfectable cells into adequate cultures for viral entry and replication.

Organoids

Organoids are 3D cell cultures that reflect the architecture, genetics, and physiology of a specific organ or tissue type. Organoids can be derived from a variety of stem cells, including embryonic, pluripotent, or tissue-specific progenitors. Specific growth factors and environmental conditions allow the organoid cultures to take on organlike properties, including the ability to be infected by viruses. Indeed, organoids have been developed for multiple viruses and organs, with much of the work focusing on viruses that infect the intestinal tract, brain, or lungs. With respect to intestinal viruses, there are two primary 3D culture systems: organoids and enteroids. Intestinal organoids are stem cell–derived,[151] whereas enteroids are epithelial cell–only cultures derived from intestinal tissue biopsies.[142] These organoids and enteroids have allowed significant advances in the study of rotaviruses, adenoviruses, and enteric viruses from the *Picornaviridae* and *Caliciviridae* families. These advances include but are not limited to new methods for culturing previously intractable viruses, replication properties of clinical isolates, determination of cellular tropism, role of innate immune pathways during infection, and testing biologics and therapeutics for antiviral activity. Figure 2.4 depicts a human intestinal enteroid infected with coxsackievirus B3.

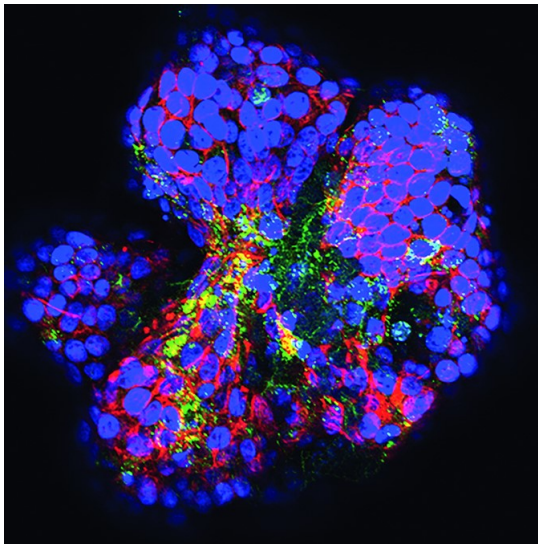

FIGURE 2.4 **Organoid culture.** Human intestinal enteroid organoid system[37] infected with coxsackievirus B3. Nuclei in *blue* (stained with DAPI), dsRNA in *green* (viral replication intermediates, stained with a dsRNA-specific antibody), actin in *red* (phalloidin). (Courtesy of Dr. Carolyn Coyne.)

The development of cerebral organoids predated the Zika virus outbreak of late 2015 by just a few years.[97] Given the link between Zika virus and microcephaly, cerebral organoids derived from embryonic or pluripotent stem cells rapidly became desirable systems for modeling the effects of Zika virus on the developing brain.[54,131] Indeed, these organoids were used to demonstrate both the preferential tropism of Zika virus for neural progenitor cells and the cytotoxic effects of the virus on these cells, thereby recapitulating pathological features observed in clinical microcephaly. Other neurotropic viruses have also been studied in cerebral organoids, including measles virus, La Crosse virus, and herpes simplex virus 1.

In 2017, lung organoids derived from pluripotent stem cells were shown to be viable models for both lung fibrotic disease and respiratory syncytial virus infection.[13] Similarly, lung stem cells were used to develop organoids that, when infected with influenza A virus, recapitulated various features of viral infection in human airway, including cellular tropism, viral replication kinetics, and induction of host innate responses.[73] The COVID-19 pandemic has further catapulted the rapid development and used of lung organoids for a variety of studies on SARS-CoV-2, including basic virological properties and testing of antivirals.[139,160]

Recognition of Viral Growth in Culture

Two classical methods for the recognition of a virus infection in culture are cytopathic effect and hemadsorption. *Cytopathic effect* comprises two different phenomena: (1) morphological changes induced in individual cells or groups of cells by virus infection that are easily recognizable under a light microscope and (2) inclusion bodies, which are more subtle alterations to the intracellular architecture of individual cells. *Hemadsorption* refers to indirect measurement of viral protein synthesis in infected cells, detected by adsorption of erythrocytes to the surface of infected cells. Cytopathic effect is the simplest and most widely used criterion for infection; however, not all viruses cause a cytopathic effect, and in these cases, other methods must suffice.

Morphological changes induced by virus infection comprise a number of cell phenomena, including rounding, shrinkage, increased refractility, fusion, aggregation, loss of adherence, or lysis. Morphological changes caused by a given virus may include several of these phenomena in various combinations, and the character of the cytopathic effect may change reproducibly during the course of infection. Morphological changes caused by a given virus are very reproducible and can be so precisely characteristic of the virus type that significant clues to the identity of a virus can be gleaned from the cytopathic effect alone (Chapter 16). Figure 2.5 depicts different cytopathic effects caused by viruses. Most important to the trained virologist, a simple microscopic examination of a cell culture can reveal whether an infection is present, what fraction of cells are infected, and how advanced the infection is. In addition, because cytopathology results directly from the action of virus gene products, virus mutants can be obtained that are altered in cytopathology, yielding either a conveniently marked virus or a tool to study cytopathology *per se*.

The term *inclusion bodies* refers generally to the observation of intracellular structures specific to an infected cell and discernible by light microscopy. The effects are highly specific for a particular virus type so that, as with morphological alterations, the presence of a specific type of inclusion body can be diagnostic of a specific virus infection. Electron microscopy, combined with a more detailed understanding of the biology of many viruses, reveals that inclusion bodies usually represent focal points of virus replication and assembly, which differ in appearance depending on the virus. For example, Negri bodies formed during a rabies virus infection represent collections of virus nucleocapsids.[110]

Hemadsorption refers to the ability of red blood cells to attach specifically to virus-infected cells.[146] Many viruses synthesize cell attachment proteins, which carry out their function wholly or in part by binding substituents such as sialic acid that are abundant on a wide variety of cell types, including erythrocytes. Often, these viral proteins are expressed on the surface of the infected cell—for example, in preparation for maturation of an enveloped virus through a budding process. Thus, a cluster of infected cells may be easily detectable to the naked eye as areas that stain red after exposure to an appropriate preparation of red blood cells. Hemadsorption can be a particularly useful assay for detecting infections by viruses that cause little or no cytopathic effect.

Virus Cultivation

The method chosen for growing virus depends on a variety of factors, including (1) the goals of the experiment, namely whether large amounts of one virus variant or small amounts of several variants are to be grown; (2) limitations in the *in vitro* host range of the virus, namely whether it will grow on embryonated eggs, primary cell cultures, continuous adherent cell lines, or suspension cell lines; and (3) the relative technical ease of alternative possible procedures. Furthermore, the precise method for harvesting a virus culture will depend on the biology of the virus—for example, whether it buds from the infected cell, lyses the infected cell, or leaves the cell intact and stays tightly cell associated. As a simple example, consider cultivation of a budding, cytopathic virus on an adherent cell line. Confluent monolayers of an appropriate cell line are exposed to virus diluted to infect a fraction of the cells, and progress of the infection is monitored by observing the development of the cytopathic effect until the infection is judged completely based on experience with the relationship between cytopathic effect and maximum virus yield. A crude preparation of virus can be harvested simply by collecting the culture fluid and freezing down aliquots that can be stored for years, if not indefinitely. In cases where large quantities of virus are needed, for example, for biophysical characterization or structural studies by x-ray crystallography or cryo-EM, virus-containing supernatants can be concentrated, typically by ultracentrifugation or antibody-based purification.

Quantitative Assay of Viruses

Two major types of quantitative assays for viruses exist: physical and biological. *Physical* assays, such as hemagglutination, electron microscopic particle counts, optical density measurements, or immunological methods, quantify only the presence of virus particles whether or not the particles are infectious. *Biological* assays, such as the plaque assay or various endpoint methods that have in common the assay of infectivity in cultured cells or *in vivo*, measure only the presence of infectivity and may not count all particles present in a preparation, even many that are in fact infectious. Thus, a clear understanding of the nature and efficiency of both physical and biological quantitative virus assays is required to make effective use of the data obtained from any assay.

Biological Assays

The plaque assay

The plaque assay is the most elegant, the most quantitative, and the most useful biological assay for viruses. Developed originally for the study of bacteriophage by d'Herelle[26] in the early 1900s, the plaque assay was adapted to animal viruses by Dulbecco and Vogt[39] in 1953, an advance that revolutionized animal virology by introducing a methodology that was relatively simple and precisely quantitative, which enabled the cloning of individual genetic variants of a virus and which permitted a qualitative assay for individual virus variants that differ in growth properties or cytopathology.

The plaque assay is based simply on the ability of a single infectious virus particle to give rise to a macroscopic area of cytopathology on an otherwise normal monolayer of cultured cells. Specifically, if a single cell in a monolayer is infected with a single virus particle, new virus resulting from the initial infection can infect surrounding cells, which in turn produce virus that infects additional surrounding cells. Over a period of days (the exact length of time depending on the particular virus), the initial infection thus gives rise through multiple rounds of infection to an area of infection, called a *plaque*. Photomicrographs of plaque foci are shown in Figure 2.6, and stained monolayers containing plaques are shown in Figure 2.7.

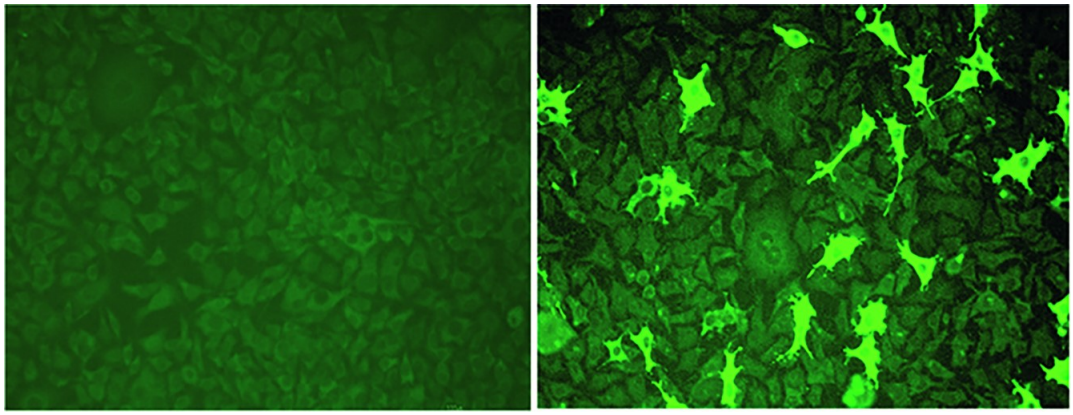

FIGURE 2.6 **Focus of infected cells in a plaque assay.** Mouse L929 cells were infected with serial dilutions of reovirus, and at 30 hours postinfection, cells were fixed and stained with a reovirus-specific antibody and a fluorescently labeled secondary antibody. The number of distinct, clustered stained cells—foci—were counted to quantify viral titer. **Left**, uninfected cells. **Right**, infected cells, zooming in on one focus. (Courtesy of Dr. Andrea Erickson.)

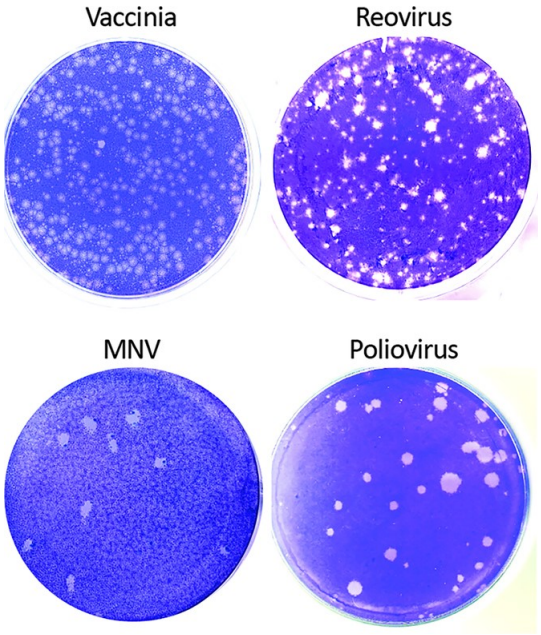

FIGURE 2.7 **Plaque assay.** Monolayers of various cells types were infected with dilutions of the viruses indicated below, and solid or semisolid overlays were added to inhibit diffusion of progeny viruses. After several cycles of replication over several days, overlays were removed, and monolayers were stained with crystal violet dye to visualize plaques. From *left* to *right*, vaccinia virus in BSC40 cells, reovirus in L929 cells, murine norovirus in BV2 cells, and poliovirus in HeLa cells. (Plaque assays images are courtesy of Dr. Don Gammon [vaccinia], Dr. Andrea Erickson [reovirus], Valerie Rodriguez Irizarry [MNV], and Dr. Kristie Ibarra [poliovirus].)

The plaque assay can be used to quantify virus in the following manner. A sample of virus of unknown concentration is serially diluted in an appropriate medium, and measured aliquots of each dilution are seeded onto confluent monolayers of cultured cells. Infected cells are overlayed with a nutrient medium containing an additive to thicken the liquid state into a semisolid, typically agar, agarose, methylcellulose, and more recently the microcrystalline cellulose Avicel. These agents help prevent formation of secondary plaques through diffusion of virus from the original site of infection to new sites, ensuring that each plaque that develops in the assay originated from a single infectious particle in the starting inoculum. After an appropriate period of incubation to allow development of plaques, the monolayer is stained so that the plaques can be visualized. The precise staining technique depends on the cytopathology; however, vital dyes such as neutral red are common. Neutral red is taken up by living cells but not by dead cells; thus, plaques become visible as clear areas on a red monolayer of cells. In cases where the virus

cytopathology results in cell lysis or detachment of cells from the dish, plaques exist literally as holes in the monolayer, and a permanent record of the assay can be made by staining the monolayer with a general stain such as crystal violet. Dishes containing an appropriate number of plaques are counted, and the concentration of infectious virus in the original sample can then be calculated taking into account the serial dilution. The resulting value is called a *titer* and is expressed in plaque-forming units per milliliter (PFU/mL) to emphasize specifically that only viruses capable of forming plaques have been quantified.

A critical benefit of the plaque assay is that it measures infectivity, although it is important to understand that infectivity does not necessarily correspond exactly to the number of virus particles in a preparation. In fact, for most animal viruses, only a fraction of the particles—as few as 1 in 10 to 1 in 10 000—may be infections as judged by comparison of a direct particle count, described later, with a plaque assay. This low *efficiency of plating*, or high particle to infectivity ratio, may have several causes. First, to determine a particle to infectivity ratio, virus must be purified to determine the concentration of physical particles and then subjected to plaque assay. If the purification itself damages particles, the particle to infectivity ratio will be increased. Second, some viruses produce empty particles, or particles that are for other reasons defective during infection, resulting in a high particle to infectivity ratio. Lastly, it is possible that not all infectious particles will form plaques in a given plaque assay. For example, infectious virus may require that cells exist in a specific metabolic state or in a specific stage of the cell cycle; thus, if not all cells in a culture are identical in this regard, only a fraction of the potentially infectious virions may be able to successfully launch an infection and form a plaque.

In addition to its utility as a quantitative assay, the plaque assay also provides a way to detect genetic variants of a virus that possess altered growth properties, and it provides a very convenient method to clone genetically unique variants of a virus. Genetic variants are considered in detail in the Virus Genetics section; in brief, they may comprise viruses that plaque only under certain conditions of temperature or drug treatment, or form plaques of altered size or shape. Because each plaque results from infection with a single infectious virus particle, unique genetic variants of a virus can be cloned simply by picking plaques—that is, literally excising a small plug of semisolid medium and infected cells from a plaque using a Pasteur pipette.

The endpoint method

Viruses that cannot be adapted to either a plaque or a focus assay but nevertheless cause some detectable pathology in cultured cells, embryonated eggs, or animals can be quantified using an endpoint method. Briefly, virus is serially diluted, and multiple replicate samples of each dilution are inoculated into an appropriate assay system. After a suitable incubation period, an absolute judgment is made as to whether or not an infection has taken place. Statistical methods have been devised to calculate the dilution of virus that results in infection in 50% of replicate inoculations, and titers are expressed as the infectious dose 50 (ID_{50}). Assay systems are various and include, for example, observation of cytopathic effect in cultured cells, yielding tissue culture infective dose 50 ($TCID_{50}$); cytopathology or embryonic death in inoculated embryonated chicken eggs, yielding egg infective dose 50 (EID_{50}); or death of an experimental laboratory animal, yielding lethal dose 50 (LD_{50}). As with the plaque assay and the focus assay, the endpoint method has the advantage of measuring infectivity; however, importantly, the unit of infectivity measured by the endpoint method may require more than one infectious particle.

Physical Assays

Direct particle count

The concentration of virus particles in a sample of purified virus can be counted directly using an electron microscope.[102,171] Briefly, a purified preparation of virus is mixed with a known concentration of microscopic marker particles such as latex beads, which can be easily distinguished from virus particles in the electron microscope. Samples of the solution containing virus and beads are then applied to an electron microscope grid and visualized following shadowing or staining. The volume of liquid applied to a given area of the grid can be determined by counting the beads. A solution of virus with a known concentration determined by microscopic particle count, the same solution can be subjected to any number of chemical or spectrophotometric analyses to yield a conversion from protein, nucleic acid, or simply absorbance at a fixed wavelength to a concentration of virus in particles per unit volume. Thus, once a microscopic particle count has been performed, future quantitative assays of purified virus are greatly simplified. Importantly, the direct particle count does not distinguish infectious from noninfectious particles.

Hemagglutination

Many viruses express cell attachment proteins that bind sialic acid, which is abundant on a wide variety of cell types, including erythrocytes. Virions can directly bind erythrocytes, causing them to agglutinate, or form a network of cells and virus, when mixed with virus particles in sufficiently high concentration. Agglutinated erythrocytes can be easily distinguished from cells that are not agglutinated, and thus, hemagglutination can be used as a simple quantitative assay for the presence of a hemagglutinating virus.

In practice, a hemagglutination assay is carried out as follows. Virus is serially diluted, mixed with a fixed concentration of erythrocytes, and the mixture is allowed to settle in a specially designed hemagglutination tray, containing wells with rounded bottoms. Erythrocytes that are not agglutinated are free to roll to the bottom of the well, forming a dense, easily recognizable button or cluster of cells. Erythrocytes that are agglutinated are not free to roll to the bottom of the well but instead evenly coat the bottom surface of the well to form what is called a *shield*. One hemagglutination unit is defined as the minimum amount of virus required to cause agglutination, and the titer of the virus solution, expressed as hemagglutination units per milliliter (HA units/mL), can be calculated taking into account the serial dilution. It is noteworthy that, such as with the direct particle count assay, the hemagglutination assay does not distinguish infectious from noninfectious particles. In addition, because it may require many particles to cause a detectable hemagglutination, one HA unit may represent many physical particles.

Quantitative Considerations in Virus Assay, Cultivation, and Experimentation

Dose-Response in Plaque and Focus Assays

Generally, the number of infectious units observed on a given plate in a plaque assay is a linear function of the dilution of the virus; thus, the development of plaques follows single-hit kinetics, proving that each plaque results from infection with a single virus particle. However, there are exceptions to the “one hit” rule. Viral coinfection can facilitate infection due to genetic processes such as complementation and

recombination, as described in more detail below. Thus, there are cases where a plaque contains two or more parental viruses.[2] Additionally, some viruses require infection with multiple particles to initiate functional infection, including multipartite viruses that package genome segments into separate virions.[94,147] Similarly, murine sarcoma viruses require coinfection with both a defective transforming virus and a nondefective helper virus, in which case the number of foci observed relative to the dilution used follows two-hit kinetics.[60]

Comparison of Quantitative Assays

As noted in the previous individual descriptions, the various quantitative assays of viruses measure different physical and biological properties, and a one-to-one correlation between assays cannot be assumed. Using influenza virus as measured by several different assays provides an example of the magnitude of differences that might be expected in the various assays: Direct particle counting by electron microscopy yields 10^{10} particles/mL, infectivity assay in eggs yields 10^9 egg infectious dose 50 (ID_{50})/mL, infectivity assay by plaque formation yields 10^8 PFU/mL, and hemagglutination assay yields 10^3 hemagglutination units/mL. Hence, relative to a direct particle count, the efficiency of virus detection for this influenza example is 10^{-1} as assayed in eggs, 10^{-2} as assayed in a plaque assay, and 10^{-7} as assayed in a hemagglutination assay. As indicated in the foregoing discussion, some differences result from different properties being measured (eg, physical particles vs infectivity), and some differences result from differences in the sensitivity of the assay (eg, direct particle count vs assay of particles by hemagglutination).

Multiplicity of Infection

Multiplicity of infection, often abbreviated "MOI," measures the average amount of virus added per cell in an infection. Multiplicity of infection can be expressed using any quantitative measure of virus titer—for example, particles/cell, HA units/cell, $TCID_{50}$/cell, or PFU/cell. Because the efficiency of plating varies depending on the method of quantitation used, some knowledge of the infectivity of the sample or the efficiency of plating is required to correctly anticipate the consequences of the use of a particular MOI. The multiplicity of infection used in different protocols can have a profound outcome on the procedure. For example, some viruses, if serially passaged at an MOI of >1 infectious unit/cell, will accumulate spontaneously deleted defective particles that are maintained during passage by the presence of complementing wild-type helper virus.[168] Passage of the same virus at very low MOI (eg, 0.01 infectious units/cell) discourages the accumulation of defective particles because few cells will be coinfected with an infectious and a defective particle, and defective particles cannot replicate in the absence of a wild-type helper. Conversely, other experiments, such as metabolic labeling, assessing the host response to infection, or quantifying the activity of a virally encoded enzyme, are done at high MOI (eg, 10 infectious units/cell) to ensure that all cells in the culture are infected and that the infection is as synchronous as possible. For such experiments, use of too low an MOI may result in an apparently asynchronous infection and a high background owing to the presence of uninfected cells in the culture.

The Poisson distribution can be used to predict the fraction of cells in a population infected with a given number of particles at different multiplicities of infection. As applied to virus infections, the Poisson distribution can be written as:

$$P(k) = e^{-m} m^k / k!$$

where P(k) equals the probability that any cell is infected with k particles, m equals MOI, and k equals the number of particles in a given cell. Sample solutions to the equation are shown in Table 2.2 for commonly used multiplicities of infection.[184] Inspection of this table and consideration of the error inherent in any virus titration involving a serial dilution leads to some significant practical guides in experimental design. Note first that in a culture infected at an MOI of 1 PFU/cell, 37% of cells remain uninfected—an unacceptably high number for an experiment designed to measure a single round of synchronous infection. An MOI of at least 3 is required to infect 95% of the cells in culture. A shortcut is to calculate the fraction uninfected cells by setting k = 0, which reduces the equation to e^{-m}, from which the fraction of cells that are uninfected can be easily calculated. Given that titers can easily be inaccurate by a factor of two, the use of a calculated MOI of 10 ensures that 99% of the cells in a culture will be synchronously infected even if the measured titer is twofold higher than the actual titer.

TABLE 2.2 The Poisson distribution for multiplicity of infection (MOI)

	MOI			
# per cell	1	3	5	10
0	0.37	0.05	0.01	0.00
1	0.37	0.15	0.03	0.00
2	0.18	0.22	0.08	0.00
3	0.06	0.22	0.14	0.01
4	0.02	0.17	0.18	0.02
5	0.00	0.10	0.18	0.04
6	0.00	0.05	0.15	0.06
7	0.00	0.02	0.10	0.09
8	0.00	0.00	0.07	0.11
9	0.00	0.00	0.04	0.13
10	0.00	0.00	0.02	0.13

One-Step Growth Experiment

The one-step growth experiment is a classic assay developed initially for bacteriophage[40] and still frequently used to determine the essential growth properties of a virus. The goal of this experiment is to measure the time course of virus replication and the yield of virus per cell during a single round of infection. The experiment is carried out as follows. Several dishes containing confluent monolayers of an appropriate cultured cell are infected simultaneously with virus at a high MOI (eg, 10 PFU/cell). After an adsorption period, monolayers are washed to remove unabsorbed virus and then incubated in culture medium. At various times after infection, virus from individual dishes is harvested, and at the completion of the experiment, the virus titer in samples representing each time point is determined. The virus yield at each point can be converted to PFU/cell (also called *burst size*) by dividing the total amount of virus present in the sample by the number of cells originally infected in the sample. Two examples of one-step growth experiments with coxsackievirus B3 or Rio Bravo virus are shown in Figure 2.8. Several features of the growth curve are noteworthy. First, during the first several hours of the infection, the titer in the cultures decreases and then increases. This initial dip in the growth curve is called *eclipse* and results from the fact that early during the experiment, virus attached to the cell surface but not uncoated remains infectious; however, infectivity is lost following uncoating during the first few hours of infection, and infectivity is recovered only after new virus is produced. The infection then enters a rapid growth phase, followed by a plateau. The plateau results from the fact that all infected cells have reached the maximum yield of virus, or have died or lysed, depending on the type of virus infection. The time interval from infection to plateau represents the time required for a single cycle of growth, and the yield of virus at plateau shows the amount of virus produced per cell. The experiment in Figure 2.8 suggests that coxsackievirus B3 has a relatively fast replication cycle, with progeny viruses detectable at between 5 and 7 hours postinfection. Conversely, Rio Bravo virus is not detected until 16 hours. One-step growth experiments to determine the length of a single replication cycle are ideally performed in the target cell of interest, as replication dynamics can differ between cell types, particularly depending on whether cell intrinsic antiviral pathways are intact.

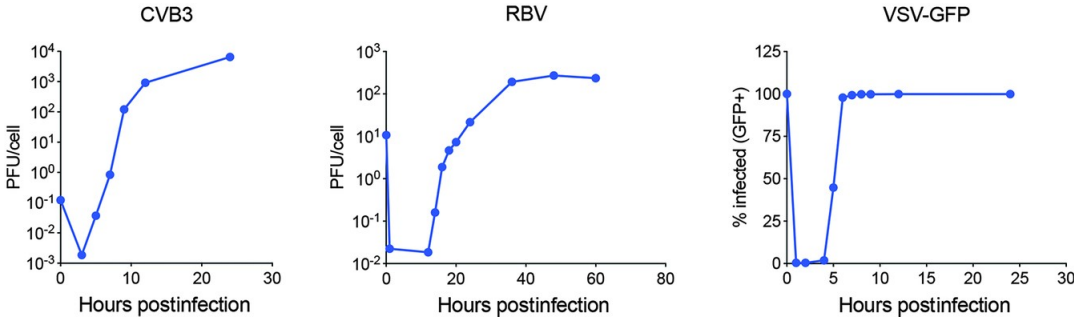

FIGURE 2.8 **One-step viral growth experiments. Left**. Caco-2 cells were infected with coxsackievirus B3 at an MOI of 0.1, and progeny viruses were collected at a variety of time points followed by plating dilutions for plaque assays on HeLa cells. Data are presented as plaque forming units (PFU) per cell. (Courtesy of Dr. Yao Wang.) **Middle**. Similar to above, Huh7.5 cells were infected with Rio Bravo virus at an MOI of 5, and progeny viruses were titered on BHK cells. (Courtesy of Dr. Ian Boys.) **Right**. Human *STAT1*$^{-/-}$ fibroblasts were infected with VSV-GFP at an MOI of 5, and serially collected supernatants containing progeny viruses were used undiluted to re-infect naive cells. Intact cells were harvested, fixed with paraformaldehyde, and the percentage of infected (GFP+) cells was quantified by flow cytometry.

Multiplicity of infection is a critical factor in the design of a virus growth experiment. A true one-step growth experiment can only be done at high MOI. If the MOI is too low and a large fraction of cells are left uninfected, then virus produced during the first round of infection will replicate on previously uninfected cells, and thus multiple rounds of infection rather than one round will be measured. A growth experiment done at low MOI has utility in that it measures both growth and spread of a virus in culture; however, the time from infection to plateau does not accurately reflect the time required for a single cycle of infection. It is also noteworthy that some mutant phenotypes are multiplicity dependent.[11]

Modern Viral Assays and Approaches

As with all fields of science, virology has modernized significantly over the past couple of decades. Whereas classical virology has often focused on the virus side of "virus-host interactions," modern approaches are increasingly considering the host side, including a detailed examination of host factors required for viral replication, as well as host responses to viral infection, in particular the immune response. This chapter primarily emphasizes approaches to study virology that are more consistent with classical themes in the field, for example, understanding viral gene function, viral replication kinetics, and virus evolution. However, we also briefly discuss modern approaches that are being used to complement classical virology on the virus side and to augment our understanding of virus-host interactions from the perspective of the host.

Viruses Expressing Foreign Reporter Genes

Genetic approaches have allowed many viruses to be modified to express a variety of reporter genes from the viral genome. Historically, these recombinant viruses expressed foreign genes such as chloramphenicol acetyltransferase or β-galactosidase, which could be monitored by enzyme assay and used as surrogates for viral gene expression. These strategies have largely been supplanted by fluorescent or bioluminescent reporters such as green fluorescent protein (GFP) and firefly luciferase, respectively.

Reporter viruses have distinct advantages and limitations relative to their nonreporter parental viruses. Viruses expressing fluorescent reporters such as GFP can be used in cell culture to quantify viral infectivity, that is, the percentage of cells that become infected. Infectivity is typically quantified by flow cytometry or fluorescence microscopy and can then be used to calculate viral titers based on Poisson distribution. Titers can be expressed as "fluorescent cell units," which is analogous to the plaque-forming units derived from plaque assays. However, the timing of viral replication needs to be considered and restricted to the first replication cycle, as viral spread will lead to more GFP-positive cells and an inaccurate assessment of true infectivity. Infectivity, as reflected by GFP positivity, can be used in many other applications. For example, a one-step growth experiment can be performed as described above, with the difference being that progeny viruses are detected by re-infecting naive cells and assessing infectivity by flow cytometry. An example is shown in Figure 2.8 with VSV-GFP. These data indicate that a single replication

cycle is between 5 and 6 hours. In this experiment, supernatants containing progeny viruses were not diluted as is standard in a plaque assay. Thus, this type of one-step growth curve can only determine the timing of a replication cycle, but it does not give information on how many infectious units of virus are produced per cell. This latter metric could be obtained if supernatants were serially diluted, and the data were back-calculated based on the Poisson distribution.

Infectivity can simultaneously be complemented with quantitation of GFP mean fluorescence intensity (MFI). Depending on the virus, GFP MFI can provide distinct information about the viral infection process. For example, many GFP-expressing RNA viruses express the reporter from the viral genome similar to other viral proteins. Thus, GFP serves as a surrogate for viral protein synthesis, and the effect of any perturbation (eg, drug treatment, genetic modification, etc.) can be quantified by GFP MFI. This also holds for viruses expressing luciferase; indeed, many drug screening efforts now rely on viral genomes expressing luciferase for high-throughput assays (discussed below). For DNA viruses with highly defined temporal gene expression patterns, such as herpesviruses or adenoviruses, GFP can inserted into specific regions of the genome and used as a surrogate to monitor the temporal dynamics of viral gene expression. In other genetic strategies, GFP can be fused to a viral protein, and provided that the fusion does not disrupt viral protein function, the expression, subcellular localization, and dynamics of the viral protein can be monitored with a variety of microscopic techniques. Both fluorescent and bioluminescent reporters can additionally be used to monitor viral dynamics *in vivo*. For example, a virus expressing firefly luciferase can be administered to a mouse, and after a defined amount of time, the animal can be injected with luciferin substrate and imaged to assess which organs and tissues are productively infected (Fig. 2.9).

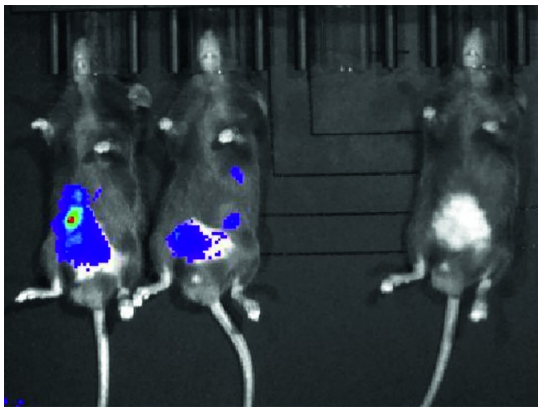

FIGURE 2.9 ***In vivo* bioluminescence imaging**. Mice were mock-infected (*right*) or infected with 10^6 PFU with gammaherpesvirus MHV68 expressing firefly luciferase under control of the M3 promoter (*left*). To quantitate luciferase activity, mice were injected intraperitoneally with luciferin and imaged within 20 minutes of injection. (Courtesy of Dr. Tiffany A. Reese.)

Reporter viruses have important limitations. Some viruses may not tolerate large foreign gene inserts due to packaging limits, negative effects on replication, or disruption of important secondary structural features in the viral genome. If the reporter gene is successfully inserted, the reporter virus is frequently attenuated relative to the parent virus. Additionally, the reporter gene may not remain stable over time. This is particularly true with +ssRNA viruses expressing foreign genes. After serially passaging, and in some cases after even a single passage, the foreign insert is lost, likely due to a recombination event that reverts the virus to "wild type." Thus, generating stocks from passaged virus is usually a suboptimal approach. Summarily, while reporter viruses are powerful tools, they have several limitations, which must be considered during experimental design.

High-Throughput Approaches to Examine Virus-Host Interactions

The field of virology has been highly amenable to advances in high-throughput approaches. Key aspects of high-throughput approaches include the ability to assay hundreds, thousands, or even tens of thousands of samples in a relatively short time frame. This is accomplished by sophisticated instrumentation such as luminometers, flow cytometers, or high-content microscopes, each of which can handle multiwell plates (eg, 96-, 384-, or 1536-well plates). Early examples of high-throughput approaches in virology include screening of a 100 000-compound library for inhibitors of SARS-CoV using cell viability as the readout.[145] Many high-throughput approaches are limited, because they can only provide readouts at a single time point. For example, a drug screen that quantifies protection from virus-induced cell killing will typically be performed at a single time point that has been predetermined using known controls. Similarly, a high-throughput screen for antibodies that inhibit infection by a GFP-expressing virus will usually use a single infection time point for the final readout. However, newer live cell imaging and analysis platforms (eg, Incucyte) allow for real-time quantitative live cell imaging, thus providing finely resolved temporal resolution of viral replication and/or virus-induced changes to the host cell.

Rapid technological advances and decreasing costs of nucleic acid synthesis have revolutionized high-throughput genetic screens across all areas of biology, including virology. After the discovery of RNA interference in *Caenorhabditis elegans*, gene silencing technology based on small interfering RNA (siRNA) quickly became the method of choice for silencing genes in mammalian cells. Targeted and genome-scale siRNA libraries were developed and screened in cell-based assays to identify host factors that were required for viral replication. The first genome-scale screens were performed with HIV-1,[9,92,183] with many other viruses to follow. These screens provided a wealth of new information about the specific host proteins required for infection and, in some cases, host factors that contributed to cell intrinsic control of viral replication. However, screening hits from lab to lab did not have extensive overlap,[10] raising concerns about the utility of this method. Similar to RNAi/siRNA technology, the CRISPR antiviral pathway in prokaryotes has also been co-opted to modulate gene expression in eukaryotic cells. CRISPR-based strategies can be used to (1) knock genes out by targeting DNA at the gene of interest, (2) reduce gene expression by targeting mRNA, or (3) induce gene expression by promoting gene-specific transcription. To date, the field of virology has gained the most traction with genome-scale CRISPR knockout libraries, which have been used to identify with high confidence and reproducibility host factors required for multiple viruses, including flaviviruses,[104] HIV-1,[122] influenza A virus,[59] and alphaviruses.[182] Conversely, several genome-scale CRISPR-based screens have also been used to identify inhibitory host factors targeting viruses such as influenza A virus, yellow fever virus, and murine norovirus.[66,120,135] Given the low cost and relative ease of performing CRISPR screens, this technology is certain to continue revealing host genes with prominent roles during virus-host interactions.

Virus Genetics

Viruses are subject to the same genetic principles at work in other living systems, namely mutation, selection, complementation, and recombination. Genetics impacts all aspects of virology, including the natural evolution of viruses, clinical management of infections, and experimental virology. For example, antigenic variation, which is a direct result of mutation and selection, plays a prominent role in the epidemiology of influenza virus and HIV in the human population, and mutation to drug resistance offers a significant challenge to the clinical management of virus infections with antiviral drugs. This section deals primarily with the application of experimental genetic techniques to basic virology.

A major goal of experimental virology is to understand the functional organization of a viral genome. This means determination of the structure of a virus genome at the nucleotide sequence level, coupled with isolation and characterization of mutant viruses. Thus, genetic analysis of viruses is of fundamental importance to experimental virology.

Before the advent of modern nucleic acid technology—that is, during a *classical* period of *forward* genetics—genetic analysis of viruses consisted of the random, brute force isolation of large numbers of individual virus mutants, followed first by complementation analysis to determine groupings of individual mutants into genes, then recombination analysis to determine the physical order of genes on the virus genome, and finally the phenotypic analysis of mutants to determine gene function. This approach, pioneered in the 1940s through the 1960s in elegant studies of several bacteriophage, was the primary method for identifying, mapping, and characterizing virus genes. The application of cell culture techniques to animal virology opened the door to classical genetic analysis of animal viruses, resulting in a flurry of activity in the 1950s through the 1970s, during which time hundreds of mutants were isolated and analyzed in prototypical members of most of the major animal virus families.[51] Nucleic acid technology introduced in the 1970s brought with it a variety of techniques for physical mapping of genomes and mutants, including restriction enzyme mapping, marker rescue, and DNA sequence analysis, which together replaced recombination analysis as an analytic tool. Mutants and techniques from the classical period continue to be of enormous utility today; however, recombinant DNA technology has brought with it *reverse* genetics, in which the structure of the genome is determined first using entirely physical methods, then the function of individual genetic elements is determined by analyzing mutants constructed in a highly targeted fashion. Furthermore, modern low-cost sequencing technology now means that thousands of complete viral genomes can be generated daily. However, additional studies are still required to understand genome structure-function.

The genetic approach to experimental virology has the profound advantage of asking of the organism under study only the most basic question—What genes are needed to survive and why?—without imposing any further bias or assumptions on the system. Organisms often respond with surprises that the most ingenious biochemist or molecular biologist would never have imagined. What follows is a summary of the critical elements of both the classical and modern approaches to virus genetics as applied to experimental virology.

Fundamental Genetic Concepts

Concepts fundamental to genetic analysis of other organisms apply to genetic analysis of viruses, and a clear understanding of these concepts is essential. The most important of these concepts are briefly summarized next.

Wild Type, Mutations, and Mutants

Wild type refers to a genotype or phenotype that predominates in nature. It is important to understand that in the context of experimental virus genetics, a virus designated as wild type can differ significantly from the virus that actually occurs in nature. For example, virus genetics often relies heavily on growth and assay of viruses in cell culture, and natural isolates of viruses may undergo significant genetic change during adaptation to cell culture. In addition, viruses to be designated as wild type should be plaque purified before initiating a genetic study to ensure a unique genetic background for mutational analysis. *Mutation* refers to a sequence alteration in the nucleic acid genome of a virus, whereas viruses containing mutation(s) in their genomes are referred to as *mutants*.

Genotype and Phenotype

Genotype refers to the actual genetic change from wild type in a particular virus mutant, whereas *phenotype* refers to the measurable manifestation of that change. This distinction is emphasized by the fact that a single genotype may express different phenotypes depending on the assay. Thus, for example, the same missense mutation in a virus gene may cause temperature sensitivity in one cell line but not another, or a deletion in another virus gene may have no effect on the replication of virus in culture but may alter virulence in an animal model.

Selection and Screen

Selection and screen refer to two fundamentally different methods of identifying individual virus variants contained in a mixed population of viruses. *Selection* implies that a condition exists where only the desired virus will grow, and growth of unwanted viruses is suppressed. Thus, a drug-resistant virus can be identified by plating a mixture of wild-type, drug-sensitive, and mutant, drug-resistant viruses together on the same cell monolayer in the presence of the inhibitory drug, thereby selecting for drug-resistant viruses that grow and against wild-type viruses that do not grow. A *screen* implies that both the desired virus variant and one or several other unwanted virus types grow under a given condition, such that many viruses must be analyzed individually to identify the desired variant. For example, in searching for a temperature-sensitive mutant (ie, a virus whose growth is inhibited relative to wild-type virus at an elevated temperature), no condition exists under which the mutant alone will grow. Therefore, virus must be plated at a low temperature where both wild-type and mutant virus will grow, and plaques tested individually for temperature sensitivity. Sometimes a screen can be streamlined by introducing a phenotypic marker into the variant of choice. For example, a knockout virus might be constructed by inserting reporter genes such as β-galactosidase or GFP into the virus gene to be inactivated. Thus, viruses containing the insertional knockout can be distinguished from unmodified viruses.[180] This latter example is still a screen, because both wild-type and mutant viruses grow under the conditions used; however, the screen is simplified because mutant viruses can be readily identified by their color, obviating the need to pick and test individual plaques. Selections have considerable advantages over screens but are not always possible.

Essential and Nonessential

The terms *essential* and *nonessential* describe phenotypes, specifically whether a given gene is required for growth under a specific condition. Most viruses are finely tuned through selection to fit a specific niche. In some cases, not all viral genes are absolutely required for virus replication in that niche, particularly for viruses with large genomes. Furthermore, if the niche is changed—such as from a natural animal host to a cell line in a laboratory—some genes that may have been essential for productive infection in the animal may not be required for replication in cell culture. Genes that are required for growth under a specific condition are termed *essential*, and those that are not required are termed *nonessential*. Because as a phenotype essentiality may be a function of the specific test conditions, the test conditions need to be specified in describing the mutation. As an example, the herpesvirus thymidine kinase gene is nonessential for virus replication in cell culture. Genes that are either essential or nonessential under a given condition present unique characteristics for analysis. Thus, mutants in nonessential genes may be easy to isolate because the gene can be deleted, although the function of the gene may be difficult to determine because, by definition, nonessential genes have no phenotype. Conversely, genes that are essential can be used to study gene function by characterizing the precise replication defect caused by a mutation in the gene; however, acquiring the appropriate mutant is confounded by the necessity for identifying a condition that will permit growth of the virus for study. Generally, viruses with small genomes have few if any nonessential genes. For example, poliovirus encodes just 11 proteins, and all are essential for complete viral replication in cultured cells.

Loss of Function and Gain of Function

Mutations that alter the function of a gene can be subclassified into two categories, loss of function or gain of function. Both loss-of-function and gain-of-function mutations are useful tools in virology. For *loss-of-function* mutations, the gene product lacks a molecular function of the wild-type gene. The inactivation of the viral gene product may be partial or complete. Examples of loss-of-function mutations include lack of vaccinia virus replication in human cells from K1L gene deletion,[124] and lack of herpes simplex virus latency reactivation from viral thymidine kinase gene deletion.[16] Conversely, for *gain-of-function* mutations, the gene product's effect gets stronger or may even acquire different or abnormal functions. Examples of gain-of-function mutations include point mutations in influenza virus HA protein that increase transmission[67,74] and a coxsackievirus capsid mutation that increases viral replication speed in cultured cells.[96] Notably, there are often fitness "tradeoffs" for gain-of-function mutants, where fitness gain in one environment confers fitness loss in a different environment.[35]

Study of Mutations and Mutants

Spontaneous Mutation

Spontaneous mutation rates in viruses are measured by fluctuation analysis,[77] a technique pioneered by Luria and Delbruck[101] for analysis of mutation in bacteria, and later adapted to viruses by Luria.[99] Fluctuation analysis consists of measuring the proportion of spontaneous mutants with a particular phenotype in many replicate cultures of virus and applying the Poisson distribution to these data to calculate a mutation rate.

Both DNA and RNA viruses undergo spontaneous mutation; however, the spontaneous mutation rate in RNA viruses is usually much higher than in DNA viruses. In general, the mutation rate at a specific site in different DNA viruses ranges from 10^{-8} to 10^{-11} per replication, whereas in RNA viruses, it is at least hundred-fold higher, between 10^{-3} and 10^{-6} per replication. The difference in mutation rate observed between RNA and DNA viruses is primarily from differences in the replication enzymes. Specifically, the DNA-dependent DNA polymerases used by DNA viruses contain a proofreading function, whereas the reverse transcriptases used by retroviruses and RNA-dependent RNA polymerases used by RNA viruses lack a proofreading function. The difference in spontaneous mutation rate has profound consequences for both the biology of the viruses and for laboratory genetic analysis of viruses. Specifically, RNA viruses exist in nature as *quasispecies*[34]—that is, populations of virus variants in relative equilibrium with the environment but capable of swift adaptation owing to a high spontaneous mutation rate. Conversely, DNA viruses are genetically more stable but less adaptable. In the laboratory, the high mutation rate in RNA viruses presents difficulties in routine genetic analysis because mutants easily revert to wild-type virus that can outgrow the mutant virus.

It is noteworthy that whereas the actual mutation rate at a single locus is probably relatively constant for a given virus, the *apparent* mutation rate to a given phenotype depends on the nature of the mutation(s), which can give rise to that phenotype. For example, spontaneous mutation to bromodeoxyuridine (BrdU) resistance in vaccinia virus may occur at least 10-100 times more frequently than spontaneous reversions of temperature-sensitive mutations to a wild-type, temperature-insensitive phenotype. In the case of BrdU resistance, any mutation that inactivates the thymidine kinase causes resistance to BrdU, and thus, there are literally hundreds of different ways in which spontaneous mutation can give rise to BrdU resistance. By contrast, a temperature-sensitive mutation is usually a single-base missense mutation, in which may exist only one possible mutational event that could cause reversion to the wild-type phenotype; thus, the apparent spontaneous mutation rate for the revertant phenotype is lower than the apparent spontaneous mutation rate to the BrdU-resistant phenotype. From a practical perspective, the apparent spontaneous mutation rate for specific selectable phenotypes may be sufficiently high such that induction of mutants is unnecessary for their isolation. However, for mutants where the desired mutational events are rare and a screen must be used rather than a selection (eg, temperature-sensitive mutants), induced mutation may be required for efficient isolation of mutants. Induced mutation is particularly useful for viruses with low error rates, such as many DNA viruses.

Induced Mutation

While many RNA viruses have mutation frequencies high enough for relatively straightforward isolation of viral mutants, the incidence of spontaneous mutations in many DNA viruses is low enough that induction of mutation is a practical prerequisite. It is usually desirable to induce limited single-base changes, and for this purpose, chemical mutagens are most appropriate. Commonly used chemical mutagens are of two types: *in vitro* mutagens and *in vivo* mutagens.[36] *In vitro mutagens* work by chemically altering nucleic acid and can be applied by treating virions in the absence of replication. Examples of *in vitro* mutagens include hydroxylamine, nitrous acid, and alkylating agents, which through chemical modification of specific bases cause mispairing leading to missense mutations. *In vivo* chemical mutagens comprise compounds such as nucleoside analogs that must be incorporated during viral replication and thus must be applied to an infected cell. One of the most effective mutagens is the alkylating agent nitrosoguanidine, which although is capable of alkylating nucleic acid *in vitro* is most effective when used *in vivo*, where it works by alkylating guanine residues at the replication fork, ultimately causing mispairing. The effectiveness of a mutagenesis is often assayed by observing the killing effect of the mutagen on the virus. Overall, the use of mutagens can increase the mutation frequency several hundred-fold, such that desired mutants may comprise as much as 0.5% of the total virus population.

RNA viruses have relatively high mutation frequencies, and increasing their mutation frequencies even more with mutagen treatment can

extinguish populations through "lethal mutagenesis." For example, poliovirus propagated in the presence of the mutagenic nucleoside analog ribavirin has an increased mutation frequency, which can dramatically reduce viral fitness.[25] Using mutagenic nucleoside analogs to induce lethal mutations in RNA viruses has been applied to several systems, ranging from HIV to coronaviruses.[123,150]

Double Mutants and Siblings

The existence of *double mutants* and *siblings* can theoretically complicate genetic analysis of a virus. A double (or multiple) mutant is defined as a virus that contains more than one mutation contributing to a phenotype. Theoretically, because the probability that a double mutant will be created increases as the dose of a mutagen is increased, there is a practical limit to the amount of induced mutation that is desirable. Double mutants are usually revealed as mutants that are noncomplementing with more than one mutant or are impossible to map by recombination or physical methods. Siblings result from replication of mutant virus either through amplification of a mutagenized stock or during an *in vivo* mutagenesis. The only completely reliable method to avoid isolation of sibling mutants is to isolate each mutant from an independently plaque-purified stock of wild-type virus.

Mutant Genotypes

There exist two basic categories of mutation: base substitution and deletion/insertion mutations. Both mutation types can occur with consequence in either a protein coding sequence or in a control sequence, such as a transcriptional promoter, a replication origin, or a packaging sequence. *Base substitution* mutations consist of the precise replacement of one nucleotide with a different nucleotide. In coding sequences, base substitution mutations can be silent, causing no change in amino acid sequence of a protein; they can be missense, causing replacement of the wild-type amino acid with a different residue; or they can be nonsense, causing premature translation termination during protein synthesis. *Deletion and insertion* mutations comprise deletion or insertion of one or more nucleotides in a nucleic acid sequence. In a coding sequence, deletion or insertion of multiples of three nucleotides can result in precise deletion or insertion of one or more amino acids in a protein sequence. In a coding sequence, deletions or insertions that do not involve multiples of three nucleotides result in a shift in the translational reading frame, which almost invariably results in premature termination at some distance downstream of the mutation. In general, nonsense mutations, frame shift mutations, or large in-frame insertions or deletions are expected to inactivate a gene, whereas missense mutations may cause inactivation or much more subtle phenotypes such as drug resistance or temperature sensitivity.

Mutant Phenotypes

In the context of experimental virology where a goal is to understand the function of individual virus genes, mutants that inhibit virus replication by inactivating a viral gene are useful. The nonproductive infections with these lethal mutants can be studied in detail to determine the precise aspect of virus replication that has been affected, thus providing information about the normal function of the affected gene. However, one must be able to grow the mutant to conduct experiments. Thus, a condition must be found where the mutation in question is not lethal—hence, the general class of mutant phenotypes, *conditional lethal*. Conditional lethal mutants are one of the most useful classes of mutant phenotypes, consisting of host-range, nonsense, temperature-sensitive, and drug-dependent phenotypes, described individually in the next section. Two additional classes of mutant phenotypes—resistance and plaque morphology—have very specific application to genetic analysis of viruses and are also described.

Host range

A host-range virus mutant is broadly defined as a mutant that grows on one cell type and not on another, in contrast to wild-type virus, which grows on both cell types. Two general subcategories of host-range mutants exist: natural and engineered. *Natural* host-range virus mutants are relatively rare, primarily because they must be identified by brute force screen or serendipity. The existence of a host-range phenotype implies that a specific virus-host interaction is compromised, which also implies that for any specific host-range phenotype, only one or a limited number of virus genes will be targeted. A classic example of a natural host-range mutant is the host range-transformation (hr-t) mutants of mouse polyoma virus, which affect both small and middle T antigens and grow on primary mouse cells but not continuous mouse 3T3 cell lines.[5] *Engineered* host-range mutants are constructed by deleting an essential gene of interest in the virus while at the same time creating a cell line that expresses the gene. The engineered cell line provides a permissive host for growth of the mutant virus because it complements the missing virus function, whereas the normal host lacking the gene of interest provides a nonpermissive host for study of the phenotype of the virus. This technology has been useful for study of a variety of viruses, notably adenovirus and herpes simplex virus, where it has facilitated study of several essential virus genes.[29,79]

Nonsense mutants

Nonsense mutants contain a premature translation termination mutation in the coding region of the mutant gene. They are formally a specific class of conditionally lethal, host-range mutants. Specifically, the permissive host is one that expresses a transfer RNA (tRNA) containing an anticodon mutation that results in insertion of an amino acid in response to a nonsense codon, thus restoring synthesis of a full-length polypeptide and suppressing the effects of the virus nonsense mutation. The nonpermissive host is a normal cell in which a truncated, nonfunctional polypeptide is made. In practice, most nonsense mutants in existence have been isolated by random mutagenesis followed by a brute force screen for host range. Nonsense mutants have three distinct advantages for the conduct of virus genetics: (1) mutants can be isolated in virtually any essential virus gene using one set of permissive and nonpermissive hosts and one set of techniques; (2) the mutations result in synthesis of a truncated polypeptide, thereby facilitating identification of the affected gene; and (3) virus mutants can be engineered relatively easily because the exact sequence of the desired mutation is predictable. Nonsense mutants have provided the single most powerful genetic tool in the study of bacteriophage, where efficient, viable nonsense suppressing bacteria are readily available. Unfortunately, attempts to isolate nonsense-suppressing mammalian cells have met with only limited success, probably because the nonsense-suppressing tRNAs are lethal in the eukaryotic host.[118,144]

Temperature sensitivity

Temperature sensitivity is a type of conditional lethality in which mutants can grow at a low temperature but not a high temperature, in contrast to wild-type virus, which grows at both temperatures. Genotypically, temperature-sensitive mutations result usually from relatively subtle single

amino acid substitutions that render the target protein unstable and hence nonfunctional at an elevated or nonpermissive temperature while leaving the protein stable and functional at a low, permissive temperature. Additionally, mutations in noncoding regions can confer temperature sensitivity, likely through effects on RNA structure.[140] Temperature-sensitive mutants are usually isolated by random mutagenesis followed by brute force screening for growth at two temperatures. Screening can be streamlined by a plaque enlargement technique in which mutagenized virus is first plated at a permissive temperature, then stained and shifted to a nonpermissive temperature after marking the size of plaques, to screen for plaques that do not increase in size at the nonpermissive temperature.[149] Replica plating techniques that permit relatively straightforward screening of thousands of mutant candidates in yeast and bacteria have not been successfully adapted to virology; thus, a screen for temperature sensitivity, even when streamlined with plaque enlargement, ultimately depends on the laborious but reliable process of picking and testing individual plaques. Temperature-sensitive mutants have the profound advantage of theoretically accessing any essential virus gene using a single set of protocols. Temperature-sensitive mutants have proved enormously useful in all branches of virology but have been particularly useful for the study of animal viruses, where nonsense suppression has not been a viable option. Cold-sensitive mutants (ie, mutants that grow at a high but not a low temperature) comprise a relatively rare but nevertheless useful alternate type of temperature-sensitive mutants.

Drug resistance and dependence

Several antiviral compounds have been identified, and virus mutants that are resistant to or depend on these compounds have been useful in genetic analysis of viruses. A few compounds have been identified that target similar enzymes in different viruses, including phosphonoacetic acid, which inhibits DNA polymerases,[64,152] and BrdU, which targets thymidine kinases.[38,156] More often, however, antiviral drugs are highly specific for a gene product of one particular virus—for example, guanidine, which targets the polio 2C NTPase[128]; acyclovir, which targets the herpes simplex virus thymidine kinase and DNA polymerase[17,143]; amantadine, which targets the influenza virus M2 virion integral membrane ion channel protein[63]; or isatin-β-thiosemicarbazone, which is highly specific for poxviruses and targets at least two genes involved in viral transcription.[19,24] The most useful drugs are those that inhibit wild-type virus growth in a plaque assay without killing cells in a monolayer, such that resistant or dependent viruses can be selected by virtue of their ability to form plaques on a drug-treated monolayer.

Drug-resistant or drug-dependent virus mutants have two general uses in virus genetics. First, they can be useful in identifying the target or mechanism of action of an antiviral drug. For example, studies of influenza virus mutants resistant to amantadine were of importance in characterizing both the *M2* gene and the mechanism of action of amantadine.[129] Similarly, viruses resistant to the mutagenic nucleoside analog ribavirin have polymerase mutations that increase fidelity of RNA virus replication, further supporting viral mutagenesis as an antiviral mechanism.[25,126] Second, resistant or dependent mutants provide selectable markers for use in recombination mapping, for the assessment of specific genetic protocols, or for selection of recombinant viruses in reverse genetic protocols. For example, guanidine resistance has been used as a marker for use in three-factor crosses in recombination mapping of poliovirus temperature-sensitive mutants[23]; phosphonoacetic acid resistance and isatin-β-thiosemicarbazone dependence have been used in vaccinia virus to assess the efficiency of marker rescue protocols,[43] and acyclovir resistance and BrdU resistance, resulting from mutation of the herpesvirus or poxvirus thymidine kinase genes, have been used in both herpesviruses and in poxviruses to select for insertion of engineered genes into the viral genome.[18,105,121]

Plaque morphology

Plaque morphology mutants are those in which the appearance of mutant plaques is readily distinguishable from wild-type plaques. Most commonly, the morphological distinction is plaque size (ie, mutant plaques may be larger or smaller than wild-type plaques); however, other morphological distinctions are possible, such as formation of clear vs turbid bacteriophage plaques. Most plaque morphology mutants affect very specific virus functions, which in turn affect the virus-host relationship in a fashion that impacts on the appearance of a plaque. Notable examples from bacteriophage research include clear plaque mutants of bacteriophage lambda and rapid lysis mutants of the T-even bacteriophage. Wild-type lambda forms turbid plaques because some percentage of cells are lysogenized and thus survive the infection, leaving intact bacteria within a plaque. Clear mutants of lambda typically affect the lambda repressor such that lysogeny is prevented and all infected bacteria lyse, resulting in a clear plaque.[81] Wild-type T-even phages produce small plaques with a turbid halo because only a fraction of infected bacteria lyse during a normal infection, a phenomenon called *lysis inhibition*. Rapid lysis mutants, which affect a phage membrane protein, do not display lysis inhibition and as a result form large, clear plaques.[68] Examples from animal virus research include large plaque mutants of adenovirus and coxsackievirus, and syncytial mutants of herpes simplex virus. The large plaque phenotype in adenovirus results from faster than normal release of virus from infected cells,[86] and the large plaque phenotype in coxsackievirus results from reduced binding to inhibitory glycans.[170] Syncytial mutants of herpesvirus express altered virus surface glycoproteins and result in fusion of infected cells, whereas wild-type virus infection causes cells to round and clump without significant fusion. Thus, syncytial mutants form large plaques readily distinguishable from the smaller dense foci caused by wild-type virus.[137] All of these specific plaque morphology mutants have value either in the study of the actual functions affected or as specific phenotypic markers for use in recombination studies, where they can be used in the same fashion as drug resistance markers.

In addition to the existence of specific plaque morphology loci in several viruses, it is noteworthy that any mutation that affects virus yield, growth rate, or spread may result in production of a smaller than wild-type plaque, which can be useful in genetic experiments. Thus, many temperature-sensitive mutants form smaller than wild-type plaques even at the permissive temperature because the mutant gene may not be fully functional even under permissive conditions, and this property is often useful in mutant isolation or for distinguishing wild-type from mutant virus in plaque assays involving several virus variants. Finally, unique functions of specific viral proteins can alter plaque morphology. Vaccinia virus encodes two proteins, A33 and A36, that are expressed on the cell surface early after infection and “mark” the cell as infected.[31] As a consequence, superinfecting virions are repelled and available to infect other uninfected cells, enabling spread. Mutant viruses lacking expression of these proteins have small plaque phenotypes.

Neutralization escape

Neutralization escape mutants are a specific class of mutants selected as variant viruses that form plaques in the presence of neutralizing antibodies. Such mutants affect the structure or modification of viral surface proteins and have been of value in studies of virus structure, antigenic variation, and virus-cell interactions.[55,70] Neutralization escape has been particularly well studied during the SARS-CoV-2 pandemic given its practical relevance for immune evasion and spread of viral variants.[172]

Reversion

Reversion may be defined as mutation that results in a change from a mutant genotype to the original wild-type genotype. Accordingly, revertants in a stock of mutant virus are revealed as viruses that have acquired a wild-type phenotype. Spontaneous reversion of missense mutations probably results from misincorporation during replication, because the reversion frequency of different viruses often reflects the error rate of the replication enzyme. Spontaneous reversion of significant deletion mutations occurs rarely, if at all, because reversion would require replacement of missing nucleotides with the correct sequence. Reversion impacts on viral genetics in two ways. First, in any genetic experiment involving mixed infections with two genetically different viruses, wild-type viruses can arise either through reversion or recombination; in most cases, it is important to be able to distinguish between these two processes. This is discussed in more detail in the later sections describing complementation and recombination. Second, as described earlier in the description of spontaneous mutation, if the spontaneous reversion rate is extremely high, revertants can easily come to dominate a mutant virus stock, thus obscuring the mutant phenotype and causing serious difficulties in both genetic and biochemical analysis of mutants.

Leakiness

Not all conditionally lethal mutants are completely defective in replication under nonpermissive conditions, and leakiness is a quantitative measure of the ability of a mutant virus to grow under nonpermissive conditions. Leakiness can be quantified with a one-step growth experiment. To quantify leakiness of a temperature-sensitive mutant, for example, cells are infected at a high MOI with wild-type or mutant virus, infected cells are incubated at either permissive or nonpermissive temperatures, and maximum virus yields are then determined by plaque titration under permissive conditions so that the growth of mutant and wild-type virus can be quantitatively compared. Ideally, for wild-type virus, the ratio of the yield for infections done at the nonpermissive temperature relative to the permissive temperature should be one—that is, the virus should grow equally well at both temperatures. For mutant viruses, the ratio of the yield for infections done at the nonpermissive temperature relative to the permissive temperature may range from <10% to as much as 100%, even for mutants that are clearly defective in plaque formation under nonpermissive conditions. Mutants that are *tight*—or grow poorly under nonpermissive conditions—are desirable for phenotypic characterization relative to leaky mutants, because leaky mutants will logically display considerable wild-type phenotypic behavior. Special cases exist where extreme leakiness is an expected and desirable trait. Specifically, virus mutants that are wild type for replication and production of infectious virions but defective in cell-to-cell spread have a phenotype characterized by defective plaque formation, which requires spread, but 100% leakiness, which does not require spread if assayed in a high MOI one-step growth protocol.[8]

Complementation

Complementation analysis provides a general method for determining whether two different virus mutants affect the same or different genes. The quantitative test to determine complementation is a two-step procedure in which coinfections are first done to induce an interaction between two mutants, and the results of those infections are quantitatively assessed by plaque titration. The test compares the ability of two mutants to grow in mixed relative to single infections done under nonpermissive conditions. Specifically, cells are first infected with two different virus mutants at high MOI so that all cells are coinfected with both mutants, and infected cells are incubated under nonpermissive conditions where neither mutant alone can replicate, for an interval sufficient to achieve maximum virus yield. Single high MOI infections under nonpermissive conditions are performed as controls. Virus is then harvested, yields are quantified by plaque titration under both permissive and nonpermissive conditions, and a complementation index is calculated.[89] If the two mutants, A and B, are in different virus genes, then in the mixed infection done under nonpermissive conditions, mutant A can contribute wild-type B gene product and mutant B can contribute wild-type A gene product. Thus, the mutants can help or complement each other, resulting in a high yield of mutant virus in the mixed infection compared to the single infections. If the two mutants affect the same gene, then the wild-type gene product will be lacking in the mixed infection. In this case, the yield from the mixed infection will be equivalent to the yield from the single infections.

Qualitative complementation tests have also been devised for use with both bacterial and mammalian viruses.[15,20,155] These qualitative tests are much easier to perform than quantitative tests and are just as reliable. In general, the tests are designed such that bacterial lawns or eukaryotic cell monolayers are infected either singly or with two viruses under nonpermissive conditions and at relatively low MOI. The MOI must be high enough so that numerous cells are doubly infected in the mixed infection, although low enough so that most cells are uninfected and a lawn or monolayer is maintained. Complementing mutant pairs produce plaques or cleared areas under nonpermissive conditions, whereas noncomplementing mutant pairs do not. A theoretical disadvantage of the qualitative test is that it does not discriminate between complementation and recombination. If recombination does occur under nonpermissive conditions, false positives occur in the qualitative test and the number of complementation groups is overestimated.[83] Nevertheless, negative tests are still a reliable measure of noncomplementation.

Complementation analysis has been of tremendous benefit in sorting mutants in many viral systems. A notable exception is poliovirus, where complementation between temperature-sensitive mutants *in vivo* is not observed. The lack of complementation in picornaviruses may be related to the unique mechanism of viral gene expression, in which all protein products are produced from a polyprotein precursor by proteolytic cleavage. If individual temperature-sensitive mutants affect structure, synthesis, or cleavage of the polyprotein precursor, they may behave as if they all belong to a single complementation group, even though they may map to different protein end products. Additionally, functional coupling of molecular processes such as translation and RNA genome replication, and RNA replication and packaging can limit opportunities for trans-complementation of protein functions.[118,119]

As a concept, complementation impacts broadly on virology and is not limited simply to the grouping of conditionally lethal mutants into genes. For example, the growth of engineered host-range deletion mutants in essential virus genes, discussed previously, relies on complementation of the missing viral function by an engineered cell line that expresses the wild-type viral gene product. In addition, the accumulation of defective virus genomes at high multiplicity passage, also discussed earlier, results from a complementing helper function provided by wild-type virus.

Recombination and Reassortment

Recombination describes a process by which nucleic acid sequences from two genotypically different parental viruses are exchanged so that the progeny contain sequences derived from both parents. In viral systems, there exist three distinct mechanisms of recombination, dictated by the structures of the viral genomes. For DNA viruses, recombination occurs by the physical breakage and rejoining of parental DNA molecules through regions of sequence homology, in a fashion similar or identical to the same process in bacteria or higher organisms. For RNA viruses containing segmented genomes, gene exchange occurs primarily through reassortment of individual parental genome segments into progeny

viruses, although intragenic recombination has been reported for orthomyxoviruses, reoviruses, and bunyaviruses.[127,130,133,153,157] For most nonsegmented RNA viruses, recombination appears to be a much less frequent event compared with DNA viruses. Recombination has been observed in several ssRNA virus families representing both positive- and negative-sense genomes; picornaviruses, coronaviruses, togaviruses, and retroviruses display relatively efficient recombination.[4,58,71,84,85,177] Recombination in RNA viruses is thought to occur during replication via *copy choice*, namely switching templates during replication such that the newly synthesized genome contains sequence from two different parental molecules.[23,85] Historically, recombination has been used to construct genetic maps of virus mutants and to construct novel virus genotypes. Although recombination mapping has been largely replaced by physical mapping techniques, such as marker rescue, a technical knowledge of recombination mapping can contribute to an appreciation of the complexity of genetic interactions between viruses.

The methods used to determine recombination frequencies are the same regardless of genome structure or mechanism of recombination. As with complementation, the quantitative test to determine recombination frequency between two mutants, called a *two-factor cross*, is a two-step procedure, but in this case, coinfections are first done under conditions permissive for replication, and then, the fraction of recombinants relative to the total virus yield is quantitatively assessed by plaque titration. Specifically, cells are first infected with two different virus mutants at high MOI so that all cells are coinfected with both mutants, and infected cells are incubated under permissive conditions so that both mutants have maximum opportunity for interaction, for an interval sufficient to achieve maximum virus yield. Single high MOI infections under permissive conditions are performed as controls. Virus is then harvested, yields are quantified by plaque titration under both permissive and nonpermissive conditions, and a recombination frequency is calculated.[89]

Recombination mapping in DNA viruses relies on the assumption that the frequency of recombination between two genetic markers is proportional to the distance between the two markers. For several DNA viruses, observed recombination frequencies comprise a continuous range from <1% up to a theoretical maximum of 50%, allowing for construction of linear genetic maps.[51]

In viruses with segmented genomes, recombination between markers on the same segment is rare but reassortment of segments is extremely efficient; thus, recombination is effectively an all or none phenomenon, with markers on the same segment displaying no recombination, and markers on different segments displaying very high levels of recombination.[132] For these reasons, genetic exchange in segmented RNA viruses is commonly referred to as reassortment rather than recombination. Reassortment analysis for segmented viruses is useful for determining whether or not two mutations map to the same genome segment but cannot be used to determine the order of markers on a given segment. Mutations can be mapped to individual RNA segments by performing *intertypic* crosses between virus types that can be discriminated either based on differential electrophoretic mobility of each RNA segment or detection of engineered mutations unique to each parental virus.[108,132]

Marker Rescue

Marker rescue is a physical mapping technique that measures directly whether a given virus mutation maps within a specific subfragment of a virus genome. The use of marker rescue is confined to DNA viruses where homologous recombination takes place and has been of enormous value in these systems. The application of the technique varies somewhat depending on the virus system under study; however, the general principles are the same. Specifically, full-length mutant viral genomic DNA plus a wild-type DNA genomic subfragment, either a cloned DNA molecule or a PCR product, are introduced into cells under conditions permissive for recombination and for wild-type virus replication. For viruses that contain infectious DNA, such as herpesviruses,[94,154] adenoviruses,[53] and polyomaviruses,[95] the mutant genomic DNA and the wild-type genomic subfragment may be cotransfected into cells. For viruses containing noninfectious genomic DNA, such as poxviruses,[159] the mutant DNA must be introduced into cells by infection with the mutant virus, which is then followed by transfection with the wild-type DNA subfragment. In either case, the protocol allows for homologous recombination between the mutant genome and the wild-type DNA subfragment. If the wild-type DNA subfragment contains the wild-type allele for the mutation, the recombination can exchange the wild type for the mutant sequence in the mutant genome, creating wild-type virus. Conversely, if the wild-type fragment does not contain the wild-type allele for the mutation, no wild-type virus, above a background of revertants, will be created in the experiment. The presence of wild-type virus can be assayed using either a two-step or a one-step protocol. In the two-step protocol, depending on the nature of the mutation being rescued, infected and/or transfected cells are incubated under permissive conditions to facilitate recombination and replication, or nonpermissive conditions to select for wild-type recombinants, then wild-type virus yields are quantified by plaque titration under nonpermissive conditions. In the one-step protocol, the infection and/or transfection is done so that only a small fraction of the cells in a monolayer are infected, and cells are then incubated under nonpermissive conditions such that wild-type virus formed during a successful rescue will form plaques on the monolayer.[159] In short, regardless of the precise method used, conversion or *rescue* of mutant virus to wild type with a given wild-type DNA fragment means that the mutation maps within that fragment. Initial marker rescue mapping experiments may be facilitated by the use of a few large but overlapping wild-type DNA fragments, and fine mapping may be accomplished with fragments as small as a few hundred nucleotides. Marker rescue mapping has completely replaced recombination mapping as a method for mapping mutations in DNA viruses, and precise genetic maps of several DNA viruses have now been constructed.

Reverse Genetics

Prior to the advent of recombinant DNA and DNA sequencing technologies, classical genetic analysis, namely random isolation and characterization of virus mutants, was one of the few effective methods for identifying, mapping, and characterizing virus genes, and the only method for obtaining virus mutants. With the current ready availability of genomic sequences for virtually all prototypical members of each virus family and a versatile package of genetic engineering tools, the experimental landscape has changed completely. One can now conduct a genetic analysis with a reasonably complete foreknowledge of the genetic structure of the virus, focus attention on individual genes of interest, and deliberately engineer mutations in genes to study their function. Termed *reverse genetics*, this process has come to dominate the genetic analysis of viruses. Reverse genetics covers a broad range of activities ranging from engineering a single nucleotide substitution in a target gene to engineering chimeric viruses to be used as gene therapy vectors, oncolytic vectors, or vaccines. Currently, virtually every significant human viral pathogen can be engineered using reverse genetic approaches. Perhaps one of the most impressive feats in reverse genetics is the resurrection of the deadly 1918 pandemic strain of influenza using genome sequences derived from archived formalin-fixed lung autopsy materials and from frozen, unfixed lung tissues from an Alaskan influenza victim who was buried in permafrost.[163]

Reverse genetic analysis involves two distinct considerations: strategies for design of a given mutation and strategies for incorporation of mutations into virus. The principles governing these strategies highly depend on the structure of a given viral genome and the strategy of virus replication and thus vary in the extreme. However, some general principles can be identified, which are discussed next, accompanied by a few

specific examples to illustrate the general principles.

Incorporation of Mutations Into Virus

The methods used for incorporation of mutations into a virus depend on several features of the individual virus under consideration, including genome size, whether or not the nucleic acid is infectious, whether the genome is composed of DNA or RNA or replicated via reverse transcription, and whether replication is nuclear or cytoplasmic.

DNA viruses and reverse-transcribing viruses

With the exception of poxviruses, which because of their cytoplasmic site of replication must carry virion-encapsidated transcription enzymes into cells during infection, virtually all DNA virus genomes (see Table 2.1) are infectious. Likewise, double-stranded DNA (dsDNA) comprising the genomic sequences of reverse-transcribing viruses that package RNA (retroviruses) or DNA (hepadnaviruses) genomes are also infectious. Thus, in these cases, the incorporation of a mutation into the virus genome is essentially an exercise in molecular cloning, and pure mutant virus is produced by transfection of the cloned mutant genome into cultured cells. In practice, the herpesvirus genome is sufficiently large such that manipulation as a full-length genomic clone presents some difficulties, and therefore, incorporation of mutations into the viral genome is often done by cotransfecting cells with full-length genomic viral DNA along with a DNA fragment containing the desired mutant allele flanked by wild-type DNA sequences. Replication is launched from the transfected infectious wild-type genomic DNA, and homologous recombination between the cotransfected mutant DNA fragment and the wild-type genome incorporates the mutant allele into a fraction of the replicating wild-type genomes[21,180] (Fig. 2.10). A similar protocol is applied to engineering poxviruses; however, because poxvirus DNA is noninfectious, virus replication must be initiated by infection with intact virus. In its simplest form, this protocol entails infection with virus bearing the wild-type target genome followed by transfection with a DNA fragment containing the desired mutation flanked by wild-type DNA sequences[125] (Fig. 2.11; identical to the protocol for marker rescue described earlier). Similar to the herpesvirus cotransfection protocol just described, homologous recombination catalyzed by viral enzymes results in incorporation of the mutant allele into a fraction of the wild-type infecting genomes. An alternate protocol for constructing poxvirus recombinants involves first infecting cells with a replication defective, nonhomologous helper poxvirus, followed by transfection with either a cloned full-length mutant genome or a mixture of fragments comprising the desired engineered genome.[32,134,178] The helper virus provides enzymes critical for launching replication of the transfected full-length mutant viral DNA genome or for homologous recombination among transfected subgenomic fragments to assemble and launch replication of the desired virus.

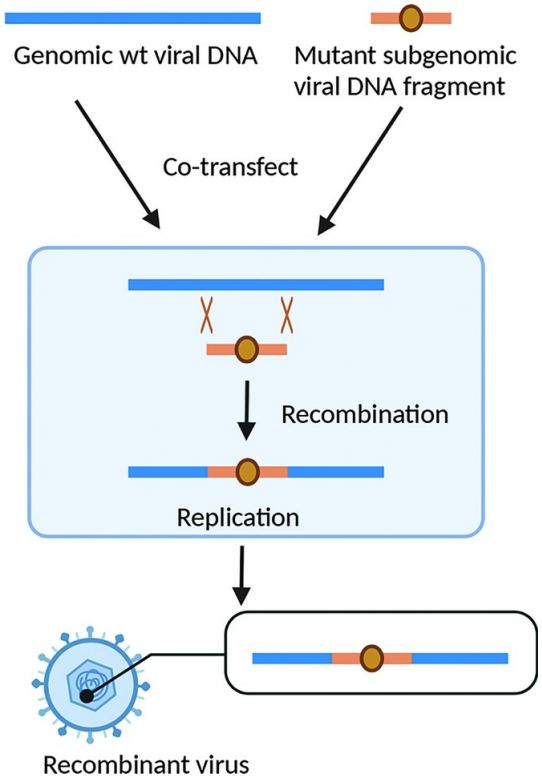

FIGURE 2.10 **Reverse genetics with large double-stranded DNA viruses containing infectious genomes.** Wild-type full-length infectious genomic viral DNA (*blue line*) is cotransfected into cells along with a subgenomic viral DNA fragment (*orange line*) containing the desired mutation (*orange circle*). Homologous recombination between the cotransfected viral DNAs takes place within the cell catalyzed by viral and/or cellular enzymes. The recombinant genome is replicated and packaged to yield recombinant virus (mixed with wild-type virus replicated from unrecombined genomes). (Created with BioRender.com.)

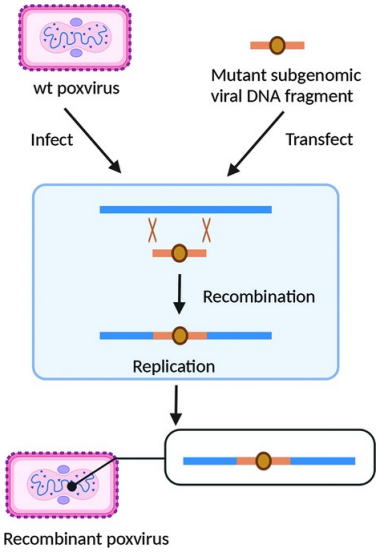

FIGURE 2.11 **Reverse genetics with large double-stranded DNA viruses containing noninfectious genomes (poxviruses).** Cells are infected with virus containing a wild-type DNA genome (*blue line*) and transfected with a subgenomic viral DNA fragment (*orange line*) containing the desired mutation (*orange circle*). Homologous recombination between the infecting viral DNA and cotransfected fragment takes place within the cell catalyzed by viral enzymes. The recombinant genome is replicated and packaged to yield recombinant virus (mixed with wild-type virus replicated from unrecombined genomes). (Created with BioRender.com.)

When mutants are engineered in cloned, infectious genomes, only the mutant allele of the target gene is present in the construction, all virus recovered from the transfection will be mutant, and no selection or screen for mutants is required. However, in situations where *in vivo* homologous recombination has been used to incorporate the cloned mutation into a wild-type genome, such as in poxviruses or herpesviruses, both mutant and wild-type viruses emerge from the mutant construction protocol, and thus, a screen or selection is required to identify the mutant of interest. For mutations in nonessential genes, this may be a relatively straightforward matter of inserting into the target gene a color marker such as β-galactosidase[180] or GFP[27] to facilitate a screen, or inserting a dominant selectable marker such as *Escherichia coli* guanine phosphoribosyltransferase[42] to facilitate a selection. For conditionally lethal phenotypes such as temperature sensitivity, although techniques exist that enrich for recombinant viruses, mutant isolation ultimately relies on a screen of individual mutants for differential growth under permissive and nonpermissive conditions.[61] The use of full-length clones of herpesvirus and vaccinia virus obviates the need for *in vivo* recombination, and thus only mutant virus will be recovered after transfection or reactivation of an engineered, mutant genome, and no mutant screen or selection is necessary.[33,111]

RNA viruses

The genomes of positive-sense ssRNA viruses (see Table 2.1) are infectious; therefore, as with most DNA viruses, the engineering of mutant viruses is largely an exercise in molecular cloning, yet formidable for large RNA viruses such as coronaviruses.[179] To recover infectious virus, complementary DNA (cDNA) clones of mutant genomes may be transfected directly into cultured cells or transcribed *in vitro* into positive-sense RNA that is then transfected into cells. Virus replication is launched by translation of the transfected RNA *in vivo*, resulting in recovery of only mutant virus. A good example of the application of this technology is the directed construction of temperature-sensitive mutants in poliovirus.[30]

Negative-sense ssRNA viruses must package in the virion a virus-coded RNA-dependent RNA polymerase so that the genome, in the form of a nucleocapsid, can be transcribed into mRNA immediately following infection. Thus, negative-sense ssRNA virus genomes are not infectious, and engineering these viruses becomes more of a challenge. Generally, the strategy consists of transfection of cells with multiple plasmids, some of which are transcribed into genome-length RNAs (encoding the desired genotype) and some of which direct expression of proteins required for genome replication, specifically a nucleocapsid protein and proteins comprising the viral RNA-dependent RNA polymerase. The expressed nucleocapsid protein encapsidates the transcribed genomic RNA, and this nucleocapsid can then be transcribed into mRNA by the expressed viral RNA polymerase, thus launching the infection and ultimately yielding pure virus of the desired genotype. Historically, the requirements for "rescue" of virus from cloned fragments are different for the segmented negative-sense ssRNA orthomyxoviruses compared to most nonsegmented negative-sense ssRNA viruses, namely rhabdoviruses, paramyxoviruses, and filoviruses, comprising most of the order *Mononegavirales*. The differences are attributable, at least in part, to the fact that the orthomyxoviruses replicate in the nucleus, whereas most of the viruses in the order *Mononegavirales* replicate in the cytoplasm. Specifically, for the orthomyxoviruses,[116] genome segments are cloned so that they are transcribed from a polymerase I promoter to yield the negative-sense genomic RNA, and the replication proteins are cloned so that they are transcribed from a polymerase II promoter to yield mRNA. Both polymerases are expressed in the cell nucleus so that after transfection of the plasmids, the viral RNAs are synthesized in the appropriate cellular compartment. The number of plasmids required for rescue can be minimized by flanking each genome segment with a polymerase I promoter at the 3′ end and a polymerase II promoter at the 5′ end so that each plasmid yields both a negative-sense genomic RNA and a positive-sense mRNA (Fig. 2.12). For most *Mononegavirales* viruses,[22] rescue is best achieved if synthesis of both the genomic RNA and the replication proteins are driven by the bacteriophage T7 RNA polymerase, which localizes efficiently to the cell cytoplasm. The T7 RNA polymerase can be supplied either by infection with a poxvirus expressing T7 RNA polymerase, by using a cell line containing a stably integrated copy of the T7 RNA polymerase gene, or by transfection of an additional plasmid designed to express the enzyme. An additional (counterintuitive) requirement for rescue of *Mononegavirales* viruses is that the plasmid encoding the genomic RNA is configured so that it is initially transcribed to yield positive-sense antigenomic RNA, which is then encapsidated with expressed nucleocapsid protein, and replicated into encapsidated negative-sense genomic RNA, which is in turn transcribed into mRNAs to launch the infection (Fig. 2.13). The use of a plasmid that expresses the negative-sense genomic RNA compromises the rescue, presumably because the negative-sense genomic RNA will hybridize in the cytoplasm with the positive-sense mRNAs for replication proteins, thus repressing their expression. Despite these generalities, examples exist of rescue of cytoplasmic *Mononegavirales* viruses using polymerase I

or polymerase II promoters.[109]

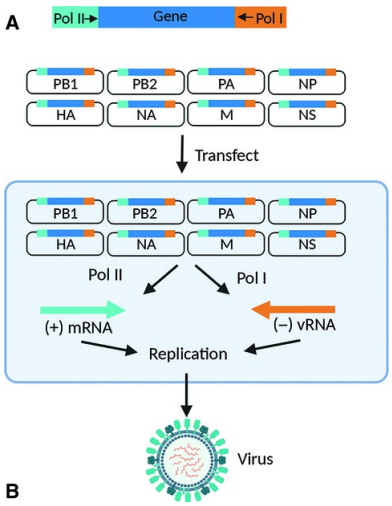

FIGURE 2.12 **Reverse genetics with orthomyxoviruses (influenza). A**. Detailed structure of cloned viral genes. Coding sequences for each viral gene (*blue*) are cloned flanked by an RNA polymerase II transcriptional promoter (*turquoise*) at the upstream (5′) end and an RNA polymerase I transcriptional promoter (*orange*) at the downstream (3′) end. **B**. Reverse genetic protocol. Cells are transfected with eight plasmids together representing the entire complement of virus genes. Transcription in the nucleus with polymerase II produces positive-sense messenger RNAs (*turquoise*) that are translated into viral proteins including the polymerase (PB1, PB2, PA) and nucleocapsid protein (NP). Transcription from the polymerase I promoter produces negative-sense genomic viral RNAs (*orange*), which are then replicated by the viral replication proteins. Further transcription, replication, and encapsidation produce virus. (Created with BioRender.com.)

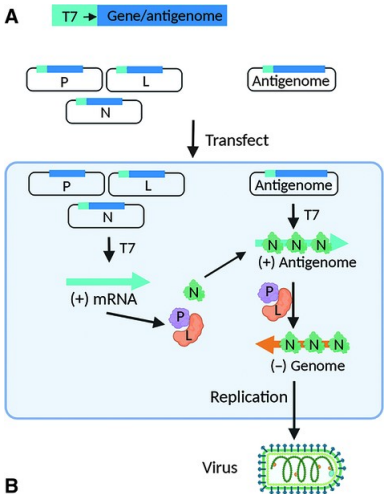

FIGURE 2.13 **Reverse genetics with viruses in the order *Mononegavirales*. A**. Detailed structure of cloned genes. Coding sequences for replication proteins or the full-length viral genome (*blue*) are cloned downstream from a bacteriophage T7 transcriptional promoter (*turquoise*). **B**. Reverse genetic protocol. Cells are transfected with four plasmids, three of which encode replication proteins (P, L, and N) and one of which contains the full-length viral genome oriented such that transcription yields a positive-sense antigenomic RNA. Transcription by T7 RNA polymerase (usually encoded by an engineered stably integrated copy in the cell nucleus) yields messenger RNA for the replication proteins (*turquoise*) plus positive-sense antigenomic viral RNA (*turquoise*). Translation of the messenger RNAs provides nucleocapsid protein (N), which encapsidates the antigenomic RNA. Antigenomic nucleocapsid is replicated by the viral polymerase (L and P) to yield negative-sense genomic viral nucleocapsid (*orange* viral RNA encapsidated with *green* N protein), which can be further transcribed and replicated to yield recombinant virus. (Created with BioRender.com.)

The segmented, double-stranded RNA (dsRNA)-containing, cytoplasmic reoviruses can be rescued using a protocol similar to that used for *Mononegavirales*.[91] Specifically, cDNAs of individual segments are cloned downstream from a bacteriophage T7 promoter, each yielding an RNA product that doubles as mRNA and the positive strand template for genomic dsDNA. Transfection of these plasmids into cells expressing T7 RNA polymerase results in synthesis of genomic segments and replication proteins, ultimately yielding pure virus of the desired genotype. T7 RNA polymerase can be supplied by any of the previously mentioned methods: cotransfection of an expression plasmid, expression from a stably integrated chromosomal gene, or infection with a poxvirus expressing the enzyme. Interestingly, this protocol did not work for all reoviruses, most notably the important human pathogen rotavirus, which, until recently, required more complex helper-mediated protocols.[162] However, an entirely plasmid-based reverse genetic system for rotavirus was developed by expressing a protein that induces cell-cell fusion and the vaccinia capping enzyme along with the viral cloned cDNAs.[82]

Mutation Design

Design of mutations for use in virology is problematic only if the gene in question is essential, necessitating isolation of a conditionally lethal mutation. For genes that are nonessential, mutation design is a simple matter of engineering a null mutation (eg, a deletion, insertion, or nonsense mutation) into the cloned gene sequence. Three basic types of engineered conditionally lethal mutations are currently in use: host-range deletion mutants, which rely on the availability of a complementing host cell; temperature-sensitive mutants constructed by clustered charge to alanine scanning; and artificially induced gene regulation. For host-range deletion mutants, the primary problem is construction of a host cell that expresses the target gene in a fashion appropriate for complementation of a null mutant in the virus. Once a cell line has been isolated, construction of the cloned mutation in the virus gene follows the same principles governing construction of a null mutation in a nonessential gene. The fundamental problem in creating temperature-sensitive mutations is that it is currently impossible to predict from primary amino acid sequence or even from three-dimensional protein structure what type of mutation will render a protein temperature sensitive. This difficulty has been partially overcome with the use of clustered charge to alanine scanning mutagenesis, in which clusters of three or more charged residues in the primary amino acid sequence of a protein are all changed to alanine.[173] In theory, charge clusters are likely to reside on the surface of the protein where they may facilitate protein-protein interactions, and neutralization of the charge by replacement with alanine may weaken such interactions without seriously disrupting the three-dimensional conformation of the protein. In practice, as much as 30% of clustered charge to alanine scanning mutants prove to be temperature sensitive, and this mutagenesis technique has been successfully used to construct temperature-sensitive mutants of both picornaviruses and poxviruses.[30,62] Lastly, conditionally lethal mutants have been constructed in poxviruses by placing essential genes under bacterial operator-repressor control in the viral genome.[136,161]

Deep Mutational Scanning

With advances in deep sequencing technologies and nucleic acid synthesis, it has become possible to query immense pools of mutated viral proteins to identify functional consequences of amino acid changes at every position in an unbiased manner.[50] This approach—*deep mutational scanning*—requires (1) a diverse library of engineered variants, (2) a system/host that links phenotype to genotype, and (3) a selection strategy. A variant library is constructed that encodes degenerate codons at every position to generate nearly all possible single amino acid substitutions. For virology applications, linking genotype to phenotype can be accomplished through engineering libraries within viral infectious clones followed by viral replication or binding assays as a phenotypic readout or by using viral protein display in yeast or mammalian cells followed by binding assays as a phenotypic readout.[115] The relative impact of each mutation is quantified by deep sequencing the variant library before selection vs after selection to determine which sequences are depleted or enriched. Deep mutational scanning has been particularly useful to examine functional consequences for mutations in viral glycoproteins, which can assist prediction of altered receptor binding, antibody binding, or membrane fusion. For example, deep mutational scanning has identified amino acid changes in SARS-CoV-2 spike protein that confer reduced antibody binding.[57]

Defective Interfering Particles

Interference refers generally to a phenomenon whereby infection by one virus results in inhibition of replication of another virus.[45] Defective interfering (DI) particle-mediated interference was first described by von Magnus,[168] who noted that serial undiluted passage of influenza virus resulted in a dramatic decrease in infectious titer while the number of particles remained constant. Essentially the same phenomenon was subsequently observed in a wide variety of RNA and DNA animal viruses, as well as in plant and bacterial viruses.[72] The mechanism of interference in each case is similar, namely virus stocks accumulate *DI particles*. DI particles are virus particles that contain genomes that are grossly altered genetically, usually by significant deletion of essential functions, but retain critical replication origins and packaging signals, allowing for amplification and packaging in coinfections with complementing wild-type *helper* virus. DI particles usually display a replication advantage relative to wild-type virus from increases in the copy number or efficiency of replication origins. DI particles actively inhibit replication of wild-type virus, presumably by competing for limiting essential replication factors. Study of DI particles has provided significant insight into viral replication, particularly structure and function of replication origins. Moreover, recent studies suggest that levels of DI genomes correlate with respiratory syncytial virus replication and disease in patient cohorts, revealing possible clinical importance.[44]

Phenotypic Mixing and Pseudotypes

If two heterologous viruses infect the same cell, then depending on the relatedness of the two viruses, the opportunity exists for packaging of either virus genome into a nucleocapsid or envelope comprised wholly or in part of structural proteins encoded by the heterologous virus. This phenomenon, termed *phenotypic mixing*, has been observed in mixed infections in a laboratory setting using both nonenveloped and enveloped viruses. Phenotypic mixing is a transient phenomenon, because infection of a cell with a single phenotypically mixed particle will result in replication and assembly only of viruses that reflect the infecting genome. Historically, phenotypic mixing experiments have contributed to understanding virus structure and assembly. There has been some speculation that phenotypic mixing may actually play a role in a natural setting, serving to maintain otherwise unfit genomes within a quasispecies over time.[175]

In mixed infections with nonenveloped viruses, phenotypic mixing has been observed between closely related adenoviruses, reoviruses, and picornaviruses.[69,133,176] Phenotypic mixing has been observed between picornaviruses as distantly related as echovirus 7 and coxsackievirus A9.[75]

In the case of enveloped viruses, phenotypic mixing consists of packaging the nucleocapsid of one virus within an envelope of a heterologous virus, and the resulting viruses are called *pseudotypes*. Pseudotype formation among enveloped viruses is relatively promiscuous, especially among retroviruses and rhabdoviruses.[181] For example, pseudotypes have been formed that contain retrovirus envelope antigens combined with genomes from rhabdoviruses, paramyxoviruses, orthomyxoviruses, herpesviruses, or coronaviruses. Conversely, pseudotypes have been formed that contain a rhabdovirus genome combined with envelope antigens from togaviruses, retroviruses, bunyaviruses, arenaviruses, paramyxoviruses, orthomyxoviruses, herpesviruses, poxviruses, or coronaviruses. Currently, the concept of phenotypic mixing and pseudotype formation is of critical utility in packaging and delivery of virus vectors, particularly because phenotypic mixing permits the tropism of a virus particle to be manipulated.[80] Pseudotyping viruses can be particularly useful in the laboratory. For example, retroviruses or vesicular stomatitis viruses pseudotyped with the SARS-CoV-2 spike attachment protein have been a useful tool because they can be used in biosafety level 2 conditions rather than the biosafety level 3 conditions required for work with bona fide SARS-CoV-2.[98,117]

CHAPTER 3

Principles of Virus Structure

Stephen C. Harrison

Introduction

How virus structures are studied

Virus symmetry

Structure and assembly of closed shells

Quasi-equivalent icosahedral arrangements

Other types of icosahedral surface organization

Frameworks and scaffolds

Mass production and specificity

Elongated shells

Multishell particles

Rearrangements in surface lattices

Two recurring globular-domain structures in icosahedral capsid proteins

Genome packaging

Positive-strand RNA genomes

dsDNA genomes

dsRNA genomes

Negative-strand RNA genomes

Viral membranes

Postassembly steps

Structural biology of virus entry

Receptors and coreceptors

Membrane fusion

Penetration by nonenveloped viruses

Perspective

Introduction

Virus particles are self-propagating carriers of genetic material. They are, in effect, extracellular organelles that pass nucleic acid–encoded information from one cell to another. They contain most of the molecular machinery necessary for efficient and specific packaging of viral genomes, escape from an infected cell, survival of transfer to a new host cell, attachment, penetration, and initiation of a new replication cycle. This molecular machinery generally works by co-opting more elaborate elements of a host cell's apparatus for carrying out related processes.

Various organizational modes have evolved to perform the functions just outlined. The most critical distinction, from a structural perspective, is between enveloped viruses—those with lipid-bilayer membranes—and nonenveloped viruses—those without such membranes. Both categories include well-known human pathogens. Examples of the former include influenza virus, HIV-1, and SARS-CoV-2. Examples of the latter include poliovirus, adenoviruses, and papillomaviruses.

The lipid bilayer of enveloped viruses is an effective protective barrier for the viral genome. Most enveloped virus particles acquire their membrane during exit from the cytosol. This step generally proceeds by budding of the assembling particle through a cellular membrane, which can be either the plasma membrane (eg, for influenza virus) or the membrane of an internal organelle (eg, the endoplasmic reticulum for dengue virus). Entry includes the reverse of budding—fusion of the viral enveloped with a cell membrane, either at the cell surface or in an internal, endocytic compartment, such as an endosome.

The tightly organized protein shell ("capsid") of a nonenveloped virus is, like the bilayer of an enveloped virus, a shield that protects the viral genome, as well the agent of viral attachment. The virus particles ("virions") assemble in either the cytoplasm or the nucleus, and in most cases

cell lysis is probably the principal route of release. Some nonenveloped viruses can be released within membrane "packages"[119,414]; the incidence of this mode of release may be more extensive than currently recognized.[205] Nonenveloped virus particles must also breach a membrane to translocate into the cytosol, and uptake by some mode of endocytosis appears to ensure that any membrane lesion during the penetration step does not allow damaging molecular leakage in either direction or major dissipation of the cell's resting potential.

Most of this chapter will illustrate with specific examples the notions just outlined, emphasizing not only the structural principles but also the importance of molecular structure for understanding relevant mechanisms in the infectious cycle. The examples, chosen to exemplify specific structure-function relationships, are by no means exhaustive, and the chapters on individual virus families contain many more relevant details, including structures of viral enzymes—proteases and polymerases—not covered here.

How Virus Structures Are Studied

Electron microscopy has been, since the 1940s, the most direct way to determine the general morphology of virus particles. Traditional thin-sectioning methods continue to be useful for examining infected cells. The thickness of a section and the coarseness of staining methods limit resolution to about 50-75 Å, even in the best cases. ("Resolution" means the approximate minimum size of a substructure that can be detected or separated in an image from its neighbor. Recall that a carbon-carbon bond length is about 1.5 Å; the diameter of an α-helix, 10 Å; and the diameter of a DNA double helix, 20 Å.) Negative staining, with uranyl acetate, potassium phosphotungstate, or related, electron-dense compounds, gives more detailed images of isolated and purified virus particles. Viruses embedded in negative stain are often relatively well preserved.[86] The electron beam destroys the particle itself very rapidly, but it leaves the dense "cast" of stain undamaged for much longer. If the particle is fully covered by the negative stain, the image contains contrast from both the upper and the lower surface of the particle, and interpretation of finer aspects of the image requires modeling or computational analysis.[88] The three-dimensional image reconstruction methods now used routinely for cryogenic electron microscopy (cryo-EM—see next paragraph) were first implemented to interpret "two-sided" images of negatively stained virus particles.[87,101,210]

Methods for preserving viruses and other macromolecular assemblies by rapid freezing to cryogenic temperatures have permitted visualization of electron-scattering contrast from the structures in the particle itself and not just from the envelope created by the surrounding cast of negative stain.[4,15,318] Moreover, regular images can be selected from a heterogeneous field, allowing study of unstable or relatively impure preparations. Rapid advances in instrumentation and in computational methods have enabled cryo-EM three-dimensional density maps at resolutions comparable to those achieved by x-ray crystallography.[143,167,214] An example from even before the most recent innovations is illustrated in Figure 3.1.[415] Such "image reconstructions" are obtained by combining information from thousands of different images of individual particles. The combination is possible, because the particles of many viruses (eg, the papillomavirus particles in Fig. 3.1) are all the same. When such uniformity is not present, for example, as in the case of a complete herpesvirus particle rather than an isolated nucleocapsid, then information from different particles cannot be combined directly. A tomographic tilt series of images from a single particle (analogous to a CAT scan in medical radiography) can be recorded instead (cryogenic electron tomography or "cryo-ET").[225] The resulting three-dimensional image is of lower resolution, as electron damage limits the information that can be obtained from an individual particle, even when the data are taken at liquid-nitrogen or liquid-helium temperatures. Tomographic reconstructions can nonetheless be very useful, as illustrated in Figure 3.2A. Averaging the images of defined substructures within a tomogram or among many tomograms ("subtomogram averaging") can yield a more detailed representation, in favorable cases at a resolution that allows fitting an atomic model (Fig. 3.3).[399]

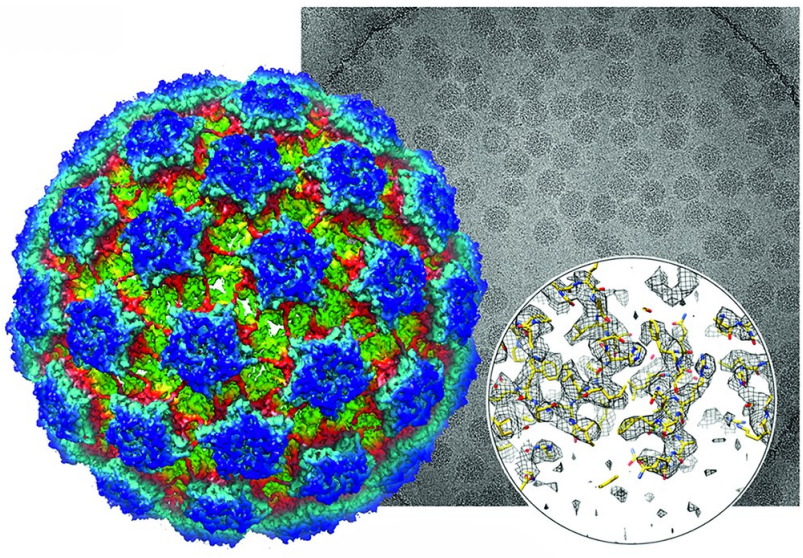

FIGURE 3.1 **Cryogenic electron microscopy (cryo-EM) of bovine papillomavirus (BPV)**. In the foreground is a color rendering of the three-dimensional image reconstruction, based on the kinds of micrographs shown in the background picture. The *circular inset at lower right* illustrates that this reconstruction provides information that extends to a nearly atomic level of detail ("resolution"); it shows a small part of the density map that resulted from the image analysis and the fit to that map of parts of the L1 polypeptide chain. (See refs.[143,415])

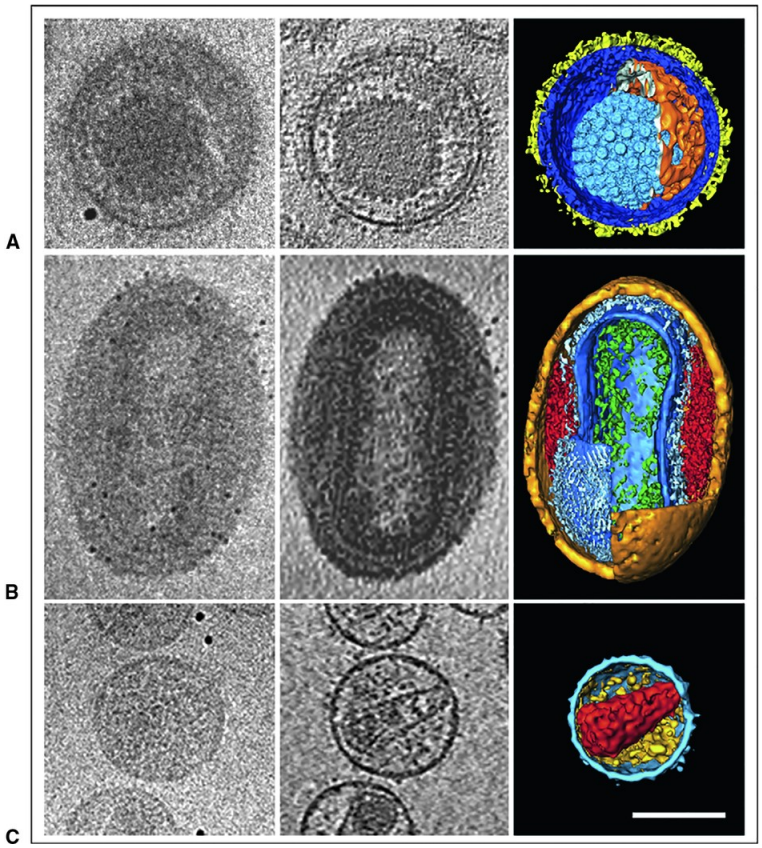

FIGURE 3.2 **Cryogenic electron tomography (cryo-ET) of herpes simplex virus type 1 (*top row*),[147] vaccinia intracellular mature virion (*middle row*),[90] and HIV-1 (*bottom row*).[37]** Images in the *left-hand column* are single, projected images; those in the *middle column*, slices through the reconstructed tomogram; those on the *right*, cut-away surface renderings of the three-dimensional tomographic reconstructions. FIGURE 3.3 **Cryo-ET and subtomogram averaging of immature and mature HIV-1 particles**. **A**. Diagram of HIV-1 Gag domains, for reference. MA, matrix; CA, capsid; NC, nucleocapsid. See also Fig. 3.24. **B**. Computational slices through cryotomograms of immature HIV-1 particles (*arrowhead* points to membrane bilayer) and viruslike particles (VLPs) lacking the MA domain of Gag (ΔMA). Without MA, the particles do not bud and do not acquire a membrane. The CA domain in the array of Gag subunits (either attached to membrane or, in the ΔMA VLP, projecting at the surface) is particularly prominent. Scale bar: 50 nm. Below each tomogram is a surface rendering of the CA lattice, determined by averaging many local regions from multiple particles ("subtomogram averaging"); one CA subunit is in color, with NTD and CTD as in **(A)**. The resolution is good enough to fit an atomic model, as shown in **(C)**, viewed face-on to the lattice (*top*) and normal to it (*bottom*, same view as in **(A)**). (**B-C** adapted from Schur FK, Obr M, Hagen WJ, et al. An atomic model of HIV-1 capsid-SP1 reveals structures regulating assembly and maturation. *Science*. 2016;353(6298):506-508. Reprinted with permission from AAAS. Ref.[348]) **D**. Slice through a tomogram of mature HIV-1 particles. Cleavage of the Gag precursor has separated CA from MA, leading to rearrangement of CA into a fullerene cone (see Figs. 3.17B and 3.24). Scale bar: 100 nm. **E**. Subtomogram averaging of the CA hexamers yields a subnanometer resolution map, into which the backbone structure of CA has been docked. (**D-E** adapted from Mattei S, Glass B, Hagen WJ, et al. The structure and flexibility of conical HIV-1 capsids determined within intact virions. *Science*. 2016;354(6318):1434-1437. Reprinted with permission from AAAS. Ref.[253])

A limitation of current cryo-EM methods is the molecular size of the smallest particle for which a high-resolution structure can be obtained.[166] That limit is roughly 100 kDa, although special techniques allow recording of high-resolution data from even smaller proteins or protein complexes. Most trimeric spike proteins of enveloped viruses are substantially larger than 100 kDa, and most viral polymerases are also amenable to structure determination by cryo-EM.[135,172,231,292] The very large number of cryo-EM structures of SARS-CoV-2 spike protein bound with Fabs of various antibodies illustrates the power of this approach.[191,430] When multiple states of a protein are present in the same sample, each one uniform enough to yield a good structure, image analysis methods permit computational classification, thus yielding structures of each state. X-ray crystallography continues to be the method of choice for obtaining structures of smaller viral enzymes, especially if high-resolution details of inhibitor complexes are a goal; it is likewise an appropriate method for structures of complexes of domains of viral glycoproteins with antibody Fabs.

Virus Symmetry

The coding capacity of a viral genome and the size of the shell needed to surround it together require that a virus particle contain many copies of one or a few protein subunits. In 1956, Crick and Watson realized that small viruses seen by electron microscopy were either rods or spheres.[85] The regularity of these particles led them to propose that they would be symmetrical assemblies, with either helical symmetry of some kind (for the rods, such as tobacco mosaic virus—TMV) or one of the three kinds of cubic symmetry (for the spherical particles, such as turnip yellow mosaic virus—TYMV). In a paper that followed theirs, Caspar showed by analysis of x-ray diffraction patterns that tomato bushy stunt virus (TBSV) has icosahedral symmetry, which is the most economical of the cubic symmetries.[57] An icosahedrally symmetric shell contains a greater number of symmetry-related subunits[54] than does a shell of tetrahedral[143] or octahedral[191] symmetry—the other two closed-shell possibilities. Hence, to contain a genome of a particular size, it dedicates fewer nucleotides of its genome to encoding the package in which they arrive than does either of the other two, leaving more room to encode other proteins, such as a viral polymerase.

Symmetry of an assembly means that certain "operations," such as rotation, relate identical configurations (Fig. 3.4). Proteins are chiral, so operations such as reflection in a plane are not possible. The symmetry operations permitted for chiral, closed-shell structures are, therefore, just rotations about axes running through the center of the particle. Icosahedrally symmetric structures have 12 fivefold axes (ie, axes about which a rotation of 72° brings the structure into self-coincidence), 20 threefold axes (120° rotation), and 30 twofold axes (180° rotation). These operations relate any one subunit to all 59 others (Fig. 3.4). The helical symmetry operations of rodlike structures have both rotational and translational components (Fig. 3.5) and can generate a helical rod of arbitrary length.

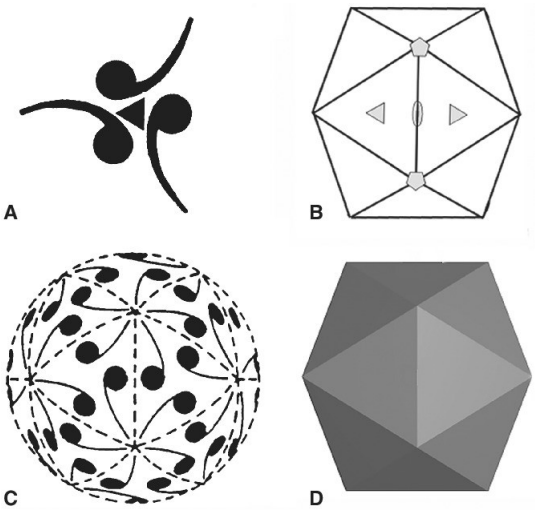

FIGURE 3.4 **Icosahedral symmetry**. **A**. Threefold symmetry: the three commas are related to each other by 120° rotations about the central axis, marked by a small triangle. **B**. Outline of an icosahedron, showing positions of some of the symmetry axis (imagined to extend from center of the icosahedral to the point on the surface marked by the symbol): fivefold, threefold, and twofold axes are marked by pentagons, triangles, and an oval, respectively. **C**. A n icosahedrally symmetry arrangement of commas on the surface of a sphere. For locations of symmetry axes, compare with panel **(B)**. **D**. Shaded surface view of an icosahedron.

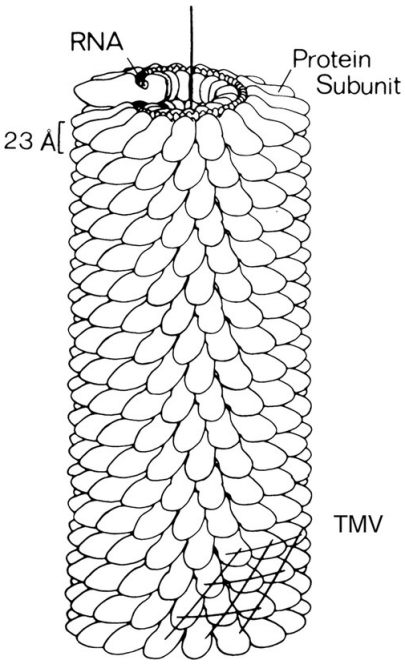

FIGURE 3.5 **Helical symmetry**. Diagram of the tobacco mosaic virus (TMV) particle. The elongated "loaves," with a groove for the RNA, represent the protein subunits. Three RNA nucleotides fit into the groove on each subunit. There are 16 1/3 subunits per turn of the

right-handed helix (ie, 49 subunits in three turns), with a rise of 23 Å as indicated. At the *lower right*, the surface lattice is drawn onto the outer particle. (Adapted from a drawing by Caspar DLD. Assembly and stability of the tobacco mosaic virus particle. *Adv Protein Chem*. 1963;18:37-121. Copyright © 1963 Elsevier, with permission. Ref.[56])

Symmetrical structures have the important property that all subunits interact identically with their neighbors and that stability of these interactions under intracellular conditions can drive self-assembly within an infected cell. In the years following the 1956 papers, it had become clear that many small, spherical viruses, such as TBSV and TYMV, contained more than 60 subunits, and Caspar and Klug proposed in 1962 that icosahedrally symmetric shells composed of certain multiples of 60 subunits would have the property that they could have nearly identical interactions among the subunits, requiring only modest flexibility in the contacts or in the subunits themselves, as shown in Figure 3.6. They called these nearly identical interactions "quasi-equivalent" and the multiples of 60 compatible with quasi-equivalent contacts, the "triangulation number" ("T-number") of the corresponding surface lattice (see Fig. 3.6 and section on quasi-equivalence, below).

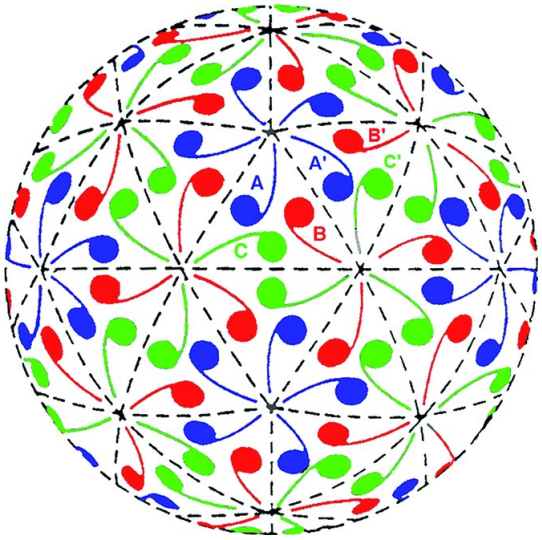

FIGURE 3.6 **Quasi-equivalent arrangement of 180 commas, in a T = 3 icosahedral surface lattice on a sphere**. Compare Fig. 3.4C, a T = 1 arrangement of 60 commas with icosahedral axes oriented similarly. The three quasi-equivalent positions within a single icosahedral asymmetric unit are shown in *blue*, *red*, and *green* and labeled *A*, *B*, and *C*, respectively, in two of the asymmetric units.

Structure AND ASSEMBLY of Closed Shells

With a typical, compact protein domain of 250-300 amino acid residues, close to the upper limit for most single protein domains, what sort of icosahedrally symmetric container can we construct? Suppose that the protein is so shaped that 60 copies fit together into a 30-Å thick shell with no significant gaps. Then the cavity within that shell will have a radius of about 80 Å, which can contain a 3-4 kb piece of single-strand DNA or RNA, tightly condensed. Some very simple virus particles conform to this description. The parvoviruses (see Chapter 6, volume 2) contain a 5.3 kb ssDNA genome, and their shells have 60 copies of a protein of ~550 residues[260] (Fig. 3.7). The capsid protein, therefore, uses up about one-third of the genome. ("Capsid," from the Latin *capsa*, box, designates the protein shell that directly packages DNA or RNA; "nucleocapsid" refers to the shell plus its nucleic-acid contents.) Likewise, the satellite of tobacco necrosis virus (STNV) contains 60 copies of a 195 residue subunit and a 1120 bp ssRNA genome, of which over half is used for the coat protein.[234] As the name implies, however, STNV is actually a defective virus, and it requires tobacco necrosis virus coinfection to propagate.

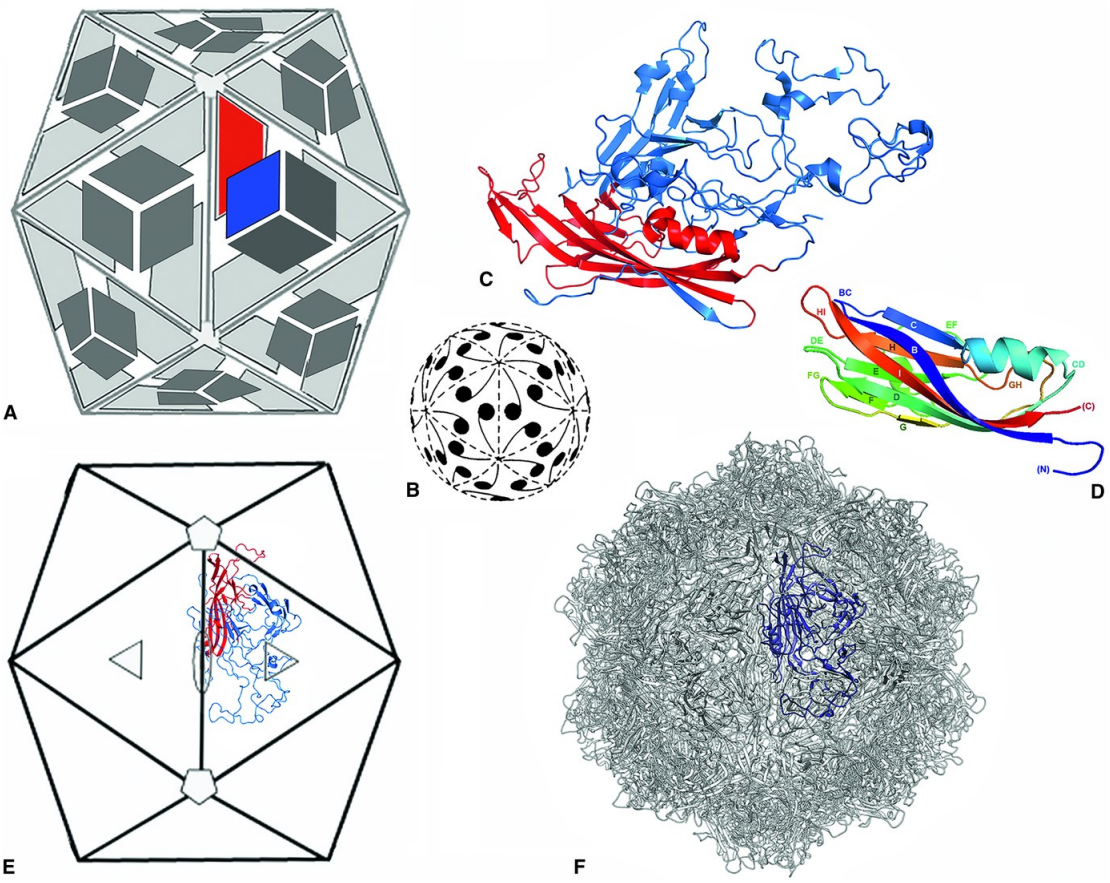

FIGURE 3.7 **Canine parvovirus (CPV): a simple, icosahedrally symmetric virion**. **A**. Icosahedron, viewed along a twofold axis, with diagrammatic representations of a protein subunit with a core domain (colored *red* on one of the subunits) and a projecting region (*blue*). Compare the subunits with the representation of commas in **(B)**, repeated from Figure 3.4C. **C**. Ribbon diagram of the CPV protein subunit; the core domain (*red*) is a β-jelly roll, from which emanate several loops that cluster to form a complex projecting region (*blue*). The simplified representation of the β-jelly roll in **(D)** is in rainbow coloring, from *blue* at its N-terminus to *red* at its C-terminus. The eight strands are lettered B-I; the loops have the letters of the strands they connect. The projecting region of the CPV subunit comprises loops BC, EF, and GH, and a short strand A, leading into the main β-jelly roll, is evident in the foreground. **E.** Icosahedron, as in **(A)**, but with a ribbon representation of one subunit; symbols for symmetry axes as in Figure 3.3B. **F**. Ribbon representation of all 60 subunits, with the subunit from **(E)** in *blue* and all others in *gray*.

More complex viruses have evolved ways to make larger, icosahedrally symmetric shells without expending unnecessary genetic resources. The simplest, but least economical, is just to use several different subunits, each of "garden-variety" size, to make up one icosahedral asymmetric unit. The picornaviruses (polioviruses, rhinoviruses, etc.) have 60 copies of three distinct proteins, VP1, VP2, and VP3, each of between 230 and 300 amino acid residues, as well as 60 copies of a small internal peptide, VP4 (see Fig. 3.8 and Chapter 2, volume 1). The shell has a cavity about 95 Å in diameter, which holds an RNA genome of 7.5-8 kb. The picornaviruses thus expend about one-third of their genome to encode the structural proteins of the virion. (The term "virion" means "virus particle," generally implying the mature, infectious structure.) We note here two other important features of picornavirus molecular architecture. First, the folded structures of VP1, VP2, and VP3 all have the same core structure—a domain known as a "jelly-roll β-barrel"[174,337] (Figs. 3.7 and 3.8). The single subunits of the parvoviruses and of STNV have the same basic fold. It is a module particularly well suited to the formation of closed, spherical shells, because of its blocklike, trapezoidal outline, but its prevalence among viral subunits may be evidence of a deeper evolutionary relationship. A second noteworthy feature of picornavirus design is that armlike extensions of the subunits tie together the assembled particle (Fig. 3.8). The importance of scaffoldlike intertwining of subunit arms was first discovered in the simple plant viruses.[163] Folding of part of the subunit and assembly of the shell are concerted processes.

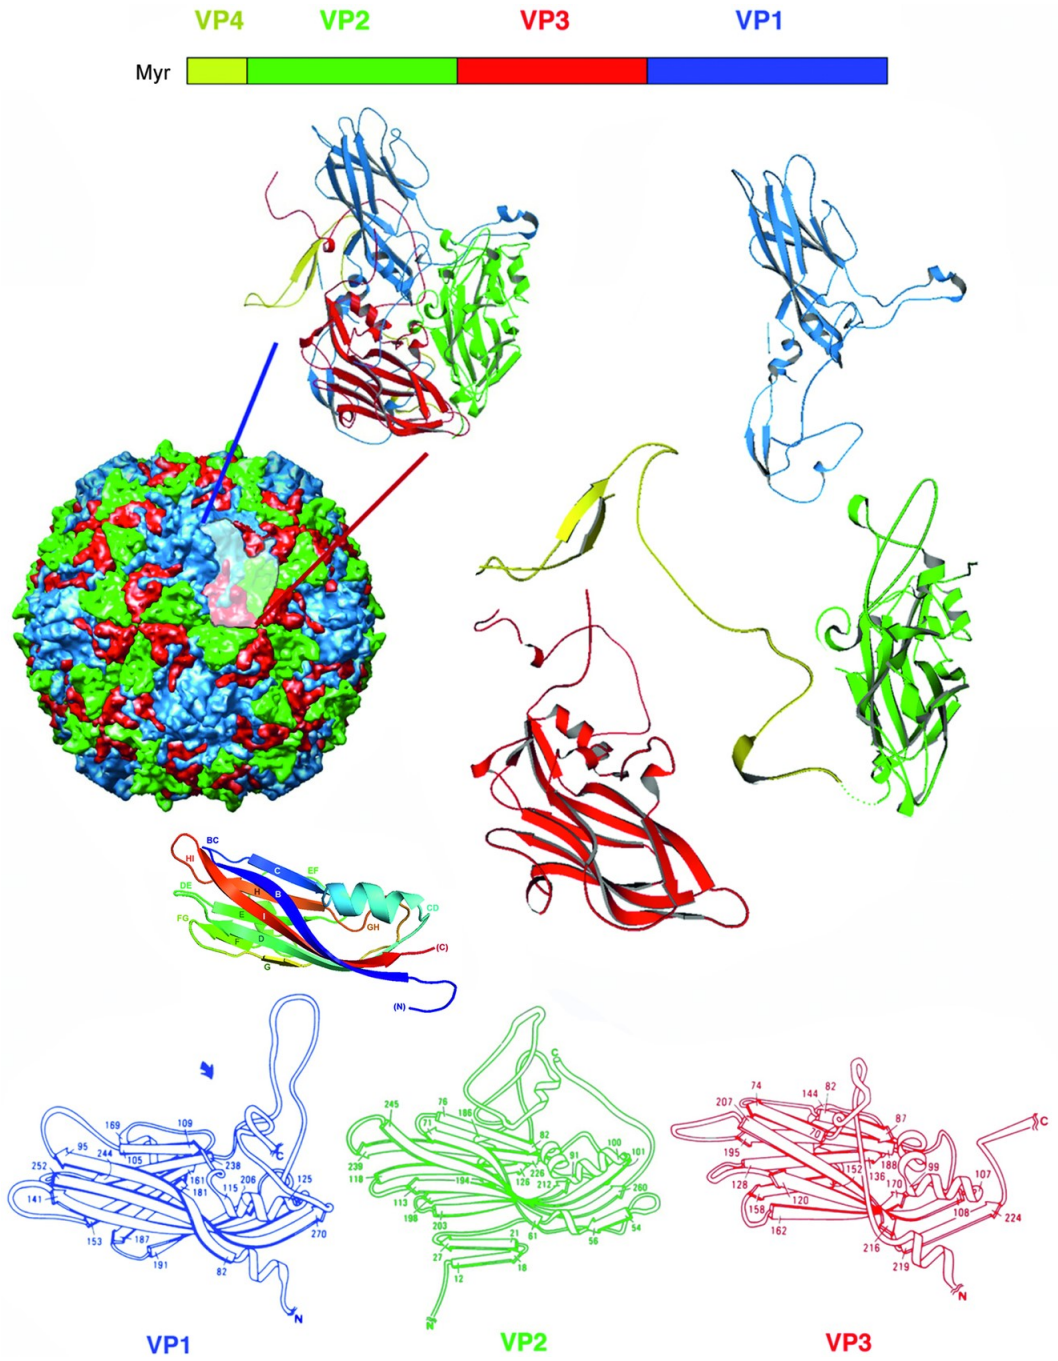

FIGURE 3.8 **Poliovirus**. *Top*: The order of structural proteins in the polyprotein encoded by the viral RNA. These domains are at the N-terminal end of the polyprotein, which is modified by myristoylation (Myr). The viral protease that cleaves between VP0 (=VP4 + VP2) and VP3 and between VP3 and VP1 is encoded by a region 3′ to the region that encodes the structural proteins; the VP4-VP2 cleavage is autolytic and occurs only after assembly of the virion precursor. *Middle*: Surface representation of the virus particle, with colors as in the bar diagram at the top. Two successively "exploded" views of an icosahedral asymmetric unit ("protomer") are shown next to the surface rendering. VP1, VP2, and VP3 each have a central β-jelly roll, with variable interstrand loops and variable N- and C-terminal extensions. The rainbow-colored β-jelly roll below the surface view is repeated from Figure 3.5D. *Bottom*: Side-by-side views of the β-jelly roll domains of VP1, VP2, and VP3, to illustrate their congruence.

Quasi-equivalent Icosahedral Arrangements

An economical way to build shells from more than 60 average-sized, identical subunits[59] is illustrated by the diagram of 180 commas in Figure 3.6. The commas have similar interactions (head to head in pairs; neck to neck in rings of three; tail to tail in rings of five or six), but they fall into three sets, designated A, B, and C. If the commas are taken to represent proteins, then the conformational differences between positions A and B, for example, involve the differences between rings of five and rings of six, for contacts involving the parts of the proteins symbolized by the tails. Protein subunits have the capacity for conformational switching needed to accommodate in this way to somewhat different packing environments, without sacrificing specificity. The alternative conformational states of a subunit then allow it to conserve many features of its interfaces with neighboring subunits ("quasi"-equivalence, as opposed to "strict" equivalence of interactions related to each other by the overall symmetry of the structure).[59]

Many plus-sense, ssRNA plant and animal viruses conform to this description of quasi-equivalent arrangements. In TBSV[163] and Norwalk and other caliciviruses,[313] there are 180 genetically and chemically identical subunits in the capsid. The subunits are actually larger than those of the picornaviruses, but most of the extra size comes from a second, projecting domain that serves functions other than the construction of a closed shell. The size of the "shell domain" ("S-domain") in both cases is about 200 residues, and the folded structure of the domain is a jelly-roll β-barrel. The TBSV diagram in Figure 3.9 illustrates important feature of the packing of these 180 S-domains. The contents of an icosahedral asymmetric unit can be described as three chemically identical subunits, with somewhat different conformations. These conformers are denoted A, B, and C, echoing the designation of commas in Figure 3.6. The principal differences among the conformers are an ordered or disordered conformation for part of the N-terminal arm and the hinge angle between the S-domain and the projecting, "P-domain." The A and B conformations are nearly identical, with disordered arms and similar hinge angles. The C conformation has an ordered arm and a different hinge angle from A and B. The ordered arms extend along the base of the S-domain and intertwine with two others around the icosahedral threefold axis. Thus, the whole collection of 60 C-subunit arms forms a coherent inner scaffold (Fig. 3.9).

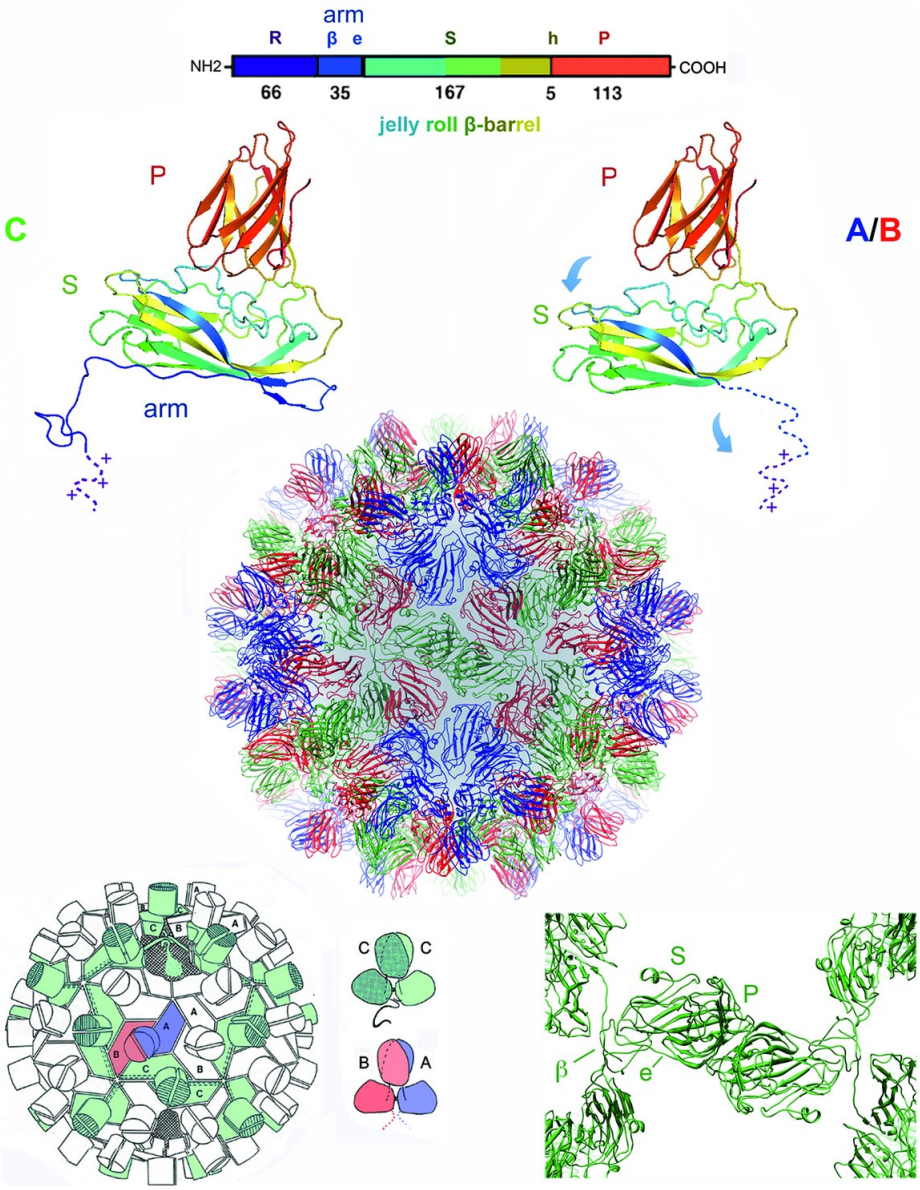

FIGURE 3.9 **Tomato bushy stunt virus (TBSV), a T = 3 icosahedral structure**. *Top*: Modular organization of the TBSV coat protein polypeptide chain. R: unstructured, positively charged N-terminal region. β, e: segments of the "arm," ordered on the C-conformation subunits and unstructured on the A- and B-conformation subunits; when ordered, the β segment forms an interdigitated "β-annulus" with corresponding segments from two other chains, and the e segment extends along the base of the subunit (see panel at *bottom*, *left*). S: shell domain, a β-jelly roll. P: projecting domain, a β-sandwich of somewhat different fold from the jelly-roll S-domain. h: hinge between the S and P domains. The color coding in the bar representation of the chain is repeated in the ribbon diagrams of the C (*left*) and A/B (*right*) conformations. Note that the two conformations differ in two respects: the ordering of the arm and the hinge angle between S and P domains (*curved arrows* on the right-hand ribbon diagram). *Center*: Ribbon representation of the entire protein coat of the virus; the colors of the A-, B-, and C-conformation subunits are as in Figure 3.6. *Bottom left*: Schematic figure, showing that the arms of the C-subunits (*green*) interdigitate around threefold axes of the icosahedral symmetry, forming a coherent inner framework. *Bottom right*: Magnified view of some of the C-subunits from the coat seen in the central part of the figure, illustrating the β-annulus (β) and the extended part of the arm (e). In the bottom center are schematic views of the C-C and A-B dimers, showing how the hinge between S and P domains correlates with the ordering of the arms. When ordered, the arms fit into the slot between S domains, which have rotated away from the contact that they have when the arms are unfolded into the particle interior).

How equivalent or nonequivalent are the actual intersubunit contacts in TBSV and related structures? Most of the interfaces are well conserved, with very modest local distortions that do not significantly change the way individual amino acid side chains contact each other. The interfaces between conformers that do exhibit noteworthy differences are those that include the ordered arms in one of the quasi-equivalent locations (the C-conformer). At these interfaces, there is a discrete switch between two states, with ordering and disordering of the arm as the toggle. Nonetheless, many side chain contacts are conserved around the "fulcrum" that relates an A/B dimer to a C/C dimer (Fig. 3.9).

Only certain multiples of 60 subunits can pack with the kind of quasi-equivalent contacts illustrated by the commas in Figure 3.6; these multiples are given by the formula $T = h^2 + hk + k^2$, where h and k are any integer or zero.[59] The multiple T is known as the "triangulation number," because, as illustrated by comparison of the 60- and 180-comma structures in Figures 3.4 and 3.6, they correspond to subtriangulations of an icosahedral net on the surface of a sphere. Such nets are known as "surface lattices." If we think of an icosahedrally symmetric structure as a folded-up hexagonal net (Fig. 3.10), then 12 uniformly spaced sixfold vertices are transformed into fivefold vertices.

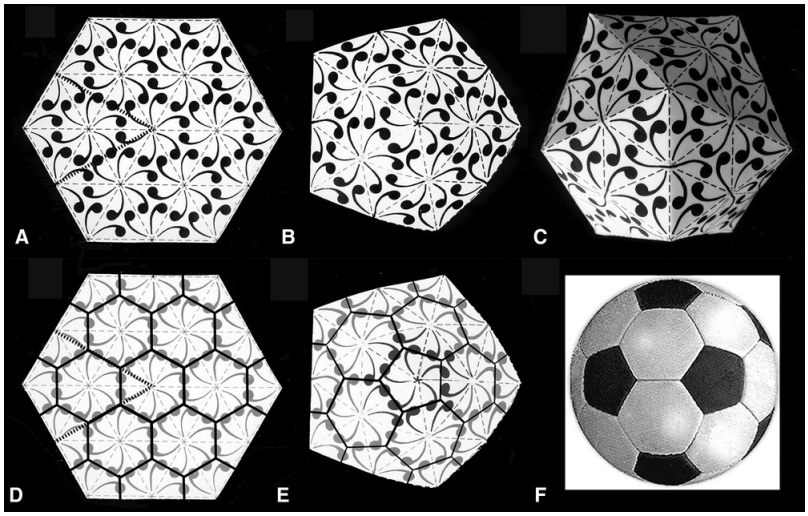

FIGURE 3.10 **Generation of curved structures from planar lattices**. **A**. Portion of a hexagonal lattice. Six triangular cells of the lattice meet at each lattice point, and each triangular cell contains 3 "subunits" (commas). Thus, there is a sixfold symmetry axis at each lattice point, a threefold symmetry axis at the center of each triangle, and a twofold axis at the midpoint of each edge. Imagine that the lattice extends indefinitely in all directions. **B**. Curvature can be introduced by transforming one of the sixfold positions into a fivefold (*center*). A 60° "pie slice" has been removed from the object in **(A)** by cutting along the *heavy dotted lines*, and the cut edges have been joined to generate the curved lattice shown here. **C**. If further cuts are made at regular intervals in an extended lattice, such as the one in **(A)**, and the edges joined as in **(B)**, a closed solid can be produced. In the case of the icosahedral solid shown here, vertices of the lattice separated by two cell edges have been transformed into fivefolds, while the intervening lattice points have been left as local sixfolds, producing a T = 4 (h = 2, k = 0) structure. Notice that the local sixfolds are actually only approximately sixfold in character; they correspond strictly to the twofold axes of the icosahedral object. **D**. Lines joining the centers of the triangular cells in **(A)** create a pattern of hexagons. **E**. When a sixfold is transformed into a fivefold, a hexagon becomes a pentagon. **F**. If second nearest-neighbor lattice points are all transformed into pentagons, a soccer-ball figure results. This is a T = 3 structure. A description of the lattice as a network of hexagons and pentagons is complementary to its description as a network of triangles. The representations in Figures 3.4B and C, 3.6, 3.7B and E, 3.10A-C, and 3.17A use triangles. The representations in Figures 3.10D-F and 3.17B use hexagons and pentagons. One representation for a given lattice can be derived easily from the other (compare Figs. 3.10A with 3.10D and 3.10B with 3.10E).

Other Types of Icosahedral Surface Organization

Hexagonal packing is an efficient way to "tile" a surface (think of hexagonal floor tiles), even if the building blocks themselves do not have sixfold symmetry. In many larger, icosahedrally symmetric virus particles, the outer-shell building blocks ("assembly units") are centered at the vertices of an icosahedral surface lattice, subtriangulated with one of the allowed T numbers, but the oligomeric building blocks themselves are not hexamers. In adenoviruses (Fig. 3.11), they are trimers, but with two similar β-barrel domains and a roughly hexagonal outline; a chemically distinct, pentameric building block, with a single β-barrel domain per subunit occupies the fivefold vertices. In the polyoma- and papillomaviruses, the assembly units are all identical pentamers (Fig. 3.1). Viewed at low resolution (eg, by negative-stain electron microscopy), all these viruses have globular "lumps" at the vertices of a lattice with one of the allowed triangulation numbers (T = 25 for the adenoviruses: Figure 3.11; T=7 for the polyoma- and papillomaviruses: Fig. 3.1), but when seen at higher resolution, the six-coordinated lumps are actually trimers or pentamers, respectively. The next section describes mechanisms by which assembly of these units conserves specificity of local interactions, an essential characteristic for well-defined molecular association in biology. The globular lumps seen by low-resolution electron microscopy were originally called "capsomeres" (meaning the "structural units" of the "capsid"); the word is still used when referring to apparent morphological units on the surface of a virus shell, particular for cases in which all capsomeres are the same and represent a defined oligomer, as in the pentameric units of polyoma- and papillomaviruses.

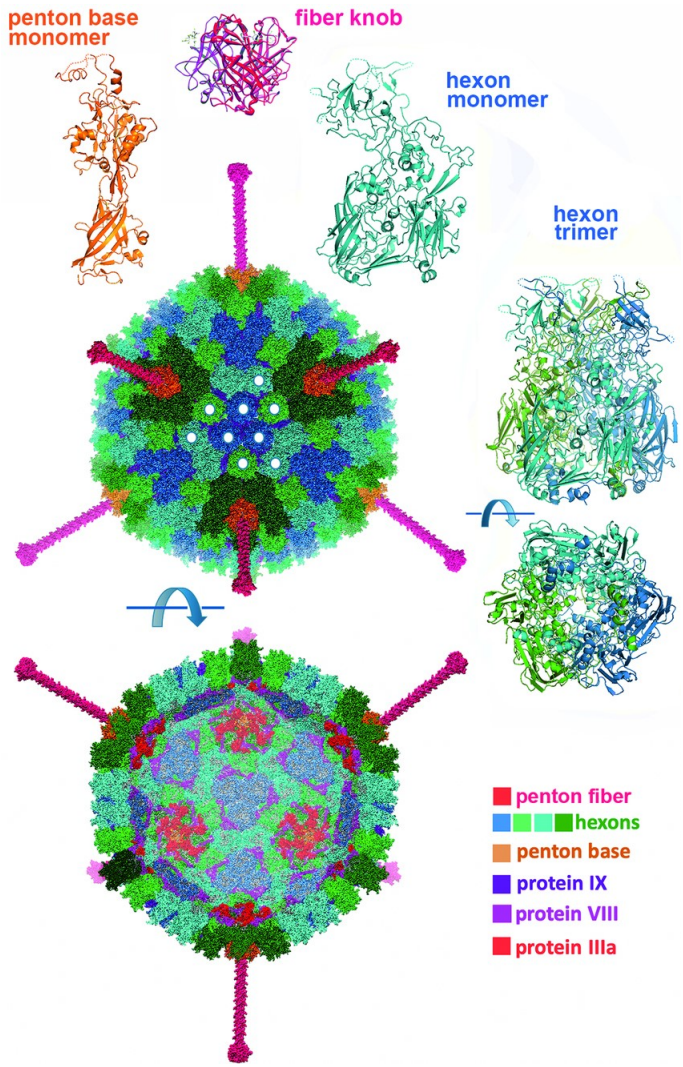

FIGURE 3.11 **Adenovirus capsid structure**. The principal building blocks—hexon, penton base, and penton fiber (trimeric rod with terminal knob)—are held together by "cement proteins" (pIIIa, pVIII, and pIX). The large images are an outside view of an adenovirus type 5 particle (*upper*) and a cutaway (note flip shown by *curved arrow*), showing the internal surface. The coiled DNA that fills the interior and proteins closely associated with it are not shown. The hexon monomer has two similar jelly-roll β-barrels; the trimer is, therefore, a pseudo-hexamer of those barrels. Note how an N-terminal extension of the monomer reaches under one of the two other subunits and how the "tower" of loops, which project to the outer surface of the virion, twists around so that the subunits intertwine tightly. Variation of these loops creates the principal antigenic differences among adenovirus serotypes. Each "group-of-nine" hexons (*white circles*, outside view) defines an icosahedral face. The cement protein, pIX (*purple*), inserts into grooves between hexons on the outer surface of the particle and holds a group of nine together; twenty such groups of nine make up most of the shell. Twelve "groups of six" (one penton base subunit, *orange-brown*, and five "peripentonal" hexons, *dark green*) fill the remaining gaps at each icosahedral fivefold position. The inside view shows the locations of pIIIA (*red*) and pVIII (*magenta*), which line the inner face of the shell at defined positions around the inward facing ends of the groups of six (really, 5 + 1) and the cluster of hexons (*dark blue*) at particle threefold axes, respectively. (Particle images courtesy of Z.H. Zhou: Liu H, Jin L, Koh SB, et al. Atomic structure of human adenovirus by cryo-EM reveals interactions among protein networks. *Science*. 2010;329:1038-1043; Dai X, Wu L, Sun R, Zhou ZH. Atomic structures of minor proteins VI and VII in human adenovirus. *J Virol*. 2017;91. Refs.[92, 236]). Subunit cartoons are from PDB 1X9P (penton base of adenovirus type 2) (Zubieta C, Schoehn G, Chroboczek J, Cusack S. The structure of the human adenovirus 2 penton. *Mol Cell*. 2005;17:121-135. Ref.[445]), 3EXW (fiber knob of adenovirus type 7) (Persson BD, Muller S, Reiter DM, et al. An arginine switch in the species B adenovirus knob determines high-affinity engagement of cellular receptor CD46. *J Virol*. 2009;83:673-686. Ref.[304]), and 1P30 (hexon of adenovirus type 5) (Rux JJ, Kuser PR, Burnett RM. Structural and phylogenetic analysis of adenovirus hexons by use of high-resolution x-ray crystallographic, molecular modeling, and sequence-based methods. *J Virol*. 2003;77:9553-9566. Ref.[342])

The flaviviruses illustrate yet another adaptation to icosahedral packing. The asymmetric unit of an icosahedral surface lattice can be represented by a (spherical) triangle with a fivefold axis and two adjacent threefold axes as its vertices (see Fig. 3.10). The flavivirus envelope protein (E) is a flat, elongated dimer[326]; three such dimers neatly fill a twofold-related pair of asymmetric-unit triangles, with the dyad of the central dimer coincident with the icosahedral twofold (Fig. 3.12).[215] The shell contains 180 subunits, but not in a T = 3 arrangement. Instead, there is a herringbone- or raftlike packing, with one dimer centered on an icosahedral twofold axis and a second dimer incorporated parallel to it, with only a local twofold axis relating its two subunits.

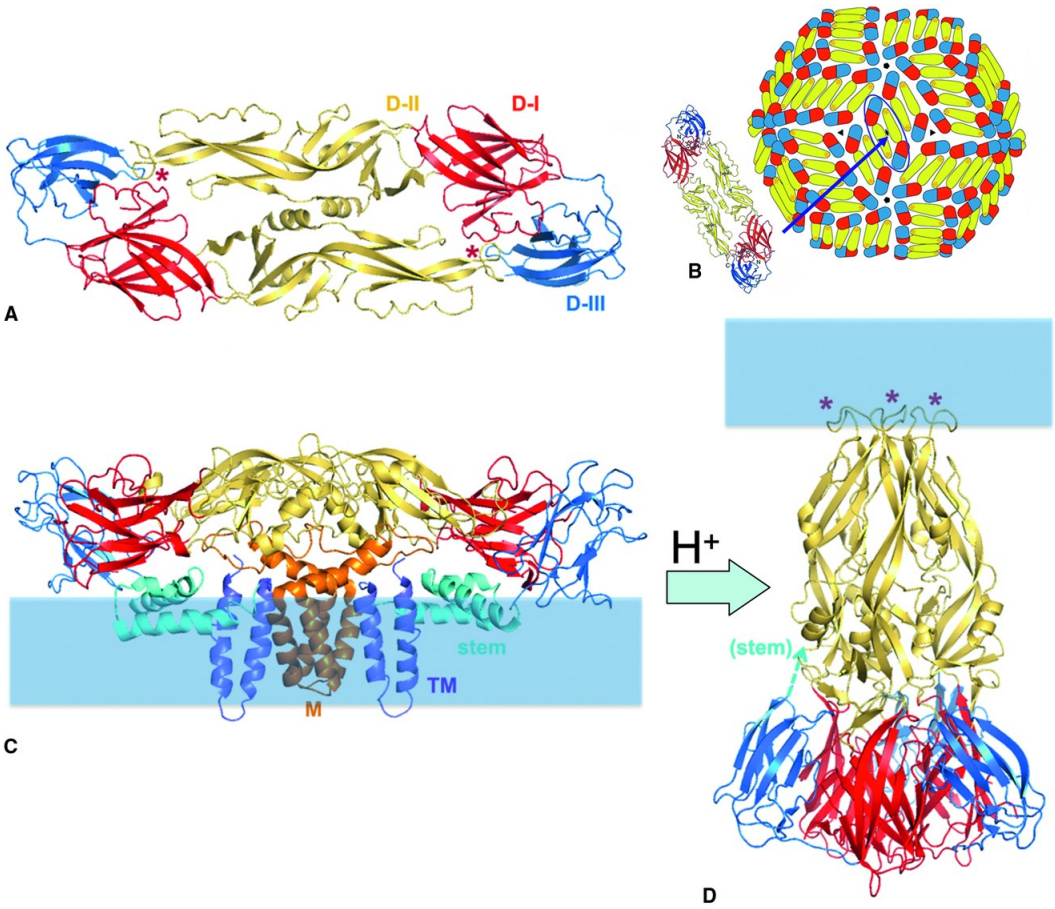

FIGURE 3.12 **Flavivirus structure**. **A**. A dimer of the dengue virus E-protein ectodomain in the conformation found on mature virions, viewed from outside the virus particle. Each subunit folds into three domains: a central domain I (*red*), an elongated domain II (*yellow*), which bears the fusion loop at its tip (*orange asterisk*), and an Ig-fold domain III (*blue*). Domain II folds from two long, disulfide-stabilized loops that emanate from domain I. The domain coloring is consistent throughout the figure. **B**. Packing of 90 E dimers on the surface of a mature virion. **C**. "Side" view of a full-length E dimer and an associated M dimer (*gold*), from a cryo-EM structure of a dengue virion (ref). The segment ("stem": *cyan*) that connects domain III with the transmembrane hairpin (TM: teal) is an amphipathic, three-helix bundle, lying at the hydrophilic-hydrophobic interface of the membrane bilayer (semitransparent *gray-blue*). **D**. Postfusion E trimer, from a crystal structure of the dengue virus E ectodomain. Other structures confirm that the polypeptide chain extends along domain III and that the distal part of the stem and the TM hairpin interact with the fused membrane. The fusion loops (*asterisks*) cluster to present a hydrophobic surface.

The arrangement of 120 copies of the inner- (core-) shell protein in dsRNA viruses is example of completely nonequivalent packing of two identical copies of a protein subunit (Fig. 3.13). There are two fully distinct environments for this protein (designated A and B in Fig. 3.13, lower right). The amino acid side chains on the lateral surface of the core-shell protein have different partners, depending on the interface in which they lie. The distortion of the subunit itself, when the VP2 subunits at A and B positions are compared, is quite small.

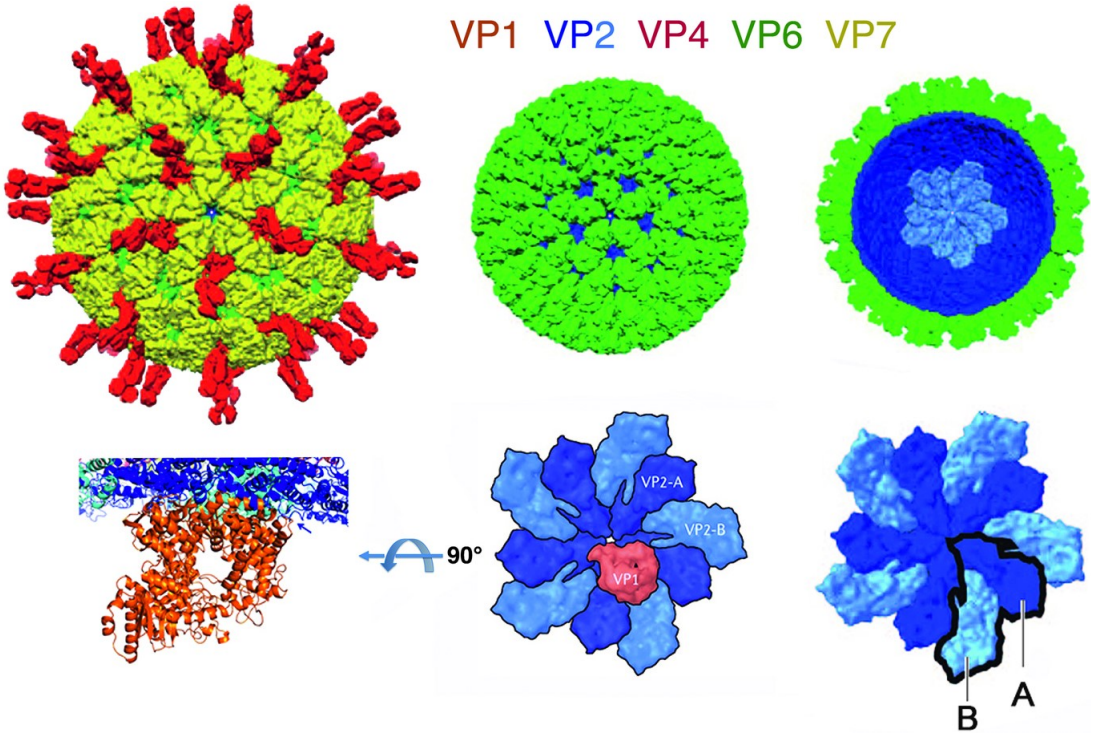

FIGURE 3.13 **Rotavirus**. Subunits colored as in the key at the top. **Top row**, *left to right*: Surface views of the triple-layer particle (TLP); double-layer particle (DLP); and DLP cutaway across the middle of the particle, showing an inside view of the VP2 layer. One VP2 decamer is in a lighter color. All views are along a fivefold axis. The eleven segments of the dsRNA genome (not shown here) fill the cavity of the particle. **Bottom row**, *right*: Magnified view of the central VP2 decamer in the cutaway view above it. The two VP2 conformers, designated A and B, are now in *dark blue* and *light blue*, respectively. The platelike subunit has a crudely triangular shape as it tapers toward the fivefold axis. A solid black border outlines one A-B pair. Note that at the A:B interface within this pair, the A subunit contacts B along a surface of the latter proximal to the apex of the triangle, whereas at the B:A interface across the *black line*, the corresponding part of the B subunit contacts a surface on A distal to the apex. That is, the contacts are completely nonequivalent. **Bottom row**, *center and left*: Position of a single VP1 (polymerase and capping enzyme) with respect to a VP2 decamer. In the tangential view on the left, the subunits are in "cartoon" representation.

Frameworks and Scaffolds

Accuracy of assembly is critical for efficient production of infectious particles. The protein subunits of TBSV or picornaviruses have extended N- or C-terminal arms augmenting a central jelly-roll β-barrel. These arms form an internal framework, such as the one illustrated for TBSV in Figure 3.9. The TBSV "assembly unit"—the oligomer of the coat subunit that forms spontaneously in solution (and by inference, in the cell following its synthesis)—is a dimer, which can have two conformations—an "A/B" dimer, with disordered N-terminal arms, and a "C/C" dimer, with folded arms.[159] The local curvature of those two conformations is different, and the framework of C/C arms fixes the overall diameter of the particle. Removal of the N-terminal arms of TBSV-like subunits leads to self-assembly of a small, 60-subunit icosahedrally symmetric particle that cannot package RNA.[136] That is, without the arms, there is no mechanism for a conformational switch. Moreover, the way the C/C arms link at threefold axes creates a framework that requires pentamers of A/B dimers to fill the gaps around fivefold axes. Related mechanisms, with variations, regulate assembly of caliciviruses.[71,201,313]

In the papilloma- and polyomaviruses, N- and C-terminal extensions (principally the latter) of the subunit globular domains tie together the pentameric building blocks, which have almost no contacts except through these extensions (Fig. 3.14).[232,365,366,415] Flexibility of the arms allows formation of the different kinds of contacts required to surround a pentamer with six other pentamers (ie, to position a pentamer at the 6- as well as at the 5-coordinated vertices of a T = 7 subtriangulated icosahedral lattice). The C-terminal arms emanate from one pentamer and dock into another. The way they dock is the same for all 360 arms, with identical interactions locking them in place, but not their configuration between the point at which they emerge from the globular domain of their subunit of origin and the point at which they dock into their target subunit. This is a different sort of "quasi" equivalence than the one described by Caspar and Klug.[59] All the nonequivalence is incorporated into a short segment of the C-terminal arm as it traverses from its pentamer of origin to its docking site in its target pentamer.[365]

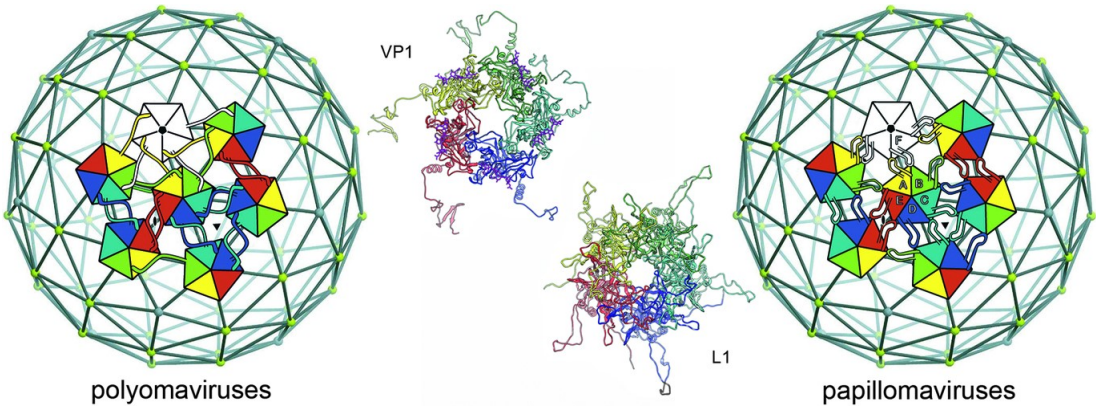

FIGURE 3.14 **Packing of pentamers in the capsids of polyoma- and papillomaviruses**. The ribbon diagrams in the center show pentamers of VP1 (polyomaviruses) and L1 (papillomaviruses), viewed from their outward-facing surfaces. Note the C-terminal arms of the subunits, which extend away from the pentamers in VP1 but loop back to it in L1. The schematic diagrams to the *left and right* illustrate the packing of these pentamers in the virion shell. The framework shows a T = 7 icosahedral lattice; VP1 or L1 pentamers are centered on both 6- and 5-coordinated positions.

Larger and more complex structures, such as adenoviruses (Fig. 3.11), have separate framework proteins, rather than using long extensions emanating from the folded domain(s) of a subunit.[218,236,322] The principal outer shell components of adenoviruses are "hexons," trimers of a subunit with two, similar jelly-roll domains[328] and "pentons," pentamers of a subunit with a single jelly-roll β-barrel domain.[445] If all the jelly-roll β-barrels were the same, the structure would correspond to T = 25 quasi-equivalence, just as if all the picornavirus jelly-roll β-barrels were the same, the particles would be T = 3 shells, like TBSV and its plant-virus relatives. A set of additional proteins cements the adenovirus structure together and determines its size (Fig. 3.11).[92,128,236,367,368] The elaborate interaction patterns of these "cement" proteins stabilize a "group of nine" hexons, centered on the icosahedral threefold axis, and a "group of six" (five hexons surrounding a penton), centered on the icosahedral fivefold axis.[223,236] The structures of adenovirus-like bacteriophages, PRD1[26] and PR772,[320] show a somewhat simpler size-determining and stabilizing framework: a "tape-measure protein" extends from the penton toward the icosahedral twofold axis, where it interacts with an identical protein running toward it from the twofold related penton (Fig. 3.15).[3] Unlike adenoviruses, the adenovirus-like bacteriophages have a lipid-bilayer membrane between the P3 layer and the internally coiled DNA.[10,17,78]

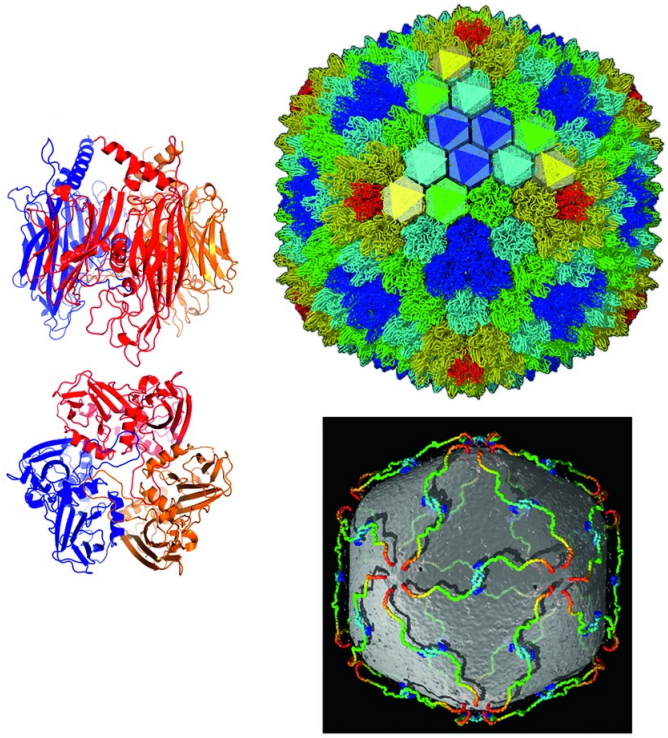

FIGURE 3.15 **Bacteriophage PRD1**. *Left*: Side and bottom views of the "hexon" protein, P3. The colors correspond to those in the ribbon diagrams of the adenovirus hexon trimer in Figure 3.11. Like the adenovirus hexon, P3 has two jelly-roll β-barrels, but the loops that project outward are much less elaborate (Courtesy of David I. Stuart, Oxford University. [Please cite the existing credit lines as references (Kindly refer to manuscript, prev. ed.). Ref.[26]). The image on the *upper right*, based on a crystal structure of the intact phage particle, is a view along a twofold axis. One threefold set of P3 trimers is highlighted by triangles. The pentons (P31) are in *red*. At the *lower right* is a view with the outer layer stripped away, to show the extended "tape-measure" protein, P30, which helps determine the size of the shell, and the lipid bilayer just beneath it. There are 60 copies of P30; each chain extends from a twofold axis (N-terminal end, *blue*) to the inner surface of a penton (C-terminal end, *red*). At the twofold axis, one P30 associates with a second, twofold-related P30.

During assembly of the heads of most double-stranded DNA bacteriophages, an internal scaffold protein directs formation of an empty precursor known as a "prohead."[54,123] Assembly of proheads that can package DNA often nucleates around scaffold components associated with the dodecameric "portal protein" situated at the unique vertex through which DNA will enter and leave and to which the tail structure will attach after DNA filling is complete.[98] Conformational signals related to DNA packaging trigger release and recycling (eg, P22) or degradation (eg, T4) of the scaffold, accompanied by a reorganization and expansion of the head (Fig. 3.16A-D).[114,199] In bacteriophage HK97, the scaffold is an N-terminal extension of the T = 7 capsid subunit, cleaved from the rest of the protein in the transition from prohead to head.[82,168,180,222,409] In dsDNA bacteriophages, and in adeno- and herpesviruses, DNA is pumped into the empty head, through the portal protein, until it reaches the tightly coiled state illustrated in Figure 3.16E.[115,116,363]

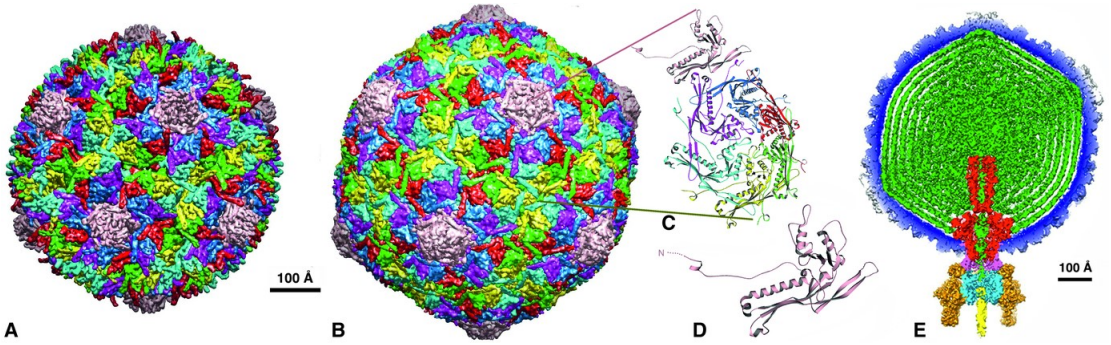

FIGURE 3.16 **Capsid reorganization and DNA packaging in tailed bacteriophages**.[199] **A**. Surface of the HK97 procapsid. The surface organization is a locally distorted T = 7 arrangement, with fivefold symmetric association of the subunit at the fivefold positions (beige) but a skewed arrangement in the rings of six subunits that surround a local six-coordinated position (colored in *magenta*, *blue*, *red*, *green*, *yellow*, *cyan*, in clockwise order).[82] An N-terminal extension of the head subunit is the scaffold for prohead assembly; its cleavage by a coassembled protease triggers rearrangement of the subunits into the expanded, thinner, more angular shell illustrated in panel **(B)**.[111] **B**. Capsid (head) of the mature HK97 particle; molecular surface, based on crystallographic model, colored as in A.[409] This view is oriented so that a fivefold axis is vertical. The image is derived from the structure of an empty capsid with 420 subunits in a T = 7 icosahedral lattice. In a wild-type bacteriophage particle, a portal protein connected to a tail replaces one of the rings of five subunits (see panel **E**). **C**. Expanded view in ribbon representation of one icosahedral asymmetric unit (ie, one of the five subunits in the pentameric ring and one each of the quasi-equivalent subunits in the hexameric ring). All subunits are chemically identical. In HK97, but not in many related bacteriophages, an intersubunit isopeptide bond, which forms during maturation, cross-links the entire coat.[111] **D**. A further enlarged view of a single, 31 kDa subunit. The 105-residue N-terminal extension that functions as an assembly scaffold is indicated schematically by a *dotted line*. **E**. Cutaway representation of a three-dimensional cryo-EM image reconstruction of bacteriophage P22. Its assembly is formally similar to that of HK97, but there is a distinct, recycled scaffold protein[54] and no covalent cross-linking of the head.[298] The packaged DNA (*green*) winds tightly around an internal extension of the portal protein (*red*).[286,378] (Images in **A–D** from VIrus Particle Explorer [VIPERdb] Website, http://viperdb.scripps.edu/. Ref.[321])

Mass Production and Specificity

A fundamental principle embodied in all the various structures just described is one of mass production. One or more standard building blocks assemble into the larger structure. In simple (T = 1) cases, such as the parvoviruses and picornaviruses, a repeating set of identical interactions determines the final structure. In the T = 3 structures (eg, many plant viruses; caliciviruses), the building block is a subunit dimer, which has two, scaffold-regulated states. In polyoma- and papillomaviruses, the building block is a pentamer of the major capsid protein, again with two states (penta- and hexa-coordinated), probably switched by interpentamer contact of the C-terminal arms.[365,366] In more elaborate cases, such as adenoviruses, the basic subassembly building blocks are hexons and pentons, and the groups of nine and six may represent further assembly intermediates, stabilized by modulators (eg, the minor "cement" proteins) to ensure the correct relative placement of hexons and pentons and a well-determined overall outcome.[323,345,425] Hierarchies of subassemblies characterize very complex particles, such as tailed bacteriophages. Head assembly and tail assembly are separate pathways, and only fully assembled, DNA-filled heads and fully assembled tails then join, ensuring that an error in one subassembly does not waste components and energy that went into the other.[54] Budding of many enveloped viruses, with distinct subassemblies for the internal and external components, embodies a similar principle.

Elongated Shells

The examples in Figure 3.17 illustrate elongated particles with caps at either end. In many of the dsDNA bacteriophages, the shell looks like a familiar icosahedral design at the poles. As the lattice approaches the equator, however, the regular interspersion of fivefolds and local sixfolds gives way to local sixfolds only, so that there is a tubular region around the middle of the particle (Fig. 3.17A).[380] The tubular region can be of varying extent; in extreme cases, it can be much longer than the caps themselves. A "Q number," analogous to the T number, describes both the extent of the equatorial tube and the rotational offset of the two, hemi-icosahedral caps.[123,266] A further variation on this theme is found in the shells formed by the CA fragment of the lentivirus Gag protein. Conical structures seen within HIV-1 particles (Fig. 3.3D) have been shown to be based on the sort of arrangement shown in Figure 3.17B, where one cap has more than 6 fivefold positions and the other has less, so that the diameters of the two caps are different.[131,132,253] (Note that if there are only sixfold and fivefold vertices in a closed surface lattice, there will always be exactly 12 of the latter.)

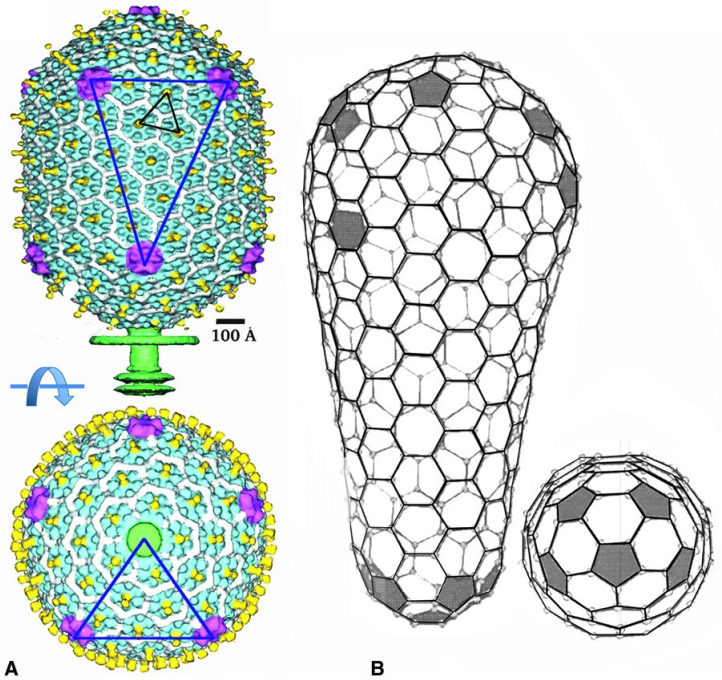

FIGURE 3.17 **Elongated shells with icosahedral caps**. **A**. Surface of a mature bacteriophage T4 head, viewed normal to the principal axis (*top*) and along the principal axis from the tail (*bottom*). The principal axis is a fivefold axis of the top and bottom caps, which are hemi-icosahedra with a T = 13l lattice. The processed major capsid protein, p23*, is in *blue*; the processed fivefold protein, p24*, in *magenta*; accessory proteins, somewhat similar in function to the adenovirus "cement" proteins, are soc, in *yellow*, and hoc, in *light gray*. The proximal segment of the tail is in *green*. An equatorial band of p23* hexamers elongates the structure: the larger, skewed triangle joins three p24* pentamers that would otherwise be related by an icosahedral threefold axis (*smaller triangle*). (Modified from Fokine A, Rossmann MG. Molecular architecture of tailed double-stranded DNA phages. *Bacteriophage*. 2014;4(1):e28281. Copyright © 2014 Landes Bioscience. Imagine each hexagon and pentagon to contain six and five CA subunits, respectively. Seven sets of locally fivefold-related subunits (*shaded pentagon*) in the upper cap and five sets in the lower one, connected by bands of sixfold-related CA subunits, generate a tapered, conelike shell. On the lower right is a view of the smaller tip of this particular capsid lattice. Note that the (local) fivefolds are not uniformly spaced, and that neither cap has overall fivefold symmetry. (Adapted from Ganser BK, Li S, Klishko VY, et al. Assembly and analysis of conical models for the HIV-1 core. *Science*. 1999;283(5398):80-83. Reprinted with permission from AAAS. Ref.[131])

Multishell Particles

Most dsRNA viruses have a genuinely multishell icosahedral organization, with some common features and some variation from group to group (see Chapters 11-13, volume 3). In virions of the mammalian dsRNA virus groups (reoviruses, rotaviruses, and orbiviruses), the innermost protein shell contains 120 copies of a large, platelike protein[145,254,324] (Figs. 3.13 and 3.18). Surrounding the inner shell is a second characteristic layer, containing, in most cases, 780 copies of a trimeric protein with a radially directed jelly-roll β-barrel and inwardly directed N- and C-termini, which together form a largely α-helical "base" domain.[144,233,251] This second layer corresponds closely to a "classical," quasi-equivalently packed, T = 13 icosahedral shell—all the interactions between adjacent trimers are variations on the same set of contacts.

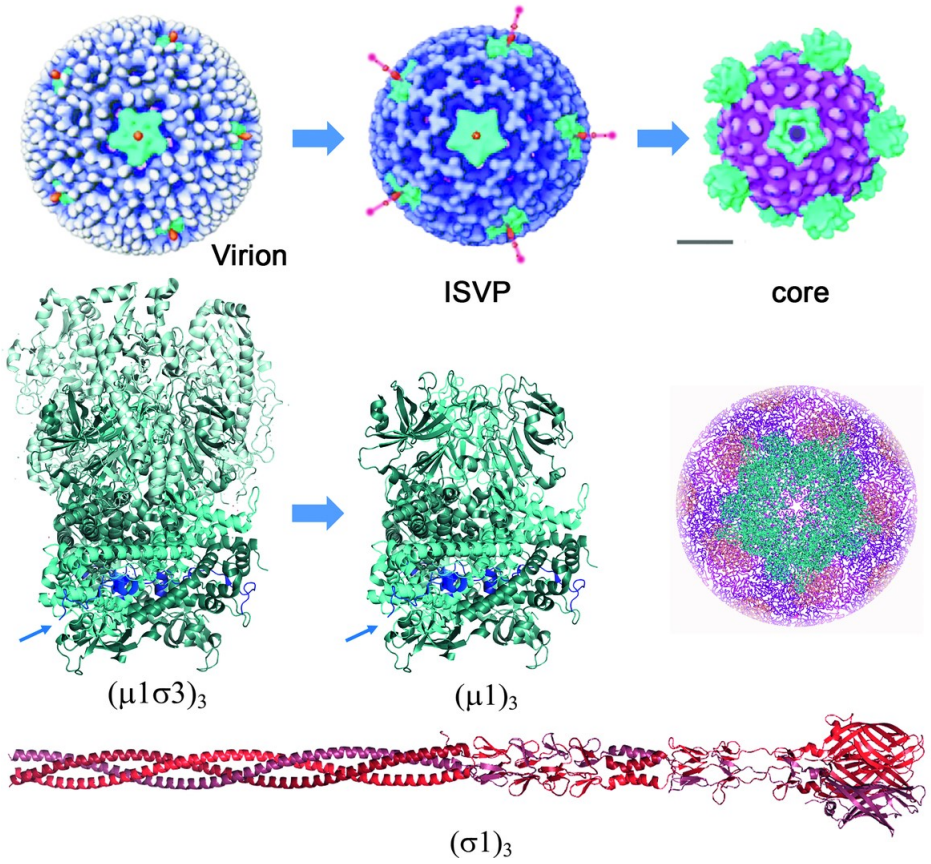

FIGURE 3.18 **Reovirus structure and transitions during reovirus entry**. *Top row*: Surface renderings of reovirus particle (*left*), infectious subviral particle (ISVP: *center*), and core (*right*). The pentameric turrets of λ2, the RNA capping protein, project through the outer shell, a fenestrated, T = 3 laevo, array of μ1σ3 heterohexamers. Proteolysis (*first large arrow*), either by cathepsins in late endosomes or by proteases in the gut, removes σ3 and stiffens the trimeric, receptor-binding spikes of σ1 (*bottom row*[104,325]), which project from the λ2 turrets. The knobs at the tip of the spikes bind receptor. Scale bar = 200 Å. (Figure adapted from Dryden KA, Wang G, Yeager M, et al. Early steps in reovirus infection are associated with dramatic changes in supramolecular structure and protein conformation: analysis of virions and subviral particles by cryoelectron microscopy and image reconstruction. *J Cell Biol*. 1993;122:1023-1041. Ref.[109]) *Middle row*: Backbone cartoons of $(\mu1\sigma3)_3$ (*left*) and $(\mu1)_3$ (*center*). The σ3 subunits are in *light blue-gray* shades; μ1 subunits are in *cyan* and two darker, related shades. The first 42 residues, myr-μ1N, separated from the rest of μ1 by autolytic cleavage, are in contrasting shades of *blue*. *Small arrow* marks the first ordered residue in the structure, near the N-terminus of μ1N; the myristoyl group may insert back into a hydrophobic slot just above the position at which the N-terminus emerges.[233,438] μ1N, released from the receptor-bound ISVP, forms membrane pores, apparently facilitating release of the core particle into the cytosol; the specific, molecular trigger of μ1N release is not known. Middle row (right): Close-up of the λ2 turret (from PDB:1EJ6). *Bottom row*: σ1 spike in cartoon representation. The three identical subunits are in contrasting shades of red. Composite of PDB:6GAP and PDB:3S6X. See Ref.[104].

Various elaborations and simplifications of the two-layer design just described differentiate the families of dsRNA viruses. For example, in the orthoreoviruses (Fig. 3.18), the T = 13 layer has gaps, through which pentameric "turrets" of yet another protein, anchored on the inner shell, project; only 600 of the potential 780 subunits are present.[46,109,324] The birnaviruses lack the 120-subunit layer altogether and have instead 780 copies of a single major capsid protein, with a shell domain that resembles those of plant and insect viruses and a trimer-clustered projecting domain that resembles the jelly-roll β-barrel in the T = 13 shell of rotaviruses and orbiviruses.[83] The T = 13 packing of the shell domain so closely recalls that of its counterparts in T = 3 and T = 4 positive-strand RNA virus structures that an evolutionary common origin of those domains seems plausible. Similarities in the RNA-dependent RNA polymerases of these viruses also suggest some shared ancestry.[293] The dsRNA bacteriophages such as φ6 contain the 120-subunit, inner shell layer and a fenestrated, T = 13 layer (rather like reoviruses), enclosed within a lipid bilayer membrane.[46,181,190,401]

Rearrangements in Surface Lattices

Icosahedral surface lattices can undergo rearrangements, which preserve the overall symmetry of the structure but change the pattern of specific intersubunit contacts. There can be an accompanying change in the diameter of the shell. These rearrangements are cooperative—that is, they occur more or less simultaneously across the whole structure. They are also "displacive"—that is, they do not require dissociation and reassociation but are instead smooth transitions from one end state to another. When dsDNA bacteriophages such as P22 insert their genomic DNA into a preformed prohead, the outer shell of the prohead expands as its subunits shift around to form the mature structure[54,82,196,199,222] (Fig. 3.16). Another well-characterized example is expansion of the T = 3 plant viruses, which occurs when the calcium ions that stabilize a particular set of subunit interfaces are removed[16,329] (Fig. 3.19). This swelling is probably the first step in disassembly: plant viruses, when injected by their vectors into the cytoplasm of a recipient cell, are exposed to a low Ca^{2+} environment. A transient expansion occurs when poliovirus binds its receptor.[24] In both the T = 3 plant viruses and the picornaviruses, internally directed "arms" of the protein subunits move

outward from the interior as expansion creates gaps in the shell. Exposure of the arms may be part of the uncoating process in the case of the plant viruses or of the membrane-penetration process in the case of the picornaviruses. Cooperativity of these rearrangements implies that a few points of inhibition can prevent the change. For example, only a few intersubunit cross-links from bound neutralizing antibodies are sufficient to block infection by a picornavirus particle.[118] The same may be true of small molecules that inhibit the subunit conformational changes needed for the receptor-triggered expansion of picornaviruses.[13,307,364]

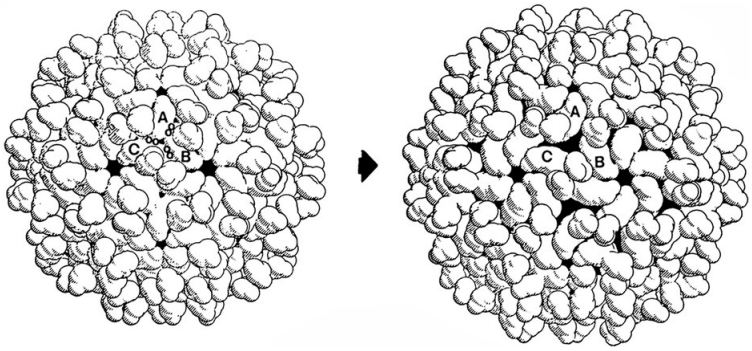

FIGURE 3.19 **Expansion of TBSV**.[329] The mature, compact particle (*upper left*) expands when Ca^{2+} ions (*small circles*) are removed. The expanded form (*upper right*) is reached by a smooth transition, in which many of the intersubunit contacts are conserved. The contacts that included the ions in the compact state have separated substantially, creating a fenestrated shell.

Helical surface lattices can also rearrange without dissociating. Contraction of bacteriophage tail sheaths is a good example (Fig. 3.20).[8,265,383] Shortening of the sheath when released from the tail plate by interactions with a bacterial cell surface is a smooth transition from one set of helical parameters to another, without gain or loss of subunits.

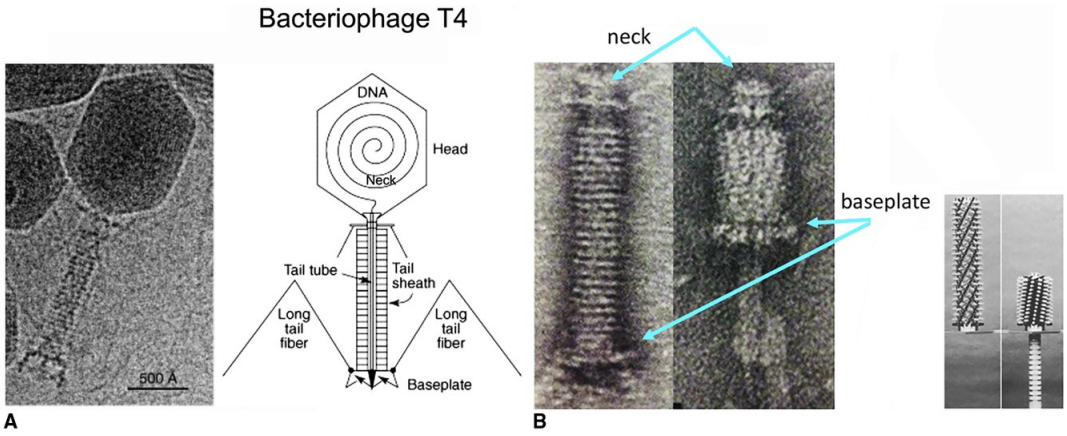

FIGURE 3.20 **Contraction of bacteriophage T4 tail sheath**. An illustration of a smooth, nondisplacive change in a structure with helical symmetry Ref.[58] **A**. Micrograph and diagram of overall structure of bacteriophage T4.[339] **B**. Surface renderings from electron micrographs of particles with extended (*left*) and contracted (*right*) tail sheaths. As the sheath contracts, it maintains its connections to the neck and baseplate, so that the baseplate—attached through tail fibers to the cell wall of the bacterium being infected—translates along the tail core, driving the tip of the core into the cell, as. Morphogenesis of the T4 tail and tail fibers. *Virol J.* 2010;7:355. http://creativecommons.org/licenses/by/2.0. Ref.[224a])

Two Recurring Globular-Domain Structures in Icosahedral Capsid Proteins

The icosahedrally symmetric shells of nearly all well-characterized, nonenveloped viruses contain one of two types of globular domain. (The known exceptions at the time of writing this chapter are the RNA bacteriophages—R17, Qβ, and their relatives[389]—and the dsRNA picobirnaviruses.[112]) One is the jelly-roll β-barrel in viruses of animals and plants, which we have described in various examples of viruses of animals and plants; it is also the principal component of icosahedral ssDNA bacteriophage capsids (eg, ϕX174).[255] The various ways this module can form a coat are quite different, and we have emphasized above the importance of framework or scaffolding components (either as extensions of the polypeptide chain of the β-barrel or as separate protein species) in directing or regulating coat assembly. What sort of evolutionary parsimony resulted in such widespread appearance of a single kind of protein module is not evident. Viruses can jump from plants to insects and from insects to vertebrates, so for these viruses, the recurrence of the jelly-roll β-barrel is unlikely to reflect a common origin that antedates host divergence. The recurrence is more likely the result of selection and gene exchange among already widely diverged host organisms.

The second recurring globular domain in viral coat proteins was discovered initially in the coat of dsDNA bacteriophage such as HK97 and subsequently found in most other dsDNA bacteriophages (T4, lambda, P22, etc.). This “HK97 fold” (Fig. 3.16) is also the core of the herpesvirus capsid subunit.[14,107,426] Like their bacteriophage cousins, herpesviruses pump their genome DNA into a preformed shell through a specialized icosahedral vertex and a dodecameric “portal protein.”[63,212,278,279] Adenoviruses, and probably their bacteriophage cousins like PRD1, with hexonlike capsid subunits, are also thought to insert DNA into a preassembled empty capsid, but the motors that effect the insertion seem to be

different from those in the herpesviruses,[189,287,433,434] and the coupling of packaging and DNA replication is different.[60] Thus, the structures of the coat proteins of two major classes of dsDNA viruses correlate with the machinery by which members of each of these classes package DNA.

Genome Packaging

Incorporation of viral nucleic acid must be specific, but it must also be independent of most of the base sequence of the genome. Therefore, viral genomes generally have a *packaging signal*—a short sequence or set of sequences that directs encapsidation. Recognition of the packaging signal depends on the nature of the genome and on the complexity of the assembly mechanism. For many plus-sense, ssRNA viruses, there is a direct interaction between the packaging signal and the capsid protein. dsDNA viruses insert genomic nucleic acid into a preformed shell, and genome recognition is a property of the virus-encoded packaging system. Negative-strand RNA viruses also rely on close coupling of replication and packaging of the RNA into an RNP.

Positive-Strand RNA Genomes

Viruses with plus-sense, ssRNA genomes (eg, most icosahedral plant viruses; picornaviruses; alphaviruses; flaviviruses) require no definite overall secondary or tertiary fold for the genomic RNA, aside from the restriction that it fits within the shell. This restriction is actually quite severe, and the RNA is packed very tightly, approximating the density of RNA in crystals.[271] Even random-sequence RNA contains a substantial fraction of its nucleotides in base-paired stem loops and related secondary structures[140]; to fit efficiently within the interior of a capsid, the RNA must pack with many of these segments of structured RNA in contact with the inward-facing surface of the shell. This result can be achieved by assembly around the RNA, without specific capsid-RNA interactions except for the packaging signal(s). Nonetheless, even in icosahedrally averaged crystal structures, segments of partially ordered RNA can often be detected, sometimes tucked into shallow grooves on the inner capsid surface.[72,120] Recent evidence, both for RNA bacteriophages and for enteroviruses, suggests that some of these segments resemble distributed packaging signals.[333,353]

In RNA bacteriophages such as MS2 and R17, a translational regulatory sequence that is probably also the principal packaging signal folds into a stem-loop structure (Fig. 3.21A).[20] A dimer of the coat protein, the assembly unit for the T = 3 particle, recognizes this structure and binds it specifically.[52,390,391] Bases in the loop and a looped-out base in the stem fit into a groove on the inward-facing surface of the subunit dimer; conserved bases make defined protein contacts. The interaction requires that the coat-protein dimer be in the A/B conformation (the conformation of the 60 dimers not centered on icosahedral twofold axes: Fig. 3.21B), and hence it is effectively a conformational switch, like the N-terminal arms in TBSV, SBMV, and many other T=3 plant viruses.[369] Degenerate versions of the specific packaging sequence are present throughout the genome; cross-linking studies and cryo-EM structures done without imposing icosahedral symmetry suggest that these more weakly binding elements may account for interactions with many of the A/B dimers, in addition to the dimer that binds the translational regulatory site.[91,211,333] The maturation protein, which replaces one dimer in the T = 3 lattice and which interacts with an F-pilus to deliver the RNA to a bacterial cell, binds stem loops at both ends of the genome.[91,211] The redundancy of packaging signal interactions can explain the robustness of specific assembly and its lack of sensitivity to mutations in the principal packaging signal. Cross-linking studies have suggested a similarly distributed set of degenerate packaging signals in parechoviruses—a group of picornaviruses.[353] Essentially all proposed or well-documented packaging signals have stem-loop structures, with one or more conserved nucleotides (or nucleotide types) exposed at the loop.

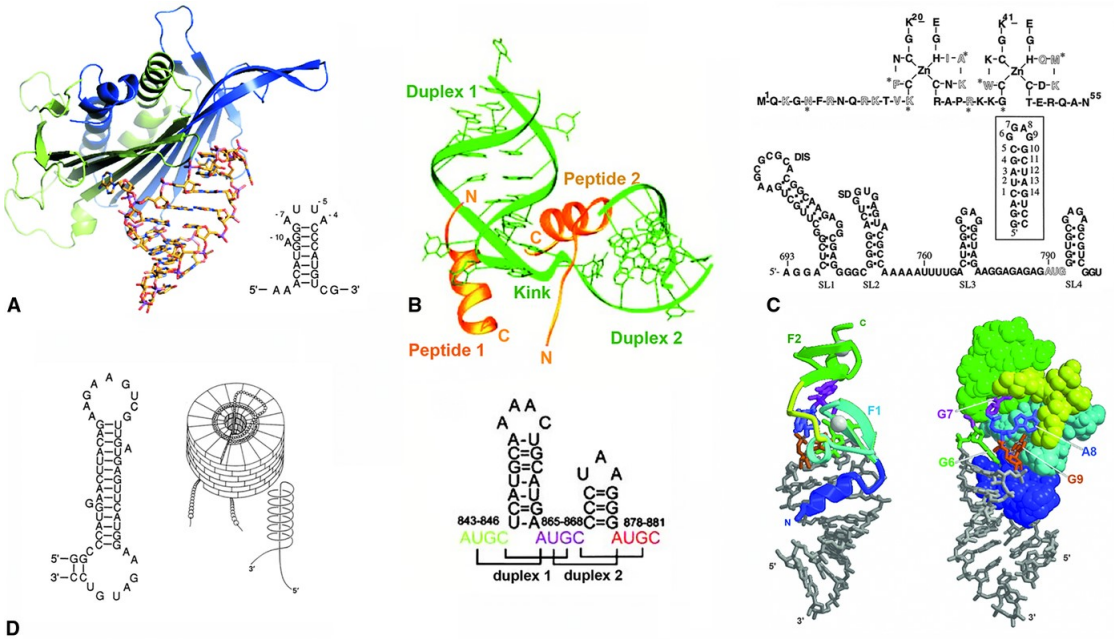

FIGURE 3.21 **Various modes of ssRNA recognition and packaging**. **A**. RNA bacteriophage. A stem-loop (sequence shown as *inset*) packs against the inward-facing surface of a protein-subunit dimer; there are specific contacts between residues in the protein and four unpaired bases (–4 –5, –7, –10). (Adapted from Valegård K, Murray JB, Stonehouse NJ, et al. The three-dimensional structures of two complexes between recombinant MS2 capsids and RNA operator fragments reveal sequence-specific protein-RNA interactions. *J Mol Biol*. 1997;270(5):724-738. Ref.[391]) **B**. Alfalfa mosaic virus. A folded, stem-loop, RNA structure (*green*) is a docking site for two N-terminal subunit arms (*gold*). The arms are unstructured until they associate with the RNA. (Modified from Guogas LM, Filman DJ, Hogle JM, et al. Cofolding organizes alfalfa mosaic virus RNA and coat protein for replication. *Science*. 2004;306(5704):2108-2111. Reprinted with permission from AAAS. Ref.[152]) **C**. HIV-1. Two "zinc-knuckle" domains (labeled F1 and F2 in the ribbon representation at

the *lower left*), near the C-terminal end of the Gag polyprotein (sequences shown at the *top*), bind a stem-loop structure in the packaging signal of the genomic RNA (*center and bottom*). Purine bases that have conserved stacking interactions are labeled in the surface representation at the *lower right*. Adapted from De Guzman RN, Wu ZR, Stalling CC, et al. Structure of the HIV-1 nucleocapsid protein bound to the SL3 psi-RNA recognition element. *Science*. 1998;279(5349):384-388. Reprinted with permission from AAAS. Ref.[96]) **D**. Tobacco mosaic virus.[47,387,444] The sequence at which RNA packaging initiates, shown on the left, is roughly 500 nucleotides from the 3′-end of the genome, and assembly of the helical particle proceeds by addition of subunits at one end of the growing helix, drawing the 5′ end up through the center of the particle, as shown on the right. Coating of the 3′ overhang proceeds more slowly at the other end of the particle.

Other nonenveloped, positive-stranded RNA viruses of eukaryotes recognize their genomic RNA, not through a groovelike site on the protein, but rather through a flexibly extended, positively charged protein arm, often at the N-terminus of the coat protein. There is an interaction of this kind between the coat protein of alfalfa mosaic virus (AMV) and a 3′-terminal segment of RNA.[152] A bound coat protein dimer is essential for replication—probably to recruit the RNA-dependent RNA polymerase. The same interaction is also likely to initiate packaging. The dimer contacts a pair of tandem RNA hairpins through a 26-residue, N-terminal arm. The two arms and the two RNA stem loops fold together into a well-defined structure, cross strutted by base pairing between conserved AUCG sequences that follow each stem (Fig. 3.21C). There are six such stem loops in the 3′ segment of the viral genome; it is possible that binding of three coat-protein dimers initiates shell assembly. Other stem-loop elements could in principle make weaker and less specific versions of this kind of interaction, but the net-positive charge of the N-terminal extensions may be sufficient for less specific condensation of the RNA.

The enveloped alphaviruses also have a multistem-loop packaging signal, recognized (with structural details not yet determined) by an extended, positively charged N-terminal arm of the nucleocapsid subunit.[39,40,126,206] There appears to some redundancy in the stem loops, all of which contain a GGG trinucleotide in the loop, as deletion of several of the eight stem loops does not compromise the efficiency of RNA packaging and virion assembly.

Retroviral packaging signals, known as *psi* sequences, associate specifically with the nucleocapsid (NC) domain of the Gag protein.[110] The dimeric 5′ leader of HIV-1 has over 20 such NC binding sites,[105] at least two of which associate specifically as stem-loop structures with two "zinc-knuckle" modules in HIV-1 NC[96,204,245] (Fig. 3.21D). The two zinc modules are flexibly linked in unbound NC, but they adopt a defined, three-dimensional organization in complex with the RNA. The association thus imparts additional order to the protein element and may also influence conformational equilibria in the RNA. Binding with lower affinity to more than the two psi-element stem loops for which structures have been determined may enhance specificity and facilitate RNA condensation,[105,245] like the lower-affinity packaging signals in picornaviruses and RNA bacteriophages. An RNA conformational switch may also accompany the initial event in packaging recognition.[105]

Assembly of helical structures requires unwinding of any base-paired stems in the RNA genome being packaged. TMV has evolved an assembly-driven helix-breaking feature into its *in vitro* characterized packaging pathway. Viral assembly begins at an internal origin sequence, about 1 kb from the 3′ end of the genome.[387,444] A 75-base sequence containing a presumptive stem-loop structure is sufficient to initiate specific encapsidation (Fig. 3.21E), which proceeds by a mechanism that requires that the 5′ end of the RNA be drawn through a channel along the axis of the assembling particle,[47] enforcing loss of local secondary structure and compensating for the free energy loss by favorable RNA-protein interactions at the growing end of the helix.

dsDNA Genomes

The best understood dsDNA packaging mechanisms are those of the tailed bacteriophages.[55,98,146,315] A pentameric ATPase, with a ringlike structure resembling that of a helicase, pumps DNA into the empty head, through a portal protein at a single, unique vertex, until it reaches a tightly coiled state, as illustrated in Figure 3.16E.[115,116,363] Removal of the scaffold leads in most cases to a substantial expansion of the head, accomplished through conformational rearrangements in the major capsid protein.[114,199] The head itself is either an isometric icosahedral shell (eg, lambda, P22, or HK97, Fig. 3.16) or a prolate one (eg, T4 or ϕ29: cf. Fig. 3.17A). In the latter cases, the scaffold protein directs the elongation. The ATPase dissociates from the portal after DNA packaging is complete,[146] allowing the portal protein to become the attachment point for the tail or DNA injection structure. The substantial internal pressure of the packaged DNA[363] may help drive injection into a target bacterium.

Various models have been proposed for the coupling of ATP hydrolysis with the concomitant transport of DNA into the head.[1,264,358,372-374] The last segment of DNA to enter remains in the channel of the portal protein. To avoid entanglement, it is likely that the leading end of the DNA attaches to the head interior.[160] In P22, a tubelike, inward projecting extension of the portal may also help direct coiling and prevent tangles[378]; closely related viruses lack the prominent tube, however. DNA insertion leads to formation of a tight, uniform coil (Fig. 3.16E). Because the DNA is tightly wound, the side to side spacing of adjacent segments is very regular; the value of this spacing is determined by the precise volume of the head and by the length of the inserted genome.[115] Viruses like bacteriophage lambda that replicate their DNA in a rolling circle mode couple DNA packaging with cleavage of the replicated concatemer. Others, such as ϕ29, have a virally encoded protein that primes synthesis of both DNA strands and that remains attached to the ends of the encapsidated genome.

DNA packaging into herpesvirus capsids closely resembles the process just described for the tailed bacteriophages (see Chapter 9, volume 2). Not only does the shell-forming domain of the major capsid protein have the HK97 fold,[14] as described above, but the portal protein, attached to a unique vertex, likewise resembles its tailed-phage counterpart.[189,241,279,327] As in dsDNA bacteriophages, the tightly packaged DNA is a uniformly spaced, liquid crystalline–like coil (Fig. 3.20), and a particularly well-ordered coil of DNA wraps around the inward-projecting surface of the portal protein.[241] The wrapping may be a sensor for DNA pressure within the head, creating a conformational signal for the transition from packaging to subsequent maturation steps (eg, concatemer cleavage by terminase, tail attachment for a bacteriophage). An alternative proposal, which does not exclude the head-full signaling function, is that it represents the attachment point for the end of the genome that enters first.

Adenoviruses have, near the left-hand end of their linear genome, a set of AT-rich repeats that determine DNA incorporation into virions (see Chapter 4, volume 2). Virions contain about 1000 copies of a protein (VII) with strong positive charge, and it is believed that this protein condenses the viral DNA within the virion core and that it may remain associated with the DNA after uncoating. In the adenovirus-like

bacteriophage PRD1, there is a unique vertex defined by the presence of proteins required for DNA packaging and injection.[139] One of these, the ATPase, is distantly related to protein IVa2 of adenoviruses and more closely related to candidate packaging ATPases for other dsDNA viruses with internal membranes.[189] Adenovirus mutant lacking IVa2 assemble only empty capsids. A separate adenovirus portal protein has yet to be identified.[5]

Polyoma- and papillomaviruses incorporate cellular histones, so that the closed, circular DNA comprises about 20-25 nucleosomes (see Chapters 1 and 2, volume 2, for references). This minichromosome is further condensed as the capsid assembles around it. Packaging of the minichromosome of polyomaviruses appears to be directed by sequences in a histone-free region.

dsRNA Genomes

The segmented genomes of dsRNA viruses require packaging mechanisms that ensure, like those of the negative-strand ssRNA viruses with segmented genomes, incorporation of a complete genomic complement. The packaged RNA is a capped, plus-sense strand; the incorporated pRdRp produces the complementary strand within the assembled particle.

Complementary studies of reo-, rota- and orbivirus assembly suggest that eukaryotic dsRNA virus genome packaging begins with association of one each of the various plus-strand RNA segments into a single complex, held together largely by specific RNA-RNA interactions.[31] Evidence for initial formation of such a "complete genome" comes from successful *in vitro* assembly of bluetongue virus (BTV) cores, which requires all 10 plus-strand segments, as well as the coincorporated RdRp and the capping enzyme.[244] For rotaviruses, the nonstructural protein 2 (NSP2), with high affinity for single-strand RNA, chaperones this process by destabilizing intrasegment secondary structure and facilitating formation of specific intersegment interactions.[32,36,179,192] The reovirus σNS protein may have a similar role.[30,428] Rotavirus NSP2 is an octamer with a central channel that could accommodate ssRNA.[192,197,217,381] A second nonstructural protein, NSP5, appears to compete with RNA for binding to NSP2, suggesting it may have some sort of cochaperone-like activity.[197] Sequences covering untranslated regions at both 5′ and 3′ ends of the segments probably contain the relevant recognition functions.

The rotavirus RdRp recognizes the 3′ end of the plus-strand though interactions in the template entry channel, likely as part of the specific packaging mechanism.[247] Other eukaryotic dsRNA virus RdRps could have similar specificities, although those have not yet been shown. Binding the 5′ cap at the cap-binding site (present on both reovirus and rotavirus RdRps[247,379]) may make the overall association tighter. For reo-, rota-, and orbiviruses, one RdRp binds specifically with a shell-protein decamer (Fig. 3.12). Thus, the RdRps associated with the 3′ ends of the genome segments in the multisegment complex, each also associated with a shell-protein, could coordinate coassembly of the shell with the RNA complex,[31] completed by addition of any required RNA-free shell-protein decamers to make a full, 12-decamer complement. Generation of the complementary strand of each segment inside the assembled particles results in a tight, liquid-crystalline packing or dsRNA, like the head-full spool of dsDNA in bacteriophages. The end of each dsRNA segment remains associated with the RdRp, but in reoviruses visualized by cryo-EM reconstructions, the rest of the segments extend away from the polymerase, rather than spooling around it.[184,235,294,436]

The various eukaryotic dsRNA viruses have between 9 and 12 genome segments. Each of the corresponding 9-12 RdRps is fixed within the core-shell close to a fivefold axis, the location at which a transcript leaves a transcribing particle[195,230] (Fig. 3.12). To enable reinitiation for the many rounds of transcription that occur when the inner capsid particle is released into the cytoplasm of an infected cell,[379] each polymerase remains associated with the 3′ end of the template (noncoding) strand of its corresponding genome segment, by binding the 5′-cap of its complementary nontemplate strand at a site near the template entry channel.[247,379] Otherwise, that terminus would "get lost" in the particle interior, greatly delaying finding an unoccupied polymerase. The likely mechanisms for some of these steps have been worked out for rotaviruses, orthoreoviruses, and orbiviruses.

Packaging of bacterial dsRNA viral genomes proceeds by a quite different mechanism from the one just outlined for their eukaryotic counterparts.[261,311] A procapsid assembles, into which each of the three positive-stranded RNA segments inserts sequentially, in a specific order. Minus-strand synthesis then occurs inside the shell, as in the eukaryotic viruses. The procapsid includes the major shell protein (similar to that of reovirus or rotavirus), the polymerase, an ATPase, and a protein thought to serve as an assembly "clamp." One copy of the hexameric ATPase, which may be a packaging helicase for plus-sense RNA, analogous in function to the packaging proteins of dsDNA bacteriophage, lies at each fivefold vertex[97]; RNA insertion appears to occur at only one of these twelve positions, however, even though all are occupied by an ATPase.

Negative-Strand RNA Genomes

The nucleocapsid proteins (N) of negative-strand RNA viruses with single-segment genomes (eg, the rhabdoviruses, VSV and rabies virus, and borna disease virus) all have closely related structures.[6,142,340] Recombinant N proteins from VSV and rabies viruses bind nonspecific RNA from the expression host and form rings of 10-14 subunits, with an N-terminal arm that embraces one neighbor in the ring and a loop near the C-terminus that extends into the other neighbor. The subunits have two lobes with a groove between them that faces the center of the ring and binds the RNA—9 bases per subunit. The recombinant VSV-N ring, a more tightly wound and circularized version of the helical ramp that the nucleocapsid forms in the bullet-shaped virion (Fig. 3.22), approximates the initial turn at the domed end of the particle, which has the 3′ end of the RNA. For transcription or replication, the polymerase must withdraw the RNA from the groove in the RNP.[6,142] The interactions of neighboring N proteins, which embrace each other through N-terminal arms and C-proximal loops, probably keep the chain of N-proteins intact even when the RNA separates from it to enter the polymerase.[193,231] The polymerases and their cofactors also organize association with the nucleocapsid protein as the nascent genome emerges from the enzyme, avoiding formation of any secondary structure and protecting the nascent RNA from recognition by innate-immune receptors in the cell.[176,193,231]

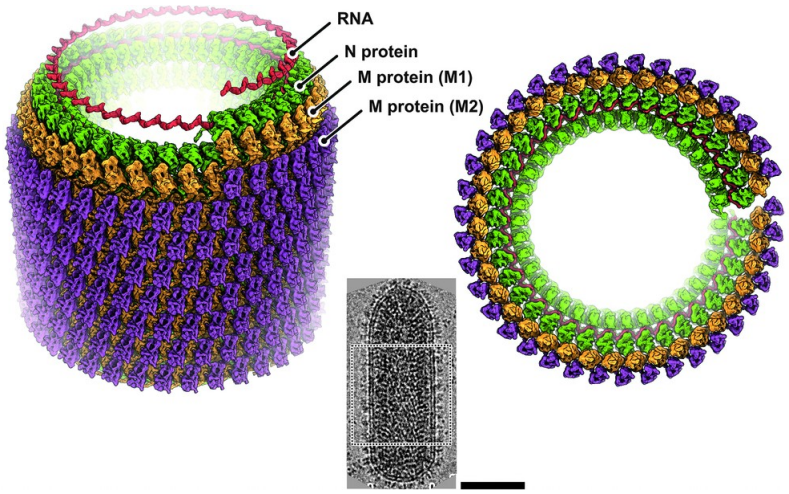

FIGURE 3.22 **Organization of RNP and M in vesicular stomatitis virus (VSV)**. *Inset* shows a cryo-EM image of a VSV particle. "Spikes" of the trimeric glycoprotein (G) project from the lipid bilayer membrane. Scale bar: 50 nm. The uniform shaft of the bullet-shaped particle is a regular helical assembly of the RNP with the M protein. There are two (identical) M subunits for each N subunits, although the outer (M2) layer is not fully occupied. The figure shows a side view and an axial view of the RNP-M1-M2 assembly. A flexible, N-terminal extension of the M subunit (not shown) interacts with the inner leaflet of the membrane bilayer; this interaction and coassembly of M and RNP appear to drive budding of the particle. (Adapted from Jenni S, Horwitz JA, Bloyet LM, et al. Visualizing molecular interactions that determine assembly of a bullet-shaped vesicular stomatitis virus particle. *Nat Commun*. 2022;13(1):4802. http://creativecommons.org/licenses/by/4.0/. Ref.[94])

Orthomyxoviruses have six to eight genome segments, packaged as ribonucleoprotein complexes (RNPs), which resemble rods folded back on themselves and coiled in a double-helical arrangement, with the three-subunit polymerase bound at one end and a loop at the other[9,117,263] (Fig. 3.23E). The lengths of the eight RNP rods in influenza A, between 300 and 1200 Å, correspond to the eight genome segment lengths, when coiled as just described; their diameter is about 120 Å.[284] Complementary sequences in the 5′ and 3′ noncoding regions determine the folded-back arrangement and bind the polymerase; sequences at either end of the coding region also contribute to specific packaging.[138,272] Serial transverse sections through elongated buds of influenza A show eight rods, seven around one, about 120 Å in diameter, extending for variable distances from the tip of the bud toward its cell-proximal end; the distances correspond to the lengths of the various genome segments.[274,284,285] Tomographic reconstructions of purified filamentous influenza virus particles show that this internal organization is retained in the budded particle (Fig. 3.23E).[50] Interfering with packaging of one segment reduces packaging of others.[272] Thus, there appears to be a sequential recognition mechanism to ensure a proper complement of genome segments, perhaps formally (although not structurally) analogous to the selection mechanism in dsRNA viruses. The influenza NP-protein, like those. Ref.[117] of the single-segment negative-strand RNA viruses, has two lobes with an RNA-binding groove between them, but the folded structures are not identical.[419] The groove that accepts RNA faces outward in the double-helical RNP and looped-out RNA could dictate specific incorporation of the eight segments.[117] The RNA that forms the central element in the seven around one arrangement may have a particularly critical role; some evidence suggests that this segment is the one that encodes polymerase subunit PB2.[272] Influenza C and D, which have only seven genome segments, still show a 7+1 arrangement, indicating a conserved packaging mechanism; the eighth segment might be a host-cell RNA or a redundant copy of one of the seven viral RNAs.[273]

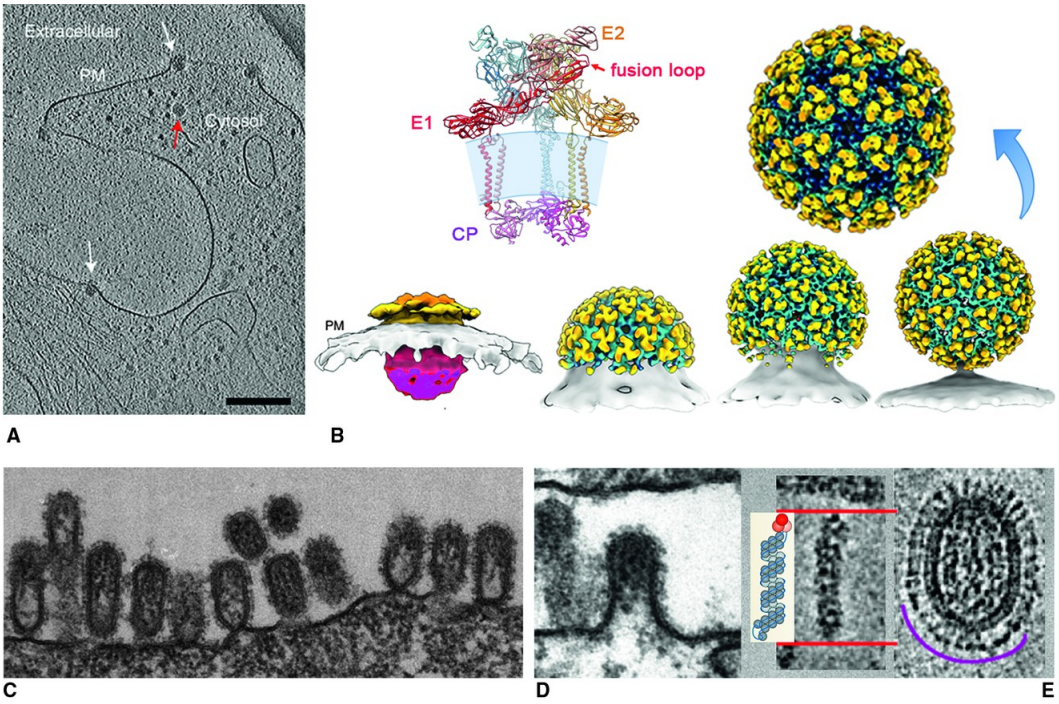

FIGURE 3.23 **Budding of enveloped viruses**. **A, B**. Alphaviruses: chikungunya virus budding at the plasma membrane. (Adapted by permission from Nature: Chmielewski D, Schmid MF, Simmons G, et al. Chikungunya virus assembly and budding visualized in situ using cryogenic electron tomography. *Nat Microbiol*. 2022;7(8):1270-1279. Ref.[74]) **A**. Cryo-ET of viruses budding at the thin edge of an infected cell. Nucleocapsids assemble in the cytosol (*red arrow*). At the plasma membrane, they recruit glycoproteins E1 and E2 (*white arrows*), which are synthesized on endoplasmic reticulum–associated ribosomes and transported through the secretory pathway to the cell surface. Scale bar: 200 nm. **B**. Molecular events in budding. *Upper left*: An E1-E2 heterohexamer (E1 in *red*; E2 in *orange*), recruited by three core protein subunits, through contacts with the E2 cytoplasmic tail. The one-to-one interaction ensures coherence of the T = 4 icosahedral lattices of the core and the external glycoprotein array. Semitransparent *blue arc* represents the lipid bilayer of the virion. In the prefusion structure at neutral pH, one domain of E2 covers the fusion loop on E1. At the acidic pH of an endosome, conformational changes in the glycoproteins allow E1 to project outward and the fusion loop to insert into the endosomal membrane. The representation of an assembled virion (*upper right*) illustrates the arrangement of the 80 E1-E2 heterohexamers on the surface of a virus particle. *Lower row*: Steps in budding, culminating in pinching off (*curved arrow*) of the infectious virion (*upper right*). Nucleocapsid: *magenta*. Surface representation of glycoproteins E1 and E2, in colors from *yellow* (outermost) to *dark green* (membrane proximal), according to distance from the center of the particle. **C**. Influenza virus. Thin section electron microscopy of slightly elongated virions budding from the surface of an infected cell. (Adapted with permission from Calder LJ, Wasilewski S, Berriman JA, et al. Structural organization of a filamentous influenza A virus. *Proc Natl Acad Sci U S A*. 2010;107(23):10685-10690. Ref.[50]) An isolated RNP is shown at roughly the same magnification on the *left*,[50] together with a schematic diagram of its helical-hairpin organization (Isolated RNP adapted by permission from Nature: Eisfeld AJ, Neumann G, Kawaoka Y. At the centre: influenza A virus ribonucleoproteins. *Nat Rev Microbiol*. 2015;13(1):28-41. Copyright © 2014 Springer Nature. Ref.[117]). The three-subunit RNA-dependent RNA polymerase (*red*) associates with the RNA termini at the membrane-proximal end. The headgroup layer of the inner leaflet of the membrane bilayer appears denser than the headgroup layer of the outer leaflet, because of its close association with M.

Viral Membranes

Most enveloped viruses (the large and very complex poxviruses and the membrane-containing bacteriophages are exceptions) acquire a lipid bilayer and associated viral transmembrane proteins by budding through a membrane of the host cell—either the plasma membrane (eg, alphaviruses, orthomyxo- and paramyxoviruses, rhabdoviruses, filoviruses, retroviruses), the ER (flaviviruses), the ER-Golgi intermediate compartment (coronaviruses), the Golgi (bunyaviruses), or the inner nuclear membrane (herpesviruses) (Fig. 3.23). The viruses direct insertion of their surface glycoproteins into the relevant host-cell membrane, through standard cellular compartmentalization pathways, such as transport through the trans-Golgi network to the cell surface or retention in the ER or Golgi; the driving force for budding may then come from membrane-coupled assembly of the internal structures, as in assembly of rhabdoviruses,[194,442] orthomyxoviruses,[305,306] and retroviruses,[375] from lateral interactions in the glycoprotein layer, as in budding of flaviviruses and of at least some bunyaviruses,[182,371,396] or from some combination of the two, as in budding of alphaviruses[41,48] (Fig. 3.23A).

The mechanisms for specific capture of the viral glycoprotein(s) by the internal components—only roughly characterized, if at all, in many cases—vary widely. The simplest mechanism, a one to one interaction of the surface glycoprotein with a membrane-facing internal protein, appears to be the case only for alphaviruses,[288,432,440] which have a T = 4 icosahedral organization for both the glycoprotein surface layer and the internal nucleocapsid (core) particle[21,22,70,73,215,270,310,316,393,395,432,435] (Fig. 3.23B). The icosahedrally organized flavivirus particles (Fig. 3.12)[73,215,280,310,314,351,359,393,395,437,439] have much weaker interactions between envelope and core proteins,[384] and expression of just the viral glycoproteins (prM and E) is sufficient to yield budded, viruslike particles with surface structures similar to those of intact virions.[7,259]

Specificity of membrane-protein incorporation is not always absolute. For example, HIV-1 buds with only a few copies of its glycoprotein on the virion surface (Fig. 3.24), and some host-cell membrane proteins can incorporate into the particle.[45,154] In the well-studied example of VSV, ectopic expression of a heterologous viral glycoprotein leads to phenotyptic mixing—incorporation of the heterologous protein into the progeny particles.[258,443] VSV chimeras, in which the coding region for a heterologous glycoprotein replaces that for VSV G thereby avoiding any mixed incorporation,[51,133,347,392] and lentivirus chimeras, with related substitutions,[198] also propagate successfully. VSV and lentivirus chimeras are particularly useful for studying entry properties of human pathogens without requiring high-level containment.

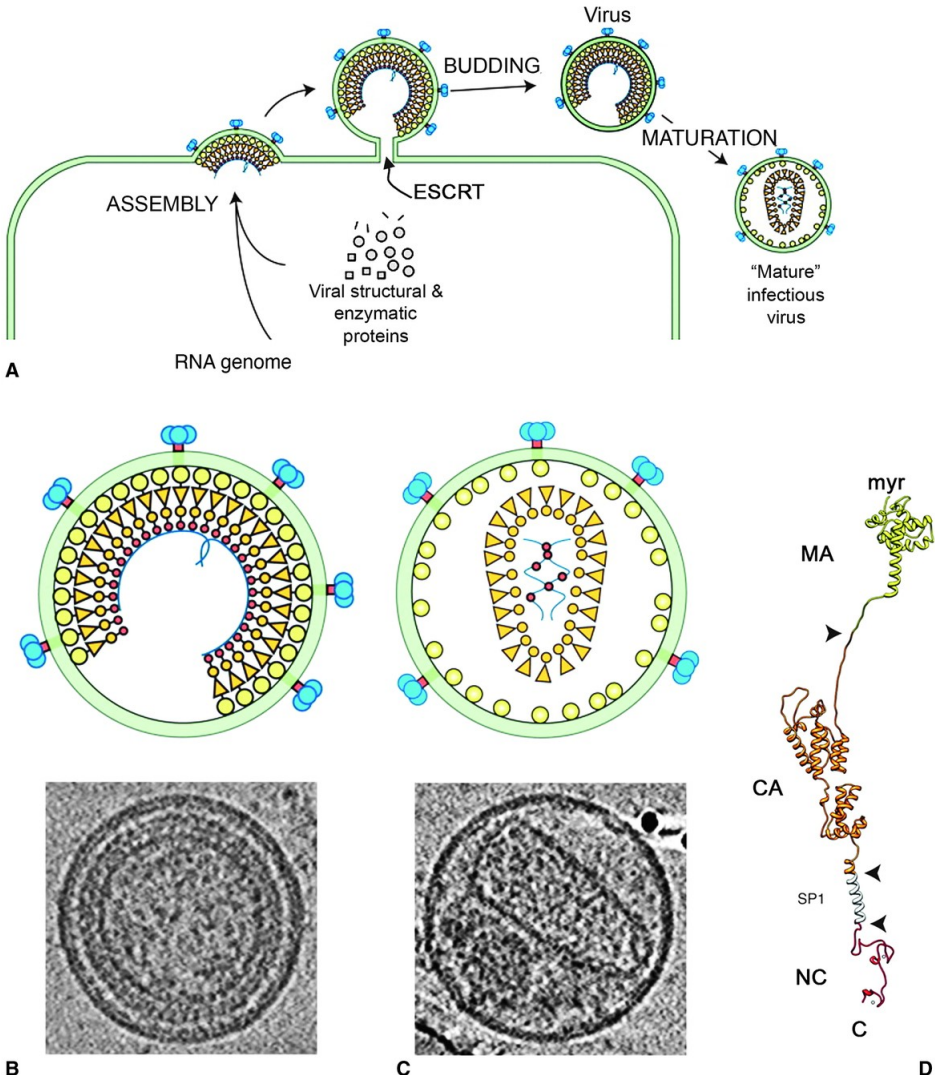

FIGURE 3.24 **Cleavage and rearrangement of HIV-1 Gag**. **A**. HIV budding at the cell surface. Pinching off requires the ESCRT pathway. **B**. Immature particle, the immediate product of budding. The Gag domains are MA (*yellow*), which interacts with the membrane both through a myristoylated N-terminus and a positively charged, membrane facing surface, CA (*orange*), which has two folded modules, and NC (*red*), which interacts with the genomic RNA (see Fig. 3.21C). **C**. Mature particle. Cleavage of Gag, by the viral protease (a domain of the Gag-Pol fusion protein produced by ribosomal frameshifting), leads to rearrangement of CA into a fullerene cone (see Fig. 3.17B) and condensation of the genomic RNA within it. *Upper panels* are schematics; *lower panels* are slices through cryo-tomograms. **D**. Cartoon of Gag, with protease cleavage sites shown as arrowheads. SP1 is a spacer peptide. (Adapted with permission from Sundquist WI, Krausslich HG. HIV-1 assembly, budding, and maturation. *Cold Spring Harb Perspect Med*. 2012;2:a006924. Copyright © 2012 Cold Spring Harbor Laboratory Press. Ref.[375])

Except for alphaviruses, flaviviruses, and members of the one family of bunyaviruses,[182,396] the sizes and shapes of most enveloped viruses vary to some degree from particle to particle. Budding of many of these pleomorphic particles depends on a "matrix" (M) protein, which lines the inner face of the viral membrane. Although the subunit structures of M proteins from different groups of viruses vary, they have analogous functions in driving bud formation and in recruiting the nucleocapsid.[385] Most are not integral membrane proteins, although coronavirus M, with a short ectodomain, three transmembrane helices, and a cytoplasmic domain of about 100 residues, is an exception.[99,275] Filamentous influenza virus particles provide an extreme example of the role of a matrix protein in budding.[282,283] Even very long filaments still contain only one eight-segment genome complement at their leading end.[75,284,285] The helical organization of the influenza-virus matrix protein, M1, allows budding to continue to arbitrary lengths under circumstances that drive it to do so[229,305,306] (Fig. 3.25). The VSV matrix protein (M) coassembles with the nucleocapsid into the helical shaft of the bullet-shaped virion; in that case, the length of the particle is fixed by the length of the RNA (Fig. 3.22). The absence of a matrix protein in bunyaviruses[183]—the largest group of enveloped viruses—appears to require that the glycoprotein (GPC, cleaved to Gn and Gc) alone provide the driving force for budding. The cytoplasmic "tail" of Gn directs RNP incorporation, and some evidence suggests that it has a matrixlike function.[371]

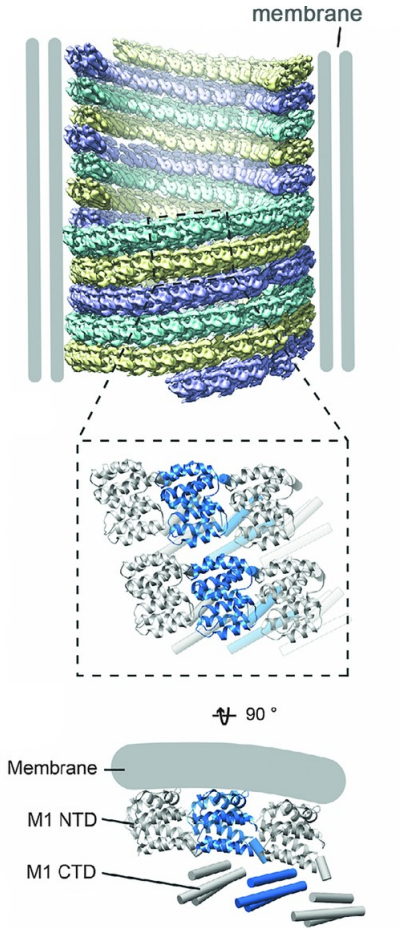

FIGURE 3.25 **Influenza M1 protein helical array beneath the membrane of a filamentous influenza H3N2 virus particle, imaged by cryo-ET with subtomogram averaging (EMD-11075, PDB-6Z5J)**.[306] *Top*: The two-domain M1 subunit assembles as a three-start helix (each in a different color). *Center*: Magnification of two adjacent helical turns, with alternate subunits in *white* and *blue*. *Bottom*: Axial view of one turn. The C-terminal domain (CTD) is not as well ordered as the N-terminal domain (NTD), and the figure shows only the CTD alpha helices, as cylinders. (Adapted from Peukes J, Xiong X, Briggs JAG. New structural insights into the multifunctional influenza A matrix protein 1. *FEBS Lett*. 2021;595(20):2535-2543. http://creativecommons.org/licenses/by/4.0/. Ref.[305])

Pinching off from the cell surface, or into the lumen of the ER or Golgi, does not require a cellular pinching activity for alphaviruses and flaviviruses; membrane-linked assembly of viral components probably provides the force needed to distort and sever the membrane bilayer.[382,405] In many other cases, however, completion of budding requires that the virus recruit components of a cellular budding machinery.[312] In the examples of such recruitment that have been studied in some detail (particularly HIV and other retroviruses, but also rhabdoviruses, filoviruses, arenaviruses, and some paramyxoviruses[406]), the virus redirects to the cell surface a set of protein complexes (the ESCRT machinery) that normally function at late endosomes, where they generate pinched-off invaginations into the endosomal lumen to create multivesicular bodies (MVBs).[134,370,398] The topology of viral budding from the cell surface is the same as the topology of lumenal vesicle formation (away from the cytosol), and the ESCRT mechanism that releases the virus particle is presumably the same as the mechanism that generates the vesicular content of MVBs. A motif in Gag or M, known as a "late domain," recruits specific ESCRT components, which then initiate assembly of the rest of the elaborate ESCRT complex.

Budding of influenza virus is ESCRT independent[66]; instead, an amphipathic helix in M2, the small, tetrameric proton channel that allows the interior of the particle to acidify before release from an endosome, appears to potentiate scission.[335] Selective incorporation of NA at the base of the budding virion[50] could in principle also be part of the scission mechanism. Although association of HA and NA with lipids characteristic of cholesterol-rich microdomains[346,377,429] has been proposed to contribute, there is no clearly defined mechanism for how lipid compositional discontinuities might lead to membrane scission.

The lipids in the viral membrane derive from the cell, and to a first approximation, the incorporated lipids represent a sample of those in the membrane through which the virus budded.[209] Viruses that emerge through the plasma membrane contain phospholipid and cholesterol in characteristic proportions, whereas those that emerge into the lumen of the ER contain almost no cholesterol. Cholesterol tends to increase the thickness of a bilayer, by restricting rotation about single bonds in the fatty-acid chains of adjacent phospholipids.[317] The lengths of α-helical transmembrane segments in viral glycoproteins vary accordingly: from about 26 residues in the HA of influenza virus (which buds at the cell surface) to 18-20 in the E protein of yellow fever virus (which buds into the ER). Within these overall regularities, specific examples show that viral envelope proteins can specify selective glycerophospholipid incorporation. For example, glycerophospholipid profiles of three different influenza virus strains grown in eggs have a substantially higher phosphatidylethanolamine (PE) content than do cells in noninfected allantoic fluid, and their compositions also differ slightly from one strain to another[185]; human cytomegalovirus particles have a similarly enhanced PE content.[239]

Postassembly Steps

For most viruses, and nearly all viruses that infect animal cells, one or more irreversible steps intervene in forming the mature, infections virion—very often, those steps include a proteolytic cleavage. The picornaviruses, already described, are a good example. In an infected cell, the principal structural proteins are cleaved from a polyprotein precursor (by a viral protease) before particle assembly, but one final, autocatalytic cleavage step occurs a Ref.[375] fter assembly—the scission of a peptide bond between VP4 and VP2 (see Chapter 2, volume 1 and caption to Fig. 3.8). The cleavage depends on the three-dimensional arrangement of the scissile bond, as found in a newly assembled precursor particle. Rearrangements of parts of the subunits following the cleavage stabilize the now mature, infectious virion. Even if processing of a precursor polyprotein is not involved, cellular or extracellular host proteases mediate critical steps in the maturation of many viruses. Many of the surface glycoproteins that facilitate membrane fusion during entry of enveloped viruses require proteolytic activation (see section on membrane fusion)—either by a furinlike protease late in the secretory pathway, by an extracellular protease after release of the assembled particle, or by a protease in the new host cell.[162]

Specific, postassembly proteolytic cleavage usually has two consequences. First, as in picornaviruses or many viral fusion proteins, it leads to a local rearrangement of polypeptide chains that stabilizes the structure. During retrovirus maturation, reorganization of the internal structure, required for infection, depends on cleavage of the Gag polyprotein by the viral protease present inside the budded particle (Fig. 3.24). Second, it allows the structure to undergo a much larger reorganization when "triggered" by binding of a specific ligand. Thus, when a mature poliovirus particle binds its receptor, an expansion occurs that allows VP4 to escape and to interact with adjacent membrane—a critical first step for translocating the particle or its genome from an endocytic compartment into the cytosol.[35,153,268] Likewise, fusion proteins of enveloped viruses undergo large-scale, fusion-promoting conformational changes when suitably triggered—for example, by binding protons in acidic endosomes or by binding a receptor or coreceptor—but in most cases, only if a critical cleavage has occurred.[161,162,360] The cleaved structure is "metastable" (but *not* the uncleaved precursor—a common misunderstanding): a high kinetic barrier separates it from the true energy minimum, in a conformation that would have been inaccessible before the cleavage. The barrier can be so large that the virus remains infectious at 4 °C for many weeks or months. Ligand binding (receptor; protons; etc.) lowers the kinetic barrier, leading to a rapid conformational rearrangement, coupled in most cases to an important step in viral entry.

Structural Biology of Virus Entry

Receptors and Coreceptors

There are no simple generalizations about virus receptors and how they bind with viral surfaces (Fig. 3.26). Viruses are "opportunistic": they evolve to recognize cell-surface molecules—for example, carbohydrates on glycolipids or glycoproteins (Fig. 3.26A) or proteins (Fig. 3.26B)—on cells of different tissues or different hosts, and they change or widen their tropism as they adapt to new surface molecules. For example, influenza virus recognizes a sialic acid-containing carbohydrate for cell attachment[301] (Fig. 3.26C). One or two mutations can change its preference from the predominant sialic acid linkage on avian cells (α-2,3) to the predominant upper-airway cell linkage in humans (α-2,6)—an important requirement for influenza viruses of avian origin to acquire human-human transmissibility (see Refs.[130,362] and Chapter 14, volume 1, for references). Most viruses have also evolved a mechanism to avoid "getting stuck" at the cell surface when emerging from an infected cell, as illustrated by the receptor-destroying activities of influenza viruses.[130] Many viruses simply bind weakly to their receptors and thus can dissociate in a reasonable time. The virulence of polyomavirus in mice is inversely related to viral affinity for its sialoglycoconjugate receptor (Fig. 3.26A), demonstrating that spread in the animal host, rather than entry into cells, is the principal correlate of pathogenesis.[23] HIV-1 has several mechanisms for downregulating its receptor (CD4) after infection, both to avoid envelope-receptor interactions within the secretory pathway and to facilitate viral release after budding (see Chapter 17, volume 3).

Broadly neutralizing human antibody that recognizes the receptor-binding pocket of influenza virus hemagglutinin. *Proc Natl Acad Sci U S A*. 2011;108(34):14216-14221. Refs.[349,407]) **C**. Influenza virus: sialic-acid binding site on the HA1 "head." **D**. SARS coronavirus (SARS-CoV): docking of the ACE2 receptor with the receptor-binding domain (RBD) of the viral glycoprotein spike.[226] The homologous interaction is essentially identical for the SARS-CoV-2 glycoprotein. *Left*: Cartoon representation of the spike glycoprotein ectodomain, with one RBD in an "up" position, and the other two in "down" positions[427] (PDB 5X5B). The subunit with RBD up is in color; the other two in *gray*. The up RBD is in *cyan*, and the receptor binding motif (RBM) on its outward-facing surface in *red*. ACE2 requires the up configuration to access the RBM. An α-helical, coiled-coil stalk, represented schematically, connects the structure shown with the transmembrane anchor of the glycoprotein. *Center*: ACE2 docking. Surface representations of ACE2 (*dark green*) and a single RBD (*cyan and red*). *Right*: The docked receptor in cartoon representation. (Adapted from Li F, Li W, Farzan M, et al. Structure of SARS coronavirus spike receptor-binding domain complexed with receptor. *Science*. 2005;309(5742):1864-1868. Reprinted with permission from AAAS.)

Many viruses require a cascade of at least two distinct receptors—one for initial cell attachment and a second for triggering fusion or penetration. The receptor used for initial attachment may be a widely distributed molecule, like sialic acid or other glycans—for example, heparan sulfate for HSV-1—or it may be a quite specific protein, like the adenovirus receptor, CAR (Fig. 3.26B), or the HIV-1 receptor, CD4 (Fig. 3.27). The molecule that triggers fusion or penetration is sometimes called a "coreceptor"—for example, the chemokine receptors for HIV-1. In the case of HIV-1, CD4 primes the envelope glycoprotein to bind the coreceptor, which in turn induces fusion activation (Fig. 3.27). An obligate order of this sort will also obtain when the primary receptor is on the cell surface and the coreceptor is on the lumenal surface of an endocytic compartment.

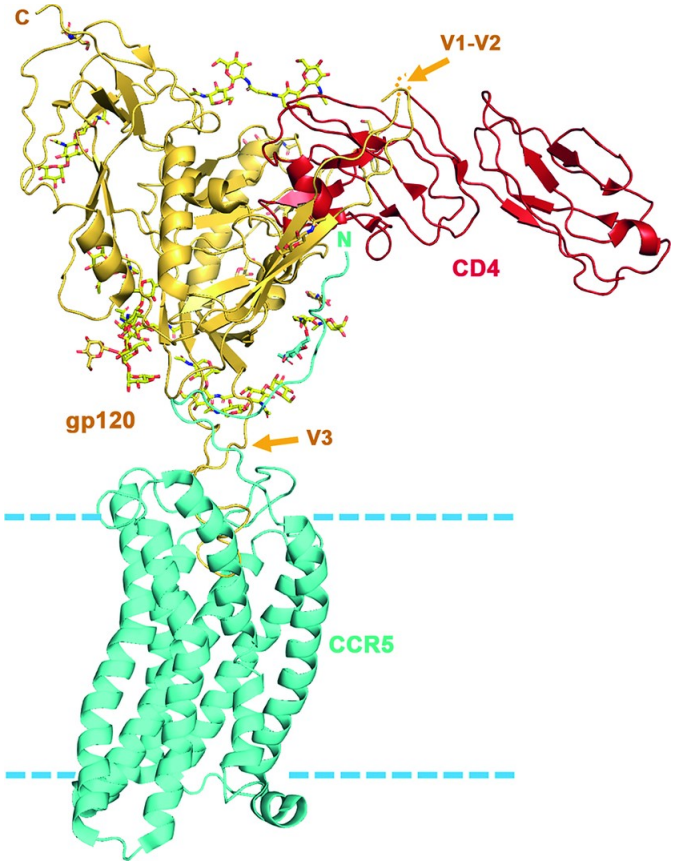

FIGURE 3.27 **HIV-1 gp120 interaction with receptor and coreceptor, illustrating how receptor (CD4) binding stabilizes conformational changes that allow coreceptor (CCR5) binding**. The first two (of four) domains of CD4 are in *red*; the receptor- and coreceptor-binding domain, gp120, of HIV-1 Env is in *yellow*; the coreceptor, CCR5, in *cyan*. CD4 binding displaces the V3 variable loop (labeled) from its position in unliganded Env trimer (in which it tucks under the V1-V2 variable loop, also labeled, now instead in contact with the first domain of CD4); the displaced V3 inserts deep into the ligand-binding pocket of the CCR5 chemokine receptor, while the long N-terminal, extracellular arm of CCR5 binds along base of the V1-V2 loop. (Figure made from PDB 6MEO . Shaik MM, Peng H, Lu J, et al. Structural basis of coreceptor recognition by HIV-1 envelope spike. *Nature*. 2019;565:318-323. Ref.[352])

Viral mutations can lead to amino acid residue changes that reduce recognition by the immune system (eg, influenza, HIV), and viral surface proteins have generally evolved structural features to sequester their conserved, receptor-binding surface from interaction with antibodies and potentially variable surfaces elsewhere. The footprint of an antibody combining site is substantial, so that even if a receptor site is exposed, it rarely matches the full extent of the surface within which amino acid residue changes will lower antibody affinity and hence escape neutralization.[79] Some viral receptor sites (eg, those on certain picornaviruses—Fig. 3.4) lie within a "canyon"[336,338]—a groove or pocket too narrow to admit the antigen-combining end of an antibody. Antibodies with unusually long or prominent heavy-chain CDR3 loops can often penetrate relatively tight cavities, but the periphery of the receptor site can generally mutate in ways that interfere with antibody binding but leave critical receptor contacts unchanged. The receptor-binding proteins of viruses such as HIV-1 (Fig. 3.27) and SARS-CoV (Fig. 3.26D) require a conformational change to expose the binding site completely. The receptor-binding motifs (RBMs) on the SARS-CoV and other coronavirus spike proteins are unusually extensive,[226] and they can encompass nearly the entire footprints of some antibodies (Fig. 3.26D). A conformational change, from receptor-binding domain (RBD) "down" to RBD "up," exposes the RBM; capture by the receptor prevents return of the RBD to its "down" conformation as long as the receptor remains bound.[416,427] The conformational dynamics thus minimize exposure of a critical epitopic region recognized by neutralizing antibodies. Moreover, because certain residues critical for antibody binding are less critical for receptor binding, immune escape mutations within the RBM do occur, as illustrated by the succession of variants during the SARS-CoV-2 pandemic.

The receptor or coreceptor interaction can have viral-entry functions other than attachment or endocytosis. For example, when poliovirus and other picornaviruses bind receptor, the interaction triggers expansion of the viral shell. Exit of VP4 from the expanded particle not only makes the rearrangement irreversible[24,153] but also allows VP4 to insert into the target-cell membrane, where it appears to help create an RNA transfer channel (see below). The receptor is a catalyst that lowers the energy barrier to an irreversible reorganization.[386] The function of this reorganization is viral entry; the triggering mechanism has evolved to allow the reorganization to occur only in an appropriate location. Reoviruses (Fig. 3.18) have an outer-layer protein, σ3, that caps the penetration protein, μ1.[109,233] Proteolytic removal of σ3 is required to make the particle competent to attach and penetrate (see Chapter 11, volume 3). There is, in addition, an essential autolytic cleavage of μ1,[281] with release of a myristoylated N-terminal peptide (μ1N) that forms pores in membranes. As described below, influenza HA folds in the ER into a stable, trimeric structure. Cleavage of one peptide bond in the HA_0 polypeptide chain primes the protein to undergo the low pH-triggered rearrangement that mediates fusion of viral and target-cell membranes. Although the barrier to rearrangement is so great at neutral pH that no conformational change occurs, proton binding in the low pH environment of the endosome lowers this barrier and triggers refolding. For HA, protons have a role analogous to that of some enveloped viral coreceptors, such as the chemokine receptors for HIV-1 or Niemann-Pick C1 for Ebola virus.[51]

Bilayer Fusion

The bilayer fusion reaction common to all the enveloped viral entry pathways is shown schematically in Figure 3.28. Good evidence suggests that it passes through an intermediate known as a "hemifusion stalk" (Fig. 3.28, center), in which the two apposed leaflets have fused, but not the distal ones.[219,249,319,356] Hemifused bilayers can then form a "fusion pore" (Fig. 3.28, right) or a structure in which the two distal leaflets create a single bilayer. Bilayers do not fuse spontaneously (eg, concentrated liposomes are quite stable), because the reaction in Figure 3.28 has a high activation barrier, both at the step between the precursor bilayers and the hemifusion stalk and at the step between the hemifusion stalk and the fusion pore. A newly opened pore may revert to a hemifusion structure ("flickering"), and the largest kinetic barrier may be for the step in which the pore dilates rather than reverts.[250,319]

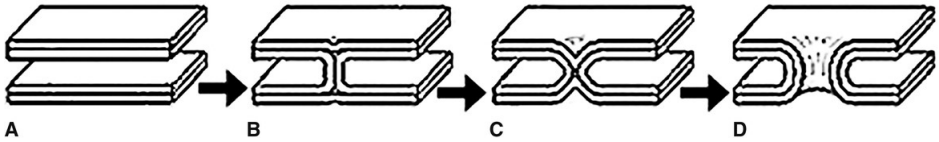

FIGURE 3.28 **Fusion of lipid bilayers**. **A**. Two bilayers. **B**. Hemifusion: only the apposed leaflets have merged, while the distal leaflets on either side remain intact. Formation of a stalk, as shown here, minimizes the area over which the two bilayers must approach each other and hence minimizes the free energy of the transition to the hemifusion intermediate. **C**. Transient opening and closing of a fusion pore. **D**. Opening and widening of the fusion pore.

Viral Fusion Proteins

Viral fusion proteins lower the kinetic barriers to fusion of viral and cellular membranes. They do so by undergoing large-scale conformational rearrangements that lead to tight apposition of the two membranes.[161,162] We can thus distinguish "prefusion" and "postfusion" conformations, as well as potential intermediates. The viral fusion proteins studied at the time this chapter was written fall into three structural classes, usually designated I, II, and III, although the fusion machinery of the otherwise well-studied hepaciviruses appears to be an outlier.[124,216] Common characteristics of fusion by all three classes are insertion of a segment of the fusion protein into the target membrane and refolding of the protein so that this inserted segment and the transmembrane anchor of the protein are adjacent, thereby bringing together cell and viral membranes. The three structural classes probably represent meaningful evolutionary categories, but the phylogeny of the fusion protein is often distinct from that represented by standard viral classification schemes based on replication strategies and polymerase phylogenies, evidently because of extensive genetic exchange. For example, members of the thogotovirus genus of the negative-strand RNA orthomxoviruses have class III fusion proteins, related most closely to gp64 of the dsDNA baculoviruses, while other orthomyxoviruses have class I fusogens.[302] Moreover, eukaryotic cellular representatives of at least two of the classes closely resemble their viral orthologs.[169,257,303]

Class I Fusion Proteins

Unlike members of the two other classes, the class I fusion proteins do not have a consistent overall folded structure. Instead, their defining characteristics are (1) synthesis as a precursor that requires a proteolytic cleavage for activation, either during passage through the trans-Golgi network in the producing cell, while exposed to extracellular proteases during transfer from one cell (or host) to another, while attached at the surface of the target cell, or while engulfed in endosomes; (2) trimeric oligomerization in both pre- and postfusion conformations, based on a central, three-chain, α-helical coiled-coil in the postfusion conformation; and (3) presence of a hydrophobic "fusion peptide" at or near the N-terminus created by the activating cleavage. The fragment C-terminal to the cleavage, with the viral transmembrane segment, is the fusogen; the fragment N-terminal to the cleavage is often a receptor-binding structure, which generally dissociates when suitably triggered, releasing its grip on the C-terminal fragment, liberating the latter to undergo its fusogenic conformational change. The final, postfusion structure is a "trimer of hairpins," as described for three examples below. The N-terminal fragment can have a wide variety of folded structures, even among viruses of a single family.

Influenza A Virus HA

Influenza A virus HA (Fig. 3.29) is the best studied class I fusion protein and one of the simplest.[412] Its properties illustrate most of the features of class I fusion-protein structures and many of the essential features of fusion proteins in general. HA_0, the uncleaved precursor, and HA_1/HA_2, the cleavage product, are almost identical in structure, except for a local shift that tucks the fusion peptide (the N-terminus of HA_2) between the splayed helices of the central coiled-coil (Fig. 3.29B). This local transition makes the cleaved form substantially more stable than the uncleaved precursor.[361] Unless induced to refold by lowered pH or by heat, HA_1/HA_2 is stable. Mutations that shift the midpoint pH of the conformational transition are at widely distributed positions,[94] suggesting that overall charge distribution determines the transition point, rather than a defined trigger (eg, titration of one or more specific residues). The HA_1 "head" is a globular domain at the end of the molecule that faces away from the virus particle. It has a binding pocket (Fig. 3.29B and C) for the receptor, sialic acid.[402]

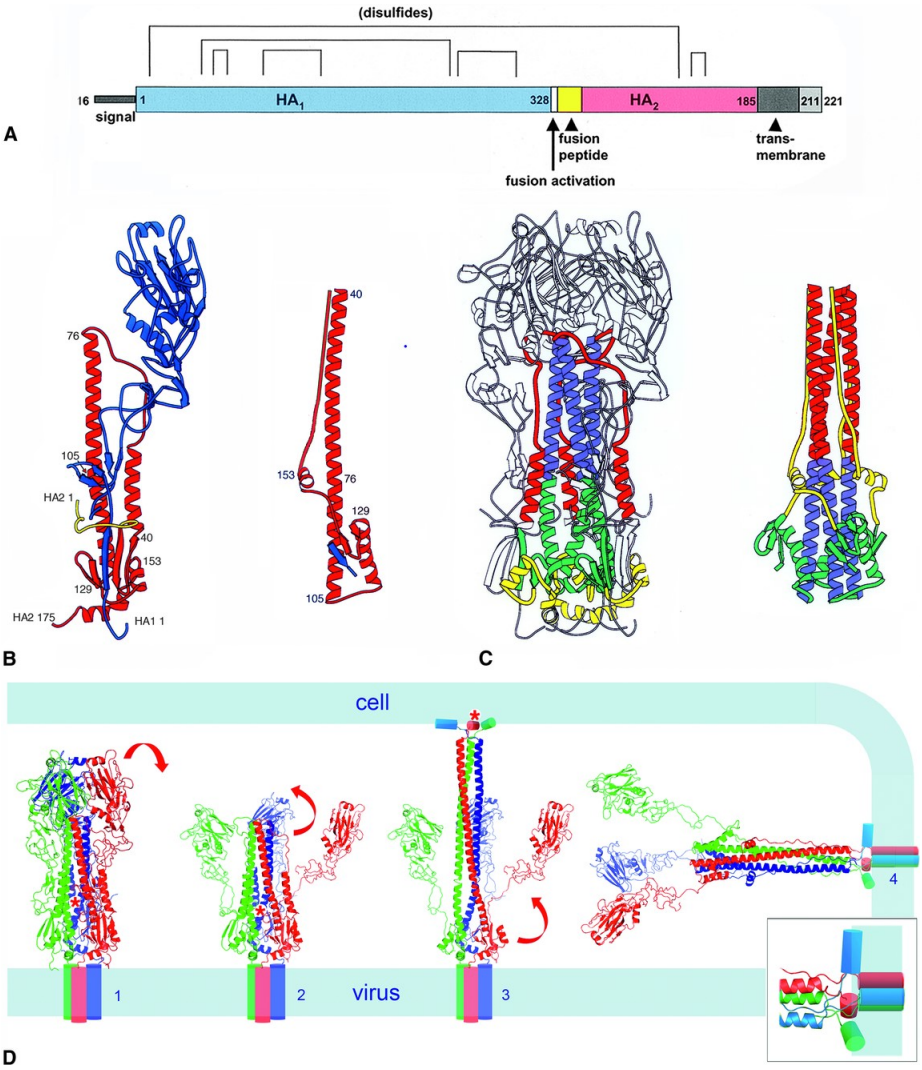

FIGURE 3.29 **Influenza virus hemagglutinin (HA): structure and fusion-promoting conformational changes**. **A**. The HA polypeptide chain. HA_1 in *blue*; HA_2 in *yellow* (fusion peptide), *red* (remainder of ectodomain), and *gray* (transmembrane and internal segments). The position of the fusion activation cleavage between HA_1 and HA_2 is a narrow white stripe, indicating excision of a single residue in many cases. The location of disulfide bonds is shown schematically above the bar. Residue numbers correspond to positions in the HA of strain X-31. **B**. The HA ectodomain monomer, in prefusion and postfusion (the latter, HA_2 only) conformations to the *left and right*, respectively. HA_1 in *blue*; HA_2 in *red*. The postfusion HA_2 structure illustrated here lacks the fusion peptide as well as additional residues at both ends of the chain. **C**. The HA ectodomain trimer, in prefusion and postfusion (the latter, HA_2 only) conformations, to the left and right, respectively. HA_1 in *black and white*; HA_2 in colors showing various segments of the ectodomain, so that their reconfiguration during the transition from the pre- to the postfusion structure is evident by comparison of the pre- and postfusion structures. Note the loop to helix transition in the C-terminal portion of the red segment (for review, see Ref.[362]). **D**. Scheme for the coupling of the fusion-promoting conformational change in HA to the fusing membranes. Stage 1: prefusion conformation. *Red asterisk* shows position of fusion peptide at N-terminus of HA_2. Engagement with a sialic-acid receptor in the target membrane is not shown. Stages 2 and 3: transition to an extended intermediate, in which the three fusion peptides of the trimer associate tightly with the target-cell membrane. The fusion peptide is shown schematically as an amphipathic helix in the membrane surface—the actual structure is probably an amphipathic helical hairpin.[242,243] Proton binding at low pH dissociates HA_1 from HA_2, although the two fragments remain tethered by a disulfide bond. Stage 4: during the transition of HA_2 from intermediate to postfusion conformation, the fusion peptide and transmembrane segment come together, thereby bringing the two membranes close enough to fuse. The final, postfusion conformation of HA_2 is locked in place by the "cap," shown in the *inset*, in which residues near the C-terminus of the HA_2 ectodomain interact with residues between the fusion peptide and the long, central α-helix.[68]

The connection between the HA ectodomain and the helical transmembrane segment has a hinge point, and the ectodomain can "lean" in various directions with respect to the membrane lipid bilayer.[28] On virions, however, the density of HA trimers studding the surface of the particle ensures an "upright" orientation, with all three receptor-binding pockets facing outward. The hinge is selectively sensitive to protease cleavage: prolonged incubation of virions with bromelain releases stable, intact, in general trimeric ectodomain, the form designated BHA (bromelain-cleaved HA) and first crystallized.[410]

Rearrangement of HA induced by proton binding (Fig. 3.29D) has three essential features.[44] One is separation of the HA_1 heads to allow a central coiled-coil to form.[27] A disulfide between a cysteine near the N-terminus of HA_1 and a cysteine near the C-terminus of the HA_2 ectodomain prevents complete dissociation and probably allows the heads to separate transiently, even at neutral pH. A second key feature of

the transition is ejection of the protected hydrophobic "fusion peptide" (Fig. 3.29D, transition from stage 2 to stage 3) from its pocket near the threefold axis of the trimer. The three fusion peptides contact each other, and the ejection is probably cooperative. Augmentation of the central coiled-coil by residues from the loop between the shorter "helix A" of HA_2 and the long central "helix B" may help pull the fusion peptide away from its extensive contacts in the cleaved, prefusion structure. A third key feature is folding back of the fusion protein (HA_2) so that the N-terminus (the fusion peptide) and the C-terminus (the viral membrane anchor) come together (Fig. 3.29D, transition from stage 3 to stage 4).[44,68,362] A likely intermediate state, for which there is good experimental evidence for fusion proteins of all classes,[49,100,129,164] is an extended structure with the fusion peptide buried in one membrane and the anchor in the other (Fig. 3.29D, stage 3). Zipping up of the C-terminal part of the HA_2 ectodomain along the core of this "prefusion intermediate" will cause the transmembrane anchor and the fusion peptide to approach each other. Formation of an intricate "cap" on the three-helix core of HA_2 probably snaps the refolded structure in place (Fig. 3.29D, inset).[68] Note that the zipping up process cannot be symmetrical, because the trimer would otherwise encase itself in lipid. The C-terminal outer-layer segments are long enough, in their unfolded state, to reach around the core of the refolding trimer. Contacts between the three outer-layer chains in the refolded structure are minimal, so that the three can zip up independently and at different rates.

The postfusion conformation of HA is a "trimer of hairpins." The N- and C-termini of each subunit lie at the same end of the elongated protein, and the polypeptide chain traverses the length of the molecule just twice—once from the N-terminus to the distal end, and once back to the C-terminus—with some modest complexity in the distal loop. The "inner core" is a trimeric coiled-coil; the "outer layer" of each subunit is largely extended chain, with a short helical segment. Other class I fusion proteins have the same postfusion characteristics (Fig. 3.30), the structure in the case of HIV-1 being particularly simple, as both inner core and outer layer are helical[29,61,246,404] (Fig. 3.30A). The two helices are sometimes designated HR1 or HRA and HR2 or HRB ("helical region 1" or "A" and "helical region 2" or "B," respectively), but the postfusion HA structure illustrates that identification of two helical regions may not always be informative. Moreover, a major part of the central coiled-coil in postfusion HA_2 is not helical in the prefusion trimer—another reason why "HR1" and "HR2" can be misleading designations. That is, no inferences can be drawn about the prefusion structures of these proteins from their trimer of hairpins postfusion conformers. Note further that in influenza HA, the N-terminal parts of HA_2 are on the outside of the spike in the prefusion conformation and on the inside in the postfusion conformation (Fig. 3.29). The protein turns itself inside out during the refolding.

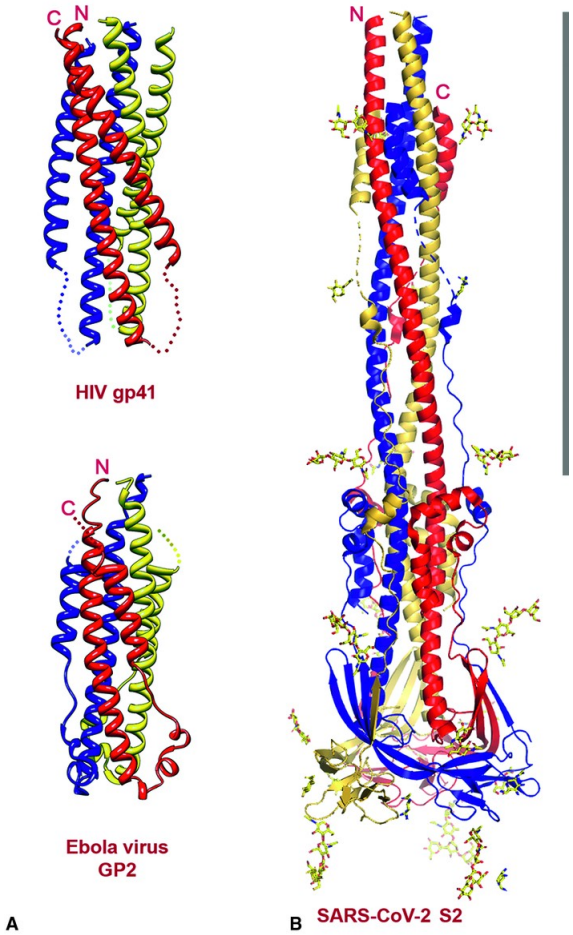

FIGURE 3.30 **Postfusion conformations of class I fusion-protein ectodomains**. **A**. Comparison of HIV-1 gp41 and Ebola virus GP2.[61,403,404,430] The fusion peptide extends from the N-terminus of the trimeric bundle; the transmembrane segment is at its C-terminus. Compare with the postfusion conformations of influenza virus HA2 in Figure 3.29C and of the paramyxovirus hPIV3 F2 protein in Figure 3.33B. The HIV gp41 structure is particularly simple: a six-helix bundle with a relatively short loop (*dotted lines*) between the inner (N-terminal) and outer (C-terminal) helices (HR1 or HRA and HR2 or HRB, respectively). **B**. Full postfusion structure of S2 from SARS-CoV-2, including the membrane-inserted fusion peptides (fp: a helical hairpin), the transmembrane anchors (tm), and a short helical segment of the cytoplasmic tail (ct), labeled for the red subunit. The N-terminus of the red subunit is indicated (the S2' site). Transparent blue region represents approximate extent of the membrane bilayer after fusion. *Gray bar* indicates the region ordinarily designated as HR1 and HR2 (see Refs.[376,441]). About 200 residues of S2 intervene between the HR1 and HR2 segments, most of them folded essentially as in the prefusion conformation. From Shi W, Cai Y, Zhu H, et al. Cryo-EM structure of SARS-CoV-2 postfusion spike in

membrane. bioRxiv/10.1101/2022.12.05.519151v1. Ref.[354a].

The influenza B virus HA is very similar in structure and properties to that of influenza A.[108] The influenza C and D orthologs, known as HEF (hemagglutinin-esterase-fusion) proteins, include an esterase activity that hydrolyses their 9-O-acetylated sialic acid receptors (Fig. 3.31A). Comparison of the influenza C HA with the influenza A and B HA structures shows that the latter have the N-terminal and C-terminal parts of the esterase domain ("vestigial esterase") but lack the central part with catalytic activity.[334]

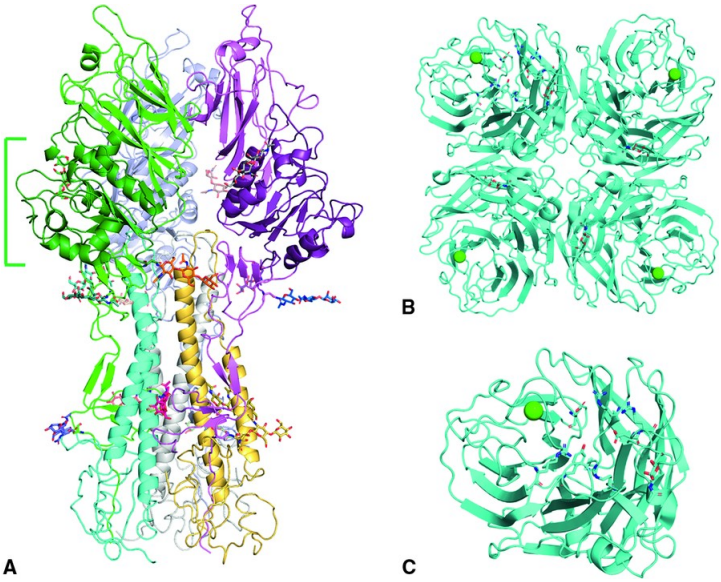

FIGURE 3.31 **HEF and NA**. **A**. Influenza C hemagglutinin-esterase. The esterase domains of the green and purple HA1 fragments are in darker shades of the same color, and the *green bracket* covers the extent of the former. The esterase, a serine hydrolase, cleaves the acetyl group from the C9 position of terminal 9-O-Ac-Neu5Ac residues, removing the viral attachment site.[170] Compare the structure with influenza A HA in Figure 3.29. From PDB 1FLC (Rosenthal PB, Zhang X, Formanowski F, et al. Structure of the haemaggluntinin-esterase-fusion glycoprotein of influenza C virus. *Nature*. 1998;396:92-96. Ref.[334]). **B**. Influenza A neuraminidase tetramer. The *green spheres* are structural Ca^{2+} ions. Some structures also show a Ca^{2+} on the fourfold axis. From PDB 2HTY. **C**. Magnification of one subunit, showing residues in the active site as sticks. (Russell RJ, Haire LF, Stevens DJ, et al. The structure of H5N1 avian influenza neuraminidase suggests new opportunities for drug design. *Nature*. 2006;443:45-49. Ref.[341]).

HIV Env

HIV-1 Env, synthesized as a heavily glycosylated, trimeric, gp160 precursor and cleaved to gp120 and gp41, is the sole HIV-1 surface protein (reviewed in Ref.[65]). The structure of gp120/gp41 on the virion surface, determined at low resolution by cryo-ET,[237] has allowed integration of various substructures, determined at much higher resolution by x-ray crystallography,[200,220,296] cryo-EM,[224,248] and NMR[103,127,308,309,417] (Fig. 3.32). The general organization resembles that of influenza virus HA, but with considerably more elaborate details. The processing cleavage, like the cleavage of HA, does not by itself lead to any large-scale reorganization, but it releases a constraint on conformational dynamics and enables gp41 to refold when sequential binding of receptor (CD4) and coreceptor (either CCR5 or CXCR4, depending on isolate) leads to gp120 dissociation.[65,267] Five variable loops (designated V1 through V5) decorate the gp120 surface,[220] enabling rapid antigenic variation and continuous escape from the on-going B-cell response in an infected host. The bipartite domain structure of gp120 allows CD4 binding to stabilize an initial transition to a more open structure, in which the three clustered V1-V2 loops at the apex of the trimer move apart, exposing the V3 loops to make important contacts with the coreceptor[238,289,295,352,400,418] (Fig. 3.27).

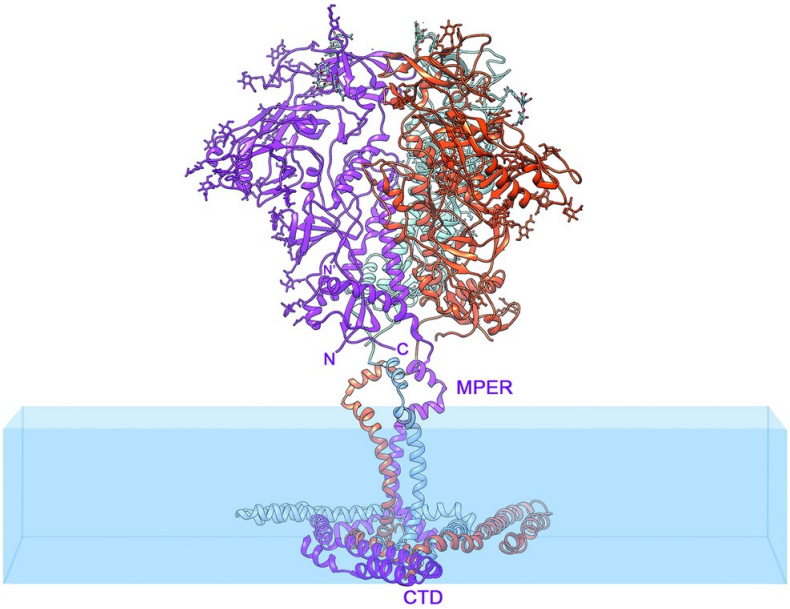

FIGURE 3.32 **HIV Env**. Composite structure of HIV, based on the structure of an unmutated, fully glycosylated, full-length Env extracted directly (in nonionic detergent) from membranes by association with the Fab of human monoclonal PG16 (Fab not shown) (PDB ID: 6ULC)[291] and NMR studies of constructs comprising the membrane-proximal external region (MPER), transmembrane helix (TM), and cytoplasmic domain (CTD) (PDB: 7LOI).[103,127,309] The approximate extent of lipid bilayer is shown (semitransparent *blue* block). The N and C termini of gp120 are marked on one subunit (*magenta*). The first ordered residue at the N terminus of gp41 of the same subunit is labeled N′; the fusion peptide immediately N-terminal to the N′ position is not ordered in the cryo-EM structure.

As in HA, a relatively flexible connection between the HIV-1 Env ectodomain and the membrane-associated components allows the trimeric "spike" to adopt a range of orientations with respect to the membrane bilayer.[291] The membrane-associated structures of gp41 are substantially more extensive than those of HA_2: they include a trimeric "membrane proximal external region" (MPER)[127]; the transmembrane helices, which are also trimer clustered[103]; and a long, elaborately folded C-terminal segment[308,309] (Fig. 3.32). Truncation of the C-terminal segment alters some aspects of the antigenicity of the ectodomain, indicating a coupling between the two, probably through constraints on conformational dynamics.[67] Dissociation of gp120 allows gp41 to refold, ultimately to a rather simple, six-helix bundle (a trimer of helical hairpins: Fig. 3.30A) from its relatively more complex set of shorter helices in the prefusion conformation.[29,61,404]

Paramyxovirus and Pneumovirus F

The fusion (F) proteins of paramyxoviruses and pneumoviruses[69,81,221,420,421] (Fig. 3.33) have a cleavage site just N-terminal to a fusion peptide, which resembles (in being hydrophobic and relatively glycine-rich) the fusion peptides in gp160 and HA_0. Cleavage is essential for fusion activity, but not for the fusion-promoting conformational change, and cleavage does not lead to dissociation of any part of the protein, as it does for HIV-1 Env. In the mushroomlike, prefusion conformation of parainfluenza virus 5, a three-strand α-helical coiled-coil, the stem of the mushroom, is the C-terminal part of the ectodomain. It connects directly (in the intact protein) to the transmembrane segment. The connection between the coiled-coil stem and the head of the mushroom is an ordered, but very extended, stretch of polypeptide chain, which wraps around the outside of the globular cap. The cap also presents a groove to accommodate the fusion peptide. A separate protein (designated HN, H, or G in various paramyxoviruses) binds receptor and triggers the conformational rearrangement of F (reviewed in Ref.[33]; see Chapter 12, volume 1). Its absence may account for the requirement of an ectopic restraint to keep even the uncleaved protein from refolding to a postfusion-like conformation.[421] In the refolded state, a long, three-strand coiled-coil forms from segments (all C-terminal to the cleavage site) that are part of the globular "cap" in the prefusion structure.[420] The C-terminal coiled-coil comes apart so that the C-terminal helices can fold back up along the outside of the newly formed coiled-coil. The length of the connection between the globular domains and these helices, which probably dissociate, unfold, translocate, and refold as they zip along the coiled-coil core, allows sufficient flexibility for this transition. None of the trimer contacts in the prefusion state are fully conserved in the postfusion structure, raising the possibility of a monomeric intermediate, but the overall geometry does permit the assembly to refold as a trimer without such dissociation. The structure of the F protein of respiratory syncytial virus (RSV), a pneumovirus, closely resembles that of PIV5, with a different organization of the C-terminal helices and a more deeply buried fusion peptide in the cleaved form.[256]

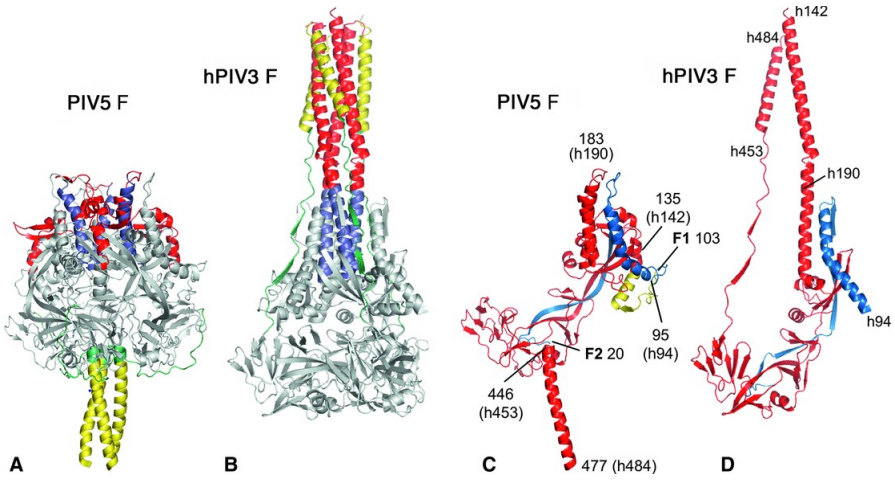

FIGURE 3.33 **The paramyxovirus fusion protein (F)**. **A**. The ectodomain trimer of parainfluenza virus 5 (PIV5 also known as SV5) F in its prefusion conformation. F1 is in black and white; F2, in color. The order of colors corresponds to the order of colors in influenza HA_2 in Figure 3.26C. The viral membrane would be at the bottom of the figure in panel **(A)**: the polypeptide chain of F2 enters the membrane immediately following the *yellow* segment, which forms a three-chain coiled-coil in the prefusion conformation. **B**. The postfusion conformation of F from another paramyxovirus, human parainfluenzavirus 3 (hPIV3). Color scheme as in **(A)**. The fused membranes would be at the top of the figure in panel **(B)**. Note that the red and blue segments toward the N-terminus of F2 have refolded into a three-chain coiled-coil, projecting the fusion peptide (not shown) toward the "top" of the trimer. Compare these segments with those of corresponding color for influenza virus HA2 in Figure 3.26C. Also note that the *yellow* segments at the C-terminus of the F2 ectodomain no longer form a coiled-coil, but rather align along the outside of the coiled-coil generated by the (*red* and *blue*) N-terminal region. **C, D**. Pre- and postfusion conformations of monomers, with F1 in *blue*, F2 in *red*, and fusion peptide (N-terminus of F2) in *yellow*. Numbers in **(C)** correspond to PIV5 F; numbers with "h" in **(C)** and **(D)**, to hPIV3 F. (Figure courtesy Ted Jardetzky, Stanford University.)

Class II Fusion Proteins

The defining characteristics of fusion proteins in this class are a three-domain subunit (domains I, II and III or DI, etc.), with an internal, hydrophobic "fusion loop" at the tip of the elongated DII; association with a second, "chaperone" protein that protects the fusion loop; and formation of a stable trimer in the postfusion state, with the three fusion loops and the three C-terminal, transmembrane anchors clustered at one end (Fig. 3.12). Found initially on flaviviruses and alphaviruses, both of which are compact, icosahedrally symmetric particles, class II proteins are also the fusion proteins of bunyaviruses and hence very widespread. They are known as E1 and E in alphaviruses and flaviviruses, respectively, and as Gc in bunyaviruses; the chaperones, as p62, prM, and Gn. Cleavage of p62 or prM generates E3 + E2 or pr + M, with release of E3 or the pr fragment. Gn does not require cleavage to allow Gc to mediate low-pH triggered fusion and viral entry. Although roughly similar in their overall, multidomain organization, in a common β-ribbon core, and in their association with the fusion protein, the chaperones of different virus families have otherwise divergent structures.[151] (An exception to this statement is the polypeptide-chain fold of alphavirus E2 and hantavirus Gn.[150])

The flavivirus E protein tiles the surface of the mature virion as a tightly associated dimer, in the herringbonelike pattern described above[215] (Fig. 3.12). On an immature particle, before cleavage of prM (the chaperone), E forms heterodimers with prM rather than homodimers with itself.[215] The prM-E heterodimers cluster as asymmetric trimers at neutral pH (eg, after budding into the ER) but rearrange into dimers at the somewhat lower pH of the trans-Golgi network, where furin cleaves prM. The "pr" domain, which covers the fusion loop, dissociates only when the particle again reaches neutral pH as it emerges from the cell[227,423,424]; the fusion loop at the tip of domain II then packs against domain III of the dimer partner. The short ectodomain of the residual M protein that remains lies between E1 and the membrane.

Alphaviruses have a T = 4 icosahedral arrangement of E1-E2 heterodimers, clustered into threefold protrusions by E2 contacts (Fig. 3.23B). E2 has three, Ig-like domains; the second of these covers the fusion loop of E1. The C-terminal tip of the E1 transmembrane helix contacts a core-protein subunit. The MXRA8 adhesion molecule, the receptor for most arthritogenic alphaviruses, binds at the interface between E1 and E2,[21] and hence both proteins in their native heterodimeric pairing participate in receptor recognition. The LDL-related LDLRAD3 receptor of VEEV inserts into a cleft between threefold-related E1-E2 heterodimers, also contacting both proteins.[22]

The organization of bunyavirus Gn-Gc on the surface of virions varies from one group of this large family to another.[151,183] Crystal structures of Gc from Rift Valley Fever virus (RVFV),[102] severe fever with thrombocytopenia syndrome virus (SFTSV),[156] Puumala virus,[411] Hantaan virus,[149] and a number of others, in either pre- or postfusion conformations, show the familiar class II structure. Partial Gn crystal structures and predicted folds are more variable, but in general, there are three domains, organized by a structurally conserved β-ribbon.[151] Despite the T = 12 arrangement on phenuivirus particles (eg, RVFV), the particles deform readily, limiting the resolution of cryo-EM structures.[157,182] Fitting crystal structures into a 13-Å resolution reconstruction of the virion indicates that the first two domains of Gn occupy the prominent rings of five- and sixfold density seen in the reconstruction and that the second domain shields the fusion loop of Gc.[157] The heterodimer interaction is reminscent of the alphavirus arrangement, even though the domains have somewhat different folded structures, but the surface clustering of the heterodimers is quite different. The hantaviruses are pleomorphic: four Gn-Gc heterodimers cluster into a fourfold complex that packs tightly on the surface of the particle but not in a locally well-ordered array.[183,228]

The postfusion trimers that form at acidic pH have very similar conformations for all class II fusion proteins (Figs. 3.12 and 3.34). The conformation of the fusion loop is very similar across essentially all group II fusion proteins, including a disulfide that locks it in a relatively unusual configuration and a projecting tryptophan side chain. A pocket adjacent to the fusion loop, conserved in most group II fusion proteins,

accommodates the headgroup of a glycerophospholipid in the postfusion trimer of RVFV Gc.[148] It probably confers some lipid headgroup affinity in other cases as well. Electron microscopy of postfusion trimers bound to liposomes show that the fusion loops insert part way into the outer leaflet of the target membrane, consistent with the position of the headgroup binding site. Figure 3.34 illustrates likely steps in the flavivirus fusion process, deduced from comparison of the pre- and postfusion conformations of dengue- and TBE-virus fusion proteins.[163,281,386,416]

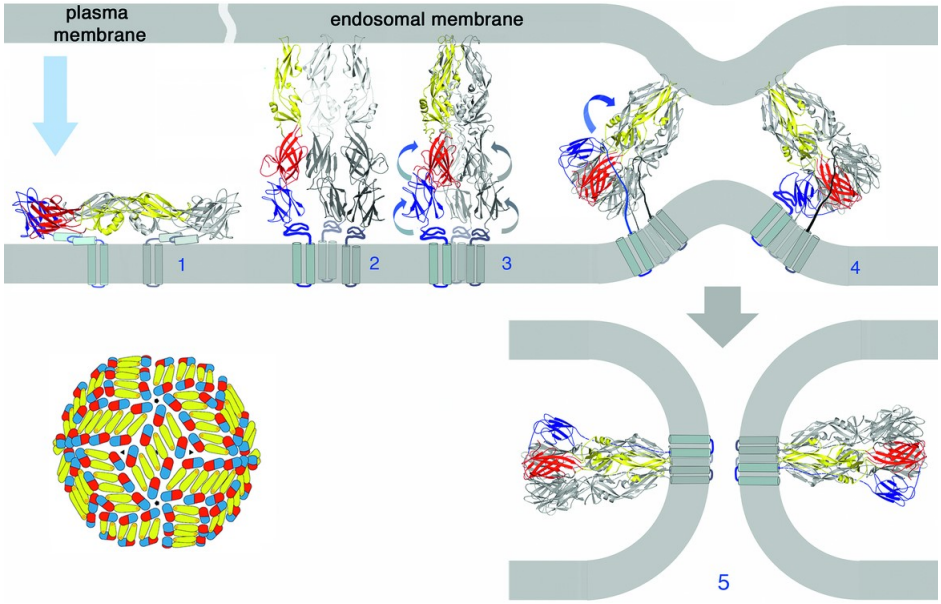

FIGURE 3.34 **Flavivirus envelope protein, E, and fusion-promoting conformational changes**. Diagram *lower left*: dimer-clustered packing of E on the virion surface. The three domains of each protein ectodomain are in *red*, *yellow*, and *blue*. Numbered sequence, starting on top row: likely series of conformational states of E and their links to viral and cellular membranes. Structures for states (1) and (5) are known (Fig. 3.12C); those for states (2)-(4), shown as monomers only (because maintenance of trimer state during the fusion-promoting transition is uncertain), are inferred from indirect data.[64,262] One subunit in each dimer or trimer is colored as in the schematic; its partner(s) are in *gray*. (1) E dimer on the virion surface. The ectodomain terminates in a helical hairpin called the "stem" (*light blue*) on the surface of the viral membrane (*lower gray bar*) and connects with a transmembrane helical hairpin. *Blue arrow* from above symbolizes a receptor interaction with domain III (*blue*). (2) Exposure to low pH (following endocytosis and acidification of endosome) dissociates the E dimer, allowing the subunits to project outward, so that the fusion loops (tip of the *yellow* domain II) encounter the endosomal membrane (*upper gray bar*). (3) Initial trimer association, requiring rearrangement across the surface of the virion. *Arrows* show presumed pattern of folding back; *upper arrows*: domain III (*blue*) flips over against domain I (*red*); lower arrows: the stem refolds to "zip up" alongside the trimer clustered domain II (*yellow*). (4) Stem continues to reorganize (asymmetrically), pulling the two membranes together. The fusion loops must be firmly anchored in the target membrane. (5) Formation of a fusion pore allows the refolding to finish, so that all three stems and all three fusion loops cluster together, restoring full threefold symmetry.

Class III Fusion Proteins

Class III fusion proteins mediate penetration of viruses as distinct as rhabdoviruses,[18,19,25,330,332] herpesviruses,[12,165,240,394] and thogotoviruses,[302] as well as insect baculoviruses.[11,202] There appears to be no proteolytic cleavage required for priming, and the fusion-inducing conformational change is in at least some cases reversible[331]: virions inactivated by prolonged incubation at pH < 6 can be reactivated by returning the pH to neutral or above, and both conformations of the multidomain, trimeric protein can be obtained from the same protein preparation.

VSV-G, the only protein on the surface of the virion, has two hydrophobic loops that can interact with membrane lipids[113] (Fig. 3.35). The connectivity of the strands joined by these fusion loops is different from the connectivity in domain II of the class II proteins (ie, the domains themselves have different folds), but the general picture is quite similar: hydrophobic residues (including at least one tryptophan) are displayed on tightly structured loops at the tip of an elongated domain. In the prefusion conformation of VSV-G, these domains face the viral membrane around the periphery of the trimer.[332] In the postfusion conformation, they cluster around the threefold axis[330](Fig. 3.35).

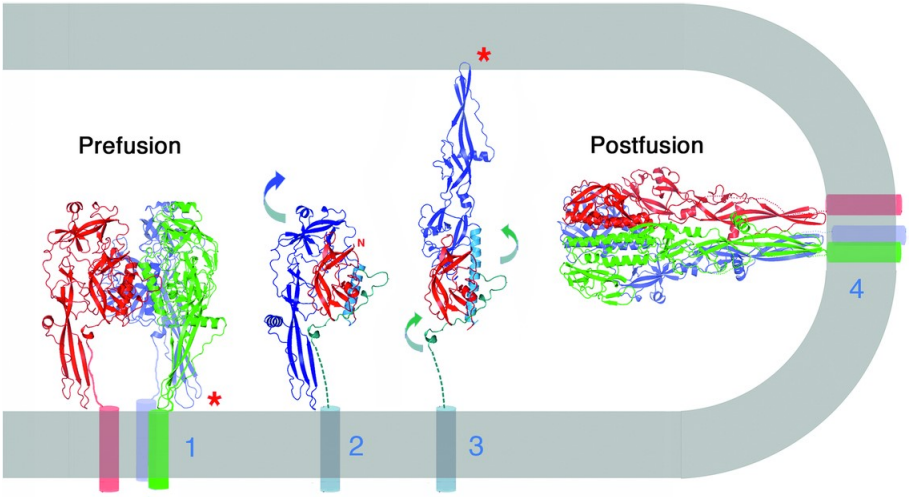

FIGURE 3.35 **VSV glycoprotein, G: structure and fusion-promoting conformational changes**. Sequence of conformational events as in Figures 3.26 and 3.31.[207] (1) Prefusion trimer of VSV G on the virion surface.[332] Subunits colored in *red*, *blue*, and *green*. *Red asterisk*: fusion loops of the green and blue subunits. (2) Conformation of one subunit of the trimer in (1), now colored to show a central, red, domain and a set of peripheral, blue domains. An axial helix (*lighter blue*) joins part of the central domain to the set of peripheral domains. In the low-pH triggered rearrangement, the blue regions reorient with respect to the red domain (*arrow*). (3) Presumed initial rearrangement, in which the domain bearing the fusion loops projects toward the cellular (endosomal) membrane, into which the fusion loops insert. The axial helix remains, augmented by a segment derived from its connection to the peripheral domains. *Arrows* indicate likely reorganization that follows: the central domain flips over and the "stem" at the C-terminus of the ectodomain zips up, bringing together the two membranes. (4) Formation of a fusion pore (not shown explicitly—compare the last two stages in Fig. 3.29) allows the three sets of fusion loops and the membrane-proximal segments of the ectodomain to cluster. Part of the stem rearrangement includes formation of helical segment, which forms a six-helix bundle with the central-region helix. The conformational details thus have features of both "class I" fusion proteins (formation of a six-helix bundle) and of "class II" fusion proteins (preconfigured, internal fusion loops that insert into the target membrane).[330]

In the rhabdovirus G protein, a core domain contains residues from the N-terminal segment of the polypeptide chain and residues from near the C-terminal part of the chain: it is a framework around which the rest of the molecule reorients (Fig. 3.35). Two other domains form a jointed, two-part fusion machinery. The result of their rotations relative to the core domain (and to each other) is to move the fusion loops away from the viral membrane and toward the target membrane. In a likely extended intermediate conformation, the C-terminal segment still connects toward the virus, while the fusion loops interact with the target. In the fully rearranged, low-pH conformation, the C-terminal segment has zipped up along the fusion domains, much as in the flavivirus fusion transition.

The herpesvirus fusion protein, glycoprotein B (gB), looks like an elongated version of VSV-G.[12,165,240] This unexpected similarity between fusion proteins of a DNA virus and a negative-strand RNA virus has allowed information about one protein (eg, the identification of the rhabdovirus fusion loops) to be carried over to the other.[158] The only high-resolution, prefusion structure of a gB determined at the time of writing is that of human cytomegalovirus.[240] Stabilization of the prefusion conformation required introducing designed mutations—inspired by strategies useful for structural studies of HIV-1 Env,[200,203,248] paramyxovirus F,[178] and coronavirus spike.[177] The gB conformational transition is triggered not by changes in pH but rather by receptor binding to another surface protein, gD.[53,213] A binding-induced conformational change in gD leads to the transition of gB to the postfusion conformation, with participation of yet another protein, the gH/gL heterodimer.[77,252]

Other Viral Glycoproteins

The influenza viruses and paramyxoviruses, both of which bud at the cell surface, require a receptor-destroying enzyme to allow them to escape rebinding to the cell from which they have emerged.[290] The receptor for influenza A and B viruses is sialic acid, and the receptor destroying enzyme is the neuraminidase (NA). The structure of NA (Fig. 3.31B), a six-blade β-propeller, resembles that of catalytic domains of various bacterial sialidases. NA is both the target of widely used influenza inhibitors (oseltamivir and zanamavir),[397] which block spread of the virus at early stages of infection, and, like all viral surface proteins, NA is a viral antigen. The receptor destroying function is a domain of the HEF protein of influenza C and D viruses (Fig. 3.31A) and a domain of the receptor-binding hemagglutin-esterase of paramyxoviruses. Like herpesviruses, paramyxoviruses have a distinct receptor-binding protein, which constrains the fusion protein in its prefusion conformation when the two are present together on the virion surface and releases it to refold when receptor binds.

Membrane Fusion

The molecular architectures of enveloped-virus fusion proteins vary substantially, as Figures 3.29-3.36 illustrate, but the events that lead to formation of a hemifusion stalk and ultimately of a fusion pore appear to be essentially the same. Interaction with one or more ligands initiates a conformation change that results in formation of an extended intermediate bridging between viral and host-cell membranes. To overcome the kinetic barrier to stalk formation, a small number (~2-5, see below) of adjacent, extended intermediates fold back toward the postfusion conformation. The free energy recovered from this favorable transition is enough to pull the membranes together over the small area enclosed by the narrow "palisade" of collapsing intermediates, and the apposed outer leaflets at the tips of the nipplelike bilayer distortions then merge. To reach the final, postfusion conformation, the fusion peptides and transmembrane anchors must come together completely, requiring the internal (cytoplasmic) domains of the fusion proteins to pass into a transiently opened, aqueous pore and to drive further pore opening by preventing reclosure.

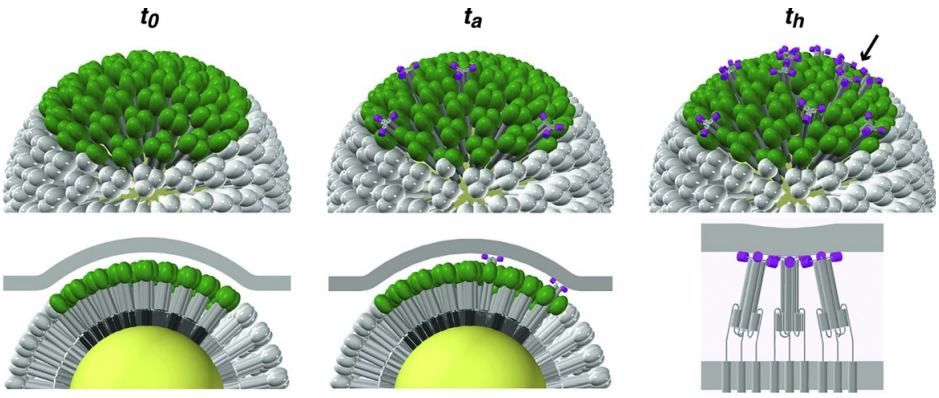

FIGURE 3.36 **Stages of influenza HA–mediated membrane fusion**. Virion dimensions in the diagram are based on a spherical particle, 55 nm in membrane to membrane diameter.[50] There are ~50 HA trimers in the contact area between the virus and the target cell, shown in *green* (HA1) and *gray* (HA2); trimers outside of the contact area are in *white*. t_0: virion engages a target membrane by HA-receptor interactions at neutral pH, but can still move freely relative to the target-membrane area of contact. t_a: as the pH drops after uptake by endocytosis, fusion peptides of HA trimers project outward and engage the target membrane, forming extended intermediates. Isolated extended intermediates do not exert enough force on the membrane to distort it toward a hemifusion stalk. t_h: engagement of fusion peptides from three *neighboring* HA_2 trimers, which can together exert the required distorting force. Rapid folding back ("zippering") of the three HAs leads to hemifusion (see Fig. 3.29D). For t_h, HA1s are left out for clarity from the *bottom panel*, which shows three neighboring trimers about to fold back. (From Ivanovic T, Choi JL, Whelan SP, et al. Influenza-virus membrane fusion by cooperative fold-back of stochastically induced hemagglutinin intermediates. *Elife*. 2013;2:e00333. http://creativecommons.org/licenses/by/3.0/. Ref.[187])

The most detailed picture of these events comes from analysis of *in vitro*, single-virion fusion kinetics of influenza virus[122,187,188] (Fig. 3.36). Initial attachment, through multiple sialic-acid contacts, establishes an extended contact zone between the virus particle and the target membrane. For influenza virus particles, that contact zone includes 50 or more HA trimers, owing to the tight packing of HA on the surface of typical influenza virus particles. When the pH falls below a critical level (about 5.5 for the H3 viruses studied), individual trimers undergo (stochastically) the first steps of the fusogenic conformational change, leading to extended intermediates that span the two membranes, with fusion peptides in the target membrane and TM segments in the viral membrane. To initiate hemifusion stalk formation requires a small number of *immediately adjacent* HA molecules, as nonparticipating HAs between any two refolding ones would interfere with drawing the two membranes close together. The number of required HAs that best fits the observations is about 3,[122,187,188] comparable to estimates from measurements of HA-expressing cells fusing with red blood cells.[93,122] (These numbers are necessarily an average. In an ensemble of fusion events, a few events might occur with just 2 HAs and others with 4, depending on local molecular fluctuations.) Related studies of flavivirus and flavivirus VLP fusion[64] and of VSV fusion[207] have led to similar conclusions, with at least 2 refolding trimers required for flavivirus fusion and between 3 and 5 for VSV.

Penetration by Nonenveloped Viruses

Nonenveloped viruses must breach a membrane to access the cytoplasm or nucleus of a cell, but unlike their enveloped cousins, they cannot do so by membrane fusion. Current experimental observations show three kinds of mechanism by which a nonenveloped particle, bound at the surface of a cell or taken up into an endosome or other internal compartment, translocates itself (or its genome) across the intervening lipid bilayer—ie, "penetrates." The first involves creation of a pore, through which the viral genome is drawn into the cell through some sort of channel. The elaborate injection structures of many bacterial viruses (eg, the T-even bacteriophage) illustrate an extreme version of this class of mechanism, which appears to be the way some single-strand, plus-sense RNA viruses penetrate. The second class, membrane "perforation," requires a more extensive, disruption of a cellular membrane (eg, the membrane of an endocytic vesicle or an endosome), in order to admit the virion, usually in altered form, into the cytosol. The third, found so far only in the parvoviruses, involves exposure of a lipase that chemically disrupts the surrounding membrane. For all three classes, binding of a receptor, coreceptor, or some other ligand induces a conformational change in the virus particle, with consequent exposure of previously buried, hydrophobic, or enzymatically active structures.

Picornavirus particle expand transiently when the bind receptor, releasing not only the N-terminally myristoylated VP4[76] but also exposing a hydrophobic N-terminal segment of VP1.[42,125,137,153,155] Myristoyl groups target proteins to membranes, and it is logical to suppose that exposure of the myristoylated peptide causes it to associate with membranes and ultimately to contribute to penetration. In keeping with this supposition, picornavirus VP4 makes pores in membranes.[95,297] Images and reconstructions from low-resolution cryo-EM and cryo-ET of poliovirus particles bound to membrane-anchored receptors suggest that some combination of the released VP4 and the exposed segment of VP1 form a channel, through which the genomic RNA can pass into such pores.[34,42,43,173,388]

For another class of single-strand, plus-sense RNA viruses, there is high-resolution evidence for the formation of such a tubelike projection. When a feline calicivirus particle decorated with a soluble ectodomain of its receptor, feline junctional adhesion molecule A, is exposed to acidic pH, an internal protein, VP2, present in 12 copies, oligomerizes into a tubelike projection at a single threefold position on the particle surface[80] (Fig. 3.37). The hydrophobic N-terminal tips of VP2, disordered in the absence of a membrane, point away from the virion surface; the logical inference is that when endocytosis of the receptor-bound virion carries it into an endosome, the VP2 tips insert into the endosomal membrane. The calicivirus and picornavirus models both resemble "just on time" assembly of a phage tail–like structure. RNA delivery would then require a mechanism for destabilizing secondary-structural elements in the RNA. One candidate "helicase" would be a ribosome or ribosome-associated factors, by analogy with an *in vitro* uncoating mechanism found for certain positive-strand RNA plant viruses. For those viruses, exposure of the 5′ end of the RNA (eg, through expansion of the virion induced by intracellular ionic conditions) leads to association of ribosomes with the still largely packaged RNA genome; progress of the ribosome along the message-sense genome and sequential formation of a polysome appears to uncoat the RNA cotranslationally.[16,38,354,355,413] A similar "striposome" mechanism could, in principle, draw RNA through a membrane pore

as well as through an opening in the viral shell.

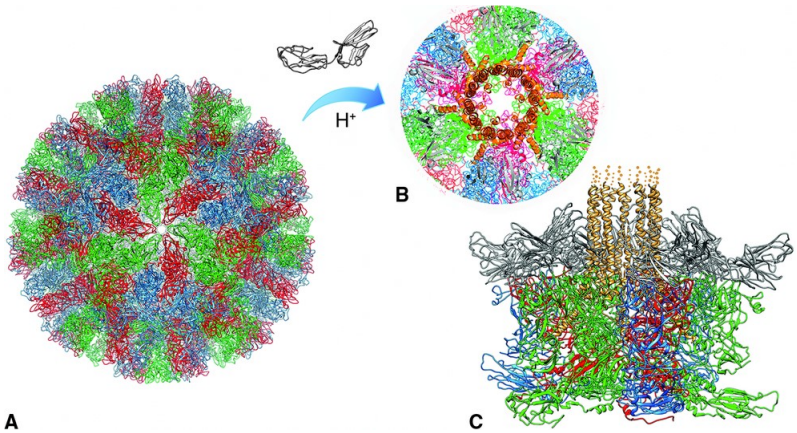

FIGURE 3.37 **Calicivirus-receptor complex at low pH: formation of VP2 portal**. **A**. Feline calicivirus particle (T = 3), viewed along a threefold axis. VP1 subunits in A, B, and C positions colored *blue*, *red*, and *green*, respectively, as in Figures 3.6 and 3.9. Dashed circle shows region of blow-up in B. B, **C**. Binding to receptor (feline junctional adhesion molecule A: fJAM-A) and exposure to pH of endosomes triggers translocation outward of 12 VP2 subunits (*orange*), which form a tubelike structure ("portal"), likely to be a route of RNA exit. An N-terminal region of fJAM-A (two Ig-fold domains, shown in cartoon representation above the *curved arrow*) associates with VP1 dimers, accompanied by local conformational changes that open a channel in the VP1 shell, viewed along the axis of the channel, in **B**, and normal to that axis, in **C**. In the latter view, *dotted lines* show the hydrophobic, N-terminal segments of the twelve VP2 polypeptide chains, likely to insert into a target-cell membrane. From coordinates in PDB files 6GSH and 6GSI. (Conley MJ, McElwee M, Azmi L, et al. Calicivirus VP2 forms a portal-like assembly following receptor engagement. *Nature*. 2019;565:377-381. Ref.[80])

Adenoviruses enter cells by endosomal uptake; penetration proceeds by disruption of the endosome containing the virion.[121,141] The subviral particle admitted to the cytoplasm lacks pentons, as a result of events triggered by receptor and coreceptor binding. Exposure of an internal viral protein, pVI, which depends on the activity of a packaged viral protease, leads to perforation of the endosomal membrane.[357,408] The membrane-disrupting properties of pVI may come from an N-terminal amphipathic α-helix.[269] Following penetration, the partially stripped virion migrates to a nuclear pore, where it disassembles and liberates its DNA for nuclear import.

Like adenoviruses, the dsRNA viruses release into the cytoplasm an intact, roughly 700-Å diameter subviral particle (called the "core" in the case of reoviruses and the "double layered particle" in the case of rotaviruses). This inner capsid particle never uncoats, however, as it contains all the enzymes necessary for mRNA synthesis and modification (see Chapter 11, volume 3). The penetration protein of mammalian orthoreoviruses is the outer-shell trimer, μ1[62,175,281](Fig. 3.27). On the virion, this protein is associated with a "chaperone" subunit, σ3; degradation of σ3 (by proteases in the gut or by cathepsins in endosomes) and autocleavage of μ1 allows μ1 to release a myristoylated, N-terminal peptide (μ1N). The released peptide, up to 600 copies of which could emerge from a single virion, forms membrane pores.[186,431] The autocleavage step is similar to the corresponding step in picornaviruses that separates VP4 from VP2; the correspondence extends not only to pore formation by the released fragment but also to the folded structure of uncleaved μ1, which, like VP1, 2, and 3 of picornaviruses, is a jelly-roll β-barrel subunit (Fig. 3.27). The sequence of events that precedes membrane perforation is quite different for the two types of virus, however.

The attachment/penetration protein of rotaviruses is VP4, which must be cleaved to VP8* + VP5* in order to activate it for entry [84] (see Chapter 12, volume 3). VP4 is not a homolog of μ1, although rotaviruses do have such a homolog, VP6, which appears to have a purely structural role[251] (Figs. 3.12 and 3.38). VP4 is a trimer that projects as an asymmetric, upright "spike,"[350] held in place by the second outer-layer protein, VP7. Only local changes accompany cleavage to VP8* and VP5*, but like class I fusion proteins, the cleaved trimer undergoes a major conformational rearrangement when suitably triggered, inserting a substantial C-terminal segment of the VP5* polypeptide chain into the membrane to which it is attached by the RBD of VP8*[2,106,171,208,422] (Fig. 3.37). A combination of live-cell imaging studies[2,343,344] and high-resolution cryo-EM structures[171,350] has yielded a moderately complete "movie" of the molecular events that accompany rotavirus penetration, but breakage of the vesicular membrane remains (at the time of writing) a molecular blind spot.

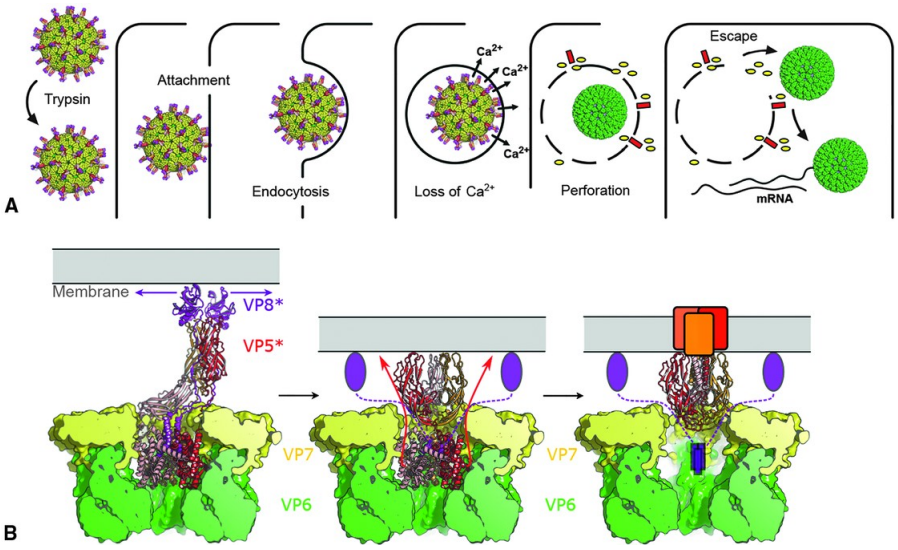

FIGURE 3.38 **Rotavirus entry**. See Figure 3.13 for overview of rotavirus structure. **A**. Scheme for stages of rhesus rotavirus infection of BSC-1 cells.[2,343,344] Tryptic cleavage of VP4 to VP8* (receptor-binding fragment) and VP5* (membrane-interacting fragment) primes the trimeric spike to mediate entry. Receptor binding (the receptor is often part of a glycolipid head group) leads to membrane invagination (clathrin-independent in some cells, but at least sometimes clathrin-mediated in others). Rearrangement of VP5* and its concomitant interaction with the surrounding membrane (details in panel **B**) allow escape of Ca^{2+}; the reduced Ca^{2+} concentration destabilizes VP7, releasing the rearranged VP5* trimer from the particle and allowing (by a mechanism yet to be determined) escape of the DLP into the cytosol. **B**. VP5* rearrangement and membrane insertion. Binding of VP8* lectin domain to glycolipid head group and transient dissociation of lectin domain from projecting part of VP5* (*left panel*) allows capture of hydrophobic loops at the tips of the VP5* domains; membrane insertion prevents reassociation of VP8* lectin domain, which is tethered at its N-terminus into the folded "foot" domain at the C-terminus of VP5* (*center panel*). Unfolding and emergence of foot domains leads to their insertion into the membrane of the cell (*right panel*). The foot-insertion step probably permeabilizes the membrane to Ca^{2+}, leading to loss of Ca^{2+} from the particle following complete engulfment.[343] VP8*, *magenta*; VP5*, shades of *red*; VP7, *yellow*; VP6, *green*. (From Herrmann T, Torres R, Salgado EN, et al. Functional refolding of the penetration protein on a nonenveloped virus. *Nature*. 2021;590:666-670. Ref.[171])

The parvovirus capsid protein has two or three forms, with the jelly-roll structure at their common C-termini and varying N-terminal extensions, determined by alternative splicing and alternative start codons.[260] The two forms in canine parvovirus (CPV), VP1 (~84 kDa) and VP2 (~67 kDa), are present in a ratio of about 5:55.[276] The additional residues in VP1, which extend into the particle interior, include an N-terminal phospholipase 2 (PLP2) domain and a linker segment with a nuclear localization sequence (NLS). From the outside of the particle, there is no apparent difference between VP1 and VP2, and structures known at the time this chapter was written do not show whether the five or six VP1 subunits are clustered or distributed. More copies would leave no room inside the shell for the DNA genome. CPV binds the transferrin receptor and enters the endolysosomal pathway by clathrin-mediated endocytosis.[89,299,300] Structural changes (presumably some expansion) at low pH cause the PLP2 of VP1 to move to the outside of the particle; enzymatic hydrolysis of endosomal lipids allows the particle to escape into the cytosol and move to the nucleus, presumably by importin recognition of the linker-segment NLS. The adeno-associated viruses (AAVs) have different receptors but follow a similar route.

Perspective

The explosion of cryo-EM–derived structures since the last edition in 2014 has illustrated, with many variations, the "principles" previously extrapolated from a handful of model examples. Most critically, it has allowed virologists to apply these principles directly to their virus of interest and to design experiments to relate structure and function in specific detail. In just over 2 years, the structural picture we have of the maturation, antigenicity, immunogenicity, receptor binding, and fusion of SARS-CoV-2 nearly rivals the accumulation of information from over 40 years of work on similar aspects of influenza virus. But it also validates the investment of those 40 years, for without the conceptual foundation established by that work and by studies of other selected viruses, much of the effort on SARS-CoV-2 would have taken far longer. The same is true, with less fanfare, for many other emerging or re-emerging viral pathogens.

What comes next? Many on-going efforts will doubtless accelerate—for example, probing the structural basis of viral antigenicity, in the interest of more rational vaccine immunogen design. Prompt structural attention to newly identified threats to global health will surely facilitate their containment. A more fundamental issue is how to relate the molecular events we can study by direct structural analysis to what happens as a virus encounters a cell. The advances in live-cell imaging and image analysis that combine with cryo-EM and cryo-ET to produce the scheme in Figure 3.38 offer a way to make this connection. Tracking individual virus particles from their initial attachment to a receptor through all the stages of internalization that lead to transcription and replication will help distinguish productive from unproductive entry pathways and resolve ambiguities about events that occur only in intact cells. Direct visualization, with comparable, single-particle resolution, of transfer from producer to recipient cell will be similarly enabling. Future editions will need movies of the structural transformations described here, in the experimentally derived "scenery" of living cells and tissues.

Acknowledgment

Introduction

Viral particles have a single mission: to transport the viral genome from an infected host cell to a noninfected host cell and to deliver it into the cytoplasm or the nucleus in a replication-competent form. The target can be a neighboring cell, a cell elsewhere in the host organism, or a cell in another organism. The process starts in an infected cell with the packaging of the viral genome and accessory proteins into a new virus particle, which is released into the extracellular space. When the virus contacts the surface of a new host cell, a complex series of events ensues tightly coordinated in time and space. These events include binding to receptors and signaling, often followed by endocytic internalization, vesicular trafficking, membrane penetration, cytosolic transport, and nuclear import (Fig. 4.1). Uncoating is an integral part of the process; the virus particle is modified, destabilized, disassembled, and eventually the genome, present in a protected and condensed form in the virion, is decondensed and exposed in a replication- or transcription-competent form. The progression of a virus particle through its entry program depends critically on cellular functions. The *Trojan horse strategy* that is used is necessary because the particles are simple and capable of limited independent functions.

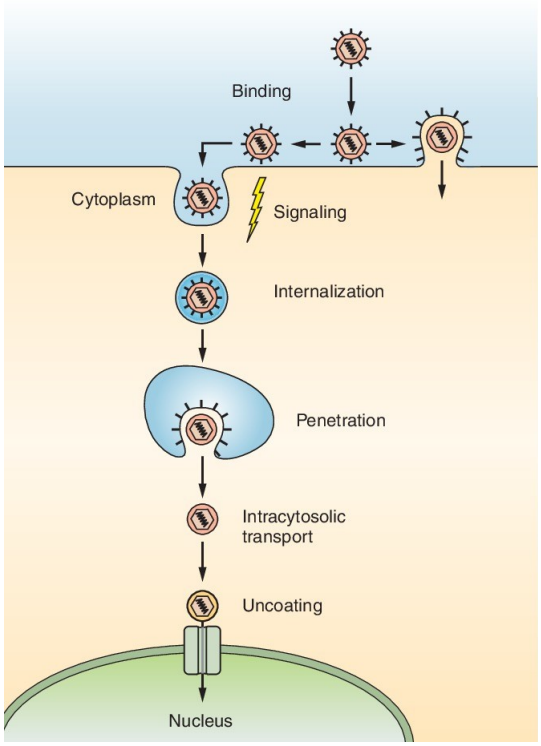

FIGURE 4.1 **Stepwise entry of animal viruses**. The entry of animal viruses involves a series of steps that start with virus binding to the cell surface. Binding is multivalent and involves cell surface molecules serving as passive attachment factors or receptors that are more active in that they activate signaling pathways, induce conformational changes in the virus, or mediate endocytic internalization. Although some enveloped viruses are able to fuse with the plasma membrane, the majority of viruses rely on internalization by different endocytic mechanisms. Internalization is followed by transport to secondary organelles (usually endosomes), where the virus receives cues to trigger the penetration process. After reaching the cytosol, the viruses or viral capsids are transported to the site of genome uncoating and replication. For most DNA viruses and a few RNA viruses, this site is the nucleus. Many viruses have evolved mechanisms that allow them to deliver their genome and accessory proteins through the nuclear pore complexes.

This chapter describes some of the general concepts that govern cellular entry of animal viruses. For information about the entry of specific viruses and virus families, the reader is referred to the virus chapters. Information relevant to the topics covered here also can be found in numerous reviews that cover early virus cell interactions.[59,114,149,159,160,177,211,231,291]

The Barriers

The first barrier that incoming viruses must overcome is the glycocalyx, a layer of glycoconjugates that covers the external surface of cells. It is composed of glycoproteins, glycolipids, and proteoglycans. The composition and thickness of this layer is variable. By binding to oligosaccharides, many viruses make use of the glycocalyx for initial attachment.

The next barrier is the plasma membrane. Responsible for the cell's exchanges with the environment, it is the most complex and most dynamic of all cell membranes. The composition and properties are regulated by the endocytic and secretory pathways and by a continuous association and disassociation of proteins that interact with the cytosolic leaflet. The plasma membrane is a highly sensitive organ for recognizing and responding to external stimuli. Viruses take advantage of this during entry.

After clearing the plasma membrane by direct penetration or by exploiting endocytic pathways, viruses and viral capsids have to reach sites deeper in the cytoplasm. The cortical actin network underneath the plasma membrane and extreme crowding constitute major barriers to movement within the cytoplasm.[253] Finally, because many viruses replicate in the nucleus, the genome and accessory proteins must travel to the nucleus and cross the nuclear envelope. This requires cooperation between the incoming virus and the nuclear import machinery.[290]

Virus Binding to the Cell Surface

Viruses can only infect cells to which they can bind. Binding occurs to *attachment factors* and *virus receptors* on the surface of the cell. To a large extent, the identity, distribution, and behavior of these cellular components determine which cell types, tissues, and organisms a virus can infect. The receptors also define, in part, the pathogenic potential of a virus as well the nature of the disease that it causes.

Virus *receptors* can be defined as cell surface molecules that bind the incoming viruses to the cell and, in addition, promote entry by (1) inducing conformational changes in the virus that lead to priming, association with other receptors, membrane fusion, and penetration; (2) transmitting signals through the plasma membrane that lead to virus uptake or penetration and prepare the cell for the invasion; or (3) guiding bound virus particles into a variety of endocytic pathways.[177] *Attachment factors* help to concentrate the particles on the cell's surface, thus enhancing entry and infection. Unlike receptors, however, they do not actively promote entry and mediate signals. Often, the interactions with attachment factors are not highly specific. In practice, the distinction between a receptor and an attachment factor is not always straightforward because the consequences of virus binding to a given surface component are difficult to assess experimentally and can vary depending on cell type and conditions.

Receptors and attachment factors constitute a diverse collection of proteins, carbohydrates, and lipids with physiologic functions unrelated to pathogen interaction. Ranging from abundant and ubiquitous to rare and species specific, they differ from one virus to the next. In the past few decades, an impressive number have been identified in different virus and host cell systems. As shown in Table 4.1, which gives a partial list, receptors include ligand-binding receptors, glycoproteins, ion channels, gangliosides, carbohydrates, proteoglycans, and so on. Some families of surface molecules seem to be favored; the immunoglobulin-G superfamily of transmembrane proteins, proteoglycans, and glycoconjugates with terminal sialic acid residues, belong to these. In addition, a large group of viruses use integrins as their receptors.[260]

TABLE 4.1 Receptor proteins for some viruses

Virus	Family	Receptor	Function	References
G-protein–coupled receptors				
HIV	*Retroviridae*	CXCR4,CCR3,CCR2b,CCR8 CCR5	Chemokine receptors	2,46,68,227
HIV/SIV	*Retroviridae*	CCR5, Bonzo/STRL-33/ TYMSTR, BOB/GPR15, GPR1	Chemokine receptors	3,80,148
Proteins with multiple membrane-spanning domains				
GALV/FeLV-B/SSAV	*Retroviridae*	PiT-1	Phosphate transport	194,270
MLV-E	*Retroviridae*	MCAT-1	Cationic amino acid transport	1
MLV-A	*Retroviridae*	PiT-2	Phosphate transport	179,280
MLV-X/MLV-P	*Retroviridae*	XPR1/Rmc1/SYG1	Transporter	13,269
HCV	*Flaviviridae*	CD81	Tetraspanin membrane protein	205
Enterovirus 71	*Picornaviridae*	SCARB2	Endosomal membrane protein	299
Ebola virus	*Filoviridae*	NPC1	Endo/lysosomal cholesterol transporter	38,52
Immunoglobulin-related proteins				
Poliovirus	*Picornaviridae*	PVR (CD155)	Adhesion receptor	172
PRV/BHV-1	*Herpesviridae*	PVR (CD155)	Adhesion receptor	94
HSV-1/HSV-2/PRV	*Herpesviridae*	Prr2/HveB/nectin-2	Adhesion	79
HSV-/HSV-2/	*Herpesviridae*	Prr1/HveC/nectin-1	Adhesion	94
Coxsackie B	*Picornaviridae*	CAR	Homotypic cell interaction	17,272
Ad-2/Ad-5	*Adenoviridae*	CAR	Homotypic cell interaction	18,272
MHV-A59	*Coronaviridae*	MHVR/Bgp1 (a)	Biliary glycoprotein	72
Human rhinoviruses (type B and A major group)	*Picornaviridae*	ICAM-1	Cell adhesion/signaling	100,258
HIV/SIV	*Retroviridae*	CD4	T-cell signaling	156
HHV-7	*Herpesviridae*	CD4	T-cell signaling	153
AAV2	*Parvoviridae*	AAVR	Type I transmembrane protein	206
Low-density lipoprotein receptor–related proteins				
Rous sarcoma virus (type A)	*Retroviridae*	LDLR	Lipoprotein receptor	12
Human rhinoviruses (type A, minor group)	*Picornaviridae*	LDLR/α 2MR/LRP	Lipoprotein receptors	111
Venezuelan equine encephalitis virus	*Togaviridae*	LDLRAD3	Lipoprotein receptor	155
Integrins				
Adenovirus	*Adenoviridae*	$\alpha v\beta 3$	Vitronectin binding	292
Coxsackie A9	*Picornaviridae*	$\alpha v\beta 3$	Vitronectin binding	223
Adenovirus	*Adenoviridae*	$\alpha v\beta 5$	Vitronectin binding	293
Echoviruses-1/-8	*Picornaviridae*	$\alpha 2\beta 1$Banks	Collagen/laminin binding	20
Foot and mouth disease virus	*Picornaviridae*	$\alpha 2\beta 1$, $\alpha v\beta 3$, $\alpha v\beta 6$	Vitronectin binding	22,117
Hantaan virus	*Bunyaviridae*	$\alpha 3$ integrins		90
Rotavirus	*Reoviridae*	$\alpha 4\beta 1$, $\alpha v\beta 3$, $\alpha 2\beta 1$		109
Cytomegalovirus	*Herpesviridae*	$\alpha v\beta 3$, $\alpha 2\beta 1$, $\alpha 6\beta 1$		82
Tumor necrosis factor receptor–related proteins				
ALV-B/D/E	*Retroviridae*	TVB	Apoptosis-inducing receptor	28
Herpes simplex virus 1	*Herpesviridae*	HveA	LIGHT receptor	39,165
Small consensus repeat–containing proteins				

Epstein-Barr virus	*Herpesviridae*	CR2	C3d/C3dg/iC3b binding	84,85
Measles	*Paramyxoviridae*	CD46	Complement inhibition	69
Echoviruses	*Picornaviridae*	CD55, neonatal Fc receptor	Complement inhibition/Fc receptor	17,182,306
Coxsackie B-1/-3/-5	*Picornaviridae*	CD55	Complement inhibition	19,241
Miscellaneous				
LCMV/Lassa fever virus	*Arenaviridae*	α-Dystroglycan	Laminin/agrin binding	36
Coronavirus-229E/TGEV	*Coronaviridae*	Aminopeptidase-*N*	Metalloproteinase	19,300
SARS-CoV/SARS-CoV-2	*Coronaviridae*	ACE2	Metallocarboxypeptidase	112,144
Arthritogenic alphaviruses	*Togaviridae*	Mxra8	Matrix/signaling modulator	303

Many viruses use multiple attachment factors and receptors. They interact with them in parallel or in series, or they use different receptors for entry into different cell types. When multiple receptors are required for productive entry, it is the convention to call the one contacted first a *receptor* and the subsequent ones *coreceptors*. A good example is human immunodeficiency virus type 1 (HIV-1), which makes use of heparan sulfate proteoglycans as attachment factors, CD4 as a receptor,[37] and CXCR4 and CCR5 (or a related chemokine receptor) as coreceptors.[21,181] In this case, the two receptors are used to induce stepwise conformational changes in the spike glycoprotein. For fusion, the hemorrhagic fever viruses, Ebola and Lassa, each engage two different receptors, one on the plasma membrane and one within endocytic carrier compartments. In both cases, binding to the primary receptor at the cell surface triggers virus uptake by endocytosis.[4,135] Within endosomal compartments, a low pH-dependent conformational change in the viral glycoproteins facilitate a receptor switch that enables endosomal escape.[38,119,143] In other cases (eg, adenovirus 2 and coxsackie B virus), two receptors seem to be needed to overcome anatomic and topological barriers.[54,186] Herpes viruses and poxviruses are able to infect a variety of cell types, probably in part because they possess proteins that can bind to several different receptors.[86,255] Cases are also seen where unrelated viruses make use of the same receptors. One well-studied example is coxsackie and adenovirus receptor (CAR) (Table 4.1), which is used as a receptor both by adenovirus 2 and 5 and coxsackie B viruses.[304]

The interaction between a viral surface protein and a receptor can be highly specific, but the affinity is often low. However, the presence of multiple, closely spaced binding sites on the surface of the virus particle allows multivalent binding, and the avidity is, therefore, frequently high. The affinity of influenza hemagglutinin for sialic acid containing glycoconjugates is, for example, in the millimolar range, but virus binding to cells is virtually irreversible.[249] That most receptor molecules are laterally mobile in the plasma membrane allows, moreover, the formation of a local *microdomain* rich in receptors under the bound virus with a composition and properties different from that in the surrounding membrane.[75] The consequences can be the inclusion of the virus in lipid rafts, or entrapment in caveolae, coated pits, and other membrane specializations. Receptor clustering can also lead to transmembrane signaling, changes in the actin cytoskeleton, and recruitment of cytosolic factors such as a clathrin coat to the plasma membrane.

Although the interaction between a virus and its receptors is generally direct, there are cases where adaptor proteins are involved. Binding of antibodies to dengue virus allows infection of macrophages via Fc receptors on the surface of these cells.[201] In this case, the virus particle is internalized as an immune complex. Instead of neutralizing the virus, the antibodies mediate expansion of the host cell repertoire. Some Flaviviruses (including dengue), Arenaviruses, Poxviruses, and Alphaviruses employ a strategy termed apoptotic mimicry, whereby bridging molecules link phosphatidylserine in the virus envelope with cellular phosphatidylserine receptors (reviewed in Ref.[5]). This strategy serves to trigger virus entry and simultaneously dampen host immune responses to infection.[24,168,174,242]

In enveloped viruses, the spike glycoproteins are responsible for receptor binding. Typically, these are oligomeric type 1 integral membrane proteins that have the bulk of their mass outside the membrane with the receptor-binding domain exposed. Other external domains in the same protein may be responsible for membrane fusion and receptor destruction. In some spike proteins (eg, the HIV-1 glycoprotein), the receptor-binding moiety is not covalently connected to the rest, which allows its dissociation once receptor interaction has occurred. X-ray crystal structures of spike glycoprotein-receptor complexes exist for several enveloped viruses (see Chapter 3).

In nonenveloped viruses, the structures that bind receptors are projections or indentations in the capsid surface. Adenoviruses have trimeric fiber proteins with globular knobs that project from the vertices.[23] The penton base protein of many adenovirus subfamilies contains in addition an exposed Arg-Gly-Asp (RGD) sequence that associates with integrins.[259] Many enterovirus receptors bind in a cleft in the capsid surface called the *canyon*, the molecular features of which have been analyzed in great detail.[225]

Role of Carbohydrates

Glycoconjugates on the cell surface have an important role during entry of many viruses as receptors and attachment factors. Glycoproteins and glycolipids, with terminal sialic-acid residues, serve as specific receptors for a variety of viruses, including orthomyxo-, paramyxo-, and polyoma viruses. The HA1 subunits of influenza A virus hemagglutinin (HA) bind terminal sialic acid residues associated with galactose through either a Neu5Ac α(2,3)-Gal or Neu5Ac α(2,6)-Gal bond.[249] Human influenza recognizes the α(2,6) linkage; avian and equine viruses, the α(2,3) linkages, whereas porcine viruses appear to recognize both. These specificities reflect the structure of the glycans expressed in the different species and play a central role in limiting cross-species transmission. The tetrameric hemagglutinin-neuraminidase (HN) proteins of parainfluenza virus 5 has specificity for α(2,3)-sialyllactose,[301] and polyomaviruses bind to specific saccharide residues in the glycan moieties of various gangliosides.[276] A difference limited to a single atom in sialic acids plays a major role in species specificity of simian virus 40 (SV40), because it binds better to the simian GM1 ganglioside, which has a *N*-glycolylneuraminic acid, than to the human, which has a *N*-acetylneuraminic acid.[35]

The list of viruses recognized as binding to glycosaminoglycan (GAG) chains (eg, heparan- and chondroitin-sulfate) is steadily growing.[11] It now includes several herpes-, alpha-, flavi-, retro-, parvo-, picorna-, pox-, and papillomaviruses. Binding often involves positively charged patches in viral surface proteins. In some cases, viruses adopt GAGs as receptors when grown in tissue culture; their surface proteins mutate and express more basic residues.[34,250] In contrast to tissue culture–adapted strains, natural isolates do not necessarily bind to GAGs. Indeed, adaptation of

different glycan receptors is likely part of the age-old war against pathogens, including viruses and their hosts, a war in which the diversity of surface carbohydrates plays an important role. Poxviruses, for example, encode one chondroitin sulfate and two heparan sulfate binding proteins, yet viral binding protein dependence and GAG usage vary with virus species and strain.[14,15]

In most cases, it is the viruses that recognize host cell glycans. However, the reverse is true when cell surface lectins bind to glycans present in the envelope proteins of incoming viruses. One such lectin is DC-SIGN, a tetrameric, C-type lectin present on the surface of immature dendritic cells. It binds *N*-linked glycans of the high-mannose type,[81] such as in glycans that have failed to undergo terminal glycosylation in the Golgi complex of the infected cells. Because glycoproteins synthesized in insect cells have exclusively high-mannose glycans, viruses introduced into the skin via insect bites are often recognized by DC-SIGN, resulting in the infection of dendritic cells. Viruses that bind to these lectins include HIV-1, Sindbis, human cytomegalovirus, dengue, and severe acute respiratory syndrome (SARS) viruses.[92,133,152,209,247,271] Thus, cells that our body uses in the front-line defense against pathogens end up serving the interests of viruses instead by spreading the infection.

Mobility of Cell-Associated Viruses

The encounter between individual viruses and the cell can be visualized live by light microscopy using fluorescent viruses. What happens depends on the virus, the receptor, and the host cell. Parvovirus particles undergo rapid binding and release events that eventually result in permanent attachment and endocytic internalization.[239] Polyomavirus particles bind firmly and diffuse laterally in the membrane for 5-10 seconds.[78] Depending on the receptor concentration, virions slide within the membrane or roll over the membrane, after which they are arrested in confinement zones defined by the cortical actin network and eventually internalized.[78,136,268] Reoviruses do not show lateral motion after binding.[73] In the case of a bunyavirus, Uukuniemi virus, the rapid clustering of receptor molecules (GFP-tagged DC-SIGN) can be seen to occur at the site of virus binding.[151]

Filopodia have been shown to play an active role by providing directed transport of surface-associated virus particles toward the cell body.[140] They are thin, mobile extensions of the plasma membrane stabilized by an actin filament bundle. Such “virus surfing” occurs at a rate of 1-2 mm/min, mirroring the rate of retrograde actin flow from the tip of the filopodia inward.[233] It is actin dependent and inhibited by inhibitors of myosin II. Although such motility of viruses is not essential for infection in tissue culture cells, it may play a role in tissues.

After endocytosis, the actin- and microtubule-dependent movement of intracellular vacuoles, viruses, and naked capsids inside the cell can also be visualized.[73,107,139,228,283] This is illustrated by fluorescent influenza A viruses, which after a slow period of actin-restricted motion in the cell periphery undergo rapid microtubule-mediated transport toward the perinuclear space where penetration by membrane fusion occurs.[139,228] In the case of adenovirus 2, the transport of capsids along microtubules is both plus- and minus-end directed, but net transport in the minus-end direction allows the virus to reach the nucleus.[266] The entry of parvovirus adeno-associated virus 2 has been traced all the way to the nucleus, inside of which it moves unidirectionally along well-defined pathways.[239]

Virus-Induced Signals

Many viruses use the host cell’s signaling systems to promote entry and optimize infection.[97,177,186] Viruses take advantage of the fact that cells are exquisitely sensitive to ligands that bind to the plasma membrane, particularly if they induce clustering of surface components. More specifically, signaling is used to trigger access to coreceptors, to induce endocytic responses, to reprogram endocytic pathways, and to induce favorable intracellular conditions for infection.

Signaling starts at the plasma membrane after binding of the virus to receptors and formation of receptor clusters. Depending on the virus, receptors, and host cells, initial binding can lead to activation of tyrosine or other kinases, which, in turn, trigger cascades of downstream responses at the plasma membrane, in the cytoplasm, and, in some cases, in the nucleus. Virus-induced signaling depends on the usual panel of second messengers (phosphatidylinositides, diacylglycerides, and calcium), and on numerous regulators of membrane trafficking and actin dynamics.

One well-studied case that demonstrates the complexity of virus-induced signaling is provided by adenoviruses 2 and 5, which use CAR and integrin $\alpha v\beta 3$ as receptors.[97,186] Endocytic internalization occurs via clathrin-coated vesicles, and penetration takes place in endosomes. The interaction with the integrin triggers activation of p85/p110, a PI(3) kinase. The synthesis of $PI(3,4)P_2$ and $PI(3,4,5)P_3$ activates protein kinase C. Small GTPases (eg, Rab and Rho family members) are also activated. One of the downstream responses is the transient activation of macropinocytosis, an actin-dependent process that results in a rapid increase in internalization of fluid.[169] This response seems to promote subsequent penetration of adenovirus from endocytic vacuoles by virus-induced rupture.

Another example is SV40, which is entirely dependent on signaling for entry. After binding to GM1 gangliosides, the virus induces local activation of tyrosine kinases, which results in actin filament reorganization, activation of caveolar dynamics, internalization of the virus in caveolar or lipid raft vesicles, and induction of long-distance transport of the virus-containing vesicles.[60,191,203,257] More than 50 different kinases were shown to regulate the entry and early steps in the infection of HeLa cells by this virus.[202]

A final example involves Kaposi sarcoma–associated herpesvirus (human herpesvirus 8).[41] The glycoprotein gB of this virus possesses an RGD sequence in the ectodomain that allows it to bind to the integrin $\alpha 3\beta 1$. Binding activates focal adhesion kinase (FAK) and Src kinases, which, in turn, activate PI(3) kinases and Rho GTPases. Furthermore, via the PI(3)K-PKCzeta-mitogen activated or extracellular regulated kinase (MEK) pathway, the virus induces the extracellular signal-regulated kinase 1 and 2 (ERK1/2). Activation of these pathways leads to major alterations in the actin cytoskeleton, and the virus is internalized by macropinocytosis in human fibroblasts.

Endocytic Pathways of Infection

Whether viruses penetrate into the cytosol directly through the plasma membrane or after endocytosis has been a hotly debated issue from the beginning of animal virology. It is now recognized that a majority of animal viruses—whether enveloped or nonenveloped—make use of endocytosis for productive infection. They exploit one or more of several endocytic mechanisms offered by cells (Fig. 4.2), and most of them enter endocytic vacuoles where penetration into the cytosol occurs often triggered by low pH. Enveloped virus families (eg, paramyxo-, herpes-, and retroviruses) that can penetrate directly through the plasma membrane because they do not require endocytosis for fusion may still depend

on endocytosis for productive infection at least in some cell types.[134,188] Here, the reason may be that fusion at the plasma membrane remains nonproductive because it does not ensure passage of the capsids through further barriers such as the actomyosin cortex.[158]

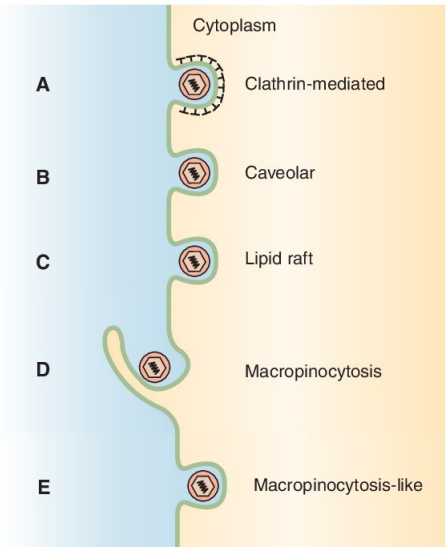

FIGURE 4.2 **Mechanisms of endocytosis used for virus entry**. Viruses can use different mechanisms of endocytosis. The majority of animal viruses enter cells by endocytosis. The mechanisms include **(A)** clathrin-mediated endocytosis, the most commonly used mechanism for virus entry; **(B)** caveolar endocytosis, a caveolin and lipid raft–dependent mechanism mainly used by polyomaviruses; **(C)** a caveolin-independent, lipid raft–mediated mechanisms with many similarities to the caveolar mechanism; **(D)** macropinocytosis, a transient, ligand-induced, actin-dependent mechanism; and **(E)** various macropinocytosis-like mechanisms which are caveolin and clathrin independent.

The main reason why endocytosis is a preferred mode of entry is most likely that endocytic vesicles offer viruses a free ride through the cortical cytoskeleton and other barriers that encumber movement of virus-sized particles in the cytoplasm. By delaying their penetration, viruses can in this way get a ride to the perinuclear region of the cell. In endocytic vacuoles, viruses can, moreover, count on receiving specific cues such as a drop in pH and exposure to proteases to trigger penetration and uncoating. Because no trace of the virus is left exposed on the plasma membrane, immunorecognition of infected cell is delayed. Moreover, for nonenveloped viruses that use membrane lysis or pore formation for penetration, it may be essential to cross membranes of intracellular organelles to minimize damage to the cell.

In recent years, the landscape of endocytosis research has expanded dramatically beyond phagocytosis and the classic clathrin-mediated endocytosis pathway. New mechanisms include caveolar or lipid raft-mediated endocytosis, macropinocytosis, and several other macropinocytosis-like pathways that operate independent of clathrin and caveolae (Fig. 4.2).[67,166,175,199,278] The situation is often confusing because the mode of uptake of a virus can vary between cell types and strains, and many viruses can make use of multiple receptors and parallel routes of endocytosis in the same cell. In addition to caveolae, SV40 can, for example, utilize a related, noncaveolar pathway.[60] Influenza A uses both clathrin-mediated and clathrin-independent pathways,[162,228,244] and HIV-1, which can fuse with the plasma membrane, can in some cell lines also make efficient use of an endocytic pathway for entry.[57]

The use of multiple entry pathways poses challenges for antiviral drug design and repurposing. For example, chloroquine, an antimalaria drug that acts by raising endosomal pH, is known to inhibit viruses that enter cells by low pH-dependent endocytosis[232] (Table 4.2). In 2005, chloroquine was shown to inhibit SARS coronavirus (SARS-CoV) infection in primate-derived kidney cells (Vero).[282] Early during the COVID-19 pandemic, SARS-CoV-2 was shown to use ACE2 as an entry receptor, and chloroquine shown to inhibit its infection in Vero cells.[112,286] Shortly thereafter, chloroquine and its analog hydroxychloroquine were repurposed for treatment of COVID-19, despite efficacy concerns.[83] When the inhibitory capacity of chloroquine and hydroxychloroquine was tested in human lung cells (Calu-3), neither could prevent entry nor infection by SARS-CoV-2.[113] Direct comparison of SARS-CoV-2 entry indicated that the virus enters Vero cells by chloroquine sensitive, low pH-dependent endocytosis, and human lung cells through chloroquine insensitive, plasma membrane fusion.[197] Which of these entry pathways SARS-CoV-2 takes depends on the transmembrane serine protease, TMPRSS2 (reviewed in Ref.[118]). When present at the plasma membrane of target cells, TMPRSS2 cleaves the viral spike protein exposing the fusion peptide, which then initiates virion fusion at the cell surface. In the absence of TMPRSS2 cell surface expression, SARS-CoV-2 virions are taken up by endocytosis and spike cleaved by cathepsin L within endosomes resulting in fusion from the endosomal compartment.[34]

TABLE 4.2 pH dependence of virus families

Low pH Dependent	pH Independent
Adeno	Corona (majority)
Alpha Borna	Retroviruses (majority) Herpes (majority)
Bunya	Paramyxo
Corona (some)	Hepadna
Filo	Pox (some)
Flavi	Rota
Orthomyxo	Picorna (most)

The use of cell type–dependent entry mechanisms likely explains the lack of *in vivo* efficacy of chloroquine and hydroxychloroquine against SARS-CoV-2 seen in large, randomized trials.[25,93] This example serves to highlight that the use of multiple receptors, redundant endocytic pathways and different modes of entry provides viruses with a degree of flexibility and adaptability that makes entry a difficult step for host organisms to protect themselves against.

The cell biology of endocytosis and its regulation is complex.[49,145] High-throughput siRNA silencing, haploid genetic, and CRISPR screens have led to the identification of host genes critical for early infection of tissue culture cells including essential attachment factors, entry receptors, and proteins required for distinct endocytic trafficking pathways.[45,110,202,216] Entry studies are often further complicated by the fact that only a small fraction of the cell-associated viruses enter productively. Because most morphological and biochemical methods fail to distinguish between particles that enter productively and those that do not, studies using these methods must be complemented with readouts based on infection (ie, the biological outcome of successful entry). This involves the use of inhibitors, dominant negative mutants, small interfering RNAs, mutant viruses, and mutant cell lines. Only a combination of methods allows pathways of productive entry to be charted with confidence.

Clathrin-Mediated Endocytosis

The clathrin-mediated endocytic pathway is used by many viruses (Figs. 4.2 and 4.3). It is a process that cells use to internalize a spectrum of receptor-bound ligands, fluid, membrane proteins, and lipids for recycling or degradation. By binding to receptors that have the internalization signals necessary for inclusion in clathrin-coated pits, viruses make use of this pathway as opportunistic ligands. Uptake is characterized by rapid kinetics (viruses are generally internalized within a few minutes after binding) and by high capacity (3000 virus particles or more per minute).[159] With a diameter up to 120 nm, coated vesicles are large enough for the endocytosis of most animal viruses. Sometimes larger particles (eg, vesicular stomatitis virus [VSV]) can be accommodated.[163]

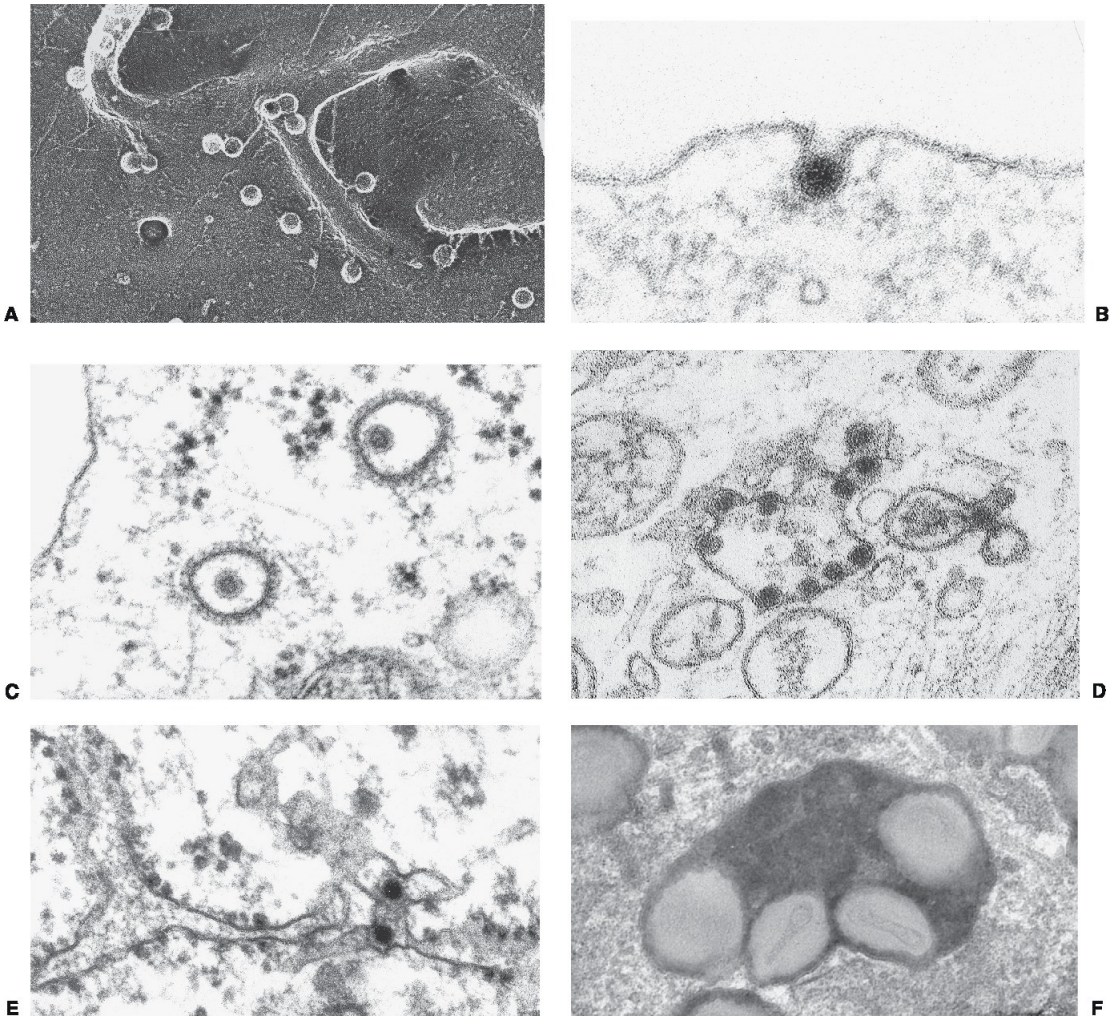

FIGURE 4.3 **Electron microscopy of virus endocytosis**. **A**. A surface replica of a BHK21 cell with Semliki Forest virus (SFV) particles attached. Although clathrin-mediated endocytosis is a continuously ongoing process, it is under stringent control. Interestingly, when the uptake of VSV, influenza, and reovirus particles has been followed in live cells, it has been observed that most are internalized by clathrin-coated pits that form *de novo* under the virus particles.[56,121,228] Only a few enter via preexisting clathrin-coated pits. Exactly how the virus induces a transbilayer signal to direct the assembly of the clathrin coat remains to be defined.

A role for clathrin-coated pits in internalization and infection can be demonstrated by inhibiting clathrin function using dominant negative mutants or depletion of adaptors such as epsin, eps15, AP2, or the clathrin chains themselves.[51,244] Inhibition of dynamin 2, a scission factor in clathrin vesicle formation, is not a sufficient indicator for clathrin involvement because dynamin 2 is also involved in other forms of endocytosis.

Caveolar and Lipid Raft–Mediated Endocytosis

The caveolar and lipid raft–mediated pathways of endocytosis were first observed for SV40 and mouse polyomavirus[7,60,221,257] (Figs. 4.2 and 4.3). They are cholesterol dependent, tyrosine kinase activated, cargo induced, and involve small endocytic vesicles. The cholesterol dependence reflects a central role of lipid rafts. Three variants of caveolar or lipid raft endocytosis are currently recognized[138]: (1) endocytosis via classical caveolae, dynamin 2 dependent; (2) noncaveolar, lipid raft–mediated endocytosis, dynamin 2 dependent; and (3) noncaveolar, lipid raft–mediated endocytosis, dynamin independent.

Caveolae constitute 70-nm flask-shaped indentations that contain caveolins and cavins as major protein components and a membrane enriched in cholesterol and sphingolipids.[199,219] Most cell surface caveolae are stationary, with a minority population undergoing a local cycle of fission and fusion with the plasma membrane.[204,279] When local tyrosine phosphorylation is activated by a virus such as SV40, caveolae become more dynamic.[138,199] With a virus particle trapped inside, the caveolae pinch off and move into the cytoplasm where they fuse with endosomes.

SV40 and other polyomaviruses also enter in vesicles devoid of caveolar proteins.[60] After association with lipid rafts in the plasma membrane or artificial liposomes, the binding of SV40 to multiple receptor gangliosides, GM1, leads to the induction membrane curvature following the shape of the virus and the formation of tight-fitting indentations of variable depth.[77] For detachment of a vesicle, these inward-oriented, virus-containing "buds" require the activation of kinases and other cellular factors. The process shares many features with the endocytic mechanism triggered by certain bacterial toxins, such as Shiga and cholera.[224]

Macropinocytosis and Macropinocytosis-like Mechanisms

Among the clathrin-independent mechanisms, macropinocytosis and related processes are commonly used by larger viruses (Figs. 4.2 and 4.3). These include vaccinia, herpes, adeno 3, and Ebola virus but evidently also in some cases by smaller viruses such as HIV-1 and influenza A.[6,126,157,174,229] Macropinocytosis is ligand triggered, transient, actin dependent, and regulated by a complex signaling pathway.[175,267] The physiological cargo is mainly composed of extracellular fluid that is trapped in large vacuoles, the formation of which depends on plasma membrane ruffling. The process differs from phagocytosis in the signaling pathways used and in that it can be activated in most cell types, not only in specialized cells.[267] In addition, by serving as a major mechanism in the elimination of apoptotic debris in tissues, macropinocytosis differs from phagocytosis by failing to activate innate immune responses and inflammation.[173]

In macropinocytosis, the interaction of viruses with the plasma membrane induces a rapid activation of receptor tyrosine kinases or integrins. This leads to a signaling cascade that usually involves the activation of GTPases Rac1 or cdc42, the p21-activated kinase (PAK1), myosin II, and numerous other kinases and signaling factors.[175] A change in the dynamics of cortical actin leads to ruffling of the plasma membrane, where the ruffles can take the form of lamellipodia, filopodia, and blebs. In the case of vaccinia virus and Kaposi sarcoma virus, internalization by macropinocytosis occurs during bleb retraction, and the viruses enter macropinosomes from which they escape by membrane fusion.[174,277]

Viruses including HPV-16, AAV2, HCMV, and measles have been purported to undergo cell type–dependent macropinocytosis-like entry.[63,142,190,235] These macropinocytosis-like pathways can deviate from classical macropinocytosis with regard to cell signaling, membrane ruffling, GTPase activity, and increased fluid uptake. For example, the entry requirements for HPV-16 are typical of macropinocytosis, including Na^+/H^+ exchange, RTK/PI3K signaling, and actin polymerization. Yet, virus internalization occurs through small uncoated vesicles and is not associated with membrane ruffling or GTPase activation.[235] On the other hand, AAV2 entry induces membrane ruffling, requires Na^+/H^+ exchange and the GTPase CDC42, but does not increase fluid phase uptake.[190] As more is learned about the mechanisms underlying macropinocytosis, it is becoming increasingly clear that there is a complex spectrum of related pathways that vary on the general theme.[176]

The Endocytic Pathway

The early endosomes in the periphery of the cytoplasm receive incoming viruses a few minutes after internalization (Figs. 4.4 and 4.5). Early endosomes constitute complex, heterogeneous organelles with tubular and vacuolar elements. They are mildly acidic (pH 6.6-6.0), which is enough to activate viruses with a high pH threshold for penetration, and these viruses are thought to penetrate from early endosomes.[160] Most viruses are not activated in this pH range and continue deeper into the degradative arm of the endocytic pathway in order to penetrate from late endosomes or endolysosomes.

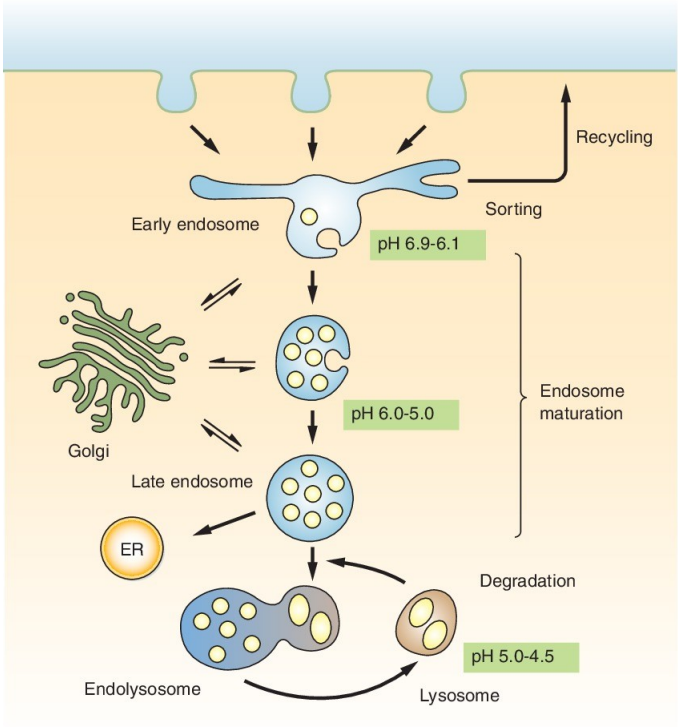

FIGURE 4.4 **The endosomal pathway**. The pathway functions as two interconnected cycles of membrane trafficking. One involves the plasma membrane, early endosomes, and a variety of carrier vesicles. Its major role is the sorting and recycling of incoming membrane components, ligands, and fluid via the endosome back to the cell surface. In this pathway, the pH does not drop below about 6.0, and the cargo is not exposed to a spectrum of lysosomal enzymes. The main function of the second cycle, the lysosome cycle, is degradative (ie, the

down-regulation of receptor-ligand complexes, degradation, and processing of incoming nutrients and their carriers, digestion of autophagic substrates, elimination of incoming pathogens, etc.). The endocytic cargo to be degraded, including viruses, is sorted from early endosomes into late endosomes, and these deliver the cargo to lysosomes 10-40 minutes after formation by fusing with them to form endolysosomes. The late endosomes undergo a complex maturation process, acquire intraluminal vesicles, and move along microtubules to the perinuclear region of the cells. Degradation occurs in the endolysosomes through the action of soluble hydrolases. Endolysosomes and lysosomes keep fusing with new late endosomes in a continuous cycle. Early and late endosomes communicate via vesicle trafficking with the Golgi complex, and late endosomes and endolysosomes have a poorly understood connection to the endoplasmic reticulum.

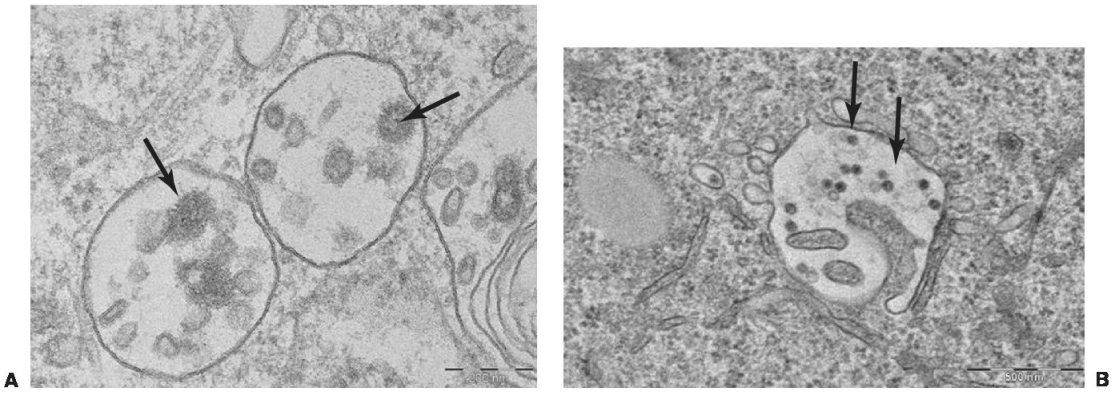

FIGURE 4.5 **Viruses enter endosomes**. Endosomes are cytoplasmic vacuoles with complex and quite heterogeneous morphology. Thin section electron microscopy reveals that many of them are filled with intracellular vesicles and membrane lamellae. **A**. Influenza A viruses (*arrows*) are here seen in multivesicular endosomes closely connected to microtubules. **B**. To understand virus entry, it is important to understand the cell biology of endosomes. There are numerous reviews that provide insights into this important topic.[26,64,102,171,173,230,237] One of the central topics is the maturation of late endosomes, a program of changes that prepares them for fusion with lysosomes.[115] The changes include a further drop in pH, a switch of predominant Rabs from Rab5 to Rab7, a switch from phosphatidylinositides (PI(3)P-PI(3,5)P_2), exchange of tethering factors for fusion, exchange of microtubule-dependent motors, formation of intralumenal vesicles, and accumulation of lysosomal membrane proteins and hydrolases. It is a complex process where the various alterations are coordinated and interdependent. The key factors include small GTPases of the Rab, Arf, and Rho families and their effectors, phosphatidylinositides and their kinases and phosphatases, protein ubiquitination and the endosomal sorting complex required for transport machinery responsible for the formation of intralumenal vesicles in endosomes, the vacuolar ATPase responsible for acidification, and various soluble *N*-ethylmaleimide–sensitive factor attachment protein receptors and tethering factors required for selective fusion events.

Late penetrating viruses such as influenza virus, minor group rhinoviruses, polyomaviruses, and bunyaviruses depend on a smoothly functioning maturation program. They require the formation of late endosomes, the reduction in pH, and transport of the endosome to the perinuclear region.[26,101,150,243] Infection can be blocked by interfering with the maturation program using inhibitors, dominant negative mutants, and siRNA depletion of endocytosis factors.

The significance of low pH in endosomes as a cue for the activation of virus penetration was discovered a long time ago.[106] It is now clear that for the majority of animal viruses, low pH is needed to trigger conformational changes in metastable viral particles and fusion proteins, thus activating membrane penetration mechanisms (see Chapter 3). Viruses with a relatively high pH threshold (pH 6.5-6.0) such as VSV are activated 3-10 minutes after internalization in early endosomes.[159] Viruses with a lower pH threshold are sorted from early endosomes into the degradative branch and penetrate later (10-50 minutes or even longer after infection) and less synchronously in late endosomes or endolysosomes that have a pH of 6.0-4.9. For example, influenza A virus, with a pH threshold of 5.6-4.9, passes via early endosomes to perinuclear late endosomes before membrane fusion occurs.[245]

Macropinosomes, the intracellular carrier vesicles formed during macropinocytosis, undergo maturation in a fashion similar to endosomes.[31,66,176] This includes acidification, a switch in Rab and phosphatidylinositide identity, and ultimately fusion with lysosomes. Unlike primary endocytic vacuoles, once formed macropinosomes do not feed into early endosomes but undergo maturation, tubulation, and recycling themselves. For this, macropinosomes rely on Rab34 and sorting nexins in addition to the classical endosomal markers.[128,265] Viruses that rely on macropinosome maturation for penetration include Ebola, HHV8, and vaccinia.[176] For vaccinia, which has a pH threshold of 4.0-5.5, macropinosome maturation, culminating in delivery of virions to late endosomal/lysosomal compartments is critical for membrane fusion and penetration.[222]

In exceptional cases, such as some of the nonenveloped polyomaviruses, viruses continue even farther, moving from late endosomes to the endoplasmic reticulum (ER) where penetration occurs through the ER membrane.[44,74,213] While this pathway is not completely understood, after uptake polyomavirus-containing late endosomes are thought to be guided to the ER through initial receptor interactions (murine polyomavirus and ganglioside GD1a),[95,275] or recruitment of cytosolic factors (BK polyomavirus interaction with Rab18).[305] Recent evidence indicates that upon arrival at the ER, two ER membrane protein complex subunits, EMC 4 and 7, facilitate docking of polyomavirus-containing late endosomes.[9] Through interactions with late endosome-associated Rab7 and ER resident protein syntaxin18, EMC 4 and 7 are thought to stabilize late endosome-ER contact allowing for transport of polyomaviruses between these two compartments.[275,305]

Penetration by Membrane Fusion

The membrane of an enveloped virus is a *de facto* transport vesicle designed for intercellular membrane traffic (Fig. 4.6). Like intracellular transport vesicles, the transport process relies on budding, fission, and fusion. The cargo is the viral capsid, which does not have to cross the hydrophobic barrier of a membrane. The fusion reaction during entry can occur with the plasma membrane or with the limiting membrane of an

endosome. On the basis of studies with VSV, it has been proposed that a virus can also fuse with lumenal membrane vesicles inside multivesicular endosomes followed by a delayed second fusion event between the vesicle and the limiting membrane of late endosomes.[101,226] The second fusion would have to depend on a cellular rather than viral fusion machinery.

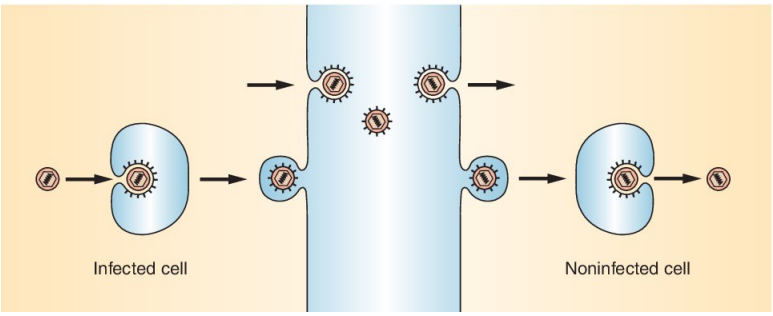

FIGURE 4.6 **Enveloped viruses use a vesicle shuttle mechanism**. They transport the capsids and the viral genome from cell to cell using a vesicle transport strategy based on membrane fission and fusion. The viral envelope constitutes the transport vesicle, and the capsid is the cargo. The vesicle is formed after capsid loading and glycoprotein sorting in the infected cell by budding and membrane fission at the plasma membrane or internal membranes. The viral envelope membrane protects the capsid during the voyage through the extracellular space. After associating with a new host cell, the virus delivers the capsid into the cytosol by membrane fusion, either at the plasma membrane or after endocytosis, at the limiting membranes of intracellular organelles. The advantage of this strategy is the viral genome, and accessory proteins can be transferred from cytosol to cytosol without the need of translocation directly across the hydrophobic barrier of any membrane.

As described in Chapter 3, viral fusion proteins are integral membrane proteins, with the bulk of their mass external to the viral envelope. They are usually glycoproteins and occur as homo- or hetero-oligomers. Many of them combine fusion and receptor-binding activities in the same molecule. To become fusion competent after folding and assembly in the ER, they are often primed by proteolytic cleavage during transit through the trans-Golgi network (TGN). Typically, the proteases responsible for priming are furin family convertases that cleave either the chains involved in fusion directly (ie, in myxo-, retro-, and paramyxoviruses) or the companion proteins in the spike protein complex (ie, alpha- and flaviviruses).[132,256,287] If virus assembly and budding occurs intracellularly, as for flaviviruses, the activating cleavages take place as the assembled viral particles pass through the TGN.[105] In some cases, such as Ebola virus and SARS-CoV-2, proteolytic activation can occur as part of the entry program by proteases present in endocytic vacuoles.[43,112]

Proteolytic priming renders fusion proteins metastable and, thus, competent to undergo large, irreversible conformational changes without added energy.[40] This is important because, to elicit fusion, they must undergo changes that dramatically alter their quaternary or tertiary structure. As a result, they expose previously hidden hydrophobic peptide segments (fusion peptides) that interact with the target membrane, and in doing so allow the proteins to be hydrophobically anchored in both membranes.[289] The conformational change is thought to provide the energy required to overcome the so-called *hydration force* that prevents biological membranes from fusing spontaneously.[217]

The changes in conformation are triggered either by low pH in endosomes or by interaction between viral proteins and receptors in the plasma membrane. Sometimes receptor binding followed by low pH is needed. This type of receptor-mediated priming, observed for some retroviruses,[183] may allow the virus particle to limit conversion of spike glycoproteins to the site most intimately in contact with the target membrane. The priming and activation of viral membrane fusion proteins as well as the mechanisms of fusion are discussed in greater detail in Chapter 3.

Penetration by Nonenveloped Viruses

Nonenveloped viruses penetrate into the cytosol through the limiting membranes of internal organelles (eg, endosomes, lysosomes, the ER). The cues that trigger penetration are similar to those used by enveloped viruses (eg, receptor-binding, low pH, redox environment). These viruses must, however, transfer their capsids, genomes, and associated proteins through a cellular membrane without the convenience of the membrane-fusion mechanism.

The mechanisms involved have proved challenging and remain incompletely understood. It seems, however, that nonenveloped viruses can use three general strategies:

a. *Membrane puncture*. The virus particle generates a pore in the membrane through which the genome is selectively released into the cytosol. The viral capsid does not enter the cytosol, and release of fluid phase markers from the lumen of the organelle is either undetectable or limited to small molecular weight compounds.

b. *Perforation*. The entire capsid is transferred through the membrane without major lysis of the membrane and little loss of lumenal fluid markers.

c. *Lysis*. The virus particles induce breakage of the membrane of cytoplasmic organelles, allowing the virus and other lumenal contents to be released into the cytosol.

The puncture or pore mechanism is favored for picornaviruses.[89,114] Some rhinoviruses and foot and mouth disease virus are acid activated and penetrate from endosomes, whereas others (eg, polio, coxsackie B, and echovirus 1) are pH independent but penetrate from endosomes or other intracellular organelles. In the case of poliovirus, which is one of the best characterized, penetration is induced by binding of a cluster of poliovirus receptor (PVR) molecules to “canyons” in the capsid surface. This triggers a large, concerted, irreversible change in the particle, the so-called *eclipse*, which leads to the formation of a penetration competent conformation. An internal protein, VP4, is released, and the myristylated *N*-terminus of VP1 inserts into the endosomal membrane.[27,87] The RNA is most likely released to the cytosolic side of the membrane through a narrow pore.[273] According to this view, penetration and uncoating occur simultaneously, and the capsid does not enter the

cytosol. Cryo-electron microscopy (cryo-EM) studies have shown that one of the icosahedral vertices interacts with five receptors that connect the modified particle intimately with the membrane.[30]

For viruses that use a perforation strategy, escape of polyomaviruses from the ER into the cytosol is mechanistically the best understood[218] (reviewed in Ref.[44]). In the case of SV40, upon arriving in the ER resident redox proteins PDI, ERp57 and ERdj5 reduce and isomerize virion disulfides.[234] This causes the disassociation of the 12 vertex pentamers composed of the major capsid protein VP1. This partial disassembly exposes minor capsid proteins VP2 and VP3.[61,192] The hydrophobic, myristylated N-terminus of VP2 inserts into the ER membrane where it is proposed to initiate the formation of a penetration "foci" through recruitment of ER proteins Bap31/Bap29 and the luminal chaperone BiP.[91,96] Accumulation of DNA J proteins to foci serves to recruit a cytosolic chaperon complex composed of Hsc70, Hsc105, SGTA, and Bag2 that facilitates the escape of the modified particle into the cytosol.[68-74,284]

Recently, cryo-EM and cryo-electron tomography (cyro-ET) studies of bluetongue virus (BTV) and rhesus rotavirus (RRV) have provided the most compelling images of the perforation mechanism to date.[108,296] BTV and RRV are each composed of three capsid layers: outer, intermediate, and inner. Both viruses are endocytosed where upon changes in endosomal conditions (pH in the case of BTV and CA^{2+} in the case of RRV) trigger the release of outer capsid proteins and subsequent conformational "activation" of the respective penetration proteins. This causes them to project from the surface of the virus facilitating their engagement with the target membranes. While the details remain unknown, this is presumably followed by fusion pore formation and delivery of intact double-capsid layer particles into the cytosol. For BTV, cryo-ET data support the opening of a single fusion pore, which expands to accommodate the double-layer particle.[296]

For parvoviruses, evidence is accumulating that the *N*-terminal domain of VP1 possesses a phospholipase 2 domain activated by low pH.[53,104] It is likely that this promotes membrane penetration of the intact virus by modifying the permeability of endosomal and lysosomal membranes. Lysis of the membrane is not detected.

Adenoviruses make use of a lytic mechanism.[240] The best studied are adenoviruses 2 and 5, which penetrate by acid-activated rupture of the endosomal membrane.[167,170] The lytic effect is thought to involve a change in the penton base and exposure of an amphipathic helix in protein VI, but the mechanism is unclear.[185] Altogether, the process is complex; it depends on low pH, the integrin receptors, cleavages in structural proteins induced by the L3/p23 viral protease, the release of fiber proteins, activation of macropinocytosis, and signaling through protein kinase C.[167,170,186]

Intracellular Trafficking

Before they can replicate, viruses and capsids delivered into the cytosol must be transported to the correct location before uncoating and replication can take place. Within the nucleus, replication usually occurs in defined foci. In the cytosol, it is often associated with specific membrane organelles (eg, the ER or the ER-Golgi intermediate compartment) or with virus factories in the perinuclear space.[193,294]

Given the extreme crowding in the cytoplasm that prevents diffusion of virus- and capsid-sized particles as well as uncondensed forms of DNA or RNA, it is not surprising that viruses rely on cytoplasmic transport systems offered by the cell.[65,99,154,251] For long-distance transport, viruses mainly exploit microtubule-mediated mechanisms. When actin filaments play a role, it is usually in short-distance movement close to the plasma membrane. Although viruses can undergo partial disassembly *in transit* through the cytosol, they postpone final uncoating of the condensed genome until they have reached their final destination. Viruses travel variable distances. To reach the cell body, neurotropic viruses that enter via axons may have to move in a retrograde direction over the full length of axons, which can be more than 1 m in length.

To move through the cytoplasm, incoming viruses have two options. They can postpone penetration into the cytosol and move as cargo in endocytic vesicles and thus benefit from the motor-driven transport of vesicles and organelles through the cytoplasm. Alternatively, they can penetrate early into the cytosol, in which case the viruses or their capsids are themselves responsible for associating with molecular motors and adaptors (eg, dynein and kinesins). The former strategy is used by viruses that enter by endocytosis, the latter by viruses that prefer to penetrate through the plasma membrane. Many viruses make use of both; part of the journey is mediated by vesicular traffic, the rest by cytosolic transport.

An exception to this is HPV, which engages cytoplasmic factors despite remaining within membrane vesicles during its entire journey from the cell surface to the nucleus (reviewed in Ref.[297]). After HPV internalization into endocytic compartments, virions are subverted to the retrograde pathway and are trafficked to the TGN, Golgi, and ER.[62,79,80] To reach these compartments, the viral protein L2 engages retromer, a cytoplasmic protein complex that selectively delivers endosomal cargo to the TGN.[238] The C-terminus of L2 contains a cell penetrating peptide within a membrane destabilizing sequence and two retromer binding sites.[210,297,302] Elegant split GFP assays showed that early during HPV entry, the cell penetrating peptide in L2 directs protrusion of the C-terminus through the endosome membrane exposing the retromer binding sites to the cytoplasm.[302] L2 then engages retromer and other cytoplasmic proteins involved in entry.[16,207] Consistent with this mechanism, L2 CPP and retromer binding site mutants, as well as depletion of retromer from target cells prevent retrograde trafficking of HPV resulting in accumulation of virions in endosomes.[146,210,302]

Viruses that enter by endocytosis then penetrate into the cytosol (eg, adeno- and parvoviruses) tend to use microtubule-mediated transport to bring capsids toward the cell center.[239,264,266] Although transport of capsids along microtubules is often bidirectional and characterized by stops, restarts, and changes in direction, net transport generally occurs in the minus-end direction toward the microtubule-organizing center (MTOC), where viruses and capsids are often found to accumulate before transport to the nucleus.[215] Whether they switch to plus-end directed motors for the final leg of transport is not known, with the exception of adenovirus. Upon reaching the MTOC, adenovirus bidirectional microtubule motility slows, and virions detach from microtubules.[285] The nuclear export protein CRM1 was found to be required for both processes, as well as association of adenoviruses with nuclear pores and genome delivery.[262,285] It is though that CRM1 may establish a perinuclear spatial gradient that serves to guide microtubule-independent movement of adenovirus from the MTOC to nuclear pores.

Priming the Uncoating Program

Penetration brings many viruses and viral capsids for the second time into a cytosolic environment. The first time is when they assemble in the

cytosol of an infected cell or when they pass through the cytosol on their way from the nucleus to the extracellular space. During entry into a new host cell, the agenda involves disassembly and uncoating instead of assembly. This means that, in the entry phase, something must be profoundly different either about the virus itself or the cell.

Usually, the difference is in the virus or the capsid because it has undergone structural alterations *in transit*. After release from the infected cell or during earlier stages of entry, the viruses are structurally *reset* so they can respond to cellular cues according to requirements of the uncoating program. The best illustration of this is provided by retroviruses, in which the viral protease induces a series of cleavages in Gag and Gag-Pol proteins during and after virus budding. The capsid is reorganized and ready for reverse transcription and for the formation of functional preintegration complexes (PICs) in the cytosol of a new target cell.[189]

Another example is influenza A, in which the switch involves a change in the properties of the matrix protein (M1). M1 serves as an adaptor between the virus ribonucleoproteins (vRNPs) and the viral membrane as well as between the vRNPs, and it plays a crucial role during assembly of these components during virus assembly and budding.[220,308] During entry, dissociation of these interactions is induced by an irreversible conformational change in M1 triggered by acid exposure in endosomes.[32] To acidify the internal space of the virus, where the M1 and the vRNPs are located, the viral membrane possesses acid-activated proton channels in the form of M2 protein complexes.[208,263] If the M2 proton channel is blocked using amantadine, a specific M2 channel blocker used as an anti-influenza drug; HA-mediated fusion occurs normally in endosomes, but the vRNP and M1 fail to dissociate from each other, and transport of vRNP to the nucleus is inhibited.[33,161]

Alphaviruses seem to use an altogether different strategy. Here, the *switch* seems to involve a change in the cell rather than in the viral capsid. A cellular factor required for uncoating of incoming capsids is inactivated during the course of infection, thus allowing assembly of progeny capsids. The factor in question is the 60S ribosomal subunit, which has high affinity binding sites for the viral capsid protein.[248,288] Incoming capsids rapidly lose capsid proteins to ribosomal subunits, and the viral RNA is thus liberated. When synthesis of structural protein starts later in an infection, newly synthesized capsid proteins bind to the ribosomal subunits and the ribosomal subunits can no longer interfere with assembly of progeny capsids.

Genome Uncoating

The entry of viruses includes partial or full disassembly as an essential, integrated part of the program. For enveloped viruses, uncoating involves loss of the envelope during membrane fusion. Often, the capsid thus released undergoes further stepwise uncoating steps. Once the capsids have reached the correct location within the cell, then, and only then, they release the replication competent form of the genome. In some cases (eg, retro-, reo-, and poxviruses), the cytosolic capsids serve as a protected site for reverse transcription of the genome or transcription of messengers prior to uncoating.[127,189] Poxviruses for example, undergo a particularly complex two-step uncoating process involving cellular and viral proteins.[130] Immediately upon cytoplasmic delivery, viral cores expand changing in shape from biconcave to oval.[58,236] This first “core activation” step correlates with the reduction of di-sulfide bonded core structural proteins, and the initiation of early gene transcription within the core.[147,236] The second uncoating step, genome release, is steadfastly dependent on viral early gene expression, suggesting that poxviruses time genome release through the expression of an early protein.[122,123] Using a virus-targeting RNAi screen, this “uncoating factor” was identified as the early poxvirus AAA+ ATPase D5, and it’s helicase activity deemed essential for uncoating.[131] In addition to D5, host proteasome activity was shown to be required for core breakdown and genome release.[178] While both D5 and proteasome activity is required, mechanistic understanding of their individual roles and interplay during poxvirus uncoating remains unknown.

Influenza A is another enveloped virus that takes advantage of host factors for uncoating. Beyond the M2-mediated priming step that serves to dissociate the vRNPs from M1, cellular aggresome components including free ubiquitin, HDAC6, and microtubule motors cooperate to physically disassemble viral capsids freeing the vRNPs, which are then shuttled into the nucleus.[10]

In the case of nonenveloped viruses, the uncoating process involves conformational changes, progressive loss of structural proteins, proteolytic cleavages, isomerization of intermolecular disulfide bonds, and weakening of intermolecular interactions.[98,114,167,187,234] For adenovirus 2, disassembly starts already at the cell surface with loss of some of the fibers followed by activation of a viral protease (the L3/p23 protease, located within the virion), proteolytic cleavage of capsid proteins, and loss of stabilizing capsid components. Final disassembly of the particle and DNA release occurs at the nuclear pore complex (NPC).

The conformational changes that accompany penetration and uncoating of polio and other picornaviruses have been extensively analyzed.[89,114,149] Depending on the virus, the initial uncoating event is triggered by receptor association, low pH, or both. Conversion from a 150S-160S particle to a slower sedimenting 135S particle occurs with elimination of the internal VP4 protein and externalization of the myristylated *N*-terminus of VP1. This leads to membrane association, followed by the release of the RNA, resulting in the RNA-free 80S particle. The single-stranded viral RNA is likely to escape through 1 of the 12 vertices, possibly aided by the VPg protein covalently linked to the 5′ end of the viral RNA.[29,129]

The capsids of viruses with a double-stranded RNA genome (eg, reoviruses) undergo many alterations in transit into the cell, but instead of releasing their genomic RNA in free form into the cytosol, they retain it in a modified capsid, which serves as an RNA replication and transcription factory.[42,246]

Nuclear Import

Most DNA viruses and a few negative-stranded RNA viruses replicate in the nucleus. To enter the nucleus, they can make use of the NPC for transport of the genome and accessory proteins into the nucleoplasm[48,55,98,290,291] (Fig. 4.7). Alternatively, the viruses may enter by rupturing the nuclear envelope, a process for which there is some evidence in the parvovirus field. These two entry routes allow infection of nondividing, terminally differentiated, interphase cells in which the nuclear envelope represents a permanent barrier. Finally, viruses and viral capsids may wait in the cytosol for the dissolution of the nuclear envelope during cell division. This mechanism, used by most retroviruses with the exception of lentiviruses and human papilloma viruses,[8,212] restricts infection to cell populations that undergo division. In principle, a fourth possibility would be penetration directly from the lumen of the ER through the inner nuclear membrane because the lumen of the ER is continuous with the space between the membranes in the nuclear envelope. Although some incoming viruses do pass through the ER and incoming viral particles have been occasionally seen between the two membranes of the nuclear envelope,[164] no evidence currently indicates that any viruses use this

pathway.

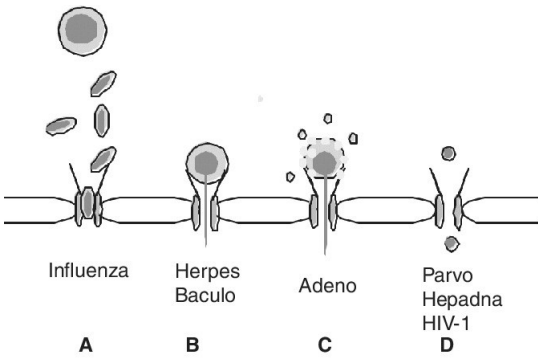

FIGURE 4.7 **Import of viruses and subviral particles through the nuclear pore complex**. To circumvent the size limitation (diameter 35-40 nm) of particle transport through the nuclear pore complex (NPC), viruses have evolved different strategies. **A**. The genome of a virus can be divided in multiple subgenomic particles with an elongated shape thin enough for individual entry (eg, influenza virus). **B**. Limited uncoating takes place in the cytosol with the generation of an opening in the capsid wall that allows the DNA to escape, leaving an empty capsid at the NPC (eg, herpes simplex virus 1). **C**. The virus dissembles after association with the NPC, allowing the genome and accessory proteins to pass through the NPC (eg, adenoviruses). **D**. The virus particles or capsids are small enough to enter as spherical particles without uncoating or major deformation with uncoating occurring in the nucleoplasm (eg, HIV-1).

Nuclear import via the NPC involves several steps: binding of import receptors, transport through the cytosol, association with the NPC, and transfer of the intact virus, a subviral complex, or a nucleic acid through the pore. To be recognized by the cellular import machinery, viruses and viral capsids make use of nuclear localization signals (NLSs) similar to those present on cellular proteins and ribonucleoprotein complexes. These signals in viral proteins are recognized by soluble receptor proteins (importins or karyopherins) that mediate recognition, transport, and docking of the viral capsids to the NPC. In some cases, the NLS and the importins involved have been identified. Exposure of the NLS is sometimes modulated by phosphorylation-induced conformational modifications to avoid premature capsid import in the infected cell,[125] and some viruses are thought to be processed by proteasomes.[281] It is also possible that viruses bind directly to the NPC without interaction with importins.

Binding of herpes simplex virus capsids to the NPC is mediated by capsid and tegument proteins.[195,200] After association with CAN/Nup214 and another NPC protein, hCG1, through the minor capsid protein pUL25, and after opening of the portal structure at one of the vertexes of the capsid, the viral DNA escapes into the nucleus, leaving an empty capsid behind at the mouth of the NPC (Fig. 4.8). Influenza A viruses deal with the problem of size limits by having a segmented genome. The eight subgenomic RNA are individually packaged into viral vRNP complexes. When interactions with the M1 protein are dissociated after exposure of the virus to low pH in endosomes, and the vRNPs are uncoated by HDAC6, they interact with importins, travel to the nucleus, and enter individually through the NPC (Fig. 4.7).[32,161,196] The vRNPs are rod shaped and, although variable in length, have a thickness of only 10-20 nm.[50]

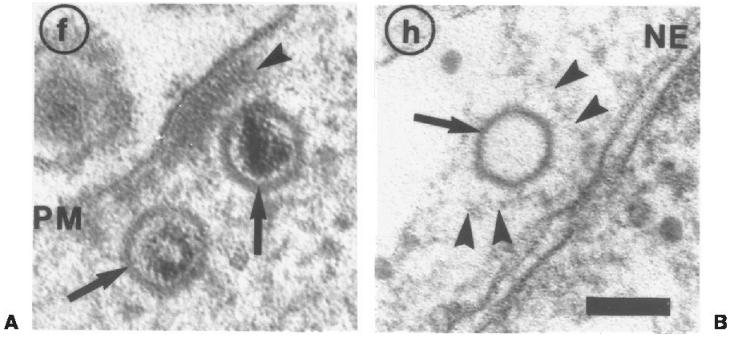

FIGURE 4.8 **Herpes simplex virus 1 (HSV-1) entry at the plasma membrane level and the nuclear envelope**. **A**. In HSV-1, virus can fuse with the plasma membrane and release the capsid and the tegument into the cytosol. A large part of the tegument can be seen separating from the capsid. **B**. After binding to the cytosolic fibers attached to the nuclear pore complex (NPC), the viral capsid releases its DNA genome through one of the pentameric facets, and an intact-looking empty capsid shell remains bound to the NPC for some time. PM, plasma membrane; NE, nuclear envelope. Space bar, 100 nm. (Courtesy of Beate Sodeik and Ari Helenius.)

Being too large, most viruses and capsids must undergo shape changes or disassembly before passage of the genome through the NPC. Partially uncoated and modified adenovirus 2 and 5 particles bind directly to the CAN/Nup214 nucleoporins on the outer surface of the NPC and to nuclear histone protein, H1.[274] For disassembly, NPC-bound capsids interact with the kinesin light chain Klc1/2, and through Nup358, the kinesin heavy chain Kif5c.[261] These interactions link viral capsids and NPCs to the kinesin-1 motor, which then physically disrupts and dislocates capsid fragments and Nups into the cytoplasm. This serves to free the linear, double-stranded viral DNA from the capsid and simultaneously disrupt the NPC providing the viral genomes access to the nucleus.[261]

The size limitation for transport through the NPC is an obvious problem. Although estimates of the functional pore diameter have been adjusted upward to 39 nm using purified nuclear envelopes,[198] only the smallest viruses and capsids are likely to enter intact without modifications. These include parvoviruses and the capsids of hepatitis B virus (HBV).[214,281] When nuclear import of injected HBV capsids through the NPC are imaged by electron microscopy, the capsids can be seen to line up on the cytosolic fibers of the NPC and inside the central channel (Fig. 4.9). Uncoating of these capsids occurs in the basket, a structure located on the nucleoplasmic side of the NPC.[214]

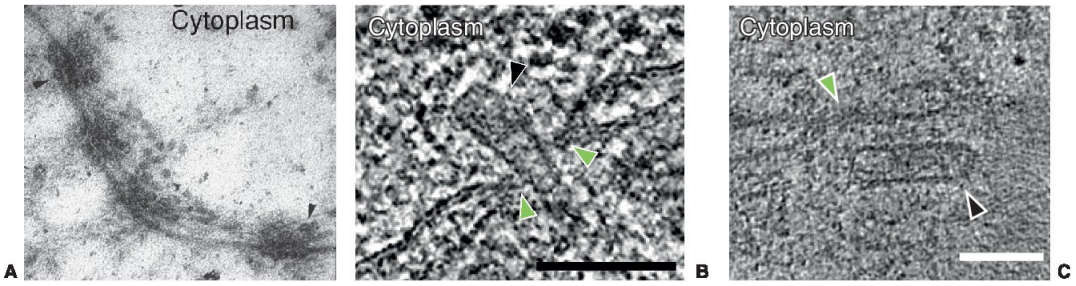

FIGURE 4.9 **Import of hepatitis B virus (HBV) and HIV-1 capsids through the nuclear pore complex (NPC)**. **A**. After injection into *Xenopus oocytes*, isolated HBV cores can be seen binding to fibers at the mouth of the NPC, and to line up in a row inside the channel of the pore. Uncoating of this capsid occurs in the basket on the nucleoplasmic side of the NPC. (Courtesy of Nelly Pante and Michael Kann.) **B**. A HIV-1 cone-shaped capsid (*black arrow head*) can be seen docked within the central channel of a NPC. *Green arrow heads* designate the edges of the NPC. **C**. A HIV-1 capsid that has lost its conical shape (*black arrow*) is seen in the nucleus of an infected cell. *Green arrow* designates the NPC. (**B and C** adapted from Zila V, Margiotta E, Turonová B, et al. Cone-shaped HIV-1 capsids are transported through intact nuclear pores. *Cell*. 2021;184(4):1032-1046.e18. Copyright © 2021 Elsevier, with permission.)

The PIC of retroviruses has been reported to be about 50-60 nm in diameter.[180] Too big to enter the nuclei without conformational adjustments, they remain in the cytosol until the breakdown of the nuclear envelope occurs during cell division.[141] Being capable of entering interphase nuclei, the PIC of HIV-1 and other lentiviruses are exceptions. The details of how and in which form lentivirus PICs are imported into the nucleus is emerging. Recent evidence gathered using 3D-correlative fluorescence light and electron microscopy (3D-CLEM) shows intact cone-shaped HIV-1 capsids docked to the cytosolic face of NPCs and within the central channel of NPCs (Fig. 4.9).[307] Supporting passage of capsids through the NPC, morphologically altered, open, empty capsid structures can be seen in the nucleus of infected cells (Fig. 4.9). Examination of NPC architecture in uninfected and HIV-infected cells by cryo-EM placed the diameter of the NPC central channel at ~64 nm, which is sufficient for the passage of 60 nm HIV-1 capsids.[307] While the HIV-1 capsids found in the central channel retain their cone shape and a hexagonal lattice —indistinguishable from capsids in mature virions—hyper-stable mutant HIV-1 capsids get stuck at the NPC.[103] This suggests that capsid flexibility or remodeling is needed for capsid passage through the NPC central channel and subsequent uncoating in the nucleus.

Transmission Directly From Cell to Cell

Discussion so far has focused on the mechanisms of entry by free viral particles attaching to the surface of cells. It is increasingly clear that there are situations in which infection occurs from cell to cell without participation of free virus particles[184,231] (Fig. 4.10). One mechanism involves fusion of an infected cell's plasma membrane with the membrane of a neighboring cell. In infected tissues and cultures, the result is the formation of multinucleated cells (ie, syncytia). Fusion in this case is mediated by viral fusion proteins expressed on the surface of the infected cell with receptors present on the noninfected cell. Commonly observed with paramyxovirus, herpesvirus, and other viruses with pH-independent fusion proteins, cell fusion provides a mechanism for transmitting infection independently of virus particle assembly.[47]

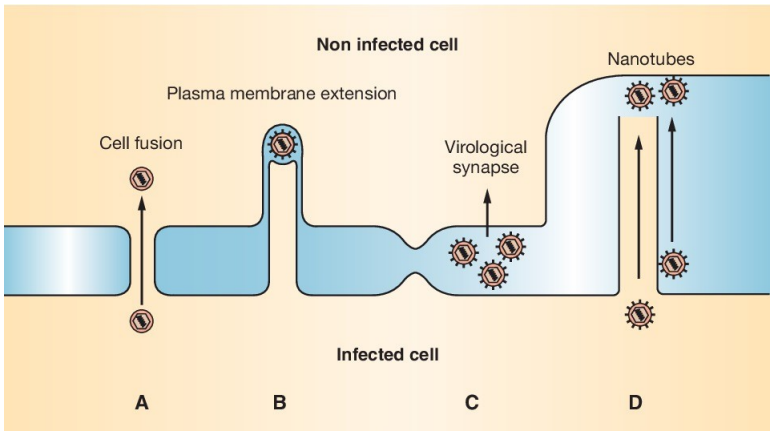

FIGURE 4.10 **Direct cell-to-cell transmission**. Several mechanisms allow infection to be transmitted via cell contacts without the release of free virus particles into the extracellular space. **A**. Due to the presence of viral fusion proteins on the surface of the infected cells and virus receptors on the noninfected cells, fusion of two cells can occur without producing virus particles. This results in the formation of syncytia. This mechanism is often seen with enveloped viruses and with fusion proteins that do not require low pH for fusion. **B**. In the case of poxviruses, extracellular viruses belonging to the so-called extracellular enveloped class of virions remain attached to the surface of the infected cell, where they trigger the formation of a motile, actin-containing, extension of the plasma membrane. This extension is thought to promote contact of the virus with the surface of neighboring cells. **C**. The infected cells can undergo polarization so that progeny viruses are selectively released into a region of the cell periphery intimately in contact with another cell. Such specialized regions are called virological synapses. **D**. Viruses can induce the formation of long actin–containing nanotubes on infected cells. Virions move within nanotubes or on the surface of nanotubes to mediate spread to distant cells. In some cases, nanotubes offer protection from neutralizing antibodies.

Other mechanisms of cell-to-cell transmission require the formation of virus particles, but these are not released freely into the extracellular space. Poxviruses such as vaccinia virus generate infectious particles called extracellular enveloped viruses, most of which not only remain attached to the cell surface after formation but also induce the formation of motile surface extensions through the polymerization of actin inside the cytoplasm.[88,99,252,295] The actin polymerization reaction helps to form membrane extensions that push the virus into contact with the

neighboring cell, thus generating an efficient mechanism for local dissemination in infected tissues.

Structures termed infectious or virological synapses were first described for the transmission of the human T-cell leukemia virus type 1 (HTLV-1).[116] These are areas of intimate contact between infected and uninfected cells reminiscent of immunological synapses. They provide a domain where virus assembly and release are focused with efficient targeting of the virus particles to the next host cell without access of antibodies from the outside.[184] Similar means of transfer have been described for herpesviruses and for the T cell to T-cell transfer of HIV. Dendritic cells that bind HIV-1 via DC-SIGN help to transport the virus to lymph nodes where they present the virus to T cells, providing an efficient system for targeted infection of host cells through virological synapses.[92,137]

Retroviruses as well as herpesviruses and several others also take advantage of nanotubes for cell-to-cell transmission (Fig. 4.10).[120] Nanotubes are long, actin-rich membrane protrusions that, under physiological conditions, mediate communication and the transfer of vesicles and organelles from one cell to another. The use of nanotubes for cell-cell virus spread was first reported for HIV-1.[254] Depending on the cell type, HIV capsids traverse nanotubes within endocytic vesicles, or intact virions surf along the outside of nanotubes, to uninfected cells.[76,124] In macrophages, this provides the advantage of being able to spread in the presence of neutralizing antibodies.[114,298]

Perspectives

The entry and uncoating mechanisms and strategies are highly variable depending on the virus and the target cell. They have in common that the viruses depend critically on the host cell and its activities. To extract the necessary assistance from the cell, viruses make use of the detailed *insider information* they have about the host organisms, their tissues, the cells, and a variety of molecular processes. This information has been acquired during millions of years of coevolution. Thus, although exceptionally simple in structure and composition, viruses are able to elicit exceedingly complex cellular responses. The induction of signals, the activation of endocytic pathways, the exploitation of intracellular targeting systems and molecular motors, and the cell-assisted mechanisms of uncoating provide examples of the ways in which viruses make use of cellular machinery during entry. As details unfold, interesting and important insights about the viruses and their hosts continue to emerge.

The entry program involves the transport of the incoming viruses and capsids through the membranes and the compartments of the cell, the stepwise dismantling of the virus particle, and the release of the genome. Entry and uncoating involve *switches* in particle structure and properties that have to occur in the right place at the right time. It is remarkable how little seems to be left to chance. In the future, these switches need more attention because they provide powerful targets for therapeutic and prophylactic intervention. Advances in cryo-EM and super-resolution microscopy promise to advance our understanding of virus protein architecture and how structure drives function.

Also, the cellular defenses against virus entry, ranging from degradation of incoming viruses to interferon-induced expression of interception proteins in the cytosol, deserve thorough study. After all, it is clear that, of the incoming cell-associated viruses, only a small fraction generally reach the intended goal.

It will be important to focus on the cellular factors involved in infection (ie, on the Trojans and not only on the Trojan horses). They represent new targets for antiviral strategies. How viruses enter tissues and cells in intact organisms remains for the most part territory uncharted. New technologies and model systems are emerging that allow work in complex 3-D tissue culture systems and at the whole animal level. A multidisciplinary approach that combines cell and molecular biology, structural biology, biochemistry, physiology, systems biology, and medicine as central disciplines is required. As important as knowing the pathogens, it will also be important in the spirit of an ancient Greek aphorism to know ourselves (ie, to understand the cell and molecular biology of the host cells).

Summary and perspectives

Acknowledgment

Replication of genetic information is the single most distinctive characteristic of living organisms, and nowhere in the biosphere is replication accomplished with greater economy and apparent simplicity than among viruses. To achieve the expression, replication, and spread of their genes, different virus families have evolved diverse genetic strategies and replicative cycles to exploit the biology of their hosts. Despite their comparatively limited genetic repertoire, viruses encode the information necessary to rewire their hosts to become viral factories. The intimacy of this relationship and the coevolution of virus and host continue to provide unique mechanistic insights into host biology at the molecular, cellular, organismal, and population levels. Understanding this interplay enriches our understanding of the biosphere in general and virus-host relationships in particular, but also creates opportunities for the rational development of antiviral drugs, and for domesticating viruses as expression vectors, live-attenuated vaccines, and pesticides. This chapter provides an overview of the replication strategies of the major virus families that infect vertebrates, attempting where possible to emphasize the general principles that guide and constrain virus replication and

evolution.

Viral Genome Diversity and Replication Strategies

Perhaps the most striking aspect of viruses at the molecular level is the diversity of their genome structures and replication strategies. Unlike cellular genomes, which consist uniformly of double-stranded DNA (dsDNA), viral genomes provide examples of almost every structural variation imaginable. As shown in Table 5.1, different families of viruses have genomes made of either double-stranded (ds) or single-stranded (ss) DNA or RNA; of either positive, negative, or ambisense polarity; of either linear or circular topology; and comprising either single or multiple segments. Each variation has consequences for the pathways of genome replication, viral gene expression, and virion assembly. This diversity argues strongly that viruses had several different evolutionary origins and can be thought of in D. J. McGeoch's evocative phrase as "mistletoe on the tree of life." As more sequences have been deposited, coupled with the recognition that only a small subset of those viruses are cultivatable, viral taxonomy has been updated. Accordingly, viruses are now classified in one of six realms the Adnaviria (filamentous dsDNA viruses of archaea), Duplodnaviria (dsDNA viruses), Monodnaviria (ssDNA viruses), Riboviria (RNA viruses), Ribozyviria (circular negative sense RNA genomes), and Varidnaviria (dsDNA that have jelly roll-like capsids). Taxonomy is further divided into 65 orders and 233 families,[128] the classifications of several vertebrate viruses are provided in Table 5.1. As more distant phylogenetic relationships and the number of genome sequences and protein structures increase, and as more powerful comparison algorithms become available, the boundaries between different classification groups fade revealing a continuum within several of the realms.

TABLE 5.1 Families and genera of viruses that infect vertebrates

Virus Family or Genera	Genome				Genome Replication	
	Type	Polarity[a]	Topology[b]	Segments	Enzyme	Intracellular site
Adenoviridae	dsDNA	Both	Linear	1	Viral DdDp	Nucleus
Anelloviridae	ssDNA	Negative	Circular	1	Cellular DdDp	Nucleus

[a]Polarity of the encapsidated genome.

[b]Topology of the encapsidated genome—note that some circularize during replication.

DdDp, DNA-dependent DNA polymerase; ds, double-stranded; RdDp, RNA-dependent RNA polymerase; ss, single-stranded.

Unique Biology of Virus Replication

As obligate intracellular parasites, all viruses depend heavily on functions provided by their host cells. This dependence, as well as the extensive metabolic overlap between host and parasite, limits the number of possible targets for antiviral therapy. Nevertheless, almost all viruses encode and express unique proteins, including enzymes, and many viruses exploit pathways of information transfer that are unknown elsewhere in the biosphere. This is particularly evident among the RNA viruses, which are the only organisms that are known to store their genetic information in the form of RNA. They accomplish this by replicating their genomes via one of two unique biochemical pathways—either by RNA-dependent RNA synthesis[104] (RNA replication) or, among the retroviruses, by RNA-dependent DNA synthesis (reverse transcription)[6,114] followed by DNA replication and transcription. Both pathways require enzymatic activities that are not usually found in uninfected host cells and must, therefore, be encoded by the viral genome and expressed during infection. Furthermore, in some families of RNA-containing viruses, those unique synthetic processes are required right at the start of the infectious cycle. This necessitates copackaging of the corresponding polymerase and other associated enzymes with the viral genome during the assembly of viral particles in preparation for the next round of infection. The

circular RNA genome of hepatitis delta virus encodes neither an RNA-dependent RNA polymerase nor a reverse transcriptase. Replication of this virus depends upon hepatitis B virus and is also dependent on the host DNA-dependent RNA polymerase II (reviewed in Ref.[113]).

Whatever the structure and replication strategy of their genomes, all viruses must express their genes as functional messenger RNAs (mRNAs) early in infection in order to direct the cellular translational machinery to make viral proteins. The various genomic strategies employed by viruses can, therefore, be organized around a simple conceptual framework centered on viral mRNA (Figs. 5.1 and 5.2). By convention, mRNA is defined as positive sense and its complement as negative sense. The pathways leading from genome to message vary widely among the different virus families and form the basis of viral taxonomy. Although it is generally believed that viruses originated from cellular organisms, perhaps fairly recently in evolutionary times, it remains possible that some RNA viruses are descended directly from a primordial "RNA world" or "ribonucleoprotein world," which may have predated the emergence of DNA and cells (reviewed in Ref.[8]).

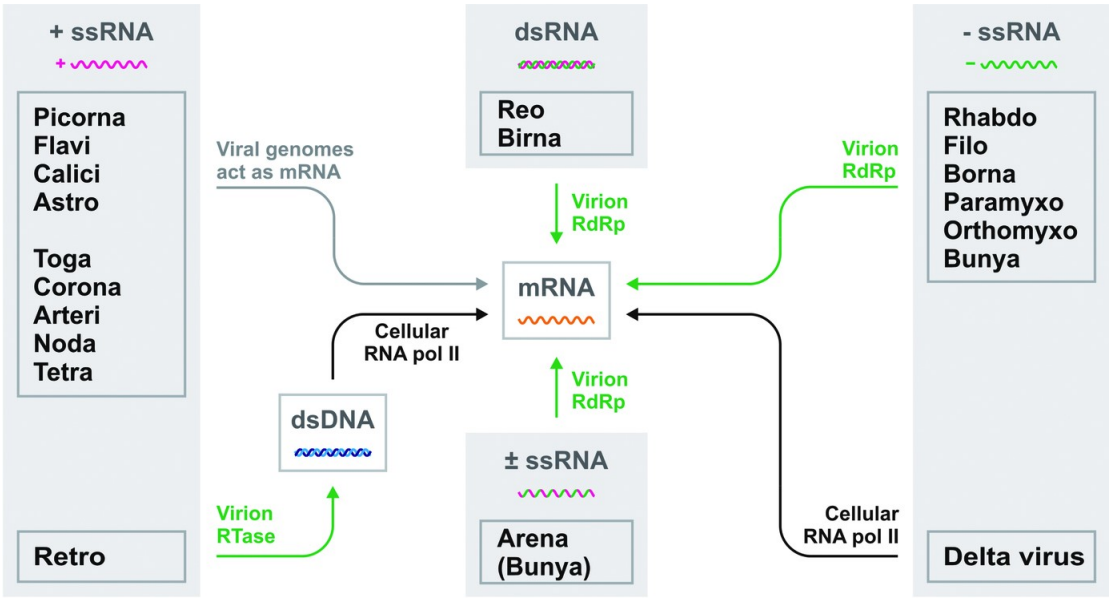

FIGURE 5.2 **Pathways of primary mRNA synthesis by RNA viruses of animals**. How RNA viruses produce mRNA at the start of infection depends upon the nature of the viral genome.

Subcellular Sites of Viral Replication

Most DNA viruses of eukaryotes transcribe and replicate their genomes and assemble progeny in the nucleus, the site of cellular DNA transcription and replication. The exceptions are the poxviruses, iridoviruses, and African swine fever virus, which replicate their DNA genomes partly or completely in the cytoplasm. In contrast, most RNA viruses replicate their genomes in the cytoplasm. However, in addition to the retroviruses that integrate DNA copies of their genomes into the host chromosomes, other notable exceptions to this generalization are the orthomyxoviruses, bornaviruses, and multiple plant-infecting rhabdoviruses, whose linear negative-sense RNA genomes replicate in the nucleus. The circular RNA genome of hepatitis delta virus (HDV) also replicates in the nucleus (Table 5.1). Each site of replication presents distinct opportunities and challenges in terms of which cellular components and pathways are available to be co-opted, and how the synthesis and trafficking of viral proteins, genome replication, virion assembly, and the release of progeny can be coordinated. For example, RNA splicing occurs only in the nucleus, so among the RNA viruses, this mechanism of accessing more than one open-reading frame in a single transcript can be employed by only the retro-, orthomyxo-, and bornaviruses that transcribe there. It is remarkable that the paramyxoviruses and filoviruses that replicate in the cytoplasm have evolved a transcriptional editing mechanism that achieves a similar result.[116,120] Irrespective of the site of replication (nuclear or cytoplasmic), the viral replication machinery itself is frequently compartmentalized within specific structures or viral-induced organelles. For example, herpesviruses form replication compartments within the nucleus at nuclear speckles.[16,101] Many RNA viruses that replicate in the cytoplasm do so in association with membranes or membrane-less inclusionlike structures that contain the viral replication

machinery[26,68] and share properties with phase-separated compartments.[55]

Evasion of Host Response to Infection

To ensure their survival, host organisms have evolved a variety of responses to combat viral infection. In turn, many viruses express specific gene products that act to circumvent one or more of those antiviral defense mechanisms. Examination of these measures and countermeasures provides a revealing glimpse into the heart of the host-parasite relationship as it plays out in nature. Host-defense mechanisms can be categorized as innate or adaptive. Among the former, which operate at the cellular level, are apoptosis, necroptosis, and pyroptosis (three distinctive cell death responses to virus infection that limit the spread of infection), the induction and action of interferons in vertebrates (inducible cytokines that render cells resistant to infection by inducing a multifaceted antiviral state), and RNA interference in plants and invertebrates (a sequence-specific mechanism of RNA degradation). Adaptive immune mechanisms operate at the organismal level and include the cell- and antibody-mediated immune response (see Chapter 10). Specific restriction factors have been identified that limit the replication of subsets of viruses. Such factors include tripartite motif containing protein 5 (TRIM5), which binds the incoming human immunodeficiency virus type 1 (HIV-1) capsid and through multiple mechanisms limits the establishment of infection (reviewed in Ref.[39]). The apolipoprotein B mRNA editing, enzyme catalytic (APOBEC) family, which induce biased hypermutation in RNA through a cytidine deaminase activity that converts C to U (reviewed in Ref.[126]). Bone marrow stromal antigen 2 (Bst2)/tetherin is incorporated into the membranes of some enveloped viruses resulting in a linking together of budding viral particles. Multiple other cellular proteins have been termed "restriction factors," the expression of most of which are stimulated by interferon (reviewed in Ref.[106]). In different viruses, mechanisms and gene products have been identified that inhibit apoptosis, intercept interferons or suppress their activities, obstruct RNA interference, either evade or suppress different arms of the adaptive immune response, or block intrinsic restriction factors.[5,38,52,53,70,79,103,107,108,117]

Viruses are sensed by the host in ways that appear to involve recognition of unique signatures present in viral genomes or gene products. Such signatures are termed pathogen-associated molecular patterns (or PAMPs) and are recognized by an array of host pathogen-recognition receptors (or PRRs). Those PRRs include the toll-like receptors (TLRs), which are membrane-associated molecules that sense invading pathogens directly at the plasma membrane or during endosomal transit. The retinoic acid inducible gene (RIG)-like receptors (RLRs), which are cytoplasmic RNA helicases that recognize the products of RNA viral nucleic-acid replication, and the absent in melanoma 2-like receptors that recognize cytoplasmic DNA. The nucleotide binding domain (NBD) leucine-rich repeat (LRR) containing receptor (NLR) family members sense bacterial peptidoglycan and some viruses. A striking example of such PRR function is the detection of off-pathway products of replication such as abortive initiation products, dsRNA, and defective viral genomes, which can serve as ligands for the cytoplasmic sensors RIG-I and melanoma differentiation association protein 5 (MDA-5) to engage in a signaling cascade that leads to the activation of interferon.[43] The net result of interferon activation is both the blocking of infection within the cell, and the preactivation of defense mechanisms in neighboring cells to render them less susceptible to infection. The latter is accomplished by the transcription of interferon (IFN)-stimulated genes (ISG), which themselves act to block various steps in the replication cycle of DNA and RNA viruses.[106] In turn, viruses themselves have evolved countermeasures to such host-defense mechanisms that act to block the induction of IFN itself or to interfere with specific ISG function.[22,46] The elaborate arms race between viruses and their hosts is described in more detail within the specific chapters dealing with individual virus families. Molecular signatures of this arms race throughout evolution are also visible in the sequences of virus and host genes (reviewed in Ref.[115]). Retroviruses provide a unique insight into this, since they integrate into the host genome. Evidence for integration of portions of other viral genomes into the host chromosome including RNA viruses such as bornavirus, and lymphocytic choriomeningitis virus, has also emerged.[35,90]

Error Prone Nature of RNA Replication

The polymerases that catalyze RNA replication and reverse transcription have minimal proofreading activities. The polymerase error rate of such RNA-dependent RNA polymerases (RdRps) and reverse transcriptases is approximately three orders of magnitude higher than that of DNA-dependent DNA polymerases and approaches the reciprocal of their genome length.[29,60,82] The net result is that the genomes of RNA viruses evolve at a much faster rate than those of their hosts. Biologically, RNA viruses, therefore, represent a swarm of sequences around a consensus sequence or master sequence.[33,69] This molecular swarm provides a fertile source of phenotypic variants that can respond rapidly to changing selection pressures by shifting its composition. As a consequence, RNA viruses can evolve up to 1 million times faster than DNA-based organisms. The error prone nature of RNA virus replication is also critical for pathogenesis in infected hosts. The diversity of viral sequences regenerated following bottleneck transmission of HIV in humans,[102] and experimental poliovirus infection of mice[94,118] provide striking examples of this *in vivo*. In the case of HIV, the resulting sequence variation achieved following transmission of a limited number of genomes is enormous and accounts for—among other phenotypes—the rapid escape of the virus from neutralizing antibody and the escape from antiviral monotherapy.

Such rapid rates of evolution are not without cost for the RNA viruses however, because higher polymerase error rates impose upper limits on genome size. The combination of replicative error rate and genome size defines an "error threshold" above which a virus cannot maintain even the sequence integrity of its quasispecies.[33] As a result, few RNA virus genomes contain more than 30 kilobases (kb) and most have between 5 and 15 kb. RNA genomes of this size are poised just below their error thresholds, and although their genetic diversity inevitably wastes individual progeny that carry deleterious mutations, the cost is offset by the potential for rapid evolutionary response to changing selective pressures. This positioning of RNA viruses—just below their error threshold—may also present an opportunity for antiviral development. Specifically, therapeutics that lead to an increase in error rate can shift the balance beyond the error threshold toward "error catastrophe." Indeed evidence has accumulated that this is one such mechanism by which ribavirin, an adenosine analog, may inhibit the replication of some RNA viruses.[21] The largest RNA virus genomes currently recognized are those of the coronaviruses, which are ~30 kb. Strikingly, for coronaviruses, the nonstructural protein nsp14 functions as a 3′-5′ RNA exonuclease that corrects errors introduced by the polymerase during replication.[28,32] Despite the presence of this proofreading mechanism, which could help maintain genome integrity, replication of coronaviruses is error prone.[28] The 3′-5′ RNA exonuclease activity also mediates RNA recombination during replication that likely also aids in maintaining genome integrity.[48]

Levels of Segmentation

Another distinctive feature of eukaryotic cells—besides their partitioning into nuclear and cytoplasmic compartments—has a profound influence on the biology of their viruses. On most mRNAs, eukaryotic ribosomes require a methylated mRNA cap structure at the 5′ end that plays a critical role in signaling the initiation of protein synthesis. As a result, eukaryotes typically conform to the "one mRNA one polypeptide chain" rule; with very few exceptions, each message operates as a single translational unit. Similarly, viral RdRps generally appear somewhat restricted in their ability to access internal promoter elements on RNA templates, and this creates a problem of how an RNA virus can derive several separate protein products from a single genome.

Through evolution, different RNA virus families have found three different solutions: fragmentation at the level of proteins, mRNAs, or genes, with some viruses using more than one of those solutions. For example, RNA viruses in the picorna-, toga-, flavi-, and retrovirus families rely on extensive proteolytic processing of polyprotein precursors to derive their final protein products.[30] Others (in the orders *Mononegavirales* and *Nidovirales*) depend on complex transcriptional mechanisms to produce several monocistronic mRNAs from a single RNA template.[2,105] Still others (in the reo-, orthomyxo-, bunya-, and arenavirus families, among others) have solved the problem by fragmenting their genomes and assembling virions that contain multiple genome segments, each often representing a single gene.[36,78,84] Among plant viruses, such RNA genome segments are often packaged into separate virions, necessitating coinfection by several virus particles to transmit infectivity,[127] but the genome segments of animal viruses are typically copackaged into single virions. In contrast, DNA viruses seldom use either genome segmentation or polyprotein processing. This is likely due to the relative ease with which monocistronic mRNAs can be transcribed from internal promoter elements of dsDNA, and the extensive use of differential splicing of nuclear transcripts to express promoter-distal open-reading frames.

Host Cell Components for Replication

Viruses depend on their host cells to support their replication, and this degree of dependency—to some extent—reflects their genome size. All viruses depend on the host translational machinery, large DNA viruses, such as mimivirus may encode specific initiation factors that may provide a translational advantage for viral genes.[18] Entry of viruses into cells usually requires specific host-cell factors and often involves co-opting of cellular endocytic pathways.[80] The end point of entry is the release of the minimal viral replication machinery into the host-cell cytoplasm to initiate infection. How viruses establish infection in the hostile environment of the host cell remains one of the least understood steps of the viral replication cycle. The input genomes must either associate directly with ribosomes, in the case of positive-strand RNA viruses, or be copied into mRNA, in the case of the negative-strand RNA viruses, dsRNA viruses, and DNA viruses. Because the particle-to-infectivity ratio of some viruses approaches 1:1, this process must be highly efficient despite its inherent challenges. Our knowledge of the subsequent viral rewiring of host-cell structures to establish replication compartments, traffic viral proteins and nucleic acids, and assemble viral particles is far from complete, but has yielded a wealth of information into host biology as well as that of the viruses themselves. Indeed, study of viruses has contributed enormously to our understanding of promoters, transcriptional enhancers, the mRNA cap structure, RNA splicing, and mechanism of translation. Similarly, critical discoveries in host-cell transport and trafficking pathways including endocytosis, exocytosis, and secretory transport were achieved because of the ability to synchronize infections with viruses. System approaches including RNA interference (RNAi), proteomics, gene-knockout studies, particularly those capitalizing on CRISPR-Cas systems (clustered regularly interspaced short palindromic repeats (CRISPR)-CRISPR associated protein [Cas]), and microarrays are helping to further transform our understanding of the virus-host interaction at the molecular level. Despite the explosion of progress in the last decade, we have yet to understand fully the complexities of the interactions of any virus with its host. Zoonotic viruses must strike a balance for optimal replication in often quite disparate hosts, likely adding further complexity to this intimate relationship. Striking examples of this are provided by members of the *Flaviviridae*, such as Dengue virus (which replicates in both its mosquito host and animals), and experimentally with many viruses including vesicular stomatitis virus (which replicates in virtually all eukaryotic cells in culture).

Structures and Organization of Viral Genomes

DNA vs RNA Genomes

Among families of viruses that infect vertebrates, those with RNA genomes outnumber those with DNA genomes by about 2 to 1 (Table 5.1); among viruses infecting plants, the disparity is even greater. Indeed, no dsDNA viruses of plants are known except for those that like the hepadnaviruses of vertebrates, replicate via reverse transcription. This remarkable observation remains to be explained, but it may suggest that non-RT dsDNA viruses arose only after animals and plants diverged. Be that as it may, the prevalence of RNA viruses attests to the evolutionary success and versatility of RNA as genetic material for smaller genomes. As discussed previously, the high error rates of RNA replication restrict RNA genome sizes to ~30 kb or less, whereas proofreading and error repair ensure sufficiently accurate replication of DNA virus genomes as large as that of the 1200-kb megaviruses and the 2400-kb pandoraviruses.[4] In addition, the fact that DNA is more chemically stable than RNA likely explains why all known viruses of thermophilic hosts have dsDNA genomes.

Single- and Double-Stranded Genomes

Although all viral genomes replicate via conventional Watson-Crick base pairing between complementary template and daughter strands, viruses that belong to different families encapsidate and transmit different molecular stages of the genome replication cycle. Families of ssRNA viruses outnumber families of dsRNA viruses by almost 10 to 1, roughly the inverse of the ratio between ssDNA and dsDNA viruses. In view of the greater chemical stability of double-stranded nucleic acids of both types, this difference calls for an explanation. Two possibilities seem plausible: First, dsRNA viruses must somehow circumvent the translational suppression that can result from the coexistence of equimolar amounts of the sense and antisense RNAs. How the dsRNA reoviruses solve this problem is addressed in Chapter 11, Volume 3. Second, dsRNA is widely recognized by the cells of higher eukaryotes as a signal for the induction of defense mechanisms that act to suppress viral replication, such as the IFN system in vertebrates (see also Chapter 9), gene silencing in plants, and RNAi in a variety of organisms.[15,43,108,125] These effects probably suffice to explain the relative scarcity of dsRNA virus families.

For these same reasons, it is important even for ssRNA viruses to limit the accumulation of replicative intermediates that contain regions of dsRNA, and the strategies to ensure this differs between the positive- and negative-sense RNA viruses. All known positive-strand RNA viruses synthesize disproportionately low amounts of the negative-strand RNA—typically 1%-5% of the levels of the positive strand—and thereby minimize the potential for dsRNA accumulation. Moreover, because the replication of these viruses appears to universally occur in sequestered

membranous compartments, there appears to be a physical separation of the replicative intermediates from the host-cell cytoplasm, likely reducing the chances of detection.[26] In contrast, negative-strand RNA viruses, which need substantial amounts of both positive- and negative-sense RNAs to use as messages and progeny genomes, respectively, prevent the complementary RNAs from annealing to one another by encasing the genomic and antigenomic RNAs with a viral nucleocapsid protein that sequesters the RNA and impedes base pairing.[3,47] Here, RNA synthesis also appears confined at some stages of infection to specific subcellular compartments that may help serve to limit detection of viral products of RNA synthesis by the innate immune system.

Positive, Negative, and Ambisense Genomes

The differences between positive- and negative-strand RNA viruses extend beyond the polarity of the RNA assembled into virions. Positive-sense RNA genomes exchange their virion proteins for ribosomes and cellular RNA binding proteins at the onset of infection. Once synthesized and assembled, the virus-specified RdRp and other nonstructural proteins replace the ribosomes to accomplish RNA replication. Virion structural proteins are reacquired during the assembly of progeny virions. In contrast, negative-strand RNA genomes and their antigenomic complements remain associated with their nucleocapsid proteins, both within the viral particles and throughout the viral replication cycle, even during RNA replication. These fundamentally different adaptations can be attributed to the fact that whereas positive-sense RNA genomes must satisfy criteria for translation that are dictated by the host cell, negative-sense RNA genomes must only satisfy the template requirements for the virus-specified RdRp because they are replicated but never translated. Although the precise mechanism by which the protein-coated templates of negative-strand RNA genomes are copied by their cognate polymerases is not fully understood, short naked RNAs that correspond to the terminal promoters can be copied by their viral polymerases.[27,66,81] Such experimental evidence is consistent with a model for RNA synthesis in which the nucleocapsid protein is transiently displaced from the template RNA during copying of the genome. Structural studies of the polymerases of multiple negative strand RNA viruses (reviewed in Ref.[99]) suggest that transient dissociation of the template RNA from 2 to 3 molecules of the template N protein would be sufficient to facilitate the copying of the genomic RNA. Precisely how such displacement is achieved is uncertain.

The dsRNA virus genomes are intermediates between the two. The parental genome remains sequestered within a subviral particle during the synthesis of the unencapsidated positive-sense mRNA transcripts, which are replicated to produce progeny dsRNAs only after being assembled into subviral core particles.[91] Although the core RdRps of each of these viruses are structurally as well as functionally analogous, the distinctions in the genomic structure likely place additional structural constraints on the viral polymerase complexes.

Linear and Circular Genomes

Genome replication not only requires an acceptable error rate as described previously but must also avoid the systematic deletion or addition of nucleotides. Genome termini are particularly troublesome in this respect, a fact that has been dubbed “the end problem.” For DNA replication, the end problem is exacerbated by the fact that DNA polymerases cannot initiate the synthesis of daughter strands and must, therefore, use primers, thus creating additional complications of replicating the primer-binding site(s). Among several known solutions, the most economical and widespread in nature is to eliminate the ends altogether by covalently circularizing the genomic DNA, as occurs in the genomes of prokaryotes. Polyoma-, papilloma-, circo-, and anellovirus genomes follow this model, and the dsDNA genomes of herpes and hepadnaviruses, although linear, in virions are covalently circularized before replication. Poxviruses and asfiviruses also have linear dsDNA genomes, but in these cases, the individual complementary strands are covalently continuous at the termini of the duplex, which provides another solution to the end problem. A similar close-ended duplex DNA is generated during the replication of the ssDNA genomes of parvoviruses (Chapter 6, Volume 2). Terminal redundancy (iridoviruses), inverted terminal repeats (adenoviruses), and the use of protein primers that do not occlude the binding site (adenoviruses and hepadnaviruses) represent the other ways that DNA viruses have evolved to ensure accurate and complete replication of their genome termini.

Unlike DNA polymerases, most RNA polymerases do not require primers, so RNA genomes are less susceptible to the end problem. Accordingly, most RNA genomes are linear molecules. Covalently closed circular RNAs are found only in HDV in animals (Table 5.1) as well as among the viroids and other subviral RNA pathogens that infect plants. Nevertheless, the termini of linear RNA genomes are vulnerable to degradation, and their replication is likely to be particularly error prone. Consequently, every family of RNA viruses has features designed to preserve the termini of the genome.[7] For example, many positive-strand RNA viruses have a 5′ cap structure and 3′ polyadenylate tail that serve to protect eukaryotic RNAs against degradation, and a similar role is likely played by the VPg that is covalently linked to the 5′ end of the picornavirus genomes,[71] and by the stable RNA secondary structures present at the 3′ end of the flaviviral RNA and other genomes. The 3′ ends of many plant virus RNAs form clover leaf structures that resemble transfer RNAs (tRNAs) so closely that they are recognized by the cellular tRNA charging and modifying enzymes.[31] In addition to playing protective roles, terminal modifications of positive-sense RNAs may also serve to bring their ends together by binding to interacting cellular proteins such as the poly(A) binding protein and cap-binding complex, thereby forming noncovalent functionally circular complexes that may promote repetitive translation by ribosomes and repetitive replication by RdRps.[56,119]

Unlike the genomes of positive-sense RNA viruses, negative-sense and ambisense RNA virus genomes lack covalent terminal modifications. Those RNA genomes are, however, present as a ribonucleoprotein complex in which the genomic and antigenomic RNAs are found encapsidated by the viral nucleocapsid protein. Terminal *de novo* initiation during replication requires a priming loop present within those polymerases that stabilizes the initiation complex, and this is distinct from transcription of the viral genome. For the nonsegmented negative-sense RNA viruses, subsequent *de novo* initiation at internal gene-start sequences of the genome is not dependent upon the key priming loop residues suggesting a different mechanism of initiation. For the segmented negative-sense and ambisense viruses, mRNA transcription is initiated by short capped mRNA primers cannibalized from host cell mRNA either in the form of pre-mRNA in the nucleus or mature mRNA in the cytoplasm. In other solutions to the end problem among the RNA viruses, retroviral genomes are terminally redundant and have direct repeats of 12-235 nucleotides at each end that maintain and restore the integrity of the termini during reverse transcription and virus replication.

Segmented and Nonsegmented Genomes

As discussed previously, segmentation of RNA genomes is one way to facilitate the production of multiple gene products in eukaryotic cells, but it also means that the various segments must each contain appropriate *cis*-acting signals to mediate their expression, replication, and assembly

into virions. In some virus families whose members have segmented genomes (eg, the orthomyxoviruses and some reoviruses), these signals comprise conserved sequences at the RNA termini, but in others (eg, the bipartite nodaviruses and tetraviruses), sequence conservation between the segments is minimal. In these latter cases, the specificity of RNA replication and assembly is presumably dictated by conserved RNA secondary or tertiary structures. Moreover, segmentation of the viral genome requires a level of coordination to ensure that the correct amounts of viral gene products are expressed and to ensure the packaging of multiple genome segments to form infectious virus particles. Furthermore, in the case of the negative-sense, ambisense, and dsRNA viruses that have segmented genomes, a mechanism is required to ensure that the polymerase is packaged into the virus particle so that the incoming segments can be transcribed into mRNA. For the dsRNA viruses, the polymerase is an integral structural component of the core transcribing particle ensuring that the polymerase and capping machinery are present within the incoming particle. Each segment of influenza virus contains the heterotrimeric polymerase complex in complex with the genomic termini. In the case of the arenavirus, Machupo, the small viral protein Z, locks the polymerase on the promoter in an inactive form.[67]

Evidently, the evolutionary barrier between viruses with segmented and nonsegmented RNA genomes is readily transversed because both genome types occur in members of the alphavirus-like supergroup, a taxonomic cluster based on phylogenetic comparisons of nonstructural protein sequences. Indeed, among the tetraviruses, segmented and nonsegmented genomes can even be found in the same family. Furthermore, the genomes of some togaviruses, rhabdoviruses, and paramyxoviruses, which are naturally nonsegmented, have been experimentally divided into segmented genomes without destroying viral infectivity,[40,111] thus confirming the flexibility of RNA genomes in this regard. Nevertheless, genome segmentation has major effects on the biology of a virus because individual segments can reassort between dissimilar strains in coinfected cells, which enables segmented genome viruses to make substantial evolutionary leaps by horizontal gene transfer. This mechanism underlies the antigenic shifts that produce new pandemic strains of the orthomyxovirus influenza virus (see Volume 1, Chapters 14 and 15).

As discussed previously, genome segmentation is almost unknown among DNA viruses, most likely because internal initiation of transcription and alternative splicing provide more facile ways to access multiple open-reading frames. Only the polydnaviruses, a family of dsDNA viruses that infect parasitic wasps and participate in a complex and unusual host-parasite relationship, show extensive DNA segmentation.[7]

cis-ACTING RNA SIGNALS AND SPECIFICITY

Replication and packaging of viral RNAs display striking specificity; both processes unerringly pick the correct viral molecules from among thousands of cellular RNAs that may be much more abundant. This is generally attributed to the presence of *cis*-acting signals that selectively channel the viral RNAs into replication and assembly complexes, but for some RNA virus genomes, these signals remain to be clearly identified. *cis*-Acting signals that have been characterized comprise in addition to linear nucleotide stretches, RNA secondary structures such as bulged stem-loops, tRNA-like cloverleaves, and pseudoknots that create distinctive three-dimensional molecular shapes that interact specifically with the viral enzymes and structural proteins. Although high-resolution structures have been determined for many RdRps, reverse transcriptases, and viral capsids, our understanding of the molecular basis of specificity in RNA replication and virus assembly is limited by the knowledge of the three-dimensional structures of viral RNA and its *cis*-acting signals at the particular stages of replication or assembly. The structural basis of RNA specificity during replication and assembly has often proved elusive, perhaps because the specificity determinants can be redundant, dispersed, or global properties of the viral genome. Furthermore, in both RNA replication and assembly, specific interaction is often followed by less-specific RNA-protein interactions that propagate the reactions. The transitions between these different stages are beginning to be explored including polymerase structures in complex with the templates at various stages of synthesis or recognition of RNA by portions of viral capsid proteins. Where structures have been attained, noncanonical base pairing in the RNA in the presence of the viral polymerase as exemplified by influenza A virus (reviewed in Ref.[121]) or the coat protein of alfalfa mosaic virus[50] can play a key role in regulating replication and assembly. Much still remains to be learned concerning the recognition of *cis*-acting RNA signals and how they promulgate RNA replication and assembly.

Our understanding of *cis*-acting regions of RNA viral genomes has also benefitted from the application of a chemical probing methodology termed selective 2′ hydroxyl acetylation analyzed by primer extension (SHAPE), first applied to provide an overview of the complete genome of HIV-1.[122] In addition to correctly identifying known structures within the HIV-1 genome, several structures were identified within the coding regions at regions close to the positions of polyprotein processing. Such structured elements are thought to lead to a slowing of ribosomes to facilitate the correct folding of the preceding region of the polypeptide chain. Application of this methodology is helping to understand the *cis*-acting elements within RNA virus genomes as well as the overall structure of viral genomes, and the discovery of more processive reverse transcriptases that allow accurate probing of longer and more structured RNAs will likely further enhance the utility of this approach.[49]

Satellite, Dependent, and Defective Genomes

Occasionally, subviral genomes arise that are neither independently infectious nor essential for infectivity, but nevertheless contain *cis*-acting signals that promote their own replication and/or packaging by the proteins encoded by another virus. Such satellite nucleic acids are parasitic on the parental virus and can modulate its replication and virulence.[109] Most commonly, they are ssRNAs, but dsRNA and ssDNA satellites are also known. Among the RNA viruses of animals, a prime example is hepatitis delta virus (or HDV), which packages its ssRNA genome in virion proteins encoded by the hepadnavirus hepatitis B virus and can severely exacerbate its pathogenicity.[112,113] Dependence of an RNA satellite on a DNA virus parent is unusual; more commonly satellite, RNAs are replicated and encapsidated by the proteins of an RNA virus parent with which they share at least some sequence homology. In some instances, satellite RNAs encode their own distinct capsid proteins, or proteins required for RNA replication (as in the case of HDV), but in others they are translationally silent. Satellite RNAs are much more common among the viruses of plants than those of animals, perhaps because the transmission of animal viruses between hosts generally involves narrower bottlenecks that select against the spread of satellites. Dependence of one virus on another is also found occasionally among viruses with DNA genomes. For example, adeno-associated virus (family *Parvoviridae*, genus *Dependoparvovirus*) requires coinfection of host cells by adenoviruses or herpesvirus to provide helper functions necessary for its replication.

In contrast to the transmission of viral infection between hosts, the spread of infection within a single animal usually involves successive episodes of localized viral replication. These conditions favor the generation and amplification of defective viral genomes, which can arise from a simple internal deletion of genes as well as more complex genome rearrangements that occur during RNA replication. Like satellite RNAs, defective RNAs parasitize the parent virus and usually interfere with its replication, but because they also depend upon it for their own survival, they typically establish a fluctuating coexistence. Most families of animal RNA viruses readily generate defective interfering (DI) RNAs in cell culture, but their influence on viral disease and evolution is less well understood (reviewed in Ref.[42]).

Expression and Replication of DNA Virus Genomes

DNA Virus Genome Strategies

Viral DNA genomes range in size from the 1.8-kb circoviruses to the 2400-kb genomes of the pandoraviruses.[4,95] This vast difference in the coding capacity means that viruses from different families vary widely in how many of the functions necessary for viral replication they encode themselves. For example, DNA viruses with small genomes such as the polyoma-, papilloma-, and parvoviruses use host-cell enzymes for transcription and replication (Figs. 5.3 and 5.4). Those with intermediate-size genomes (up to 35 kb) such as adenoviruses encode much of their DNA replication machinery including a DNA polymerase, terminal protein, and ssDNA binding protein, but they employ cellular RNA polymerase II and III for transcription (Fig. 5.5). Those with larger genomes (150-350 kb), such as the herpesviruses and poxviruses, encode DNA polymerases and binding proteins. In the case of herpesviruses, multiple specific transcription factors serially modify the promoter specificity of RNA polymerase II (Fig. 5.6), or in the case of the poxviruses multi-subunit transcriptase complexes perform all the functions of mRNA capping and polyadenylation as well as RNA transcription (Fig. 5.7). Hepadnaviruses buck this general trend in that they are small genomes (3 kb) but encode the DNA polymerase/reverse transcriptase that executes their unique mechanism of DNA replication via an ssRNA intermediate (Fig. 5.8).

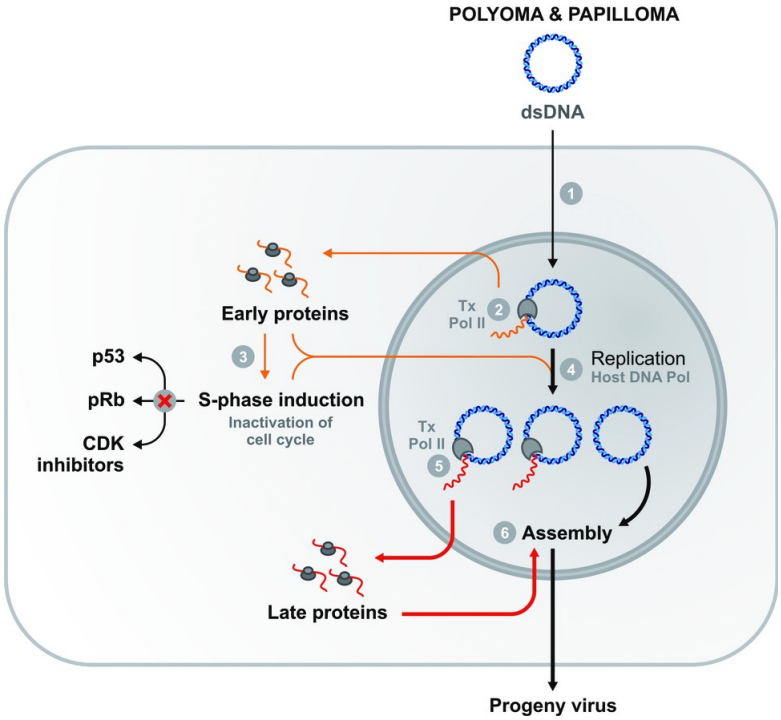

FIGURE 5.3 **Simplified view of the replication scheme of *Polyomaviridae* and *Papillomaviridae*.** The circular dsDNA genome is transported to the nucleus (*step 1*) where cellular RNA polymerase II transcribes the early genes (*step 2*) that encode the viral oncoproteins or transforming (T) antigens. The products of *step 2* interfere with the host-cell cycle control proteins p53 and pRb or interact with inhibitors of cyclin-dependent kinases (CDKs) to stimulate cellular DNA replication (*step 3*). In nonpermissive cells that cannot support the vegetative replication cycles and, therefore, survive the infection, these early events can lead to neoplastic transformation. In permissive cells, the viral DNA is replicated by the host-cell DNA polymerase (*step 4*), following which cellular RNA pol II can transcribe the late genes that encode viral structural proteins (*step 5*). The assembly of viral particles occurs in the nucleus (*step 6*). The thickness and color intensity of the *arrows* signifies the predominant events.

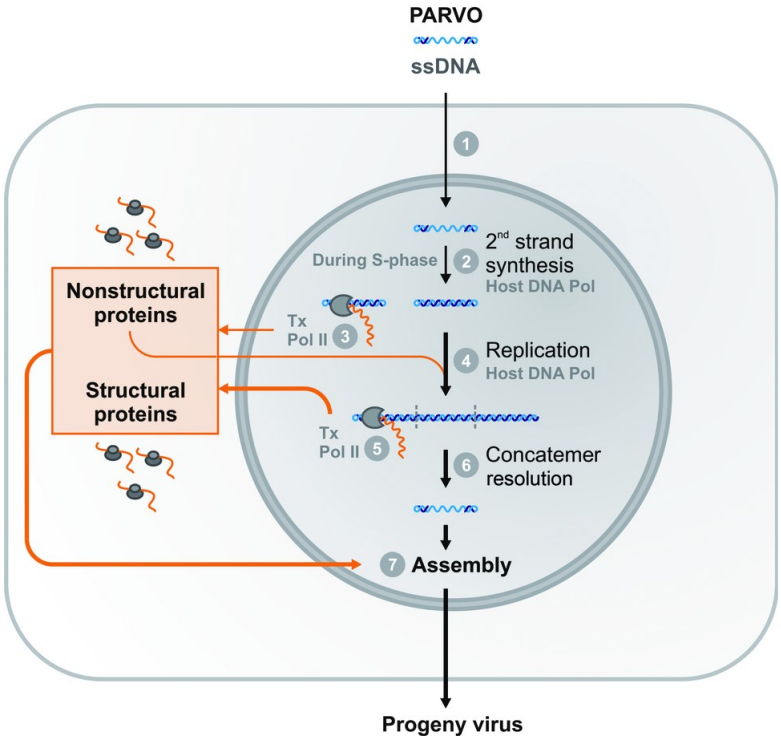

FIGURE 5.4 **Simplified view of the replication scheme of *Parvoviridae***. Following entry, the linear ssDNA genome is delivered to the nucleus (*step 1*) where self-primed second strand synthesis is mediated by the host DNA polymerase during the S phase of the cell cycle (*step 2*). The resulting dsDNA hairpin is transcribed by the cellular RNA polymerase II (*step 3*) to produce mRNAs that encode viral nonstructural and structural proteins and is ligated to form a covalently continuous duplex. The nonstructural proteins promote further DNA replication by the host DNA polymerase, which occurs via a rolling hairpin mechanism to produce double-stranded concatemers of the viral genome (*step 4*). The concatamers are templates for transcription by host RNA polymerase II to produce further viral proteins (*step 5*), and they are resolved (*step 6*) prior to assembly (*step 7*) into viral particles.

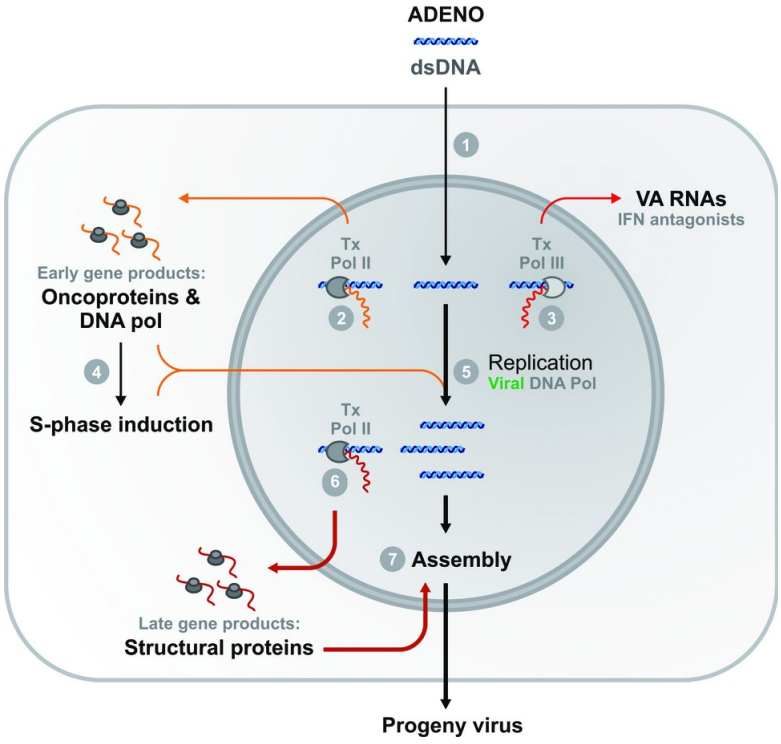

FIGURE 5.5 **Simplified overview of the replication scheme of *Adenoviridae***. The linear dsDNA genome is delivered into the nucleus (*step 1*), where it is transcribed by the host cell RNA polymerase II (*step 2*) to produce the early gene products including oncoproteins and the viral DNA polymerase. In adenoviruses of primates, the host RNA polymerase III also transcribes the genome to produce VA RNAs that act as interferon antagonists (*step 3*). The early gene products override cell cycle controls and inhibit apoptosis (*step 4*) as well as provide the essential viral polymerase components for genome replication (*step 5*). Following DNA replication, the late genes are transcribed by the host RNA polymerase II from a single major late promoter, and following extensive differential splicing provide the viral structural proteins (*step 6*). Virus assembly (*step 7*) occurs in the nucleus.

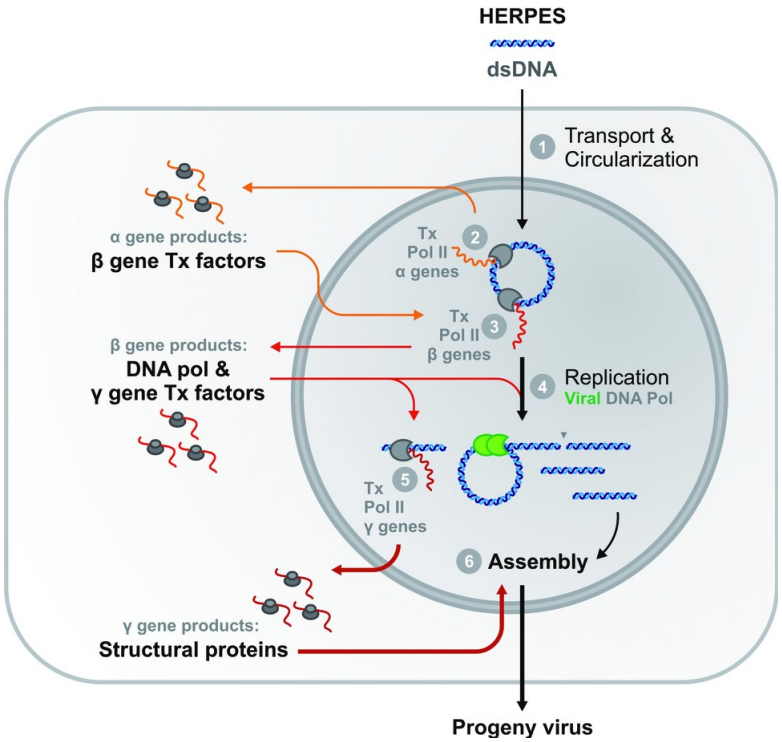

FIGURE 5.6 **Simplified overview of the replication scheme of *Herpesviridae***. The linear genomic dsDNA genome is delivered to the nucleus, where it undergoes covalent circularization (*step 1*). Cellular RNA polymerase II transcribes the immediate-early *α* genes (*step 2*) that encode transcription factors that mediate the host RNA polymerase II recognition of the promoters for the delayed-early *β* genes (*step 3*). Those genes encode the viral DNA polymerase and other proteins required for genome replication (*step 4*) as well as transcription factors required for the pol II–mediated expression of the late *γ* genes that encode most of the structural proteins (*step 5*). Virions assemble in the nucleus (*step 6*) and exit through the nuclear pore. The assembled virion contains the necessary transcription factors for expression of the immediate-early *α* genes on infection of the next cell. Note that this scheme represents only the vegetative cycle of *Herpesviridae* replication. Readers are referred to the individual *Herpesviridae* chapters regarding the establishment, maintenance of, and reactivation from latency.

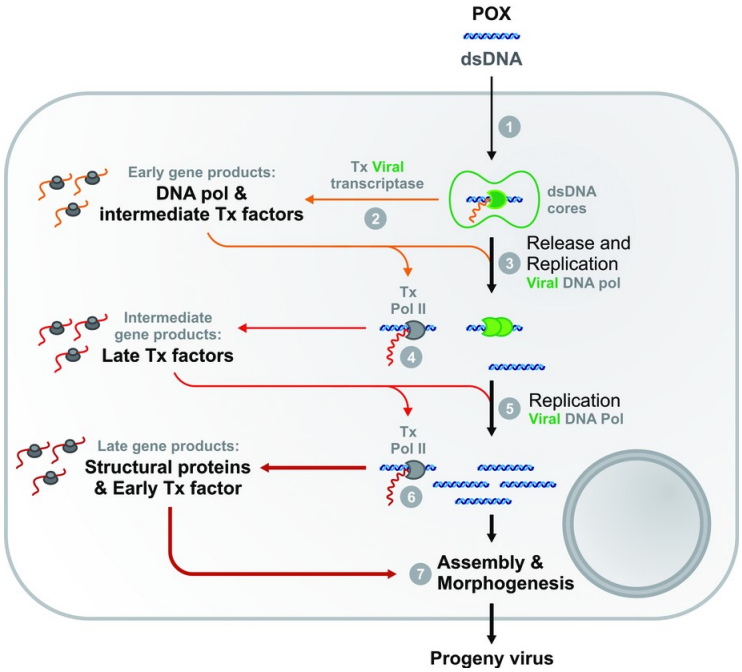

FIGURE 5.7 **Simplified scheme of the replication of *Poxviridae***. Entry delivers the viral core containing the dsDNA genome into the cytoplasm—the site of viral RNA synthesis (*step 1*). In the cytoplasm, the multisubunit virion DNA-dependent RNA polymerase transcribes the early viral genes (*step 2*), which comprise ~50% of the genome. The early gene products include factors that mediate the release of the dsDNA into the cytoplasm (second stage uncoating), the viral DNA polymerase and associated enzymes required for replication (*step 3*), and transcription factors that direct the viral RNA polymerase to transcribe a limited number of intermediate genes (*step 4*). DNA replication proceeds via a rolling hairpin mechanism (*steps 3 and 5*) similar to that for parvoviruses and is concurrent with the expression of the intermediate gene products (*step 4*). The intermediate gene products include transcription factors required for late gene expression (*step 6*). The products of late gene expression encode most of the structural proteins as well as the viral transcriptase and

associated factors that will be required at the start of a new infection. Progeny genomes, viral structural proteins, and membranes of the host cell participate in the assembly of viral particles that undergo extensive morphogenesis and maturation (*step 7*) prior to release.

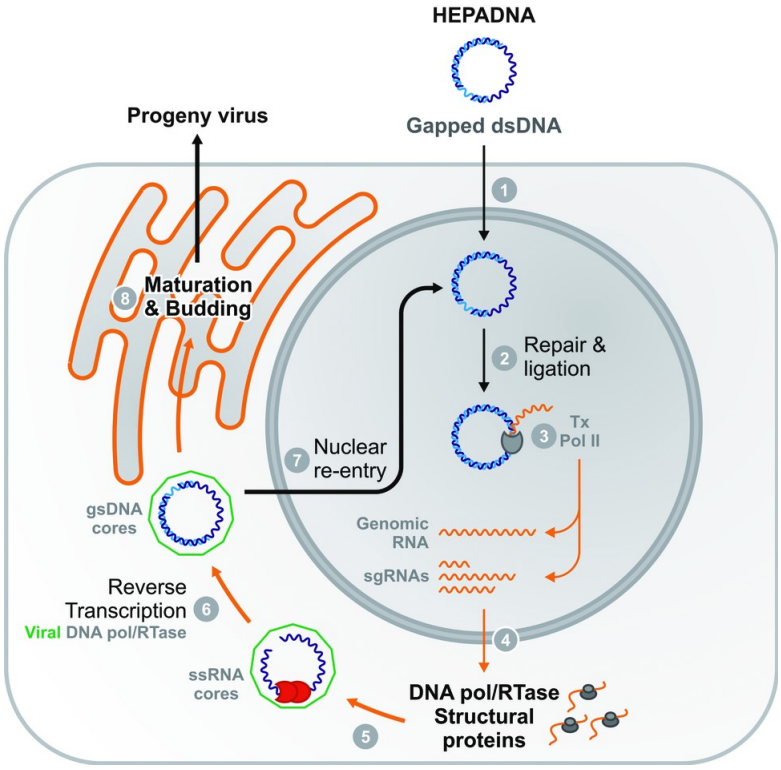

FIGURE 5.8 **Simplified replication scheme for *Hepadnaviridae***. Following entry and partial uncoating (*step 1*), viral cores containing the gapped dsDNA genome migrate to the nucleus where the dsDNA genome is repaired and ligated into a covalently closed circle (*steps 1 and 2*). This repaired genome is transcribed by the host-cell RNA polymerase II (*step 3*) to yield terminally redundant pregenomic RNA and subgenomic RNAs for the viral structural and nonstructural proteins (*step 4*). In the cytoplasm, the viral DNA polymerase, reverse transcriptase (RTase), and core proteins associate with the pregenomic RNA to form immature cores (*step 5*) that mediate polymerase-primed reverse transcription of the pregenomic RNA to yield gapped dsDNA genomes (*step 6*). The progeny cores either then enter the nucleus (*step 7*) to repeat the cycle or can bud through the endoplasmic reticulum to yield viral particles (*step 8*).

Because cellular DNA synthesis occurs during the S phase of the cell cycle and not at all in terminally differentiated G0 cells, viruses that depend on the host DNA polymerase must either wait for the infected cell to enter S phase spontaneously, as in the case of parvoviruses, or early in infection, they must express one or more viral oncogenes to override the regulation of the cell-cycle control proteins p53 or pRb and thereby stimulate infected cells to enter S phase, as in polyomaviruses and papillomaviruses. Inactivation of pRb releases cellular transcription factor E2F, which induces expression of the cellular DNA polymerase α primase, DNA polymerase δ, ssDNA binding protein, and several critical cellular enzymes that are involved in both the *de novo* and the salvage pathways of deoxynucleotide triphosphate (dNTP) biosynthesis, including ribonucleotide reductase, thymidylate synthetase, dihydrofolate reductase, deoxyuridine triphosphate nucleotidohydrolase (dUTPase), and thymidine and thymidylate kinases. Viruses with large DNA genomes (eg, herpesviruses and poxviruses) encode some of those enzymes themselves and can thus replicate in nondividing cells and other environments that would not normally support DNA replication, such as terminally differentiated cells of the nervous system (some herpesviruses) or even the cytoplasm (poxviruses). Although these viral genes are often dispensable for virus replication in actively dividing cells in culture, they can exert a profound influence on viral virulence in infected organisms and thus provide targets for chemotherapeutic intervention. For example, the thymidine kinase gene of some herpesviruses (but not the host enzyme) phosphorylates the prodrug acyclovir to generate a dNTP analog that terminates nascent strands during DNA synthesis.[34]

Regulation of Viral Gene Expression

During the early, prereplicative phase of the infectious cycle of a typical DNA virus, a subset of so-called immediate early viral genes is expressed to produce mostly catalytic quantities of nonstructural proteins required for DNA replication and host-cell manipulation. After DNA replication, a different set of genes is expressed (late genes) that direct the synthesis of stoichiometric amounts of the structural proteins required for viral assembly. Expression of the early genes is often concomitantly repressed. This early/late switch, which is a common feature of many DNA virus families, can be understood as an evolutionary adaptation that gives viruses an advantage in competing with the host cell for gene expression: early gene expression is modest, whereas later during the postreplicative stage of the infectious cycle, increased gene copy numbers enable the virus to dominate the protein synthesis capacity of the cell. In addition to the early and late genes, sets of intermediate genes have been identified in the poxviruses and herpesviruses, with each temporal class encoding factors that switch on the next in a transcriptional cascade (Figs. 5.6 and 5.7). For the viruses in these families, transcription factors for immediate early genes are expressed late in infection and assembled into progeny virions in preparation for the next infectious cycle.

At the start of infection, immediate early viral promoters face stiff competition from overwhelming numbers of cellular promoters. To successfully recruit RNA pol II and other components of the transcriptional machinery, many DNA viral genomes contain enhancers: *cis*-acting regulatory elements that facilitate the assembly of transcription complexes by binding multiple cellular transcription factors and other accessory proteins. A defining feature of enhancers, which were first identified in the genome of the polyomavirus simian vacuolating virus 40 (SV40), is that they exert their effects from either upstream or downstream of promoters and can act over distances of several kilobases.

Efficient transcription from late promoters usually requires one or more early gene products, as well as cellular transcription factors that may differ from those used by the early promoters. Dependence on specific cellular transcription factors can limit the expression of late genes to particular cells or tissues where the necessary factors are naturally expressed. For example, transcription of late papillomavirus genes requires a specific transcription factor that is expressed only in fully differentiated skin cells. As a result, the replication cycle is stalled after DNA replication (Fig. 5.3, step 4) until the cell differentiates.

Infection of cells with herpesviruses and poxviruses increases the rate of mRNA degradation.[19] In some herpesviruses, that is mediated by a protein component of the infecting virions called vhs (virion host shutoff). Although enhanced turnover is not specific for cellular mRNAs, some host cell mRNAs are not subject to the suppression and viral mRNAs are readily replenished by robust transcription of the viral genome so that the net result is the selective suppression of host protein synthesis.[1] In addition, the rapid turnover of viral mRNAs accelerates the transitions in the transcriptional cascade.

Mechanisms of DNA Replication and Transcription

Most DNA viruses produce functional viral mRNAs by usurping the transcriptional machinery of the cell (Fig. 5.1). This machinery includes RNA pol II, multiple transcription factors, poly(A) polymerase, guanylyltransferase, methyltransferases, and the pathway of mRNA export from the nucleus. Even viruses with unusual genome structures such as parvoviruses and hepadnaviruses use these cellular components because their genomes are rendered into dsDNA before transcription (Figs. 5.4 and 5.8). Only DNA viruses that replicate in the cytoplasm (pox-, irido-, and asfiviruses) use virus-specific enzymes for transcription and posttranscriptional modification of their mRNAs (Fig. 5.7). Because these enzymes are virion structural components, they can often be purified more readily than their cellular counterparts, and in the case of the vaccinia poxvirus and *Chlorella* virus, their reactions and structural properties have been well studied.[51,59,61] The majority of RNA viruses also replicate in the cytoplasm and employ virus-specific enzymes to synthesize and modify their mRNA.[25]

Viral DNA genomes replicate by at least five different mechanisms, which are summarized as follows (for more details, readers are referred to the chapters that describe each viral family).

1. The circular dsDNA genomes of polyomaviruses and papillomaviruses (Fig. 5.3) replicate bidirectionally from a single AT-rich origin via the RNA-primed synthesis of continuous leading strands and discontinuous lagging strands at both replication forks. Circularity of the genome aside, the reactions at the replication forks closely resemble how the host chromosome is replicated.[37,77]

2. In stark contrast, the linear dsDNA genome of adenoviruses (Fig. 5.5) is replicated by a protein-primed synthesis of only the leading strand, resulting in displacement of ssDNA from each end of the parental duplex. The termini of the displaced strands anneal via inverted terminal repeats, creating duplex panhandle structures that serve as secondary origins of replication. The primer (preterminal protein) is the product of an early gene, and a copy of this protein is covalently bound to the 5′ end of each of the daughter strands.[23,75]

3. The linear dsDNA of herpesvirus genomes is first circularized and then replicated from one or more internal origins, most likely by an RNA-primed mechanism that eventually produces dsDNA concatamers (Fig. 5.6). Progeny DNA can undergo isomerization by homologous recombination between internal and terminal repeated sequences, and unit length genomes are resolved from the concatamers during packaging into virions.[83]

4. Despite their different structures and sizes, poxvirus (Fig. 5.7) and parvovirus (Fig. 5.4) genomes replicate by similar mechanisms. The close-ended duplex poxvirus genome (or the closed-ended duplex intermediate in parvovirus replication) is nicked near its terminus, and the newly generated 3′ end serves to prime DNA synthesis using the complementary strand of the duplex as template. This initial self-priming event is reproduced by partially base-paired hairpin structures located at each end of the duplex genome, resulting in so-called “rolling hairpin” replication. For both poxviruses and parvoviruses, the product is a dsDNA concatamer from which unit length genomes are excised by resolution of concatamer junctions.[10,20,123]

5. Finally, in the most tortuous mechanism of all, hepadnaviruses (Fig. 5.8) replicate their dsDNA genome by a full-length pregenomic ssRNA transcript made by RNA polymerase II. Pregenomic RNA is then reverse transcribed by the viral-encoded DNA polymerase/reverse transcriptase to produce dsDNA progeny. In contrast to retroviruses (Fig. 5.9), DNA integration is not required for hepadnavirus replication, the genome being maintained as a circular episome in the nucleus of infected cells. Caulimoviruses—the only dsDNA viruses that infect plants—use a similar reverse transcriptase (RT)-mediated replication strategy. To prime first-strand DNA synthesis, hepadnavirus RTase uses a domain of the polymerase itself. This differs from the tRNA-primed strategy employed by retroviruses and caulimoviruses.

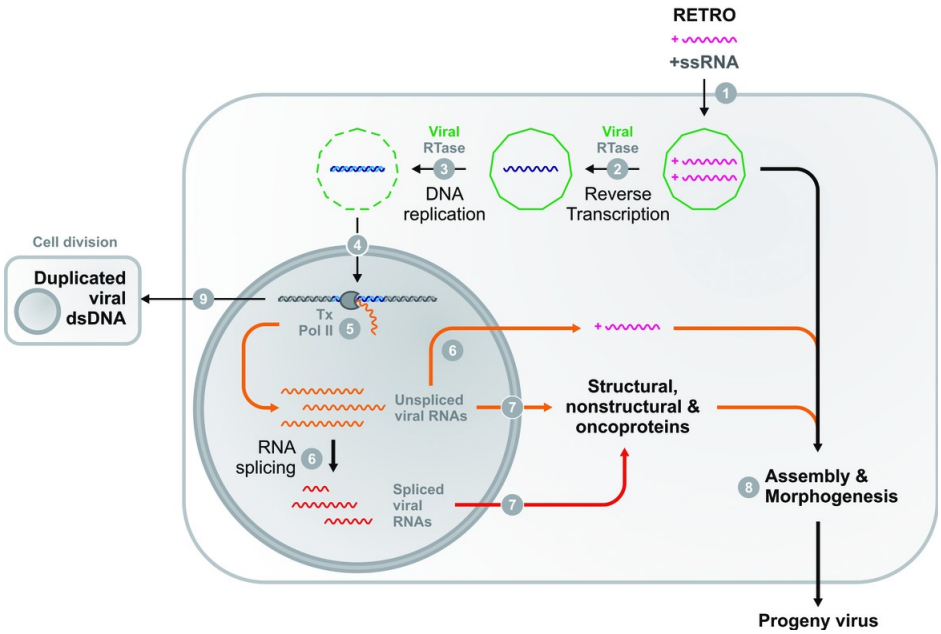

FIGURE 5.9 **Simplified replication scheme of *Retroviridae***. Following entry and partial uncoating (*step 1*), the viral genome is copied into dsDNA by the reverse transcriptase (*steps 2 and 3*) and integrated into the host chromosome by the virion DNA integrase (*step 4*). The integrated viral genome (provirus) is transcribed by the host-cell RNA polymerase II (*step 5*) to produce viral transcripts that function as precursors to the mRNA for the viral proteins (*steps 6 and 7*) as well as progeny genomes for assembly into infectious particles (*step 8*).

The polymerases employed for these strategies of replication are structurally and functionally homologous—yet they accomplish replication via very distinct mechanisms. Thus, the evolutionary origin of such disparate mechanisms of replication remains uncertain.

Remarkably, protein-primed replication is discontinuous. In the three known examples—adenovirus, poliovirus, and hepadnaviruses—the first few nucleotides of the genome are templated from an internal motif rather than at the very 3′ end of the parental genome. This necessitates a jump or realignment of the protein-primer product together with the polymerase to the 3′ end of the parental genome to complete synthesis of the daughter strand. In the case of adenovirus, the first templated nucleotides added to the primer are positions 4-6 of the genome, which then realigns with the 3′ end of the genome to complete daughter-strand synthesis following annealing of the nascent strand to the first three nucleotides of the parental genome.[23] For hepadnaviruses, the first four nucleotides are added to the RTase from a stem loop positioned at the 5′ end of the pregenomic RNA. The RTase nascent strand RNA product leaps almost 3 kb and then continues processively to complete synthesis of the daughter strand. Among the RNA viruses, the picornaviruses employ an internal stem loop termed the *cis*-acting replication element (cre) within the parental strand to template the uridylylation of a protein primer, VPg.[92] This primer is then repositioned together with polymerase at the 3′ end of the genome to prime synthesis of the new strand. Such protein-primed mechanisms likely aid in maintaining the integrity of the genome ends, which contain vital signals for replication.

Latent and Persistent Infections

In addition to the typical vegetative replication cycles illustrated in Figures 5.3 through 5.8, many DNA viruses establish latent or persistent infections of their hosts. Several distinct mechanisms of persistence have been identified with different viruses, but they all involve suppression of viral cytopathic effects, long-term maintenance of the viral genome, and evasion of the cellular and organismal defenses. For example, herpesviruses typically establish latent infections in which the viral genome is maintained as a circular episome in the nucleus, expressing at most only a few viral genes and yielding no infectious virus. Such latent herpesvirus infections persist throughout the life of the host, successfully evading host immune surveillance, yet able to reemerge at intervals as productive lytic infections. Because of its importance for human health, understanding the establishment and maintenance of herpesvirus latency and the mechanisms that regulate the reemergence of infectious virus are the subject of intense study (see Volume 2, Chapters 8-15). In the case of human herpesvirus 4 (Epstein-Barr virus), which infects B lymphocytes and causes mononucleosis, latent infections can be established and maintained in cell culture; this has greatly facilitated experimental study of the mechanisms involved. For other herpesviruses, the establishment and maintenance of latency occur in less-accessible cell types that pose additional challenges to understanding latency.

Viral Oncogenes and Neoplastic Transformation

In cells that somehow survive DNA virus infection, such as nonpermissive cells that express early genes but cannot replicate viral DNA or produce infectious progeny, the expression of viral oncogenes and the consequent loss of cell cycle control can lead to neoplastic transformation and the formation of tumors in infected animals. Unlike typical retrovirus-induced tumors, where the entire viral genome is integrated into the host chromosome as an essential step of the viral replication cycle, tumors induced by DNA viruses rarely contain a complete viral genome or produce infectious virus. Instead, they typically express only the viral oncogenes from integrated copies, disrupting cell cycle control by inactivating p53/pRb or by activating cyclin-dependent kinases, for example. Alone among the DNA viruses that replicate in the nucleus, parvoviruses do not induce tumors because they are unable to override cell cycle controls. Some poxviruses induce the formation of self-limiting benign tumors when they secrete a virus-encoded growth factor that induces surrounding cells to divide.

Expression and Replication of RNA Virus Genomes

RNA Virus Genome Strategies

The type of RNA genome dictates the first biosynthetic steps following infection. For example, the message sense positive-strand RNA viruses, excluding the retroviruses, all initially deliver their genomes to ribosomes to ensure the synthesis of essential proteins to establish viral replication (Figs. 5.10 and 5.11). Consequently, the viral genomic RNA alone is infectious once delivered into a host cell—a fact that greatly facilitated the genetic manipulation of such viruses. That the RNA alone was infectious was first shown for tobacco mosaic virus, in experiments that helped establish that genes were comprised of nucleic acids.[44] By contrast to the genomes of positive-sense RNA viruses, those of the negative-strand RNA viruses, retroviruses, and double-stranded RNA viruses all must deliver into the cell a protein RNA complex that contains within it the viral polymerase.

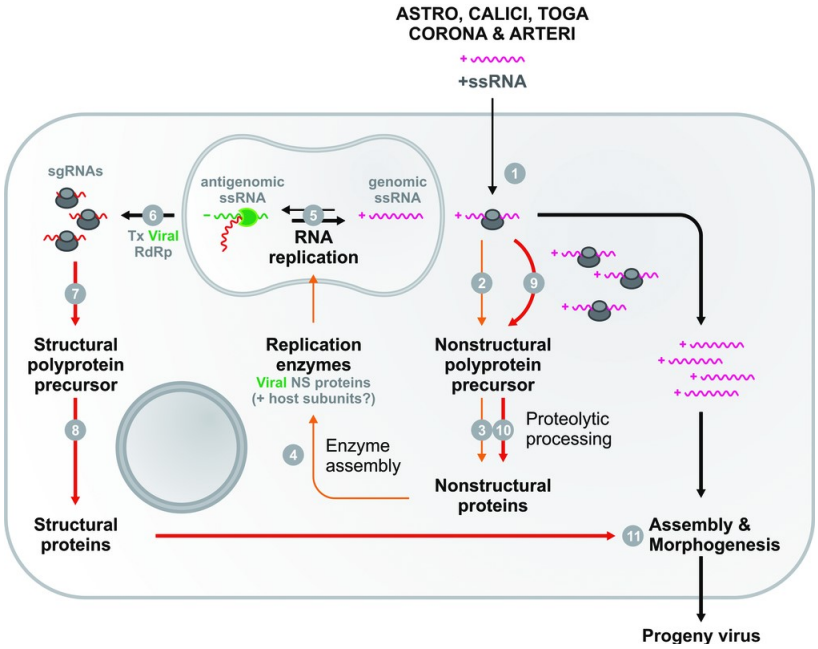

FIGURE 5.10 **Simplified replication scheme of positive-strand RNA viruses that produce subgenomic RNA**. Following entry and uncoating (*step 1*), the genomic RNA is engaged by the host-cell ribosome to produce the nonstructural proteins including the RdRp (*steps 2 and 3*). The viral replication enzymes together with host components form replication compartment in which the genomic RNA is replicated into an antigenome and progeny genomes (*steps 4 and 5*). The viral RdRp also transcribes one or more subgenomic RNAs (*step 6*) that encode viral structural proteins (*steps 7 and 8*). Replicated genomes are translated to amplify the production of viral proteins (*steps 9 and 10*) and may be used as templates for further replication. The genomes are assembled with viral structural proteins (*step 11*) to yield progeny virions. The scheme by which the *Coronaviridae* and *Arteriviridae* synthesize their subgenomic RNA is different from that employed by the *Toga-*, *Astra-*, and *Caliciviridae*.

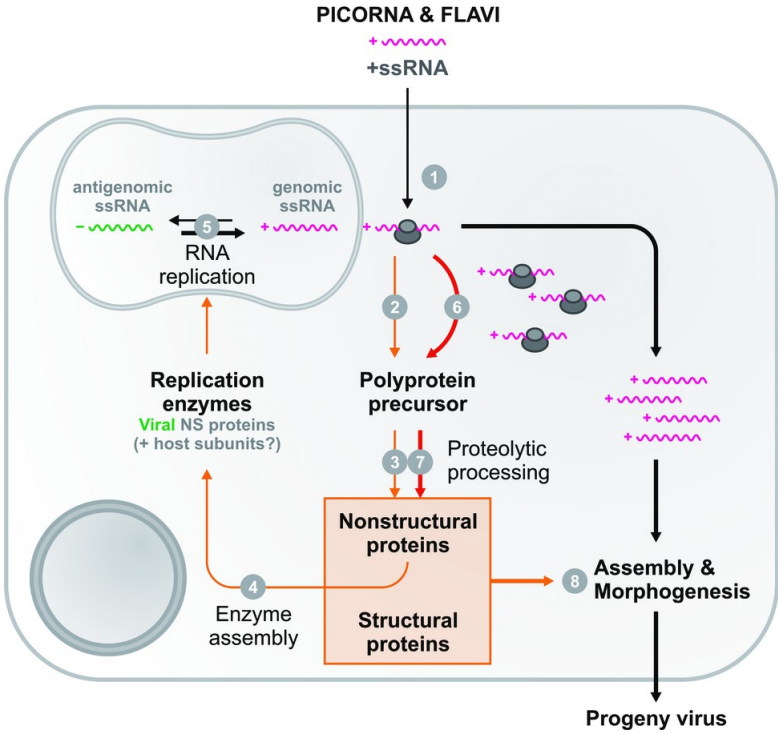

FIGURE 5.11 **Schematic of the replication cycle of positive-strand RNA viruses that do not make subgenomic RNA**. Following entry and uncoating (*step 1*), the genomic RNA is used directly as an mRNA to synthesize both structural and nonstructural proteins (*steps 2 and 3*). The nonstructural proteins, including the RdRp and host components, establish a membrane-associated replication compartment in which the genomic RNA is copied into antigenomic RNA and progeny genomes (*steps 4 and 5*). Replication produces additional genomic RNA that can be used for further translation and genomic amplification (*steps 6, 7, and 5*) as well as assembly with the viral structural proteins (*step 8*) to yield progeny virions.

The positive-sense RNA viruses fall into two general groups, those that transcribe subgenomic RNAs (Fig. 5.10) and those that do not (Fig. 5.11). Viruses that do not transcribe subgenomic RNA are translated by the host ribosomes to produce one or more polyprotein precursors that undergo a set of in *cis* and in *trans* cleavage reactions by viral-encoded proteases.[30] Those cleavage reactions result in the production of the individual nonstructural proteins essential for the replication of the viral genome, including the establishment of the site of viral replication. For viruses that produce a single polyprotein, the precursors of the catalytic components are generated in equimolar amounts to the structural proteins. In some cases, control over the abundance of the catalytic components is provided by the accumulation of intermediates in the processing cascade in which one or more of the catalytic activities are absent.[110] Such components can play crucial structural or regulatory roles in the establishment of replication compartments. Viruses that produce two polyprotein precursors always employ an internal ribosome entry site (IRES) to drive the expression of the second polyprotein. Because the translation of the second polyprotein is independent of the first, the proteins are not produced in equimolar amounts, allowing for some regulation of the abundance of the different proteins.[57] For viruses that produce subgenomic RNAs, the input genome is first translated into a precursor of the nonstructural proteins that includes the RdRp. The genome is then subsequently copied into one or more subgenomic mRNAs that encode the structural proteins. The production of subgenomic mRNAs facilitates the synthesis of distinct amounts of the structural and nonstructural proteins—such that the structural proteins are often produced in vast molar excess of the catalytically essential nonstructural proteins.

In contrast to the naked RNA of the positive-sense RNA viruses, that of the negative-sense, ambisense, and dsRNA viruses is noninfectious (Figs. 5.12-5.14). This is because the infectious unit is a ribonucleoprotein complex comprising the genomic RNA associated with the necessary viral polymerase components for synthesis of mRNA.[84,124] In the case of the negative-sense and ambisense RNA viruses, the input genomic RNA is copied by the viral polymerase complex into mRNA (Figs. 5.12 and 5.13). The input genomes are then replicated to yield antigenomes, a process that requires newly synthesized viral nucleocapsid protein to coat the nascent RNA strand.[84,124] For the negative-sense RNA viruses (Fig. 5.12), the antigenomes are positive sense, but they do not serve as templates for translation, rather they function exclusively as templates for genomic replication.[84,124] The negative-sense orthomyxoviruses and bornaviruses replicate within the host-cell nucleus, whereas the mammalian infecting rhabdoviruses as well as the paramyxoviruses and filoviruses replicate in the cytoplasm. A further important distinction is that the rhabdo-, filo-, paramyxo-, and bornaviruses sequentially transcribe a series of 5-10 monocistronic mRNAs from a single genomic template, whereas the orthomyxoviruses synthesize only a single mRNA from each segment. In the case of the ambisense RNA viruses, the genomic and antigenomic RNAs have both message and antimessage polarity. Those RNAs are not directly translated and instead serve as templates for synthesis of single monocistronic mRNAs during transcription or as templates for genome replication (Fig. 5.13).[36] In contrast to all other negative-strand RNA viruses, the circular ssRNA genome of HDV does not require a specialized viral polymerase for copying. Rather, the HDV genome is transcribed and replicated by the host DNA-dependent RNA polymerase II in a unique RNA-templated reaction.[112]

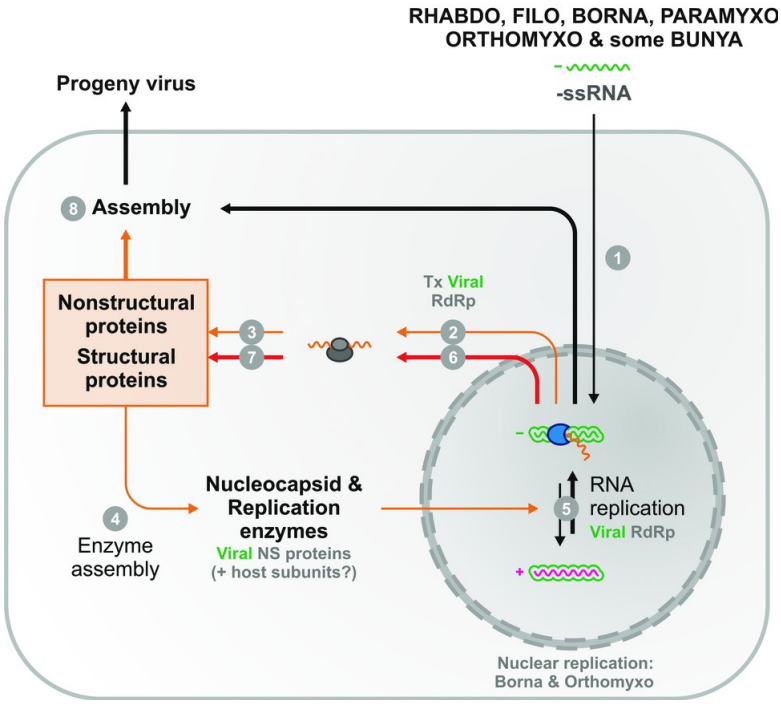

FIGURE 5.12 **Simplified replication scheme for negative-sense RNA viruses**. Following entry and partial uncoating (*step 1*), the encapsidated viral genomic RNAs are transcribed by the virion RdRp into mRNAs (*step 2*) that encode the viral structural and nonstructural proteins (*step 3*). For the *Orthomyxoviridae* and *Bornaviridae*, transcription occurs in the nucleus (reflecting their need for splicing), whereas for the *Rhabdo*, *Filo*, *Paramyxo*, and *Bunyaviridae*, this occurs in the cytoplasm. Replication is concomitant with encapsidation of the genomic and antigenomic RNAs (*steps 4 and 5*), and the newly produced genomic RNAs serve as templates for further mRNA production (*step 6*) as source of further viral proteins (*step 7*) as well as for assembly of progeny virions (*step 8*). The segmented negative-sense RNA viruses transcribe each genomic segment into a single transcript (which can be alternately spliced in the case of the orthomyxoviruses). The nonsegmented negative-sense RNA viruses sequentially transcribe a series of 5 to 10 monocistronic

mRNAs from the genomic template.

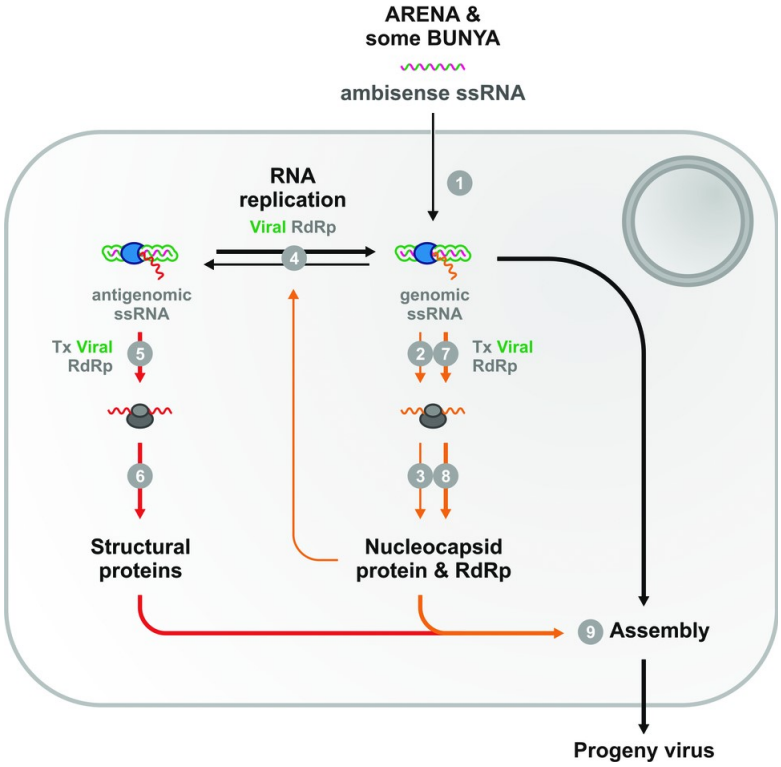

FIGURE 5.13 **Replication scheme for the ambisense RNA viruses**. Following entry and partial uncoating (*step 1*), the encapsidated genomic RNAs are transcribed by the virion RdRp to yield mRNAs (*step 2*) that encode the viral nucleocapsid protein and RdRp (*step 3*). These proteins catalyze the synthesis of antigenomic RNA (*step 4*), which serves both as templates for transcription of additional mRNAs (*step 5*) that encode the remaining viral proteins (*step 6*), as well as templates for production of more genomic RNA (*step 4*). The replication products (both genomic and antigenomic) can serve as further templates for transcription of mRNA that encode both viral structural and nonstructural proteins (*steps 5 through 8*). The genomic RNAs are also assembled together with the structural proteins into infectious viral particles (*step 9*). Note some bunyaviruses are also simply negative sense.

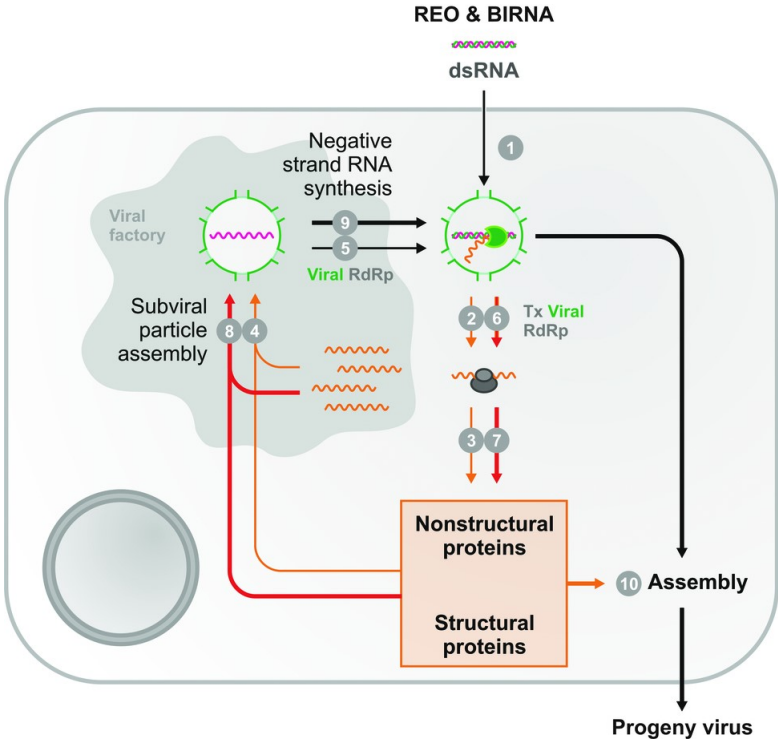

FIGURE 5.14 **Simplified replication scheme for dsRNA viruses**. Following entry and partial uncoating (*step 1*), the dsRNA segments within viral cores are transcribed by the core-associated RdRp to produce mRNA (*step 2*) for the viral proteins (*step 3*). These form subviral particles around the mRNA (*step 4*), which are then copied to produce genomic dsRNAs (*step 5*). RNA synthesis and replication likely occur within a specific cytoplasmic factory established by the viral proteins. Progeny subviral particles contribute to viral

gene expression (*steps 6 and 7*) and replication (*steps 8 and 9*) and assemble with outer shell proteins to form progeny virus particles (*step 10*).

For the dsRNA viruses, the segmented genomes are delivered into the cell as a subviral particle that remains intact for transcription of the mRNA (Fig. 5.14). The polymerase and RNA-modifying enzymes form a structural element through which the nascent mRNA strand passes and is cotranscriptionally modified. The ssRNA and their encoded proteins reassemble into new subviral particles that can direct the synthesis of antigenome RNA and form a dsRNA genome. Those progeny subviral particles can serve as templates for the production of further mRNA, and the viral protein or can be packaged into new virions.[78]

The positive-sense RNA genomes of retroviruses (Fig. 5.9) use a distinct mechanism for replication. Here, the incoming ssRNA is copied into a dsDNA provirus using the virally encoded reverse transcriptase—an essential component of the incoming virion.[6,114] This dsDNA is integrated into the host genome, where it is copied into differentially spliced transcripts that either serve as template for production of viral proteins or for production of viral progeny.

Regulation of Gene Expression

In contrast to DNA viruses, which exhibit clearly demarked early/late-phase gene expression, most RNA viruses show little differentiation between the pre- and postreplicative phases of the infectious cycle and express their genes at roughly the same relative levels throughout infection. In cases where some temporal regulation of gene expression occurs, the differences are subtle and mostly accompanied at the transcriptional level by modulation of mRNA levels.

Although DNA viruses utilize alternate translational control mechanisms as well as RNA viruses, translational control is especially prevalent among RNA viruses. The rate-limiting step for translation of cellular mRNA by the ribosome is at the process of initiation, and more specifically recognition of the mRNA cap structure by the cap-recognition protein eIF-4E, part of a multi-subunit complex. The cap-recognition complex then facilitates the recruitment of the small subunit of the ribosome in complex with other initiation factors. This complex then scans to the first AUG on the template RNA, typically localized within 100 or so nucleotides of the mRNA cap structure. Following this scanning to the AUG, the small subunit is joined by the large ribosomal subunit, and polypeptide chain synthesis is initiated. The poly(A) tail present at most cellular mRNA structures stimulates translation, as it is bound by the poly(A)-binding protein that bridges interactions with the eIF-4G component of the cap-recognition complex. This may serve to functionally circularize the mRNA to facilitate ongoing translation. There are many notable exceptions to this general mechanism that have been exploited by RNA viruses. This reflects the fact that although superficially many RNA virus positive-sense transcripts resemble cellular mRNAs, there are distinctions at both the 5′ and 3′ ends of the RNA that are accompanied frequently by an altered mechanism of translational initiation.

One of the best known examples of an altered mechanism of translational initiation was provided by studies of how the genomes of picornaviruses—which lack a 5′ mRNA cap structure and instead contain a genome-linked protein VPg—are expressed. The 5′ untranslated regions of picornavirus genomes are unusually long (several 100s of nucleotides, including several AUG-specifying triplet) and are highly structured. Those structured elements termed internal ribosome entry sites (or IRES) serve to recruit the ribosome directly to the viral RNA[93] without the need for a full complement of initiation factors for translation. Indeed, in some viruses, such as cricket paralysis virus, the ribosome is recruited to the IRES without the need for any of the initiation factors that are essential for conventional translation. Such altered mechanisms are exploited by viruses to facilitate the efficient translation of the viral mRNA, thereby outcompeting cellular transcripts for translation ensuring the robust synthesis of viral proteins.

There are also many RNA viruses that produce mRNAs that lack a polyadenylate tail, the dsRNA reoviruses and rotaviruses, many of the ambisense arenaviruses and bunyaviruses, as well as numerous positive-strand RNA viruses. On most cellular mRNAs, the polyadenylate tail is generally thought to function as an element that stabilizes the mRNA and additionally favors translation by facilitating recycling of ribosomes through a protein-mediated bridging mechanism that brings the 5′ and 3′ ends of the mRNA together. Such circularization is likely achieved by direct RNA-RNA interactions in the case of some positive-strand RNA plant viruses—such as the luteovirus, barley yellow dwarf virus.[65]

A further mechanism of regulation of translation initiation exploited by RNA viruses is a translation termination-reinitiation strategy. This strategy involves the termination of translation of an upstream open-reading frame followed by the reinitiation at a proximal (<40 nt away) downstream open-reading frame. The stop and start codons are frequently found in an overlapping arrangement, but in distinct reading frames to one another, and termination is essential for the subsequent reinitiation. This strategy is exploited by the positive-strand RNA calciviruses, such as feline calicivirus and murine norovirus, as well as the negative-strand RNA viruses influenza B virus and respiratory syncytial virus.[97] Evidence from studies of calicivirus translation implicates the presence of a secondary structure in the mRNA that may function to “tether” the small ribosomal subunit to the transcript before reengagement of the large subunit.

Suppression of termination is also exploited during the translation of many viral mRNAs, notably those of the alphavirus and retrovirus families, as a mechanism of producing a protein with an extended C-terminus. In the case of some retroviruses, a *cis*-acting regulatory element at the Gag-Pol junction functions to suppress termination of translation by leading to the misreading of the UAG termination codon to form the Gag-Pol polyprotein. Processing of this polyprotein then provides the viral reverse transcriptase and integrase. A second strategy is used by Rous sarcoma virus as well as other retroviruses, termed ribosomal frameshifting. A slippery sequence in the template leads to a realignment of the tRNA and the subsequent accessing of an altered reading frame. Such a mechanism is also exploited by other positive-strand viruses (notably the *Coronaviridae*) as well as several DNA viruses.

Structural and Nonstructural Proteins

By definition, virus-specified structural proteins are incorporated into virus particles, whereas nonstructural proteins are found only in infected cells. However, negative-sense, ambisense, and dsRNA viruses assemble their RdRps and associated enzymes into progeny virions and, therefore, encode predominantly or exclusively structural proteins. In addition to the polymerase, virus-encoded enzymes often include one or more proteases, an RNA helicase, mRNA capping enzymes, poly(A) polymerase, sometimes a nuclease, and in the case of retroviruses, a DNA integrase.

The proteases process the primary translation products of which they are a part by cleaving them at highly specific target sequences. Host

proteins are also subject to proteolysis by viral proteases conditioning the infected cell environment to favor viral replication. In some picornavirus-infected cells, inhibition of host-cell protein synthesis is facilitated by viral protease–mediated cleavage of the eIF-4G component of the cap-recognition complex. Similarly, protease-mediated cleavage of nuclear pore components blocks mRNP export. Particularly among the larger RNA viruses, RNA helicases may be required to disrupt intermolecular or intramolecular base pairing during RNA synthesis, although some RdRps are capable of melting RNA duplexes without help. Guanylyl and methyltransferases construct the 5′ caps found on the mRNAs of most eukaryotic RNA viruses (reviewed in Ref.[24]) except for the picornaviruses, which are uncapped, and the orthomyxoviruses, arenaviruses, and bunyaviruses, which acquire their caps by stealing them from the host using a virus-encoded cap-dependent endonuclease.[81,96] The cap structures of the *Mononegavirales* are formed by an altered mechanism involving a guanosine diphosphate (GDP)—polyribonucleotidyltransferase present within the same polypeptide chain that contains the polymerase and mRNA cap methylase activities.[72,73,85,86] A similar mechanism operates for the coronaviruses where a domain of the viral polymerase nsp12 transfers RNA to the amino terminus of the nsp9 protein and subsequently to GDP.[89] At their 3′ ends, most animal virus mRNAs carry untemplated poly(A) tails, although 3′ tRNA-like structures are common among plant RNA viruses. Polyadenylation is usually ascribed to a stuttering side reaction of the viral RdRp rather than to a separate poly(A) polymerase, as found in poxviruses, although the enzymology of the reaction remains to be clearly defined.[84,124] Comparisons among the amino acid sequences of viral RdRps establish clear phylogenetic relationships that also reflect other differences in viral genome structures and strategies. Moreover, the atomic structures of viral RdRps show clear resemblance to one another as well as to reverse transcriptases and DNA-dependent RNA and DNA polymerases. Although the overall levels of amino acid sequence homology among these diverse polymerases are statistically insignificant, RdRps share many of the characteristic polymerase motifs that occupy critical positions in the three-dimensional architecture of the polymerase active site. Taken together the structural similarities of their RdRps firmly anchor the RNA viruses to the rest of the biosphere and suggest that despite their diversity these viruses probably escaped from cellular origins to establish a horizontally transmissible parasitic existence using polymerases that radiated from a common ancestor.

Host Cell Factors

Proteins provided by the host undoubtedly play essential roles in RNA virus replication, although different cellular proteins have been implicated in different virus systems. The clearest example comes from the RNA replicase enzymes of the RNA bacteriophages Q*β* and MS2, which, in addition to the single phage-specified polypeptide that provides the polymerase active site, contain four cell-specified subunits: the *Escherichia coli* ribosomal protein S1, two translation elongation factors (EF-Tu and EF-Ts), and a strand-specific RNA-binding protein, host factor 1.[9] In view of the similarity of their host components, the distinct specificities of the Qβ and MS2 replicases for their cognate RNA templates must be determined by their unique viral subunits. The unexpected recruitment of translation factors to assist RNA replication —despite the evident differences between these two processes—may reflect underlying biochemical similarities in the RNA–protein interactions involved.

Translation factors have also been implicated in the replication of RNA viruses of eukaryotes. For example, a subunit of the initiation factor eIF-3 binds to the brome mosaic virus RdRp and increases its activity,[100] and several other host proteins have been found to associate with viral RNAs in infected cells. One of the difficulties in definitively assigning whether such proteins are just passengers, or active players in the replication of the viral genome, is often the lack of *in vitro* replication assays and/or genetically tractable host systems. Substantial progress has been made in this regard with the use of genetic, chemical, RNAi, as well as proteomic screens to hunt for host factors that are required for viral replication. Reconstructing the replication cycle of viruses in yeast[62,88] has permitted screens in collections of gene knockouts in *Saccharomyces cerevisiae*, and the application of RNAi has extended such screens to invertebrate and vertebrate cells.[17] The use of haploid human cells and gene-trap retroviruses allowed the discovery of host-cell factors that are essential for the entry into cells of a number of viral pathogens.[13,14] Most recently, the application of genome-wide loss of function screens based on CRISPR-mediated inactivation of host genes has led to an explosion of information on the virus-host relationship (reviewed in Ref.[98]). Although in some cases the overlap of “hits” between seemingly similar screens is low—likely reflecting technical difficulties of such large scale screens—the convergence on specific pathways exploited by viruses for their replication is generally high.[45] Such systematic analyses provide a potentially fertile source for understanding the virus-host relationship; however, the detailed mechanistic understanding of how specific host proteins mediate viral replication lags behind.

In addition to host proteins, host nucleic acids also appear to participate directly in the replication of some RNA viruses. One such example is provided by host micro RNAs that function to titrate cellular gene expression by promoting transcript turnover or by sequestration. Work with hepatitis C virus (HCV) identified a liver specific microRNA-122—which regulates cholesterol biosynthesis—that binds to two sites at the 5′ end of the viral genome and enhances HCV replication.[63] Additional host miRNA that regulate HCV replication both positively and negatively have been identified.[74] Such control of viral replication extends beyond the RNA viruses and further serves to underscore the intimate relationship between viruses and their host cells.

Compartmentalization of Replication Sites

Unlike the phage replicases, the RdRps of eukaryotic viruses are invariably found associated with some type of supramolecular assembly: host-cell membranes for positive-sense RNA viruses, nucleocapsids frequently found as inclusionlike structures for the negative-sense RNA viruses, and subviral particles arranged as factories for the dsRNA viruses. The positive-strand RNA viruses (Figs. 5.10 and 5.11) represent the best-characterized examples of membrane-associated replication complexes.[26] In most cases, the membranes are extensively rearranged, often—although not exclusively—derived from the endoplasmic reticulum, and invariable topologically arranged as an invagination of the membrane of the endoplasmic reticulum (ER) to form an open-necked crucible. Within each vesicle are a relatively small number of genomic templates —possibly as few as one, along with the viral replication machinery and cellular proteins that appear to play a role in the formation of the vesicular structure. In the case of the flaviviruses, genome wide loss of function screens identified the host oligosaccharyltransferase (OST) complex as required for viral RNA replication, playing a structural role in this process likely tethering the replication machinery to the membrane.[76] The prevailing model is that such vesicular structures represent the sites of viral RNA replication, and that the nascent RNA chains are rapidly exported to the cytoplasm. In many cases, virion assembly sites are juxtaposed to such compartmentalized replication sites, which likely facilitates the coordination of the replication and assembly of viral particles.

For the negative-sense RNA viruses that replicate in the cytoplasm (Fig. 5.12), the viral replication machinery is typically found in inclusionlike structures that are often rich in cellular chaperones such as heat shock protein (hsp)70. Although such inclusionlike structures are not essential for RNA synthesis—they are absent at the onset of infection and at a time at which the intracellular environment is likely most hostile for viral

replication—such structures have been shown to be active sites of RNA synthesis.[54,68] Likewise, dsRNA viruses establish factories or viroplasms (Fig. 5.13) in the infected cell that are sites of RNA synthesis and assembly.[11] Such compartmentalization of the replication machinery is, therefore, a conserved theme across a spectrum of viruses. Although such sequestration may both facilitate catalysis and sequester the viral replication machinery from surveillance by host defense machinery, it is largely uncertain what events lead to the establishment of such sites. Although there is a strong correlation between compartment formation and viral replication, examination of the very initial replication events including establishment of such sites remains challenging.

Mechanisms of RNA Replication and Transcription

The simplest mechanism of RNA replication is that used by HDV in which rolling circle synthesis by RNA polymerase II makes multimeric RNAs of both positive and negative polarity. *cis*-Acting ribozymes then cleave linear RNA monomers from these concatamers and covalently circularize them to produce mature antigenomes and genomes, respectively.[112] Although this simple mechanism is shared by several viroids and other subviral RNA pathogens of plants, HDV is the only RNA pathogen of vertebrates known to replicate by a rolling circle mechanism. Far more commonly, ssRNA genomes are replicated via the synthesis of complementary RNA monomers produced by successive rounds of strand displacement during end-to-end copying of linear templates.[12] However, both ends of the RNA are generally required for template activity, suggesting that even linear RNAs may be functionally circularized, perhaps to facilitate reiterative replication and hinder erosion of the termini.

The relative abundance of the genomic and antigenomic RNAs is regulated in different ways in different virus families. In the case of Qβ, negative-strand RNA synthesis is limited by the requirement for an additional host subunit that is not required for positive-strand RNA synthesis.[9] In other virus systems, distinct *cis*-acting RNA signals are largely responsible for determining the relative template activities of the complementary strands, although it is possible that different host factors are involved here as well. For the togavirus Sindbis, negative-sense RNA is synthesized only by a short-lived version of the RdRp, which is an intermediate in the proteolytic processing pathway of the viral nonstructural proteins.[64] As infection proceeds, increased viral protease activity cleaves this transient intermediate and thereby switches the template specificity of the RdRp to the synthesis of positive-strand RNA.

There are two general mechanisms of initiation by RdRps: primer-dependent and primer-independent mechanisms. The majority of RNA viruses appear to employ a primer-independent mechanism. Some of the best studied examples of this are provided by the bacteriophages Qβ, MS2, and ϕ6, as well as by eukaryotic viruses HCV, and reo-, rota-, vesicular stomatitis virus, and influenza A virus. The general mechanism by which *de novo* initiation occurs is that the RdRp initiates synthesis by forming a phosphodiester bond between the initiation nucleoside triphosphate (iNTP) and a second NTP. Atomic structures of polymerases engaged in the steps of initiation have provided remarkable insights into this process including the identification of residue that stabilize the initiating nucleotides termed “priming residues.” The second general mechanism is a primer-dependent mechanism of initiation. The primers themselves can come in different flavors, for example, the picornavirus RdRps use a small viral-encoded protein, VPg, that is covalently uridylylated by the polymerase on an internal RNA structure at a single A residue.[92] This primer, polymerase complex then relocalizes to the terminus to prime the initiation reaction. Nucleic acids can also serve as primers for RNA synthesis, and here there are two currently known variations of this mechanism of primed initiation. The first of these is exploited by the RdRps of the segmented negative-strand RNA viruses: *Orthomyxo-*, *Bunya-*, and *Arenaviridae* to prime messenger RNA synthesis. Here, a virally encoded endonuclease cleaves a short capped primer from either host-cell pre-mRNA in the case of the *Orthomyxoviridae* or mature cytoplasmic mRNA in the case of the *Arena-* and *Bunyaviridae*.[96] Such primers then base pair with the ends of the template to prime synthesis of the viral mRNA. Sequence analysis of the stolen host cell mRNA primers in influenza virus–infected cells identified that some primers contain a host-derived translation initiation AUG, which can yield additional proteins or N-terminal extensions on viral proteins.[58] Remarkably, these cap-snatching polymerases can also initiate “*de novo*.” For the arena and bunyaviruses, this *de novo* initiation occurs not by initiation of synthesis opposite the terminal nucleotide but by initiation at the penultimate nucleotide followed by a subsequent realignment of the nascent strand to “prime” the process of replication.[41] This strategy termed “prime and realign” may help ensure the integrity of the termini is maintained during copying. For the orthomyxovirus influenza A virus, the process of prime and realign is only employed during synthesis of the genomic RNA copy of the segments. During synthesis of the antigenomic copy, the polymerase initiates at the 3′ terminus directly.[87]

Summary and Perspectives

Mechanistic studies of viral replication have led us to some of the most fundamental discoveries in biology and provided critical knowledge to facilitate the development of vaccines and antiviral therapeutics to combat disease. The global burden of infectious disease caused by existing viruses and the ongoing threat of emerging viral infections further emphasizes the need to fully understand the mechanisms by which viruses replicate. Such studies promise to continue to uncover strategies to combat disease and to harness viral replication for beneficial purposes both in the laboratory as expression vectors, gene knockout tools, neural circuit tracers, and probes of cellular, organismal, and population biology but also in the clinic as potential vaccines, delivery vehicles, and imaging tools. The industrial applications of viruses are equally profound—as polymers, as well as tools to make microcircuits and even as potential fuel cells. All these applications of viruses have depended on our current understanding of the replication machinery and the strategies of viral replication. With the ability to simply manipulate viral genomes combined with the new burst in discovery of viruses from large scale sequencing projects and the ease with which host genomes can now be manipulated the future of fundamental studies of viral replication promises to be even more informative than the exciting past.

CHAPTER 6

Virus Assembly and Maturation

Christopher J. Neufeldt • Eric Hunter

Partitioning of proteins within the cell

Nuclear import and export of proteins and nucleic acids

The secretory pathway of the cell

Intracellular targeting and assembly of virion components

Assembly of nonenveloped viruses in the nucleus

Assembly of enveloped viruses in the nucleus

Assembly of viruses in the cytoplasm

Assembly of enveloped viruses at cellular membranes

Complex interactions with the secretory pathway

Modification of the secretory pathway

Incorporation of the nucleic acid genome during the assembly process

DNA viruses

RNA viruses

Postassembly modifications and virus release

Proteolytic cleavage and virus maturation

Nonproteolytic maturation events

Role of viral and cellular proteins in membrane extrusion

Mechanisms to facilitate the release of nascent particles

Cell-associated and noncanonical spread of infection

Virus assembly, a key step in the replication cycle of any virus, involves a process in which chemically distinct macromolecules are transported, often through different pathways, to a point within the cell where they are assembled into a nascent viral particle. A diversity of strategies and intracellular assembly sites are employed by members of the various virus families to ensure the efficient production of fully infectious virions. Nevertheless, a virus, irrespective of its molecular structure (membrane enveloped or nonenveloped) or the symmetry with which it assembles (icosahedral, spherical, or helical), must be able to take advantage of the intracellular transport pathways that exist within the cell if it is to achieve this goal. The end product of this selection process is assembly of each virus at a defined point within the cell. This chapter will focus on the cell biology of these intracellular targeting events, the intermolecular interactions that mediate targeting, and the assembly steps themselves.

Most viruses encode a very limited number of gene products. They are, therefore, dependent upon the cell not only for biosynthesis of the macromolecules that constitute the virus particle but also for the preexisting intracellular organelles and sorting mechanisms that the virus can utilize and, in some cases, modify to achieve delivery of those macromolecules to the sites of virion assembly. Since delivery depends on the same sorting mechanisms that the cell uses to delineate its subcellular organelles, the viral macromolecules must possess targeting signals similar to those of the components of those organelles. For a virus such as adenovirus, which assembles its nonenveloped capsids in the nucleus, this means that, following translation in the cytoplasm, each of the structural proteins of the mature virus must have the necessary protein-targeting information to be efficiently routed through the nuclear membrane to the assembly site. The situation is more complicated for a membrane-enveloped virus, such as influenza virus. For this virus, which assembles and releases virions from the apical surface of the epithelial cells that it infects, there is a necessity to ensure that the surface glycoproteins of the virus are correctly sorted by the secretory pathway of the cell to apical membranes. In addition, nucleocapsids, assembled in the nucleus, must be transported into and through the cytoplasm to the same location. As will be discussed below, the intracellular site at which the final phase of assembly and budding of an enveloped virus takes place is most often defined by the accumulation of the viral glycoproteins at a specific point in the secretory pathway of the cell. This also implies that there is specific molecular recognition of the virally encoded, membrane-spanning envelope components by the cytoplasmic nucleocapsids in order for a productive budding process to occur. Thus, interactions between proteins of viral and cellular origin, between viral proteins and nucleic acids and lipids, as well as between the viral proteins themselves are at the heart of the assembly process.

Partitioning of Proteins Within the Cell

For an actively growing eukaryotic cell, there is a constant need to transport proteins and nucleic acids from their site of synthesis to the specific intracellular domains where they must function (Fig. 6.1). Proteins synthesized on cytosolic ribosomes, for example, must be transported to specific regions of the cytoplasm, to mitochondria, and into the nucleus, while those synthesized on membrane-bound ribosomes will enter the

secretory pathway and be targeted to specific organelles along the way. At the same time, messenger RNAs (mRNAs) and integral RNA components of the ribosome, rRNAs, must be transported out of the nucleus. Proteins that participate in these intracellular trafficking processes have evolved to contain specific motifs that ensure the correct localization of the protein within the cell. Viruses have similarly evolved to take advantage of these preexisting pathways in order to accumulate, in specific locations, the necessary components for assembly of a nascent virus.

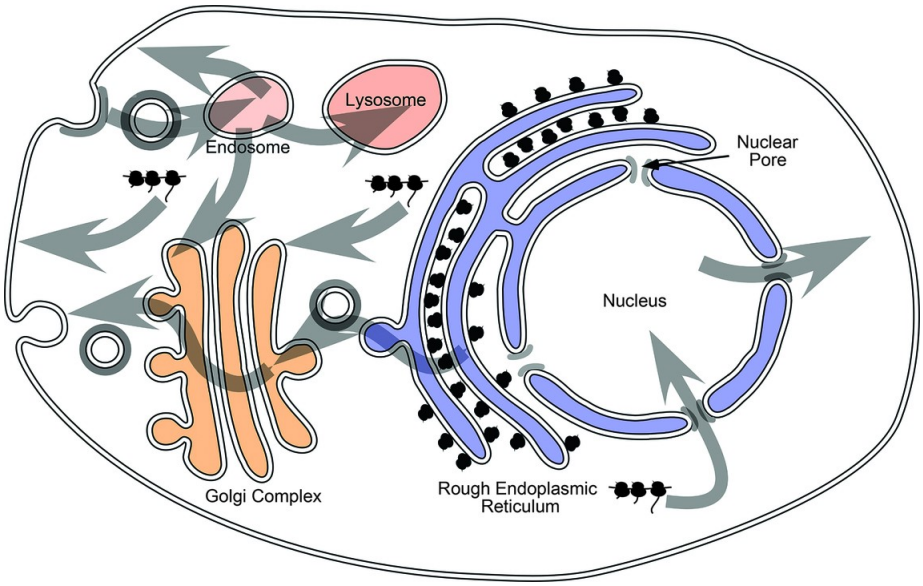

FIGURE 6.1 **Protein localization in a mammalian cell**. Membrane proteins destined for the plasma membrane traverse the secretory pathway of the cell. They associate with the endoplasmic reticulum cotranslationally and are translocated across the ER membrane via a proteinaceous pore—the translocon. Proteins are transported from the ER to the Golgi complex and on to the plasma membrane unless they contain specific amino acid motifs that localize or retain them at an intermediate location. Transport from one compartment to the next is via coated vesicles. Some membrane-spanning (integral membrane) proteins contain endocytosis motifs in their cytoplasmic domain that facilitate incorporation into clathrin-coated endocytic vesicles. Such proteins can be sorted back to the plasma membrane, to the trans-Golgi compartment of the secretory pathway, or to a lysosome for degradation. Proteins destined for the nucleus contain nuclear localization signals. These are short amino acid sequences that allow interaction with the nuclear pore machinery for transport across the nuclear membrane. Some proteins shuttle between the nucleus and cytoplasm and contain in addition a nuclear export signal.

Nuclear Import and Export of Proteins and Nucleic Acids

The Nuclear Pore Complex

Since the *nucleus* is segregated from the cytoplasm by an inner and outer membrane, access to and egress from this subcellular domain is mediated by specialized structures termed nuclear pore complexes (NPCs).[197,256] There are ~3000 NPCs on the nuclear envelope of an animal cell and each provides a proteinaceous channel between the nucleus and cytosol. The NPC itself is a very large structure with a molecular mass exceeding 50 mDa that exhibits eightfold symmetry and is constructed of multiple copies of ~30 different proteins called nucleoporins (Nups). Negative stain, combined with crystallography and cryoelectron microscope reconstructions of these complexes reveal a 125-nm diameter core structure in which eight spokes in a radially symmetrical arrangement join to form three main rings surrounding a central channel. Initial studies of partially purified NPCs indicated that this had a diameter of ~43 nm,[5,126,134] but recent cryoelectron tomography studies have revealed a substantially greater diameter—57-64 nm.[240,299] Attached to both faces of the central framework are peripheral structures, cytoplasmic filaments, and a nuclear basket assembly, which interact with molecules that transit the NPC.[78] The channel is filled with flexible, filamentous FG-nucleoporins, which are characterized by regions of multiple Phe-Gly repeats, and that form a “virtual gate” restricting transport into and out of the nucleus.[239] Small molecules and proteins may be able to passively diffuse through the NPC, but it acts as a molecular sieve for macromolecules. Larger proteins and macromolecular assemblages, such as the HIV capsid, must be actively moved through what is clearly a dynamic, malleable transporter structure that has the capacity to accommodate macromolecular complexes with diameters >55 nm.[299]

Nuclear Localization Signals

Proteins that are actively transported into or out of the nucleus are characterized by the presence of amino acid motifs that allow them to interact with the nuclear transport machinery. For import into the nucleus, these motifs are termed nuclear localization signals (NLS), and for export, nuclear export signals (NES). NLS motifs, such as that first identified in the SV40 T antigen,[120] are not only necessary for nuclear localization of the proteins in which they are present but are also sufficient to actively direct large foreign proteins, such as β-galactosidase, into the nucleus. Although there is no conservation of sequence in different NLS motifs, they are generally short (<20 amino acids), rich in basic amino acids, and frequently preceded by proline residues (Fig. 6.2A). Some NLS, such as that in the adenovirus DNA-binding protein, are bipartite and require two separate short clusters of basic residues in order to be functional.[298]

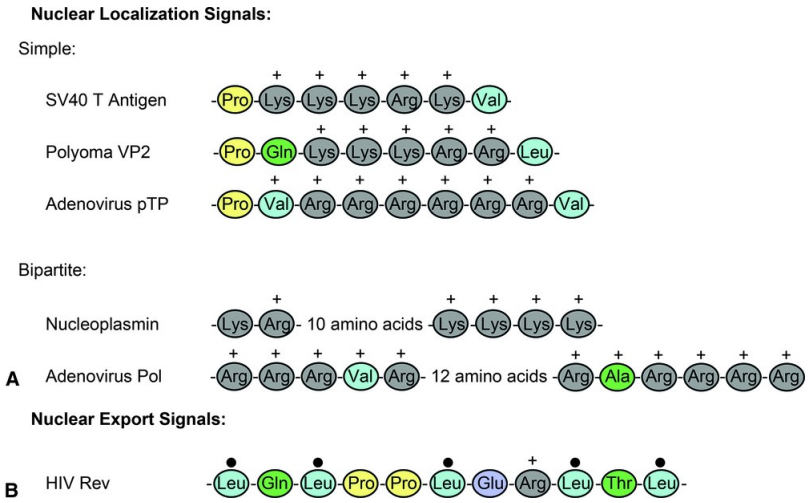

FIGURE 6.2 **Nuclear localization and export signals**. **A**. Nuclear localization signals (NLS) are the amino acid motifs that direct proteins into the nucleus are termed nuclear localization signals (NLS). Simple NLS sequences, such as those present in the SV40 virus T antigen or polyoma virus VP2, often contain a proline residue followed by a stretch of basic residues. This short sequence can relocate large proteins such as β-galactosidase into the nucleus. Bipartite NLS sequences, such as those present in nucleoplasmin or the adenovirus polymerase, are characterized by two stretches of basic amino acids separated by a variable spacer sequence. These NLS sequences are recognized by import receptor molecules such as importin-α. **B**. Proteins that shuttle into and out of the nucleus, such as Rev, possess a second motif, the nuclear export signal (NES). These motifs are characterized by a pattern of conserved leucine residues.

To be exported from the nucleus, proteins contain an NES. This nuclear transport signal is also short (~10 amino acids) and contains a pattern of conserved leucines[174] (Fig. 6.2B). Some proteins, such as Rev of HIV-1, possess both an NLS and an NES and appear to shuttle back and forth between the cytoplasm and the nucleus.[161]

Nuclear Transport Pathways—In and Out

The process of nuclear import is a two-stage process. In the first stage, the newly synthesized NLS-containing protein interacts with cytosolic receptor proteins that then bind to FG-Nups that make up the filaments on the cytoplasmic side of the NPC; a process referred to as “docking.” This complex is then translocated, in an energy-independent process, through the nuclear pore into the nucleus, where the complex is disassembled, allowing the transported protein to become functional.

The best-characterized protein import receptor is importin-α or karyopherin-α. After binding its NLS-containing cargo, importin-α interacts with importin-β, which then mediates docking with the NPC.[125] Most nuclear transport receptors (NTRs) belong to one large family of proteins (karyopherins), all of which share homology with importin-β (also named karyopherin-β). Members of this family have been classified as importins or exportins on the basis of the direction they carry their cargo. Importins and exportins are regulated by the small GTPase Ran, which is highly enriched in the nucleus in its GTP-bound form. Importins recognize their substrates in the cytoplasm and transport them through nuclear pores into the nucleus. In the nucleoplasm, RanGTP binds to importins, inducing the release of their cargoes. In contrast, exportins interact with their substrates only in the nucleus in the presence of RanGTP and release them after GTP hydrolysis in the cytoplasm, causing disassembly of the export complex (Fig. 6.3).[257] Thus, the directionality of transport is regulated by whether Ran is complexed with GDP or GTP.

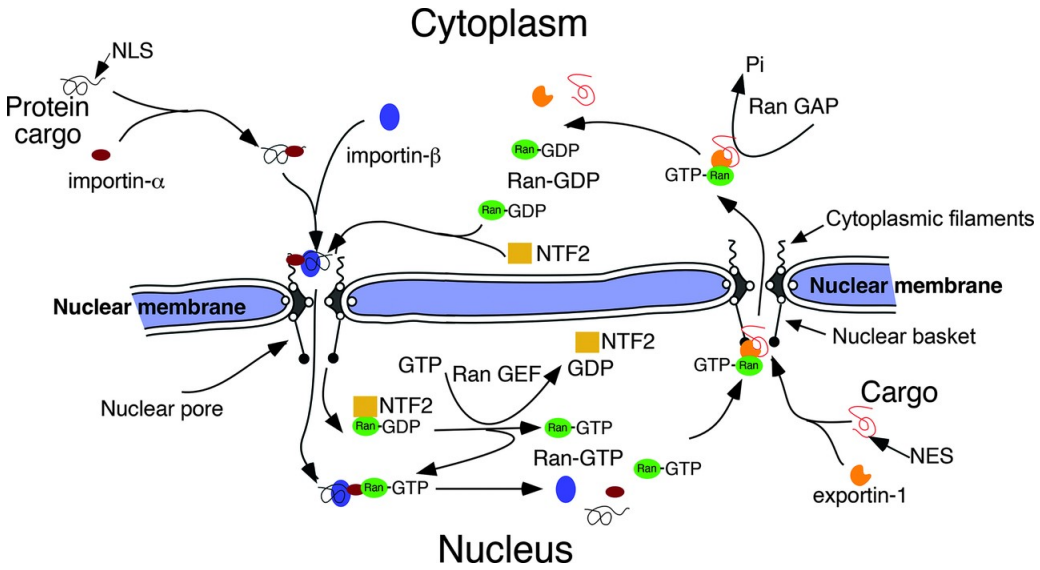

FIGURE 6.3 **Nuclear import and export pathways**. A protein bearing an NLS is recognized and bound by importin-α. Importin-β binds to this complex and carries it to the cytoplasmic filaments of the nuclear pore where together they mediate translocation of the

protein complex into the nucleus in an energy-independent process. In the nucleus, Ran-GTP binds to the importin complex and it dissociates delivering the protein cargo into the nucleus. Proteins destined for export out of the nucleus bind to exportin-1 via their NES. This complex together with Ran-GTP binds to nucleoporins localized to the nuclear basket of the pore complex and initiates translocation into the cytoplasm. Once there, Ran-GTP is converted to Ran-GDP by a Ran-GTPase–activating protein (RanGAP-1), causing the cargo-exportin-1-Ran complex to dissociate, thereby delivering the cargo to the cytoplasm.

Active transport of large molecules in either direction across the nuclear pore involves interaction with the FG-Nups. The FG repeats in these filamentous proteins provide binding sites for the nuclear transport receptors as well as other molecules, such as NTF2, involved in this process. While the exact mechanism by which the importin-cargo complex is carried through the nuclear pore is not known, recent studies have shown that low affinity interactions between NTRs and FG-Nup proteins allow a series of ultrafast docking and release cycles, which enable a rapid exchange of FG-motifs from the NTR binding pockets. This process is crucial for the fast and selective transport of NTR-cargo complexes through the NPC.[163,212]

The Secretory Pathway of the Cell

Proteins of both viral and cellular origin that are destined for the outer membrane of the cell travel along a highly conserved route known as the secretory pathway. This complex series of membrane-bound subcellular compartments, through which proteins pass sequentially, includes the endoplasmic reticulum (ER), an intermediate membrane compartment, and the cis-, medial-, and trans-compartments of the Golgi apparatus (Fig. 6.1). Proteins that traverse this pathway, such as the envelope glycoproteins of viruses, enter via the ER. Insertion of proteins into the ER occurs during translation, through a process termed translocation. The ER network of tubules and sacs defines a unique environment in which protein modification and folding can occur isolated from the cytoplasm. Because polyribosomes, in the process of translating proteins that are translocating into the secretory pathway, are bound tightly to the ER membrane, regions containing them are known as the rough ER.

Translocation

Translating ribosomes are directed to the ER membrane by a short sequence in the nascent polypeptide known as the signal peptide (SP). In most proteins, this 15-30 amino acid sequence, which contains a core of hydrophobic amino acids, is located at the N-terminus of the protein. Shortly after the SP emerges from the ribosome, it is bound by a ribonucleoprotein complex known as the signal recognition particle (SRP). SRP consists of a 300-nt 7SL RNA in complex with six protein subunits, RP9, SRP14, SRP19, SRP54, SRP68, and SRP72. SRP54 is a key component in cotranslational protein targeting, having a hydrophobic groove in which the SP is thought to bind. The act of SRP binding transiently arrests any further translation and directs the ribosome to an SRP-receptor on the ER (Fig. 6.4). The cycle of SP recognition by SRP, targeting to the SRP receptor and recycling of SRP into the cytoplasm, is regulated by GTP binding and hydrolysis. The latter is carried out by GTPases in SRP54 and the α-subunit of the SRP-receptor.[98,188]

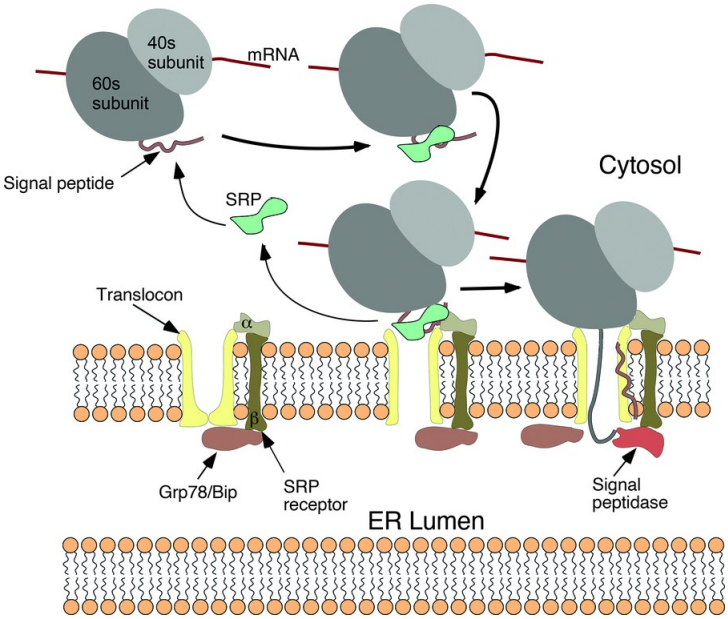

FIGURE 6.4 **Protein translocation into the secretory pathway**. Translation of a protein destined for the secretory pathway proceeds until the signal peptide exits the ribosome. The SRP binds to the signal peptide and the ribosome and arrests translation. The ribosome-SRP complex moves to the ER membrane where SRP binds to its receptor (SRP receptor). This interaction, with concomitant hydrolysis of bound GTP, releases SRP and mediates a tight interaction between the ribosome and a proteinaceous channel, the translocon or p61p. The release of SRP and binding of the signal peptide to components of the translocon induces a conformational change that widens a constriction in the channel and allows resumption of translation to occur. The chaperone protein, Grp78/Bip, present in the lumen, is poised to facilitate the folding of the nascent polypeptide chain as it emerges from the pore. The signal peptidase complex removes the signal peptide cotranslationally from those proteins that have a cleavable signal peptide. Secreted proteins will continue to traverse the translocon until they are completely located in the lumen of the ER. In contrast, for integral membrane proteins, translocation will stop following introduction of the hydrophobic anchor domain into the translocon, and transition into the lipid bilayer occurs through a single lateral opening in the pore.

Following the initial docking of the translationally arrested complex, the ribosome becomes tightly associated with the ER membrane via the translocon, a gated, aqueous, protein channel that spans the ER membrane. Concomitant with this process, the SRP and its receptor are released, the signal peptide is introduced into the channel, and translation resumes. The components and structure of the translocon have been

identified through biochemical and cryo-EM approaches in mammalian cells and genetic approaches in yeast. It is comprised of a heterotrimeric, multiple (12) membrane-spanning complex known as the Sec61p (composed of Sec61 alpha, beta, and gamma chains), which, based on crystal structures of archaebacterial Sec61p homologue SecYβγ, form a porelike central cavity with a single lateral opening to allow transition of membrane-spanning domains into the lipid bilayer.[272] Cryo-EM studies allowed the determination of the structure of a porcine 80S ribosome-Sec61 complex in both an idle and translating state at 3.4 and 3.9 Å resolution. This structure showed that Sec61 interacts with the ribosome primarily through conserved loops between helices 6 and 7 and between helices 8 and 9 of the α-subunit, as well as the N-terminal helix of Sec61γ.[276] Further high-resolution cryo-EM studies determined the structure of an active Sec61 channel that had been opened by a signal sequence, showing that the signal peptide could displace helix 2 of Sec61α allowing the former to move laterally toward the lipid bilayer (depicted graphically in Fig. 6.4).[277] Additional proteins (eg, the translocating chain-association membrane or TRAM protein) are necessary for optimal translocation. It is unlikely that the central pore of the translocon ever allows free diffusion between the cytosol and the lumen of the ER, since these compartments are chemically distinct. A constriction in the channel appears to be plugged by a short helix and widening of the constriction as well as displacement of the plug have been linked to conformational changes induced by SRP binding to the complex.[272] GRP78/Bip, a member of the Hsp70 family of chaperone proteins located in the lumen of the ER, plays multiple roles in gating the channel and facilitating translocation. The chaperone is then poised to facilitate the folding of the nascent polypeptide chain as it emerges from the pore, although this binding is not essential for translocation to proceed. The signal peptide, in those proteins with a transient N-terminal sequence, is cleaved from the rest of the polypeptide by a complex of five proteins called the signal peptidase shortly after it enters the lumen of the ER (Fig. 6.4).

For secreted proteins, translocation of the polypeptide through the translocon continues until the entire protein is present in the lumen of the ER. In contrast, integral membrane proteins, such as the envelope glycoproteins of viruses, contain a stop-transfer, membrane-anchor sequence that is generally located toward the C-terminus of the protein. Following the translation of this short (~25 amino acids) mostly hydrophobic sequence, the translocon undergoes a conformational change, likely similar to that observed with the signal peptide, which allows the membrane-spanning domain to be associated directly with the lipid bilayer. The product of this process is a type-I integral membrane protein (Fig. 6.5), such as the influenza virus hemagglutinin, in which the N-terminal ectodomain is in the lumen of the ER and the C-terminus is in the cytoplasm. In some proteins, such as the influenza virus neuraminidase, a longer N-terminal signal peptide also functions as the membrane anchor. In this case, the signal peptide is not cleaved from the polypeptide chain and the sequences C-terminal to it are translocated into the ER lumen, resulting in a type-II orientation. Multiple membrane-spanning proteins, such as the M-protein of the coronaviruses, appear to possess hydrophobic sequences that are alternatively recognized as signal and stop-transfer sequences, and translocation of such proteins may involve multiple Sec61 heterotrimers.[188,248]

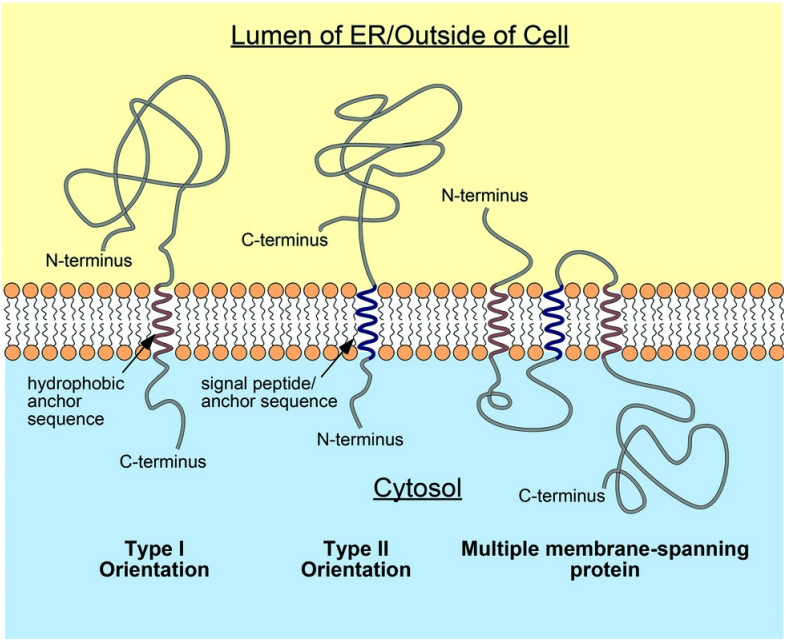

FIGURE 6.5 **Protein topology**. Proteins with type-I orientation generally have a cleavable N-terminal signal peptide that is removed cotranslationally from the nascent protein. The protein continues to be transferred into the lumen of the ER until a hydrophobic anchor sequence is translated and enters the translocon. Translocation then stops and the protein transitions from the protein pore into the lipid bilayer. Thus, type-I integral membrane proteins, such as the hemagglutinin of influenza virus, have their C-terminus in the cytoplasm and their N-terminus in the lumen of the ER (topologically equivalent to outside the cell). In type-II proteins, such as the influenza virus neuraminidase, the signal peptide forms the membrane anchor domain, so that at the end of translation, the C-terminal sequences are translocated into the lumen of the ER, leaving the N-terminus in the cytoplasm. For multiple membrane-spanning proteins, such as the M-protein of the coronaviruses, translocation is initiated at the first signal peptide sequence and continues until the first anchor domain. It is reinitiated following translation of a subsequent signal sequence and stopped again following translation of a second anchor. The exact mechanism by which this is accomplished without dismantling the translocon at intermediate steps in the process is not understood.

Posttranslational Modifications

Protein folding and quality control: Proteins enter the lumen of the ER in an unfolded state, and the process of folding into a transport-competent conformation is facilitated by interactions with molecular chaperones and folding enzymes located there. This collection of proteins includes BiP, calnexin (Cnx), calreticulin (Crt), GRP94, and protein disulfide isomerase (PDI). In addition to assisting in folding the nascent molecules, these proteins retain incompletely folded molecules in the lumen and act as a quality control system for the secretory pathway.[29]

Oligomeric proteins, such as the receptor/fusion proteins of enveloped viruses, also assemble into their quaternary conformation in this compartment. For many of these molecules, oligomerization appears to be a pre-requisite for transport out of the ER.

Glycosylation: A majority of proteins that traverse the secretory pathway are modified by the addition of oligosaccharide side chains either to the amino group of asparagines (N-linked glycosylation) or through the hydroxyl group of serines or threonines (O-linked glycosylation). N-Linked moieties are added cotranslationally in the lumen of the ER, where mannose-rich oligosaccharides are transferred by oligosaccharyltransferase from a lipid (dolichol) carrier to asparagine residues present in NXS/T motifs (where X is any amino acid but proline) within the protein. Trimming of terminal glucose and mannose residues from the branched oligosaccharide occurs in the ER and is closely linked with the Cnx- and Crt-mediated quality control process.[29] Further trimming of mannose residues followed by addition of other sugars (*N*-acetylglucosamine, galactose, fucose, and sialic acid), to yield complex oligosaccharide structures, occurs in the Golgi complex. O-Linked oligosaccharides are also added in this organelle.

Transport Through the Secretory Pathway

Transport of soluble and membrane-spanning proteins from one compartment of the secretory pathway to the next has traditionally been interpreted as being mediated by the formation of coated membrane vesicles that travel to and fuse with the target organelle.[13] Thus, once the process of protein folding and quality control has been completed in the ER, proteins would be sequestered into these transport vesicles prior to transit to the Golgi complex. While vesicular trafficking may occur for some proteins, recent studies suggest a more complex process involving specific regions of the ER known as the ER Exit Sites (ERES).[7,281] High-resolution microscopy studies show that these sites are composed of a cluster of vesicular-tubular membranes devoid of ribosomes near the ER.[281] Formation of these structures requires the coat protein II complex (COPII) that both stimulates membrane extrusion and plays a critical role in cargo protein selection.[56,281] Budding is initiated when a small myristylated protein (Sar1) is converted to the GTP-bound form, allowing it to bind to the membrane and recruit coat proteins (Sec23, Sec24, Sec13, and Sec31) in a stoichiometric manner.[56] Sorting signals displayed on the cytosolic surfaces of transmembrane protein cargo direct it into ERES, in some instances through physical association of the sec23-sec24 components in a sorting signal dependent manner.[128] Soluble proteins and transmembrane proteins lacking COPII sorting signals depend on a diversity of transmembrane adaptor proteins that can link them to the budding machinery. These include the ER-Golgi intermediate compartment-53 (ERGIC-53), p24 family of receptor proteins, as well as a set of multiple membrane-spanning ER vesicle (Erv14p, 26p, and 29p) proteins that can facilitate concentration of soluble proteins in COPII vesicles.[56]

Formation of the coat itself induces membrane curvature and vesicle budding. While initially thought to coat the vesicles bound for the Golgi complex, it now appears that COPII forms a collar that defines the boundary between the ER and the ERES, where it facilitates selective cargo concentration.[246] In mammalian cells, long “pearled” tubules, having the appearance of a series of interconnected vesicles, have been observed extending several microns from the ERES toward the Golgi complex and in close association with microtubules.[281] These transport tubules were associated with a second coat complex, COPI,[281] previously thought to only mediate retrograde transport of vesicles from the Golgi to the ER, as well as anterograde transport through the Golgi.[192]

A key question is how membrane traffic is directed to specific organelles within the cell, and over the past few decades, it has become clear that phosphoinositides are key determinants of compartmental membrane identity. As such they can direct membrane dynamics by providing spatial and temporal cues. Reversible phosphorylation and dephosphorylation of the inositol ring by phosphoinositide kinases and phosphatases generates seven distinct phosphoinositide species, which are specifically enriched in different organelles.[64] The plasma membrane is highly enriched in phosphatidylinositol 4,5-bisphosphate, while the Golgi apparatus and the *trans*-Golgi network (TGN) are characterized by phosphatidylinositol 4-phosphate. In contrast, endosomal vesicles are enriched in phosphatidylinositol 3-phosphate. Each specific membrane environment directly impacts the localization and activity of effector proteins and membrane-integral proteins such as receptors that interact with these lipids.[209] Such membrane receptors, incorporated into transport vesicles, can mediate docking of the vesicle with the target organelle and appear to define the specificity with which the cargo protein is delivered. Rab-GTPases and tethering proteins also appear to play an important role in defining the initial vesicle-target interactions. The latter are composed of two classes of protein: coiled-coil tethers (CCTs) and multisubunit tethering complexes.[21,292] SNAREs (soluble *N*-ethylmaleimide–sensitive factor attachment protein receptors) are generally accepted to mediate the final stage of vesicle docking and the subsequent membrane fusion events that are critical to transport.[23,103] A vesicle-specific SNARE (v-SNARE) interacts with a target-membrane–specific SNARE (t-SNARE) complex (generally comprised of three peptides) during this process. Two additional proteins, the *N*-ethylmaleimide–sensitive factor (Nsf) and soluble Nsf attachment proteins (SNAPs), act to disassemble the complex following fusion, allowing the SNARE components to be recycled.[103,110]

Protein Localization

Subcellular localization of proteins within the secretory pathway appears to be determined by a combination of sorting/targeting signals that mediate interactions with the coat complex for inclusion in a transport vesicle, and retention signals that localize the protein to a specific compartment within the secretory pathway. Localization is enhanced by the interplay of anterograde and retrograde transport that allows retrieval of proteins inadvertently transported beyond their target location. The classical example of this is the KDEL peptide sequence found on soluble proteins that are localized to the lumen of the ER.[171] Proteins containing this sequence are efficiently retrieved from the cis-Golgi by the KDEL receptor, which is incorporated into COPI vesicles for trafficking back to the ER. Similarly, membrane-spanning proteins localized to the ER have, at the C-terminus of the cytoplasmic domain, a dilysine (KKXX) COPI binding motif, which ensures their efficient retrieval from the Golgi complex.[108] This type of motif is utilized by the primate foamy viruses to concentrate the envelope glycoprotein complex (gp80/gp48) in the ER/intermediate compartment, where virus budding occurs.[87] For integral membrane proteins, retention signals often appear to be associated with the membrane-spanning domain(s) of the protein, as is the case for the coronavirus M protein, and may reflect preferred association with specific lipid compositions of the membrane within a particular component of the secretory pathway (see below).

The Golgi Complex

The Golgi complex represents a unique organelle within the secretory pathway in that it is comprised of a series of membrane bound compartments that are the sites for specific biochemical modifications to proteins and oligosaccharides, as well as locations where specific protein sorting decisions are made. Proteins transported from the ER enter the Golgi complex via the endoplasmic reticulum Golgi intermediate

compartment (ERGIC), and after traversing the cis-, medial-, and trans-cisternae, exit via the trans-Golgi network (TGN). The ERGIC matures in successive steps into cis-, medial-, and trans-Golgi and then the TGN through a process that is counterbalanced by retrograde transport of lipids and contents to the ER or earlier Golgi cisternae and is mediated by COPI-coated vesicles.[88,96] Each of the compartments provides a spatially distinct site for maintaining an ordered set of enzymes involved in the process of oligosaccharide maturation. They are also the sites at which proteins undergo O-linked glycosylation, through the addition, at certain serines and threonines, of monomeric sugar residues. It is in the trans-Golgi cisternae and trans-Golgi network where viral glycoprotein precursors, such as the Env polyprotein of the retroviruses, are cleaved to their mature forms through the action of members of the furin family of proteinases—enzymes that normally function to process cellular substrates such as polypeptide hormone precursors. This cleavage event is critical for the generation of a biologically functional glycoprotein and thus for virus infectivity.

Intracellular Targeting and Assembly of Virion Components

Viruses can be nominally divided into two groups based on the presence or absence of a lipid bilayer envelope. The nonenveloped viruses can assemble in the cytoplasm or nucleus and generally, for those that propagate in animal cells, exhibit icosahedral symmetry (see Chapter 3). For these viruses, the viral structural proteins and genomic nucleic acid must be targeted to or retained at the subcellular domain at which assembly occurs. Enveloped viruses, by their very nature, must acquire a lipid bilayer from one of the cell's membranes during the process of assembly. In some viruses, such as the herpesviruses and some retroviruses, this envelopment step takes place after the assembly of an intact capsid shell, while for others, the processes of envelopment and capsid assembly occur concomitantly. Some viruses undergo transient envelopment and in some cases re-envelopment during the process of assembly.

For nonenveloped viruses, the tightly assembled structure of the icosahedral shell forms a protective coat that prevents degradation of the genome by environmental factors. For enveloped viruses, the integrity of the nucleocapsid structure is less critical since the membrane provides a barrier to external degradative enzymes.

Assembly of Nonenveloped Viruses in the Nucleus

Many nonenveloped viruses, such as adenovirus, assemble their capsids in the nucleus. Adenoviruses are nonenveloped icosahedral viruses, 70-100 nm in diameter, that have a protein shell surrounding a DNA core. The protein shell (capsid) is composed of 252 capsomeres of which 240 are hexons and 12 are pentons. Each penton consists of a five-subunit base (polypeptide III) and a trimeric fiber (polypeptide IV) that extends out away from the shell. The hexon capsomeres are comprised of trimers of three tightly associated molecules of polypeptide II (Fig. 6.6).

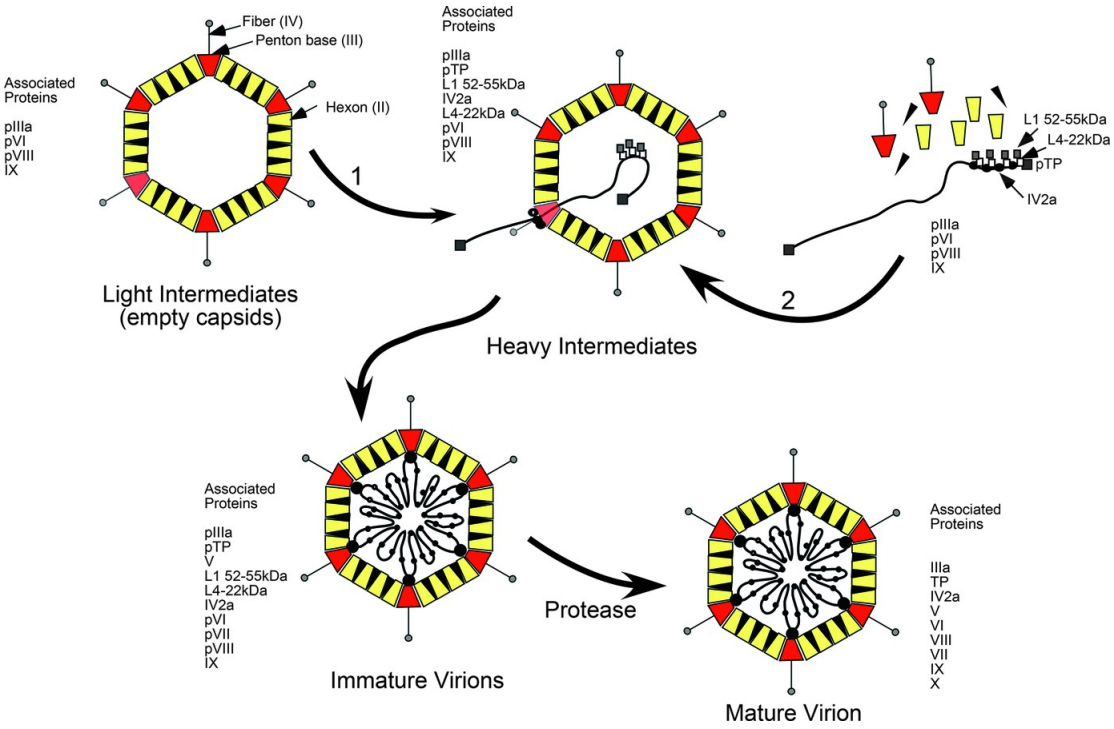

FIGURE 6.6 **Assembly pathway for adenoviruses**. Following transport into the nucleus, the hexons and pentons are proposed to assemble into empty capsids (previously known as light intermediates of assembly) around scaffolding proteins. These nonstructural scaffolding proteins are lost on packaging of viral DNA, which is inserted into this structure via a packaging sequence at the left end of the genome. The mechanism of insertion appears to be similar to DNA phages and involves a portal complex. The pIV2a protein may represent the ATP-hydrolyzing component required to drive DNA through the portal structure in the procapsid. Heavy intermediate forms of the capsid probably represent those in which DNA packaging is incomplete and the DNA is fragmented. Precursor core proteins would be packaged into the empty capsid along with the genome to form immature virions. Proteolytic cleavage of the precursor proteins by the viral proteinase yields the mature virion.

For a nonenveloped virus such as adenovirus, which replicates exclusively in the nucleus, there is a strong dependence on nuclear targeting/transport pathways to export newly synthesized mRNAs out of the nucleus and to import structural proteins back into the nucleus. Nuclear import of the major capsid protein, hexon or polypeptide II, depends upon the involvement of a second adenovirus protein, the pVI (precursor) polypeptide, which acts as a nucleocytoplasmic shuttling adapter and provides the necessary NLS for transporting the hexon into the

nucleus.[285] Trimer formation is in turn dependent upon yet another virus-encoded, chaperone–like protein, L4 100K, which transiently binds to the newly synthesized hexon monomer and mediates its association with two additional monomers.[33] Thus, the most abundant structural protein of the adenovirus capsid needs to interact with two additional virus-encoded factors in order to attain the correct tertiary structure and subcellular location for assembly.

The two other proteins that form the 12 vertices of the capsid, penton and fiber, appear to assemble independently in the cytoplasm. Mutations in the C-terminus of the penton that block assembly into pentamers do not prevent transport into the nucleus,[121] indicating that each monomer has an active NLS. In contrast, the fiber must form trimers to be efficiently transported to the nucleus,[187] even though this protein has an active NLS located at its N-terminus. It seems likely that the penton base and fibers are transported independently into the nucleus and assemble into the intact penton at the site of assembly.

Although two distinct pathways for adenovirus capsid assembly have been postulated from a large body of work in this area, it now appears that an empty procapsid is first formed around scaffolding proteins, in a manner similar to that observed with DNA phages.[3] Results from experiments that combined kinetic labeling with temperature-sensitive replication mutants and additional site–directed mutants have yielded the assembly scheme shown in Figure 6.6. A number of viral products appear to act as scaffolding proteins around which shells are assembled and which facilitate the encapsidation process. These proteins are present in the intermediate capsidlike particles but are absent once DNA has been encapsidated.[52] Disruption of adenovirus capsids with denaturants results in the release of groups of nine hexons that are associated with the faces of the icosahedron and which lack the peripentonal hexons. Under acidic conditions, these nanomers can reassemble to form icosahedral shells that lack the 12 vertices, which would normally be composed of the penton and the five peripentonal hexons, raising the possibility that hexon nanomers are intermediates of adenovirus capsid assembly. Following procapsid assembly, DNA and associated core proteins are then subsequently packaged into these empty shells to yield “immature virions” that then undergo proteolytic maturation through the action of the viral protease. Recent studies have demonstrated that the ~6-8 copies of the pIV2a protein, which binds to the packaging sequence, are present at a single apex of the mature virion.[40] This, and the fact that the pIV2a protein contains motifs (the Walker A and B boxes) associated with the binding and hydrolysis of ATP, suggests that it may represent the ATP-hydrolyzing component required to drive DNA through a portal structure in the procapsid. Consistent with this, mutations that either prevent synthesis of pIV2a or prevent binding of ATP to the protein block genomic packaging and result in the assembly of empty procapsids.[193]

Assembly of Enveloped Viruses in the Nucleus

Two enveloped animal virus families, the herpesviruses and the orthomyxoviruses, utilize cell components that are located within the nucleus in their replication and initiate their assembly within that compartment. In addition to importing into the nucleus the necessary components for assembly, these viruses must also export large nucleoprotein complexes back out into the cytoplasm.

In some respects, the herpesviruses represent a hybrid between a nonenveloped virus, such as adenovirus, and a more conventional enveloped virus such as a retrovirus, in that they utilize the compartments of the secretory pathway to transport and envelop large capsid structures from the nucleus to the outside of the cell. Members of this group of large viruses follow a complex assembly pathway in which genomic DNA is first replicated and encapsided in the nucleus. There they assemble an icosahedral capsid shell that is 160 Å thick and 1250 Å in diameter. The major component of this protein shell is pUL19, which forms both the pentameric and hexameric capsomeres necessary to assemble the icosahedral structure. Associated with the outer surface of the hexamers is the abundant small protein pUL35. Two additional proteins, pUL38 and pUL18, in a 1:2 ratio form heterotrimeric triplexes, which fit between and link together adjacent capsomeres.[179] Scaffolding proteins are essential for HSV-1 capsid assembly/maturation and in their absence incomplete and aberrantly shaped capsids are assembled. As with adenovirus, the major capsid protein lacks a nuclear targeting signal, and its transport into the nucleus requires an interaction with either the scaffolding protein (pUL26.5) or the triplex protein pUL38, which presumably provide the necessary NLS. pUL18 similarly requires pUL38 for nuclear localization, while pUL35 appears to be directed there via its interaction with pUL19.[217]

Studies of virus-infected cells together with *in vitro* assembly studies have provided valuable insights into the assembly process.[160,181] These studies point to a pathway in which pUL19, pUL38, and pUL18 assemble around a scaffold to form an icosahedral but predominantly spherical procapsid—the “B-capsids” identified by electron microscopy. Although not required for capsid formation, in its presence the portal complex apparently initiates capsid formation leading to its incorporation into the nascent capsid.[180] Cleavage of the scaffolding protein at a site near its C-terminus by the viral protease removes a 25-amino acid sequence that is necessary for binding to pUL19. The resulting disassociation and release of scaffold allows for packaging of the viral DNA genome and induction of maturation of the capsid into a more angular icosahedral structure, the previously identified “C-capsids.” DNA enters the procapsid through a unique vertex composed of the portal protein pUL6, which is assembled into rings composed of 12 subunits to form the portal complex.[182] The pUL6 portal resembles the connector or portal complexes employed for DNA encapsidation by double-stranded DNA bacteriophages such as φ29, T4, and P22. In the absence of an active proteinase, the scaffolding proteins remain associated with the protein shell preventing packaging of the viral DNA and the procapsid is unable to mature.[183]

Unlike adenoviruses, which accumulate in the nucleus and are released on lysis of the cell, herpesviruses exit the nucleus by a process termed nuclear egress, that first involves capsid budding into the lumen of the nuclear membrane. This process is dependent on the products of two highly conserved genes, UL31 and UL34, which encode a phosphoprotein and a type II membrane protein respectively. Nuclear localization of pUL31 is dependent upon its interaction with pUL34.[124] These two proteins form a heterodimer that represent the nuclear egress complex (NEC).[213] Although both proteins are present in the primary enveloped virions present in the lumen of the nuclear membrane, they are absent from mature virions, consistent with a model in which herpesvirus virions are first enveloped at the inner nuclear membrane, de-envelop by budding through the outer nuclear membrane, and are re-enveloped in the cytoplasm.[68] In the first step of nuclear egress, capsids bud at the inner nuclear membrane to form perinuclear enveloped virions (PEVs) in the perinuclear nuclear space. PEV formation involves localized disruption of the nuclear lamina, docking of capsids at and deformation of the inner nuclear membrane to form a nascent bud, and pinching off of the bud to release PEV. These are distinct from mature enveloped virions in having a smooth membrane and thin tegument layer.[92] PEV formation is subject to regulation since DNA-containing capsids are preferentially enveloped, likely due to specific interactions with UL31.[9] In order for capsids to access the cytoplasm, the PEV must undergo de-envelopment, losing their envelopes and NEC coats following fusion with the outer nuclear envelope. Several aspects of this process remain obscure, including how PEV target the outer rather than the inner nuclear membrane and which viral protein mediates membrane fusion.[68] Re-envelopment of cytoplasmic capsids occurs by budding into specialized vesicles that appear to be derived from multiple organelles, including the trans-Golgi network and early endosomes.[6,142] The complexities of

this latter interaction and subsequent steps in assembly will be discussed later in this chapter.

In order for influenza virus to take advantage of its unusual capacity to "steal" the capped 5′ ends of host cell mRNAs to initiate its own mRNA synthesis, transcription and viral RNA replication must occur in the nucleus (see Chapter 5). Genomic (minus sense) RNAs are replicated by a different mechanism to yield templates for mRNA synthesis as well as progeny viral genomes. The eight viral RNA segments of this virus are packaged into individual RNPs containing the four proteins of the transcriptase complex (PB1, PB2, PA, and NP, each transported into the nucleus by a functional NLS sequence) and the nuclear export protein (NS2/NEP) but are not exported into the cytosol until late in infection when the viral matrix protein (M1) begins to be synthesized.[146] It has been shown that the vRNPs remain in the nucleus of cells if either M1 or NS2/NEP is not synthesized. NS2/NEP does not interact directly with vRNPs, rather it mediates (RanGTP-dependent) formation of a bridge between the cellular export receptor Crm1 and the N-terminal domain of M1, which in turn binds to the vRNP via its C-terminal domain. This "daisy-chain" complex of (Crm1-RanGTP)-NEP-M1-vRNP is likely what mediates the export of vRNP across the nuclear envelope.[4,177] M1 association with the vRNPs also appears to be important for preventing their re-entry into the nucleus, likely by masking the NLS on the component proteins.[67] Thus, the matrix protein of influenza virus is a key modulator of vRNP transport into and out of the nucleus.

Assembly of Viruses in the Cytoplasm

While targeting and import of proteins into the nucleus or secretory pathway involves well-characterized motifs on the proteins involved, the processes by which proteins are targeted to destinations within the cytoplasm remain less well defined. Most viruses, even those that are nonenveloped, initiate or complete their assembly in association with membranes of the secretory or endocytic pathways. Association of viral proteins with membranes acts to enrich viral proteins or genomes in specific cellular domains to increase the efficiency of assembly steps and organizing the different viral process.

Intracytoplasmic Transport and Assembly of Retroviral Capsids

Retroviruses are enveloped viruses that, for the most part, complete their assembly by budding through the plasma membrane of the infected cell. For these viruses, the immature capsid of the virus is assembled from polyprotein precursors that must be transported through the cytoplasm to the inner leaflet of the membrane. The viral glycoproteins, on the other hand, must be transported through the secretory pathway of the cell to the cell surface where they colocalize with the nascent, membrane-extruding capsid (Fig. 6.7). All replication competent retroviruses contain four genes that encode the structural and enzymatic components of the virion. These are *gag* (capsid protein), *pro* (aspartyl proteinase), *pol* (reverse transcriptase and integrase enzymes), and *env* (envelope glycoprotein). However, the product of the *gag* gene has been shown to possess the necessary structural information to mediate intracellular transport, to direct self-assembly into the capsid shell, and to catalyze the process of membrane extrusion known as budding.[230] For most retroviruses, the nascent Gag polyproteins are transported to the plasma membrane where assembly of the capsid shell and envelopment occur simultaneously (Fig. 6.7, pathway 1). Viruses that undergo this "type-C" form of morphogenesis include members of the alpha- and gammaretroviruses. Lentiviruses and deltaretroviruses assemble their capsids in a similar fashion in most cell types. In the second morphogenic class of retroviruses, the "type B/D" class, the Gag precursors are targeted first to an intracytoplasmic site where capsid assembly occurs. These assembled immature capsids are then transported to the plasma membrane where they undergo budding and envelopment (Fig. 6.7, pathway 2). Viruses that undergo this process of assembly and release include members of the betaretroviruses. Members of the spumavirus family also assemble immature capsids in the cytoplasm, but they are targeted to the ER or ERGIC for envelopment (Fig. 6.7, pathway 3).

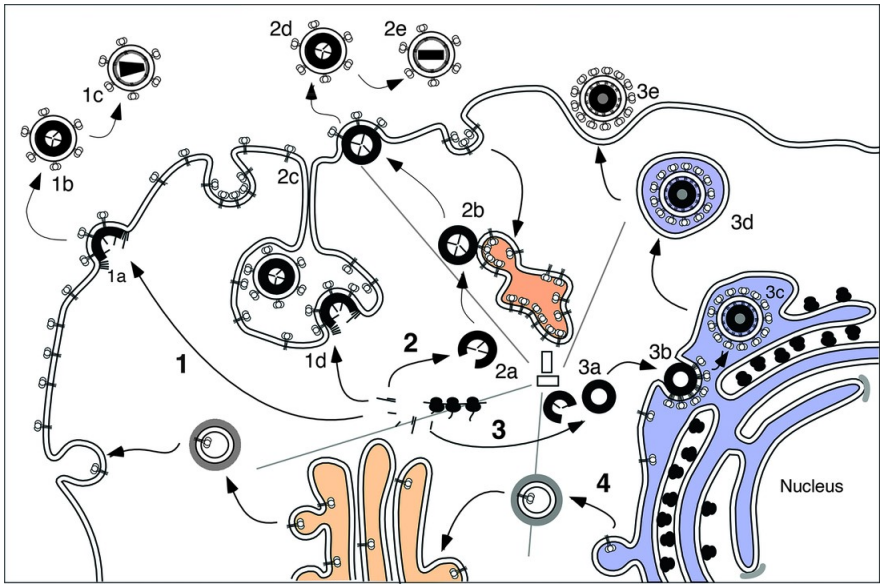

FIGURE 6.7 **Assembly of retroviruses**. The assembly pathways of retroviruses that exhibit C-type morphogenesis (*pathway 1*), B-/D-type morphogenesis (*pathway 2*), and that of the foamy viruses (*pathway 3*) are shown. The envelope glycoproteins are translated on membrane-bound polysomes and for most retroviruses are transported to the cell surface through the cell's secretory pathway (*pathway 4*), although glycoproteins destined for incorporation into virions are likely endocytosed and interact with Gag intracellularly (*pathway 2b*). For all morphogenic classes, the Gag proteins are synthesized on free polysomes. In the case of the C-type morphogenic viruses (ie, RSV and HIV), the Gag and Gag-Pol proteins migrate either individually or in small multimers to the plasma membrane where immature capsid assembly and envelopment occurs concurrently (*1a*). At some point in this pathway, the viral genomic RNAs associate with the Gag and Gag-Pol precursors and are incorporated into the developing capsid. For HIV in macrophages assembly can occur on deep invaginations of the plasma membrane to which Env has been targeted (*1d*). In the case of the B-/D-type viruses, polysomes translating Gag and Gag-Pol precursors are first transported via microtubules to an intracytoplasmic, pericentriolar assembly site (*2a*) where they

assemble into immature capsids. The immature structures are then transported, most likely in association with endosomal vesicles (*2b*), to the plasma membrane (*2c*) where they associate with the envelope glycoproteins and induce viral budding. For both classes of retroviruses, the capsids of the nascent immature particles appear as doughnut-shaped structures and contain unprocessed Gag and Gag-Pol precursors (*1b and 2d*). The mature virus particles contain electron-dense cores with morphologies characteristic of the virus (*1c and 2d*). The maturation step is required for infectivity and is the result of the activation of the viral protease, which cleaves the Gag and Gag-Pol precursors into the internal structural and enzymatic proteins of the virus. For the foamy viruses, Gag and Pro-Pol precursors also assemble into immature capsids in a pericentriolar site (*3a*), but budding primarily occurs at the ERGIC compartment where the viral glycoproteins are retained (*3b*). The enveloped virion is presumably transported to the plasma membrane by transport vesicles (*3d*). Maturational cleavage of the immature core is limited to removal of 4 kd from the C-terminus of the precursor; the mature infectious virion maintains an immature morphology (*3e*).

While the size and protein content of the precursor varies between different retroviral families, at least three *gag*-encoded proteins are found in all retroviruses; these are the matrix protein (MA), the capsid protein (CA), and the nucleocapsid protein (NC). In addition to these functionally conserved domains, the Gag precursor can, depending on the virus encoding it, contain additional peptide sequences (Fig. 6.8) whose functions in virus assembly and future cycles of infection are only now being resolved.

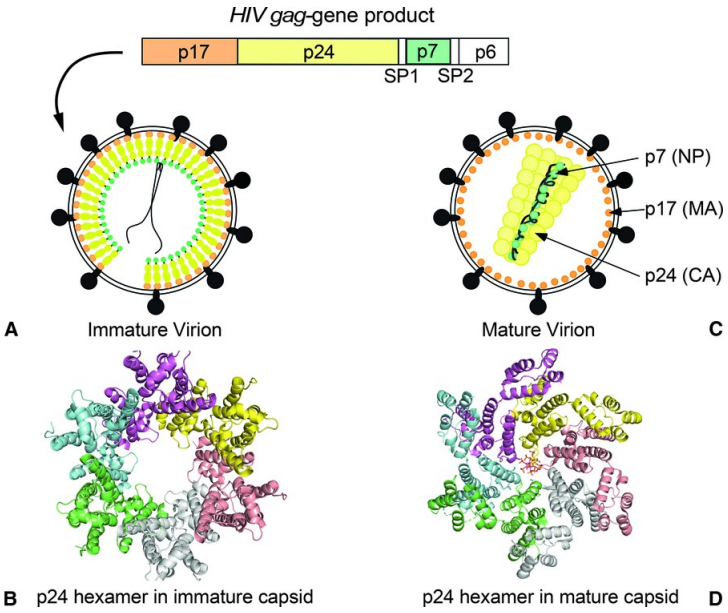

FIGURE 6.8 **Immature and mature HIV virions with p24 hexameric rearrangement 2022**. The Gag precursor polyproteins of all retroviruses contain beginning at the N-terminus, matrix (MA), capsid (CA), and nucleocapsid (NC) domains linked in this order. The *gag* gene of the lentivirus human immunodeficiency virus (HIV) is shown. The specific name associated with the Gag cleavage products is derived from their respective apparent molecular weights ($\times 10^{-3}$). Immature virions **(A)** are assembled from Gag and Gag-Pro-Pol precursor proteins arranged in hexamers **(B)** primarily through molecular interactions of the p24 domain that stabilized by the SP1 domain, which forms a six-helix coiled-coil structure. Following proteolytic cleavage of the precursor to its component proteins, a major structural rearrangement occurs to form the conical core **(C)** comprised of a more tightly spaced p24 hexamer that is now stabilized by interactions between the NTD and the small molecule, inositol 6-phosphate **(D)**.

The molecular details by which the capsid precursor proteins are directed to the site of assembly are incomplete, but the process appears to be mediated primarily by the MA domain of the Gag precursor. In most retroviruses, the matrix protein contains two elements involved in plasma membrane targeting. The first of these is an N-terminal myristic acid, which is normally sequestered but can be induced to insert into the hydrophobic lipid bilayer via a myristyl switch.[228] The second is a surface patch of basic amino acids that mediate the initial interaction of Gag with the negatively charged, phospholipid head groups of the membrane. Mutations that interfere with either myristylation or the charged residues can abrogate plasma membrane targeting, and in some instances the mutated Gag precursors are targeted to internal membranes.[191]

In the betaretroviruses, where capsid assembly and virus budding are discrete events, a genetic dissection of this process has shown that Gag-containing precursors express a dominant sorting signal (the cytoplasmic targeting/retention signal or CTRS) that targets the proteins to the initial assembly site.[39] Studies suggest that the CTRS interacts with Tctex-1, a light chain of the microtubule-associated dynein motor, and directs nascent Gag proteins and translating polysomes to the centriolar region of the cell where immature capsid assembly occurs.[243,275] Efficient transport of these capsids out of the assembly site is dependent on both the presence of the M-PMV Env protein and endosomal trafficking and appears to reflect a requirement for Gag-Env interactions at the pericentriolar recycling endosome.[203] It is likely that similar preassembly complexes also participate in the intracellular transport of human immunodeficiency virus-1 (HIV-1) Gag proteins since their transport is modulated by the cellular adaptins AP-1, AP-2, and AP-3, and intracellular interactions with Env direct Gag assembly to specific plasma membrane regions of the cell.[10,62] Although in macrophages HIV-1 Gag was initially thought to be targeted to a late endosomal compartment for intracellular assembly and budding, more recent studies suggest that these compartments are derived from deep invaginations of the plasma membrane (Fig. 6.7, pathway 1d).[10] Targeting by HIV-1 Gag for assembly in part reflects recognition of enriched regions of phosphotidylinositol 4,5 bisphosphate ($PI(4,5)P_2$) in the plasma membrane by the highly basic MA domain. Depletion of this lipid component by overexpression of the cognate phosphatase (5-phosphatase IV) redirects HIV-1 assembly away from the plasma membrane to internal membranes.[190]

Irrespective of the assembly site, Gag precursor proteins must associate in a reproducible fashion to assemble into a nascent immature capsid. Mutational analyses of *gag* genes, as well as *in vitro* assembly studies, have shown that the CA and NC domains of Gag play a critical roles in

assembly; MA is dispensable for this process.[49,77] NC binding to RNA may act to nucleate the capsid assembly process, while CA, which is the key structural component of the immature capsid and of the conical mature viral capsid, forms a symmetrical hexameric network of proteins. CA is comprised of two major domains, an N-terminal domain (CANTD) connected through a short flexible linker to the C-terminal domain (CACTD), with the latter required for capsid dimerization and Gag oligomerization. Cryoelectron tomography studies of immature HIV-1 capsids have revealed a curved hexameric lattice with a radial distribution of Gag from the membrane-associated N-terminal MA region to the internal C-terminus (Fig. 6.8). Gag hexamers are stabilized by SP1, a region C-terminal to CA which forms a six-helix bundle, which in turn is stabilized by a small molecule, inositol hexakisphosphate (IP6).[65,130] A striking observation in the context of HIV-1 is that released immature virus particles have an incomplete protein shell, with the ordered Gag lattice covering, on average, only two-thirds of the membrane surface.[28,287]

For most retroviruses, capsid assembly drives the process of membrane-extrusion known as budding. As we will discuss below, in order for an infectious virus to be formed, the Gag precursors (or for other viruses, NPs) and surface glycoproteins of the virus must be targeted to the same region of the same membrane. In this way, during virus budding, a proper complement of glycoproteins can be incorporated into the nascent virion.

Assembly of Enveloped Viruses at Cellular Membranes

For most enveloped viruses, the location within the cell at which envelopment takes place is determined by the targeting to or retention of the viral glycoproteins at that site. Indeed, with the exception of the retroviruses, the efficiency of virus budding and particle release is highly dependent on the presence of the envelope glycoprotein(s), and in its absence few particles are produced. Since the glycoproteins define the site of virus budding, specific interactions between the viral NP and the glycoproteins, sometimes mediated by a matrix protein, must take place to drive bud formation and ensure that the genome of the virus is incorporated. For each of the viruses that assemble at intermediate points within the secretory pathway, fully assembled viruses must traverse the remainder of the pathway in order to be released from the cell (Fig. 6.9). Glycoproteins on these released viruses have complex oligosaccharides and are most likely modified by the Golgi-localized enzymes on the way to the cell surface.

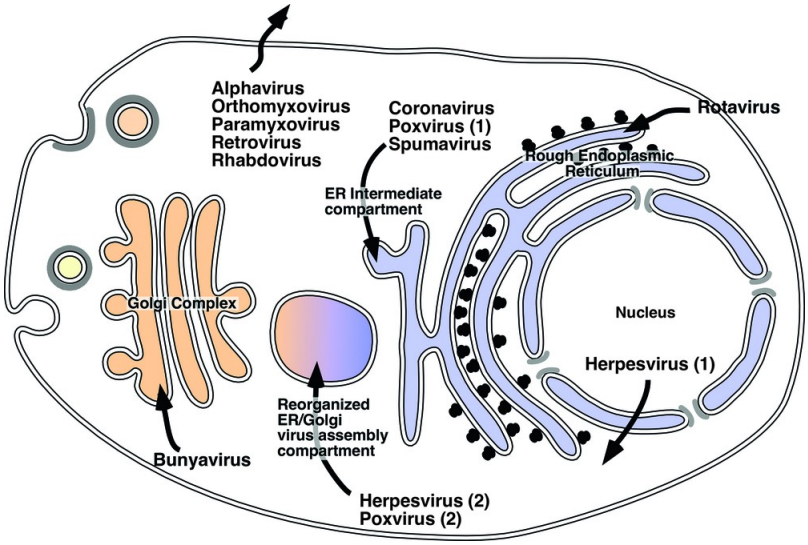

FIGURE 6.9 **Viral assembly at cellular membranes**. Schematic representation showing the intracellular locations at which enveloped virus assembly takes place. For each virus that is enveloped at organelles within the secretory pathway, the virions must traverse the remainder of the pathway to be released from the cell. Rotaviruses appear to utilize the ER membrane as a scaffold for assembly of virion proteins—the capsids that form during the assembly process are only transiently enveloped and nonenveloped particles accumulate in the lumen of the ER. Coronaviruses localize the three membrane proteins (E, M, and S) in the ER-Golgi intermediate compartment and virus budding occurs into the lumen of this compartment of the secretory pathway. In contrast, the vaccinia virus nucleocapsid appears to be wrapped by a double membrane derived from this compartment (poxvirus (1)) but remains free in the cytoplasm so that it can then be further enveloped by a reorganized membrane compartment derived from ER and Golgi-derived membranes (poxvirus (2)). Similarly, herpesviruses initially bud into the lumen of the nuclear membrane (herpesvirus (1)), but after fusion and release of the capsid into the cytoplasm, it is re-enveloped by membranes from a reorganized ER-Golgi–derived assembly compartment (herpesvirus (2)). The G1 and G2 glycoproteins of bunyaviruses colocalize in the trans-Golgi compartment to direct budding of nucleocapsids at this location. For the retroviruses, which can assemble and release virus particles in the absence of envelope glycoproteins, the envelope glycoproteins appear to direct virus budding to the basolateral plasma membrane of polarized epithelial cells.

Assembly at the Endoplasmic Reticulum

For positive-stranded RNA viruses from the *Flaviviridae* family, genome replication and assembly of virus particles occurs on specialized ER membranes (Fig. 6.10). Within this group, infection by members of the *flavivirus* genus, including dengue virus and Zika virus, leads to a reorganization of cellular ER-derived membranes to form vesiclelike compartments within the ER leaflet that facilitate virus replication and act to initiate assembly events on adjacent membranes.[48,86,284] Viral genomic RNA is transported out of the replication vesicles and directed either toward translation or assembly, likely dependent on the abundance or availability of viral structural proteins. Initiation of the assembly process is orchestrated by the viral nonstructural protein NS2A, which is involved in the proteolytic processing of the structural proteins and chaperoning of viral RNA.[288] To initiate assembly, the polyprotein precursors composed of capsid (C) and the premembrane protein (prM) are proteolytically cleaved both on the cytosolic and luminal sides of the membrane to release capsid from the membrane and allow the glycoproteins to form trimeric spike structures.[14] This process is coordinated by NS2A and is facilitated by the viral protease NS2B/3 protease

in the cytosol and host peptidases in the ER. Once released from the membrane, capsid protein can form dimers that associate both with the viral RNA genome and glycoprotein cytosolic domains. Delivery of the viral genome to the site of assembly appears to also be coordinated by NS2A through interactions with the 3'UTR region of the genome. The viral glycoproteins are maintained at the site of assembly in the ER through a cytosolic ER retention sequence in the viral envelope (E) protein.[104] Virion assembly is initiated by the viral C protein, which forms bridging interactions between the viral genomic RNA and the membrane glycoproteins, prM and E. These interactions are thought to stabilize the capsid oligomers to drive budding into the ER membrane. The lack of visible preassembled C proteins suggests that encapsulation and budding occur simultaneously.

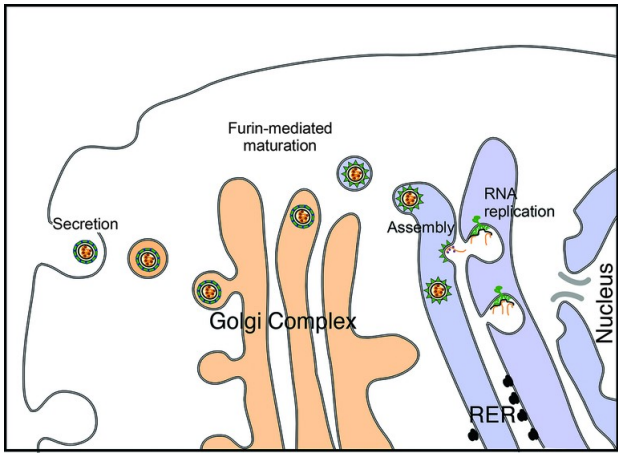

FIGURE 6.10 **Flavivirus assembly**. Flavivirus genome replication occurs in specialized vesicles that form within ER membranes. Virus assembly sites form on adjacent ER membranes through interactions between virus structural proteins and newly synthesized genomic RNA. Virions bud into ER membranes in a process simultaneously with nucleocapsid formation. Once in ER lumen, immature virus particles traffic to the Golgi complex where the prM glycoprotein is cleaved by the host furin protease to form mature virus particles. Mature virions travel to the plasma membranes in secretory vesicles where they are released into the extracellular space.

Hepatitis C virus, another member of the Flaviviridae family, also buds into ER membranes, but *de novo* viral particles are secreted through lipid export pathways rather than the normal secretory system.[244] At later stages in the HCV infection cycle, viral components required for assembly, including the HCV capsid protein, core, the viral envelope glycoproteins, nonstructural NS5A, and genomic RNA, are recruited to virus assembly sites surrounding lipid droplets (LDs).[164] NS5A interacts with viral RNA and is thought to be involved in recruitment of the viral genomes from the site of replication to assembly complexes through interactions with the LD-associated proteins. Accumulation of viral factors on the surface of LDs is accompanied by rearrangements in ER membranes to surround LDs, forming membrane-wrapped assembly sites.[129] This creates an environment that is highly enriched for both the viral and host lipid factors required for assembly. HCV core proteins associate with both viral RNA and envelope proteins, which are thought to facilitate budding into the ER. Although the precise location of budding within this assembly site and kinetics of egress are still unclear, it has been shown that the VLDL export pathway is required to produce highly infectious virus particles and that extracellular particles exist as lipid hybrid structures associated with apolipoproteins.

Assembly at the Endoplasmic Reticulum-Golgi Intermediate Compartment

The coronaviruses are positive-stranded RNA viruses with large (30 kb) genomes packaged in a helical nucleocapsid. The nucleocapsid acquires its envelope by budding into intracellular organelles including the ERGIC, a pre-Golgi compartment of the secretory pathway, or lysosomes. Coronaviruses invariably encode three envelope proteins, each of which contain membrane targeting sequences that drive the localization of assembly to specific cellular membranes. The spike protein (S), which determines the host-range of the virus, is a type I glycoprotein that forms the distinct bulbous peplomers of the virus. S proteins from several coronaviruses are transported to the plasma membrane, although they contain both ER retention and endocytosis signals that can redirect it to the ERGIC.[63,112,138,229] In the case of SARS coronaviruses, protein localization to the cell surface can cause cell to cell fusion events leading to syncytia formation. The most abundant virion protein is the membrane (M) glycoprotein. M spans the lipid bilayer three times exposing a short N-terminal domain outside the virus and a long C-terminus inside the virion. The small envelope protein (E), which is only a minor component of virions, is the key to defining the site and nature of coronavirus envelopment.[101] E is a hydrophobic type 1 membrane protein that localizes to the ERGIC and induces the formation of tubular, convoluted membrane structures characteristic of virus infection.[47,210] The E protein of the avian coronavirus infectious bronchitis virus (IBV) appears to be retained in the ERGIC by a novel ER retrieval signal (RDKLYS-COOH) and localizes M to this site through intermolecular interactions.[133] Combined expression of the three membrane structural proteins E, M, and S increases the amount of S and M proteins retained in the ERGIC, suggesting that a combination of cellular targeting signals and intermolecular interactions between viral proteins are required to determine the assembly site.[270]

For most coronaviruses, coexpression of E, M, and S results in the assembly and release from cells of viruslike particles (VLPs) containing these three viral membrane proteins.[270] In the case of SARS coronaviruses, this process also requires the nucleocapsid (N) protein for efficient VLP formation.[25,247] The enveloped VLP form a homogeneous population of spherical particles indistinguishable from authentic virions in size and shape.[274] Only M and E are required for efficient particle formation and expression of E alone can mediate particle release.[143] The S glycoprotein is thus dispensable for virus particle assembly but is retained in the Golgi by the M protein, which appears to direct its assembly into virions. In infected cells, S protein trimers are observed to be enriched on the luminal side of budding membranes at the ERGIC assembly sites.[123,157] On the cytosolic side of membrane, M protein directs the incorporation of nucleocapsids containing the genome length RNA into virions at the budding site in ERGIC membranes.[175]

Spumaviruses are another class of viruses that assemble in ERGIC. Although a majority of the retroviruses are enveloped at the plasma membrane of the cell, for most members of the spumavirus genus, this occurs on internal membranes. In human fibrosarcoma cells, primate

foamy virus (FV) Gag and Env appear to colocalize predominantly in the trans-Golgi region of the cell,[293] but in other cells, immature capsids appear to bud into the ERGIC region of the secretory pathway. This is consistent with the observation that expression of the primate FV Env complex, gp80/gp48, in the absence of other structural proteins, results in its localization to the ER. A dilysine ER retrieval motif at the C-terminus of gp48 is responsible for this localization, and mutation of either lysine results in efficient transport of the protein to the PM. While a greater fraction of capsids bud from the PM in mutant virus–infected cells, envelopment of capsids at the ER is still observed.[87] A second distinguishing feature of foamy viruses is the dependence of capsid envelopment on Env expression.[11] As with the betaretroviruses, assembly of immature FV capsids is targeted to the pericentriolar region of the cell by a CTRS located around an arginine residue at position 50 in Gag.[293] They are then transported to the ER (or PM) for envelopment. In the absence of FV Env, these preassembled capsids do not associate with membranes or initiate budding. Recent experiments have shown that it is the posttranslationally cleaved (148 amino acids long), membrane-spanning, signal peptide domain of the foamy virus Env that mediates capsid membrane association/envelopment and that this protein is incorporated into the virus in the process.[135]

Assembly in the Golgi Complex

Bunyaviruses are negative-stranded, enveloped viruses with a segmented genome that assemble in tubelike virus factories that are built around the Golgi complex and are connected to mitochondria and RER Figure 6.9, reviewed in Ref.[279] By physically juxtaposing viral RNA replication and assembly, these factories appear to allow accumulation of RNPs that can associate with viral glycoproteins and bud into the lumen of swollen Golgi stacks. In general, bunyaviruses encode two type I glycoproteins Gn (previously G1) and Gc (G2) that are translated as a polyprotein precursor together with the nonstructural protein NSm.[105] Gn and Gc are cotranslationally cleaved from the precursor protein by signal peptidase, which cleaves after the internal signal sequence that mediates translocation of Gc. For bunyaviruses from the *Nairoviridae* family, additional cleavage events by furinlike or SKI-1/S1P-like proteases are required for Gn and Gc maturation. The two glycoproteins have been shown to fold with distinctly different kinetics, but once properly folded, form a Gn-Gc heterodimer that is transported to the Golgi complex where virus budding occurs. Gc expressed in the absence of Gn is retained in the ER, while Gn expressed alone is targeted to the Golgi reviewed in Ref.[93] The Uukuniemi virus Golgi localization signal of Gn has been mapped, through analysis of mutations and glycoprotein chimeras, to the membrane proximal half of the 98 amino acid long cytoplasmic tail of the protein. Glycoprotein retention in this case appears, therefore, to depend on interactions between the cytoplasmic tail of Gn in the Gn-Gc heterodimer with components residing on the cytoplasmic side of the Golgi membrane. However, while all bunyavirus Gn-Gc complexes accumulate in the Golgi, the exact location and nature of the signal(s) that ensure this do appear to differ among the genera.[279]

During assembly of bunyaviruses, the helical ribonucleoproteins, consisting of the three single-stranded genomic RNA segments and the associated nucleocapsid (N) protein and the viral RdRp, accumulate in the Golgi component of the virus factories and through interactions with the Gn and Gc cytoplasmic domains initiate the budding of virus particles into the Golgi lumen. The region of the secretory pathway at which Gn-Gc heterodimers accumulate clearly defines the budding site since in the presence of brefeldin, a drug that redistributes Golgi components to the ER, virus budding occurs into the ER.[93]

Assembly at the Plasma Membrane

Members of several virus families undergo their envelopment at the plasma membrane. These families include the togaviruses, the rhabdoviruses, the para- and orthomyxoviruses, and the retroviruses. In each of these cases, the viral glycoproteins, either as hetero-oligomeric complexes or homo-oligomers, have traversed the entire secretory pathway to be delivered to the plasma membrane of the cell. Assembly at the plasma membrane obviates the need for the assembled virus to navigate additional compartments of the secretory pathway, since virions are released directly into the external milieu of the cell. Alphaviruses are among the best characterized of these different viral systems since a combination of biochemical, genetic, and structural information has been amassed to shed light on the complexity of this assembly process. The major glycoproteins E1 and E2 of the alphaviruses are translated from a subgenomic 26S RNA as a p62, 6K, E1 precursor complex. The 6K and E1 proteins are released from the precursor by signal peptidase but remain in a complex with p62. This complex protects E1 from low pH during trafficking until, following transport to the Golgi, p62 is processed to E2 and E3 by the host furin protease.[234] Stable trimers of E1-E2 heterodimers are then transported to the PM, where they form a lattice that associates with nucleocapsids formed from the capsid (C) protein and genome length RNA. Although not strictly required for budding, the 6K protein as well as the viral TF protein, produced through a ribosomal frameshift in the 6K coding region, greatly enhance the process of alphavirus assembly.[234] The 6K and TF proteins travel to the PM with the E1-E2 complex, but only the palmitylated TF protein is incorporated into virions.[114,211] At the plasma membrane, budding occurs at specialized membrane domains that are characterized by accumulation of E2 and the absence of host proteins.[82]

Cryo-EM analyses of mature alphavirus particles revealed a detailed structure of this enveloped virion.[144,170] These studies have shown that both the envelope as well as the core display icosahedral symmetry. Surprisingly, however, the trimers of E1 and E2 are located at the threefold and quasi-threefold symmetry axes of the pentameric and hexameric order of the nucleocapsid. Moreover, the heterodimers of each spike splay out above the membrane in a skirtlike fashion, traverse the lipid bilayer individually, and interact with three underlying capsid (C) proteins that belong to three separate capsomeres. This creates a complex network of molecular interactions where the glycoprotein-capsid protein interactions mediate not only the binding of the nucleocapsid to the spikes but also stabilize the connections between the capsomeres.[114] Above the membrane, the skirts formed by the E1-E2 heterodimers form lateral connections that mimic the pentameric and hexameric arrangement of the capsid. These interactions may facilitate the process of budding by providing a multivalent binding site for the capsid, as well as by providing a force for membrane bending. Budding, however, requires a cooperative interaction between the glycoproteins and the capsid protein, since in the absence of either budding does not occur. Moreover, mutations in the cytoplasmic tail of the E2 protein alone can abrogate budding. Two models have been proposed for assembly.[82] In the first, glycoprotein trimers assemble around a preformed nucleocapsid that is associated with the inner leaflet of the PM. This model is supported by observations of abundant preformed nucleocapsids in the cytosol of infected cells and through microinjection of *in vitro* assembled nucleocapsids that can induce budding.[36,251] The second hypothesizes that it is through interactions between E1 and E2 heterotrimers that the icosahedral structure of the virus is established and that interactions between the E1-E2 heterodimers and C proteins organize the nucleocapsid similarly. Evidence for the latter model came from deletion mutants in C that are defective in the formation of intracellular capsids but which nevertheless can associate with E1-E2 to facilitate the release of T = 4 icosahedral capsids.[76]

For the negative-strand RNA viruses, orthomyxoviruses, paramyxoviruses, and rhabdoviruses, an additional protein, the matrix protein, mediates the interactions between the viral glycoproteins and the RNP and appears to play a key role in envelopment. These proteins are able to

bind to membranes through hydrophobic domains or, as with the retroviruses, through a cluster of positively charged residues that initiates electrostatic interactions with the PM. Cross-linking studies have demonstrated that these M proteins form homo-oligomers in the virus and can self-associate *in vitro* or when expressed at high levels in cells. As discussed earlier, the M1 protein of influenza virus acts to mediate the transport of RNPs from the nucleus to the site of virus assembly on the plasma membrane. After nuclear export, M1-vRNP complexes associate with Rab11a-containing vesicles in the perinuclear region, which appear to move along cytoskeletal components of the cell.[8] The importance of the M protein in the paramyxovirus budding process was inferred from the defective measles viruses found in subacute sclerosing panencephalitis that are unable to assemble virus particles and that have mutations in the M protein coding region.[19] The development of reverse genetics systems for the negative-stranded viruses, in which mutations can be reintroduced into the viral genome, has allowed a more rational approach to examining these questions. Construction of rhabdovirus genomes that lack the M coding region resulted in a dramatic ($>10^5$-fold) decrease in the release of virus particles and those that were released lacked the characteristic bullet-shape morphology. The defect could be complemented by expression of M in trans.[154] Thus, in the rhabdoviruses, the M protein condenses the helical RNP into its characteristic shape and mediates the envelopment process. Similarly, for the orthomyxoviruses, M proteins can define the shape of the virus particles,[26] and while in the absence of M1 particles can be released, this is a much less efficient process and the resulting virus particles are less infectious.[225]

Reverse genetics approaches have also shed light on the role of the G glycoprotein in rhabdovirus assembly and of the hemagglutinin (HA) and neuraminidase (NA) in orthomyxovirus assembly. Rhabdoviruses that lack the G-protein coding domain do assemble and release bullet-shaped particles, but at only 3%-10% the efficiency of wild type.[153,220] Initial studies with G proteins lacking a cytoplasmic tail suggested that this domain might be important in the budding process; however, more recent studies have shown that while there is a general requirement for a short cytoplasmic tail, it is amino acid sequence independent and that G proteins with large C-terminal extensions can be efficiently incorporated into virions, thereby leaving the basis for M protein interactions with G unresolved (reviewed in Ref.[111]). While foreign glycoproteins can be efficiently incorporated into rhabdovirus particles (creating pseudotype particles), they do not stimulate budding.[218] This is consistent with experiments that have identified a domain within the extracellular membrane–proximal stem (GS) of vesicular stomatitis virus (VSV) G that is required for efficient VSV budding. Recombinant viruses encoding glycoprotein chimeras with 12 or more membrane-proximal residues of the GS, as well as the G protein transmembrane and cytoplasmic tail domains, produced near wild-type levels of particles. In contrast, those with shorter regions produced 10- to 20-fold fewer particles. It is possible, therefore, that this region of the G protein membrane proximal domain modifies the membrane to facilitate the budding process.[220] VSV assembly begins with the formation of an RNA-N protein nucleocapsid ribbon, which is then bound by M, P, and L proteins in an uncondensed state.[214] The RNP is then recruited to membranes enriched for M and G proteins, where it condenses, forming a tight ring that represents the tip of the bullet-shaped particle, which are then forced to curl into larger rings that eventually tile the helical trunk. The assembling structure is stabilized by the binding of M protein to the outside of the nucleocapsid, which in turn forms a triangular platform for binding G-trimers and the lipid membrane.[84]

In influenza virus, the fact that the cytoplasmic domains of all three membrane proteins (HA, NA, and M2) are highly conserved in all isolates of the virus, pointed to a role for these domains in assembly of enveloped virus. Early studies indicated that HA proteins with foreign cytoplasmic tails are not incorporated into virions, although HAs lacking this domain can be incorporated at levels 50% that of wild type.[173] Studies using reverse genetics have confirmed these findings and have shown that the short (6 amino acid) cytoplasmic domain of NA also plays an important role in morphogenesis. Viruses encoding the truncated NA protein were released less efficiently and were larger and more filamentous. However, in viruses encoding tail-less versions of both HA and NA a 10-fold reduction in virus release was observed and morphogenesis was drastically altered. Virus particles released from these cells were greatly elongated with an extended irregular shape and a reduced level of viral RNA. Similarly, truncation of the cytoplasmic tail of M2, which binds to M1, results in much reduced virus infectivity, coupled with reduction in the amount of packaged RNA and budding efficiency.[152] More recent studies have found a nonuniform distribution of HA and NA within virus particles, and this distribution, seen in budding membranes, is important for the formation of infectious virions, with proper glycoprotein distribution requiring M protein.[37] Thus, it appears that for influenza virus, interactions between M1, M2, and the viral glycoproteins proteins at the plasma membrane are all important for envelopment and morphogenesis.[176,225]

With the exception of the spumaviruses, glycoprotein-capsid interactions are not absolutely required for the assembly and release of enveloped retrovirus particles; the Gag precursor alone contains the information necessary to be specifically targeted to the plasma membrane and to drive budding. Nevertheless, for members of the lentivirus family, such as HIV and SIV, that encode envelope glycoproteins with a long (150+ amino acid) cytoplasmic domain, a specific interaction between this region of the transmembrane (TM) component of Env and the MA domain of the Gag precursor appears to be necessary for Env incorporation. For these viruses, mutations in MA or in the cytoplasmic tail can abrogate Env incorporation.[130] Further evidence for an Env-Gag interaction is derived from polarized epithelial cells, where retroviral glycoproteins define the PM domain at which virus budding and release occur (see below).

Several viruses appear to make use of cholesterol- and sphingolipid-rich domains on the plasma membrane known as lipid rafts to assist in the concentration and organization of viral components for assembly.[34] These rafts are characterized by their insolubility in detergent at low temperatures (4 °C), and proteins associated with them remain in the insoluble fraction following extraction from cells. Both HA and NA of influenza virus cluster in lipid rafts via targeting signals that have been mapped to both their transmembrane and cytoplasmic domains, and it is hypothesized that, through interactions with the clustered glycoproteins, M1 and the vRNPs are organized for budding.[177] Consistent with these observations, the lipid bilayer of influenza virions is enriched in cholesterol and sphingolipids and appears also to be in ordered domains.[237] Similarly, the glycoproteins and capsid precursors of HIV-1 have been shown to associate with lipid rafts, and depletion of cholesterol from the plasma membrane impairs HIV-1 particle production.[278] Gag-Env interactions appear to be required for Env association with lipid rafts, since mutations in either MA or the cytoplasmic domain of the gp41TM protein that interfere with Gag-gp41 interactions prevent Env association with rafts.[16] Although it was initially assumed that VSV assembled independently of rafts, it has been shown that G clusters in microdomains and can colocalize on the PM with proteins known to be located in rafts.[206] Thus, it is possible that VSV also utilizes rafts to organize its components for assembly.

Targeting of Viral Glycoproteins in Polarized Epithelial Cells

Many viruses initiate their infection of a host by interacting with cells at an epithelial surface. Individual cells within an epithelial layer are tightly connected by junction complexes that form a barrier to diffusion of molecules throughout the cell membrane and divide the cell surface into two distinct plasma membrane domains: the apical domain, which faces the exterior, and the basolateral domain, which faces the interior.

As a result of differential targeting of lipids and protein components to apical and basolateral membranes, epithelial cells in tight monolayers are highly polarized with each plasma membrane domain having a distinct lipid and protein composition.[222] The assembly and release of many viruses from epithelial cells is also highly polarized, occurring selectively at either the apical or basolateral surface. Influenza virus releases newly assembled virions from the apical surface of polarized epithelial cells, while VSV and many retroviruses are released from the basolateral membrane. In the absence of other viral proteins, VSV G protein and several retroviral Env proteins are transported to the basolateral surface, while influenza virus HA, NA, and M2 are targeted to the apical membrane.[45,176] Sorting of proteins to one or the other domain occurs in the trans-Golgi network, and recent evidence suggests that proteins destined for the basolateral surface contain within their cytoplasmic domain motifs that direct the protein to that membrane. In the VSV G protein, a tyrosine-based motif within the cytoplasmic tail appears to be critical for basolateral targeting.[266] Similarly, tyrosine-based endocytosis motifs in the cytoplasmic domain of both the MuLV and HIV Env proteins are important for their polarized expression and for basolateral budding of their cognate viruses.

Apical transmembrane proteins appear to contain two signals that probably act cooperatively in targeting to the apical surface. Glycosylation in the ectodomain and a signal in the membrane-spanning domain function together to ensure association with sphingolipid-cholesterol–enriched membrane domains or rafts, which have been proposed to mediate apical transport in polarized epithelial cells.

In polarized epithelial cells, and in the absence of a basolateral targeting signal, retroviral Env proteins are delivered to and virus buds from both membranes with equal efficiency, arguing that interactions with Env guide Gag to the basolateral surface.[137] The rhabdoviruses differ in this regard, in that even when the basolateral targeting signal for G has been mutated such that G is transported to the apical surface, virus assembly still occurs predominantly at the basolateral surface. Similarly, under conditions where the influenza virus HA is directed to the basolateral surface, virus budding remains predominantly apical. In these viruses, therefore, it appears that the internal components of the virion possess independent targeting signals that direct them to their respective membranes.[176]

Infection of lymphocytes by HIV-1 and MuLV results in polarized virus assembly at the uropod where virologic synapses are formed and result in efficient cell-cell spread.[62,113] Polarized virus assembly and release may, therefore, be important in determining the pathogenesis of viral infections since it can influence, in a major fashion, the pattern of virus spread in the infected host.[45]

Complex Interactions With the Secretory Pathway

While a majority of enveloped viruses undergo assembly and envelopment at a single site within the secretory pathway, some viruses have a more complex interaction that can involve de-envelopment or re-envelopment as part of their assembly pathway.

Rotavirus Assembly Within the ER

Rotaviruses are nonenveloped viruses that undergo transient envelopment at cellular membranes as an essential step in the formation of the mature double-shelled (triple layered) virus that is retained within the lumen of the ER until cell lysis. As with the reoviruses, the nucleocapsid, in this case containing 11 double-stranded RNA segments, is assembled in electron-dense cytoplasmic inclusions located close to the ER membranes, known as viroplasms. This assembly domain is dependent on expression of two nonstructural proteins, NSP2 and NSP5, and mutations or silencing of either gene product results in its abrogation.[73,139,202] In the viroplasm, genome replication occurs within early assembly structures that mature through the addition of multiple viral protein layers.[198] Following dsRNA synthesis, VP6, the most abundant protein of the virus, surrounds the inner core to form double-layered nucleocapsids with an outer icosahedral shell. They appear to bud directly into adjacent membranes that contain the two outer shell proteins VP7 and VP4. A nonstructural protein NSP4, which forms hetero-oligomers with the two outer shell proteins, mediates the interaction of the immature particle with the ER membrane.[162,189,264]

The exact topology of VP7 in the ER is not known. The mature protein has a cleaved signal peptide but is retained in the ER as if it were an integral membrane protein.[119,254] VP4 is thought to associate with VP7 and NSP4 just prior to budding of the nucleocapsid into the ER. Enveloped particles can be observed in the lumen of the ER, which then undergo a process of calcium-dependent de-envelopment, forming a triple layer particle an outer icosahedral shell of VP7 and VP4.[208] This process seems to be directed by VP7 since the silencing of this protein did not block the budding of double-layered particles into the ER but arrested maturation at the membrane-enveloped particle stage in this compartment.[227] The rapid association of VP4 with lipid rafts and the nonlytic release of rotaviruses from the apical plasma membrane of gut epithelial cells has led to the suggestion that the budding membranes surrounding the viroplasm might be ERGIC derived and that lipid rafts may play a role in transport of virus directly from this region to the PM.[50,60] Thus, this nonenveloped icosahedral virus appears to transiently utilize membranes of the secretory pathway as a scaffold on which to assemble an icosahedral shell and a nontraditional vesicle-mediated route to the PM.

Herpesvirus Envelopment in the Cytoplasm

As we described above, herpesvirus capsids that are assembled in the nucleus undergo a complex series of envelopment and de-envelopment steps termed “nuclear egress” in order to release the capsids into the cytoplasm (see: Assembly of Enveloped Viruses in the Nucleus and Fig. 6.11). It is here that tegument proteins of the mature virus, a collection of proteins including transcription factors located between the viral capsid and its lipid bilayer in the mature particle, are proposed to associate with the capsid prior to its re-envelopment by specialized vesicles that appear to be derived from multiple organelles, including the trans-Golgi network and early endosomes.[6,142] For herpes simplex virus and pseudorabies virus, glycoproteins of the gE/I complex together with gM appear to be essential for the re-envelopment step, and in their absence, intracytoplasmic aggregates of tegument-associated capsids are formed.[27]

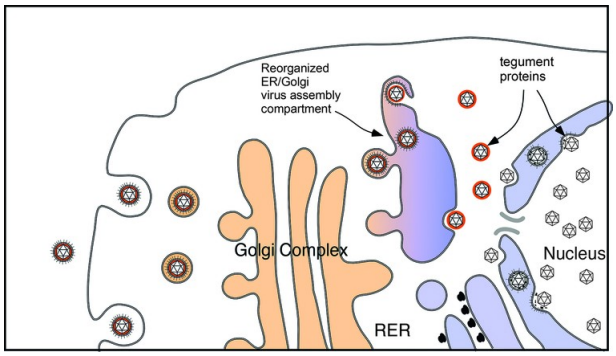

FIGURE 6.11 **Herpesvirus assembly**. In the re-envelopment pathway, nascent assembled capsids bud into the lumen of the nuclear membrane utilizing a subset of virally encoded glycoproteins. These enveloped particles then fuse with and are released from the outer nuclear membrane into the cytoplasm. There they associate with the tegument proteins and are transported through the cytoplasm to be enveloped by reorganized ER-Golgi–derived membranes that contain the full complement of virion glycoproteins.

Some of the clearest evidence for this complex assembly pathway comes from studies of HCMV and human herpesvirus 6 (HHV-6). In these viruses, the tegument is a dense structure that can be observed in electron micrographs. Enveloped virions in the lumen of the nuclear membrane display no evidence of tegument but acquire this layer following loss of the nuclear-derived envelope and subsequent release into the cytoplasm.[223,268] Studies of the glycoproteins of the gamma herpesvirus, Epstein-Barr virus, also support this model. Distribution of the viral glycoproteins gp110 and gp350/220 is consistent with the former being incorporated in virions at the nuclear membrane then lost on budding into the cytoplasm, while the latter is acquired only during re-envelopment in the cytoplasmic vesicles.[89] Similarly, studies of the lipid composition of extracellular HSV-1 virions indicate that it is similar to that of the Golgi complex and distinct from that of the nucleus.[273] Why would viruses evolve to utilize such a complex assembly strategy? Perhaps the most persuasive argument comes from the perspective of the neurotropic alphaherpesviruses. These viruses infect nerve endings in the periphery, but DNA replication and capsid assembly must occur in the cell body. In order to initiate a second round of infection at the nerve synapse, viral components must be transported down the axon. Thus, by separately transporting the viral capsids on microtubules and viral glycoproteins by the vesicular pathway, the site at which infectious virus is assembled can be much more accurately controlled.[159,267]

Poxvirus Acquisition of Multiple Membranes

Poxviruses, exemplified by vaccinia virus, exhibit an equally complex interaction with the secretory pathway. These large DNA viruses, which encode all of the machinery necessary for genomic replication and transcription, propagate entirely in the cytoplasm in specialized areas designated virus factories (see Chapters 67 and 68). The assembly and envelopment of these viruses is particularly complex since they apparently can be enclosed by multiple lipid bilayers reviewed in Ref.[46,219] The first recognizable structure is a crescent-shaped membrane that appears to be comprised of a single lipid bilayer with an external protein lattice constituted of trimers of the D13 protein.[100,262] Initial electron microscopy studies suggested that the crescent membranes that wrap the immature virions (IVs) are formed *de novo* within the virus factories,[55] and additional high-resolution electron microscopy experiments have been interpreted as support for the conclusion that the crescents are formed from a single membrane.[102] Nevertheless, the origin, mode of formation, and composition of these crescent membranes remain controversial. A number of investigators have provided evidence that these envelopes are composed of two closely apposed membranes, which are derived from the intermediate compartment (IC) of the secretory pathway.[215,252] Colocalization of IC resident cellular proteins with several vaccinia virus membrane proteins (A17L, A14L, and A13L) known to be critical for the formation of IV membranes have supported this model.[127,232] However, subsequent studies have shown that transport of proteins from the ER to the IC and Golgi is not necessary for IV formation, and that there is a transport pathway from the ER to the assembling IV.[106] Moreover, epitope tagging of the L2 protein, an early poxvirus protein essential for crescent formation, showed that it was associated with the ER tubules throughout the cytoplasm and in some instances appeared to be continuous with the membrane crescents.[148] The D13 protein, which forms a honeycomb lattice on the outer surface of the IVs, is critical for crescent formation and appears to act as a scaffold for their formation through its interaction with the N-terminus of the membrane spanning A17 protein.[20] Interestingly, Rouiller and coworkers have reported that the virus core of the related African Swine Fever virus core is also wrapped by specialized regions of the ER.[226] More recently, 3D electron tomography analysis using mutants that pause assembly at intermediate steps has revealed transient connections between immature viruses and ER membranes, providing further evidence that crescent membranes are ER derived.[282]

The process by which the nucleoprotein/transcription machinery is targeted into the immature envelopes is unclear, but a multiprotein complex of seven viral proteins, A15, A30, D2, D3, F10, G7, and J1, appears to be critical. Repression of several of these viral products yields the same phenotype; the failure of viral membranes and viroplasm to associate with each other.[261] Maturation of the IV to the infectious intracellular mature virus (IMV) involves a series of proteolytic cleavages of vaccinia structural proteins.[46] The mature virus particles are transported out of the assembly areas toward the periphery of the cell, where additional membranes that are derived from the trans-Golgi or early endosomal compartments wrap them to form the intracellular enveloped virus (IEV).[249,250] The membranes of these compartments contain vaccinia proteins that will be present in the external enveloped virus (EEV). Wrapping requires the participation of at least one protein present on the IMV and two EEV membrane proteins. It thus appears to be driven by interactions between vaccinia-encoded membrane proteins.[22,221] It is likely then that the IEV contains at least three concentric membranes, one derived from the ER and two from the Golgi/endosome. These particles are then transported via a reorganized actin cytoskeleton (so called actin-tails) to the plasma membrane,[51] where membrane fusion releases the infectious EEV form of the virus.

Modification of the Secretory Pathway

Transcription and Assembly of Poliovirus on a Disassembled Secretory Pathway

Poliovirus is a nonenveloped positive sense RNA virus that modifies the host cell extensively during its replication. Once introduced into a target cell, the genomic RNA is translated into a long polyprotein precursor that contains both structural and replicative proteins of the virus (Fig. 6.12). Early in the replication of the virus, there is a massive rearrangement of the intracellular membranes into clusters of vesicles 200-400 nm in diameter.[233] The altered membranes appear to have characteristics of autophagosomal vesicles since they have two membranes and contain, in addition to the viral RNA replication machinery, a number of autophagosomal proteins including LAMP1 and LC3. Moreover, stimulation of autophagy increased poliovirus yield, and inhibition of the autophagosomal pathway decreased virus yield, suggesting subversion of this pathway by poliovirus.[109,265] Electron microscopy studies suggested that the induced vesicles are derived from the host cell secretory pathway, since they appear to be connected to ER membranes early in infection and to the trans-Golgi network at later stages of infection.[155] These observations are supported by inhibitor studies demonstrating virus-induced vesicle formation and poliovirus replication are blocked by brefeldin A.[107] Viral RNA transcription occurs in close association with these vesicles, and both viral RNA and viral proteins known to be required for RNA replication have been shown by electron microscopy to be associated with their cytoplasmic surface.[18,269] Similarly, priming of RNA synthesis by the protein primer, VPg, appears to require membranes.[263] For poliovirus, the viral precursor protein 2BC when expressed alone was shown to cause both membrane vesiculation and the formation of multilamellar structures,[38] but it is in combination with poliovirus protein 3A, which causes the inhibition of ER to Golgi protein traffic,[66] that membrane alterations most consistent with the pattern in poliovirus-infected cells are observed.[259]

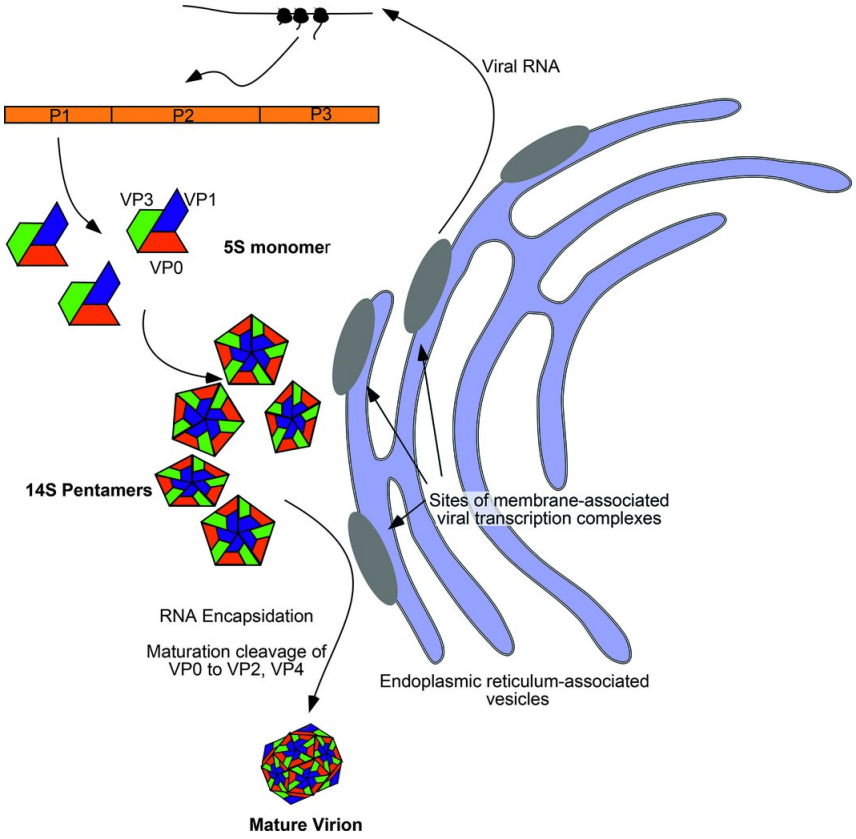

FIGURE 6.12 **Poliovirus assembly**. The P1 precursor protein is cleaved via an autocatalytic event from the nascent polyprotein and is then cleaved twice by the 3CD-protease to yield VP1, VP2, and VP0. This cleavage is essential for assembly of the 5S monomers into 14S pentamers. It is likely that 12 of these pentamers associate directly with nascent genomic RNA that is being transcribed from membrane-bound transcriptional complexes to assemble an immature 150S provirion. Maturation cleavage of VP0 to yield VP2 and VP4 results in conversion of these immature provirions into the 160S mature virion.

The formation of vesicular platforms for transcription may also be necessary for efficient capsid assembly. The poliovirus capsid appears to be assembled in a sequential process in which the 5S protomers containing VP1, VP3, and VP0, assemble to form 14S pentamers, which in turn are assembled into virus capsids (Fig. 6.12). Pentamers may associate with newly synthesized genomic RNA on intracytoplasmic vesicles and then assemble to form RNA-containing capsids upon completion of the RNA. This assembly pathway is supported by immunoelectron microscopy studies showing that pentamers associated with the replication complex can, if released by detergent, rapidly assemble into empty capsids —arguing that the vesicle prevents assembly of the capsid and keeps the pentamer in an appropriate configuration for association with the RNA.[205] In this instance, poliovirus appears to have circumvented the problems of intracytoplasmic localization of replicative and structural components by utilizing a membranous organizing center. Interestingly, mature polio virions can be found within vesicles that have been secreted from infected cells indicating that virus particles can form on the interior of virus-induced vesicles, which are then secreted as quasi-enveloped species.

Modification of Post-Golgi Vesicle pH by the Influenza Virus M2 Protein

The influenza hemagglutinin is synthesized as a precursor protein (HA0) that in the case of the avian influenza viruses is cleaved in the trans-Golgi by furinlike proteinases to the biologically functional HA1-HA2 heterodimer, three of which in turn form the trimeric HA complex (see Chapters 3 and 42). The influenza virus HA present on an infecting virion is activated to its fusogenic state by the low pH of the endosome. Thus, the similarly low pH of the trans-Golgi network and post-Golgi vesicles poses a problem for the virus during the assembly phase of its life cycle, if it is to maintain HA in a functional prefusogenic form. This is apparently solved by the action of the M2 protein, a small tetrameric protein

that forms cation-selective ion channels that can reduce the pH of the trans-Golgi network by pumping out hydrogen ions.[207,258]

Incorporation of the Nucleic Acid Genome During the Assembly Process

While the processes involved in the assembly of structural components of a virus are complex and interplay intimately with those of the host cell, they merely provide a mechanism by which the genomic information of the virus can be packaged into a protective environment for transfer to additional host cells. As such, the assembling virus must have evolved to efficiently select its genomic nucleic acid out of the pools of RNA and/or DNA that are present at the assembly site. Packaging of viral genomes generally involves a cis-acting sequence in the nucleic acid—the so-called packaging sequence—and a structural component(s) of the virus that can recognize and bind this element.

DNA Viruses

As described earlier, for adenovirus, an empty procapsid is first formed around scaffolding proteins, in a manner similar to that observed with DNA phages. Following procapsid assembly, DNA and associated core proteins are then subsequently packaged into these empty shells to yield "immature virions" that then undergo proteolytic maturation.

Early studies indicated that "light" virus particles contain subgenomic length viral DNA with an over-representation of left-end sequences. Subsequent studies showed that a cis-acting packaging sequence that is absolutely required for encapsidation of viral DNA is located within the left 390 bp of the genome. This region is highly conserved between different adenovirus subtypes and, in Ad 5, overlaps with two distinct enhancer elements for E1A transcription. Deletion of the packaging domain abrogates viability, but infectivity can be restored by substitution of the left-end sequences at the right end of the genome.[95,97] The packaging sequence only functions if it is within 600 bp of the inverted terminal repeat (ITS) but is not dependent on the ITS itself.[195] Mutational analyses showed that this packaging region contains at least seven functional AT-rich units called A-repeats. These repeats are functionally redundant but not functionally equivalent. Moreover, a sequence homology shared by the most important A repeats, 5′-TTTG-N_8-CG-3′, is essential for packaging domain function. Overexpression of an A-repeat multimer competes in *trans* resulting in a dramatic decrease in viral yield without affecting DNA replication or late-transcription, suggesting the involvement of limiting viral protein components in packaging.[91,238] It seems likely from a variety of genetic analyses, *in vitro* DNA binding studies, and chromatin immunoprecipitation approaches that the viral IVa2 protein together with the L4-22K protein bind directly to the A repeat sequences to initiate packaging.[72,194,196] The L1 52/55K protein, which is also critical for DNA packaging, is a part of this complex perhaps through interactions with IVa2 or L4-22K.[196,204]

Packaging of the herpesvirus genome is equally complex. As with the large DNA phages, herpesvirus DNA replicates to yield concatamers of genomes in a head to tail arrangement, and so packaging must be linked to the generation of genomic length units of DNA. In this virus, two packaging sequences, *pac1* and *pac2*, located within the terminal *a* repeats appear to be important for both recognition and cleavage of the DNA.[59] As with the DNA phages, a combination of cleavage recognition sequences and "head-full" packaging appears to ensure the incorporation of unit-length genomes into the procapsid. Studies utilizing a temperature-sensitive protease mutant of HSV-1, which accumulates procapsids (containing an uncleaved scaffolding protein) at the nonpermissive temperature, but which can remove the scaffold and package DNA upon temperature shift to the permissive temperature, have shown that ATP is necessary for DNA packaging to occur but DNA synthesis is not.[41,57] At least seven viral proteins, products of the genes UL6, UL15, UL17, UL25, UL28, UL32, and UL33, are required for cleavage and packaging of HSV-1 DNA. When cells are infected with HSV-1 mutants lacking the function of any of the seven genes, capsid formation, and DNA replication occur normally, but no packaging takes place. By analogy with the DNA bacteriophages such as P22, the portal vertex, assembled from 12 copies of the UL6 gene product, likely forms the docking site for these packaging proteins. Sequence analysis reveals that another critical component, encoded by the UL15 gene, shares homology with gp17, the large catalytic subunit of the bacteriophage T4 terminase. Thus, the product of this gene, together with that of UL28, which can specifically recognize the *pac* site, may play a direct role in the cleavage of viral DNA replication intermediates into monomers.[2,291]

RNA Viruses

For retroviruses, genomic packaging represents a particularly difficult problem since the assembling capsid must select genomic RNAs from a large pool of viral and cellular mRNAs that are also present in the cytoplasm. Viral RNAs to be specifically packaged are identified by the presence of an RNA sequence named the packaging signal or psi (ψ) and are selected from the cytoplasmic pool by a specific interaction with the zinc knuckle motif(s) of the NC domain of the Gag precursor.[54,140] The cis-acting RNA element is located at the 5′-end of the viral genome, has the capacity to mediate the packaging of heterologous RNAs, and is comprised of a series of stem-loop structures that each contribute to the strength and specificity of the signal. One of the best characterized, although perhaps most complex, ψ-sequence is that of HIV-1, which is now known to span the 5′ untranslated region of the genome, as well as downstream nucleotides in the Gag region for optimal packaging efficiency. This 5′ untranslated region, which can confer packaging specificity on foreign RNAs, includes the TAR sequence that is important in Tat-mediated transcriptional control, the adjacent poly-A loop, and four stem loops that incorporate the primer binding site (PBS), the dimerization sequence (DIS), the 5′-splice donor (SD), and the packaging signal (ψ), respectively. Gag has been shown to bind specifically to this region, with PBS, DIS, and ψ stem loops each providing independent high affinity binding sites. Disruptive and compensatory mutations within the TAR, Poly(A), PBS, DIS, and ψ elements indicate that the structure of the stem loops is important for packaging.[44,151] NMR analyses of SL3 in the presence and absence of the NC protein have shown that tight binding is mediated by specific interactions between the amino- and carboxyl-terminal CCHC-type zinc knuckles of the NC protein and nucleotide bases of the RNA loop.[58,140,295] In the context of the Gag precursor protein, however, an internal loop and the lower part of SL1 was discovered to be the major binding site on genomic RNA.[1]

Regions of retroviral genomes that promote genome packaging often overlap with segments that promote the RNA dimerization, which is necessary for packaging of the diploid genome. Moreover, there is mounting evidence that dimerization and packaging events are intimately coupled. An elegant structural analysis by D'Souza and Summers showed that dimerization of the MuLV genome results in an altered secondary structure in the psi region of the RNA, which exposes conserved UCUG elements that bind NC with high affinity. These elements are base paired and do not bind NC in the monomeric structure.[53] Thus, for MuLV, the problem of ensuring the encapsidation of two genomic RNAs has been solved by linking exposure of the packaging recognition sequence to dimer formation itself. For HIV-1, genomic RNA destined for dimerization and packaging is distinguished from those targeted for translation by the number of 5′ terminal G residues present. RNAs with a single G sequester the 5′ cap dimerize and can be packaged, whereas in those with 2 or 3 5′ G residues, the cap is accessible and recognized by the

translation machinery.[30]

The cellular location in which Gag:RNA recognition occurs remains an unanswered question. Parent et al. have provided strong evidence that for Rous sarcoma virus, genome packaging is dependent on Gag trafficking through the nucleus, a process that is mediated by NLS and NES signals in the MA domain of Gag.[80,94,200] However, the role of nuclear trafficking of HIV-1 Gag in RNA packaging remains unresolved and controversial.[140,200] Recent experiments by Hu and colleagues suggest that HIV-1 RNAs form dimers preferentially in the cytoplasm and that dimerization, mediated by the DIS sequence in the genome, is critical to efficient packaging into virions.[165,166] Live cell imaging of the incorporation of genomic RNA into assembling virions showed that in the absence of Gag, genomic RNA molecules were highly dynamic and did not localize at specific sites at or near the plasma membrane (PM). In contrast, in the presence of Gag, genomes were targeted to specific sites on the PM, where after initially exhibiting slow lateral movement they became fixed, and were the site for accumulation of additional Gag molecules.[115,117]

Genomic RNA packaging signals in other RNA viruses are less well defined. In the alphaviruses, this appears to involve direct binding of genomic RNA by the capsid protein. A short (132 nt) segment of RNA in the region of the genome encoding the nonstructural proteins, nsP1 or nsP2 depending on the alphavirus species, is critical for this interaction and for efficient packaging of genomic RNA. Like the retroviral psi-sequence, this packaging sequence (PS) has also been predicted to form a series of stem-loop structures.[122] The N-terminal third of the capsid protein is basic and is unstructured in the crystal structure; however, the balance of evidence suggests that the PS interacts strongly with a conserved sequence between residues 81 and 114 of the capsid protein.[156] While this sequence in the nsP coding region greatly enhances packaging, viral genomes without this sequence can still be packaged, albeit with low efficiently, through nonspecific interactions between RNA and capsid. This indicates that both specific and nonspecific interactions between viral genomes and capsid proteins are important for assembly events, but the genome packaging sequence increases the specificity of this process for viral genomes. Similarly, MHV genomes contains a packaging signal sequence that also increases the specificity for packaging of full viral genomes over the more abundant subgenomic RNAs but is not necessary for packaging.[149] For other positive-sense RNA viruses, multiple low-affinity capsid-binding signals found throughout the viral genome appear drive nucleocapsid assembly. For the bacteriophage MS2, numerous low-affinity RNA-capsid interactions facilitate a two-step process were RNA is first partially condensed, which then allows for higher order interactions that lead to encapsidation.[24] For hepatitis C virus, numerous low-affinity packaging signals are also found throughout the genome, which are thought to act synergistically in a mechanism that would parallel that of the MS2 bacteriophage.[253] Since assembled capsids have not been visualized in the cytosol of infected cells, it is thought that the final nucleation step occurs simultaneously with envelopment, but the precise mechanisms remain unclear.

For segmented viruses, such as the orthomyxoviruses or the reoviruses, genomic packaging requires that a complete set of segments be packaged together in a single virus particle. For influenza virus, reverse genetic approaches have shown that the signals for transcription and replication of an RNA segment are located in the 22 5′-terminal and the 26 3′ terminal nucleotides of the RNA.[141] These studies do not, however, address how a full complement of RNAs is selected during assembly. Two models have been proposed to accomplish this. The random incorporation model assumes a common structural feature in all the vRNPs, which enables them to be incorporated randomly into virions. Support for this model comes from the observation that an influenza A virion can possess more than eight vRNPs.[12,70] The selective-incorporation model predicts the presence of specific structures in each vRNA segment, leading to their individual incorporation into virions. Numerous lines of evidence strongly support a selective model for genome packaging.[185] First is data showing that defective RNA segments could inhibit the packaging of the parental segment into virions.[69] Second was the finding that viruses grown in the presence of bacterial neuraminidase and antibody to NA retained an extensively deleted NA vRNA, suggesting that the altered NA segment participates in viral replication and carries structural features required for its incorporation into virions.[289] Experiments utilizing reverse genetics approaches have further supported the selective incorporation model by demonstrating that all eight vRNA segments must be present for efficient virion formation and that sequences within the coding region of the NA vRNA encode a signal that drives incorporation of this segment into virions. Subsequently, genome packaging signals unique to each of the other seven viral RNA segments have been identified.[79,132,185] Electron microscopic studies of serially sectioned influenza virus A particles, which showed the RNPs organized in a distinct pattern (seven segments of different lengths surrounding a central segment), also support a model where the eight segments are cooperatively packaged into virions through intersegment associations[185] (Fig. 6.13).

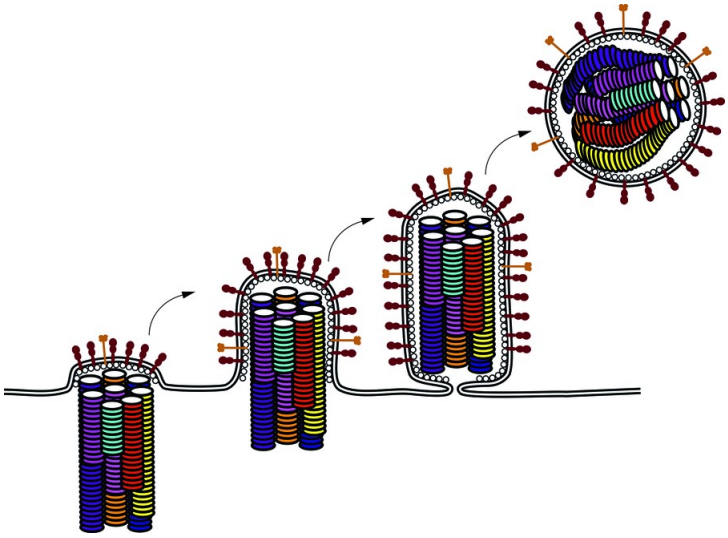

FIGURE 6.13 **Influenza virus budding**. Incorporation of influenza virus genome segments into budding virions at the plasma membrane involves specific packaging sequences found in each genome segment ribonucleoprotein (RNP) complex. These RNP complexes assemble at the plasma membrane in a 7 + 1 configuration through interactions with viral glycoproteins HA and NA. Both glycoproteins and the M1 protein contribute to bud formation and virion shape. Scission and release of the virus particle is facilitated by

viral M2, which localizes to the neck of the budding virion. (Modified from Noda T, Kawaoka Y. Structure of influenza virus ribonucleoprotein complexes and their packaging into virions. *Rev Med Virol.* 2010;20(6):380-391. Copyright © 2010 John Wiley & Sons, Ltd. Postassembly Modifications and Virus Release

Proteolytic Cleavage and Virus Maturation

Proteolytic enzymes play important roles in the process of assembly for many viruses and in a postassembly maturation step that is required for the development of an infectious particle for others. These cleavage events can act as molecular switches that introduce flexibility as well as irreversibility into the assembly process. Additionally, maturation events can function to limit reinfection or glycoprotein fusion events before newly assembled virus has exited the cell.

Proteolytic cleavage in the case of the alphaviruses, for example, is used to allow protein domains, translated from a single mRNA, to enter different transport pathways in the cell. The C protein, which is encoded at the 5′ end of the subgenomic 26S mRNA, folds cotranslationally into an active serine proteinase that cleaves itself from the growing polypeptide chain. This releases the C protein into the cytoplasm for capsid assembly while freeing up the N-terminus of the signal peptide for the p62 glycoprotein precursor, which can then bind SRP and direct the ribosome to the ER.[82]

Numerous proteolytic cleavage events are required for flavivirus particle formation and production of infectious particles.[14,184] Dengue virus C proteins are initially synthesized with a 3′ transmembrane domain, which anchors it in the membrane and connects it to the luminal prM glycoprotein. Proteolytic cleavage of this domain by signal peptidase on the luminal side and the viral serine protease NS2B/3 on the cytosolic side initiates budding by allowing the glycoproteins to form oligomer structures and the C protein to initiate nucleocapsid formation. Enveloped flavivirus particles form by budding into the ER in an immature form that contains the precursor prM glycoprotein on its surface. During transit of these immature viral particles to the plasma membrane through the secretory pathway, the prM glycoprotein is cleaved by the host protease furin to form pr and M. Once secreted from the cell, the pr domain is released from the viral particle, freeing the fusion peptide to form infectious particles.

In the herpesviruses, proteolytic cleavage of the scaffolding protein occurs after assembly of the procapsid is complete and is a prerequisite for DNA packaging. The scaffolding proteins of HSV-1 are encoded by a pair of overlapping genes, UL26 and UL26.5, in which the open reading frame of UL26 is an in-frame N-terminal extension of that of UL26.5. The product of the smaller gene is the abundant scaffolding protein pre-VP22a, while the larger gene encodes a protease precursor, which cleaves itself internally to give the proteins VP24 (protease) and VP21. Temperature-sensitive mutants in UL26 that have an inactive proteinase at the nonpermissive temperature are blocked at the procapsid stage of assembly reviewed in Ref.[216]

A somewhat more complex proteolytic pathway is utilized by the picornaviruses to regulate the release of both structural and replicative protein components from the single polyprotein precursor that is translated from its positive-stranded RNA genome (Fig. 6.12). The initial event in this proteolytic cascade is the primary cleavage in which the P1 structural protein precursor is separated from the P2-P3 precursor. This reaction is catalyzed by the 2A proteinase, which hydrolyzes a Tyr-Gly bond at its own amino-terminus. While cleavage of the P2-P3 region is carried out by the 3C proteinase at Gln-Gly bonds, the efficient cleavage of the structural protein precursor at the VP0-VP3 and VP3-VP1 boundaries is catalyzed specifically by the 3CD precursor that includes the viral polymerase. Cleavage of the P1 precursor appears to be a prerequisite for entry of the capsid proteins into the assembly pathway. The final processing step is cleavage of VP0-VP4 and VP2. This autocatalytic, maturational cleavage occurs late in the assembly pathway and appears to be linked to encapsidation of the viral RNA genome. It is likely that the structural alterations that accompany the cleavage event both stabilize the capsid and irreversibly commit the virus to the conformational changes induced on receptor binding that are necessary for productive infection of cells.[99]

A similar maturational cleavage is required following assembly and envelopment of retroviral capsids. As we have described earlier, the retroviral capsid is assembled from polyprotein precursors that are encoded by the *gag* gene. The viral aspartyl proteinase is encoded by the *pro* region of the genome and is translated from unspliced, genome length RNA by a ribosomal frameshift mechanism as a Gag-Pro or Gag-Pro-Pol precursor protein (see Chapters 48 and 50). The presence of the Gag sequences ensures that this key enzyme is targeted to and incorporated into the assembling capsid. The mechanism by which the protease is activated late in the assembly process (most probably after envelopment is complete) is not known. Since the active enzyme is a homodimer of two protease subunits, it has been postulated that dimerization of proteinase precursors in the nascent capsid might allow a functional enzyme to form. However, in the betaretroviruses, the immature capsid contains a full complement of proteinase precursors, which are not activated until late in envelopment at the plasma membrane. Immature capsids of the betaretrovirus M-PMV are stable when isolated from infected cells, but the protease can be activated to cleave the assembled precursors to their mature products by treatment with the reducing agent dithiothreitol, suggesting that modification of cysteine residues might act to regulate the initiation of proteolysis.[201]

Cleavage of the Gag precursors in the immature capsid is accompanied by a major morphological rearrangement in which the mature NC protein condenses the genomic RNA inside a CA shell (Fig. 6.7)—the electron-dense core structure of the virus seen in electron micrographs.[85] Cleavage at the N-terminus of CA induces a conformational change in the protein that allows an N-terminal β-hairpin loop to form, while cleavage at the C-terminus removes the CA-SP1 six-helix bundle. This disassembly and structural rearrangement of CA redirects assembly from a “spherical” immature capsid to that of the conelike core-shell structure formed by CA hexamers and pentamers.[130,150] Maturational cleavage, as in the case of poliovirus, results in an irreversible commitment to the entry pathway. It prevents a simple reversal of the assembly process and presumably through the formation of the core allows the rearrangement of RNA and the reverse transcriptase into a conformation that is optimal for reverse transcription of the genome. In the absence of cleavage, reverse transcription cannot occur and the virions are noninfectious.[260]

Adenoviruses, like retroviruses, undergo a maturational cleavage after assembly that is essential for infectivity. The immature virions formed after DNA packaging contain five precursor proteins that must be processed before the mature infectious virion is produced. These include components of the core and the preterminal protein (pTP) used to initiate DNA synthesis. The 23-kD adenovirus proteinase, which is encoded by the L3 region of the genome, is inactive in its purified form. It requires an 11 amino acid peptide present at the carboxy-terminus of pVI and viral DNA as cofactors for its activity. This unique use of DNA as a cofactor ensures that proteolytic maturation of the virus cannot take place

until packaging of DNA is complete.[52,145]

Nonproteolytic Maturation Events

Hepatitis B virus particles undergo several postassembly modifications to form infectious particles but, unlike many other virus maturation events, these do not rely of proteolytic cleavage. HBV capsids form around viral RNA, which is then reverse transcribed and replicated to form mature capsids containing the dsDNA genome.[242] The synthesis of dsDNA alters the capsid structure, directing it for envelopment and secretion. Once outside the cell, the HBV envelope protein S antigen undergoes a time-dependent morphological change, altering their membrane orientation to expose the receptor-binding domain.[241] Mature HBV particles bind to heparan sulfate proteoglycans, which are abundant in many tissues. Therefore, this maturation strategy ensures that HBV virions can circulate in the blood long enough to arrive in the liver without being sequestered. Once in the liver, specific environmental conditions seem to promote conversion from immature to mature particles resulting in liver-specific infection.

Role of Viral and Cellular Proteins in Membrane Extrusion

It is clear from the discussions in previous sections that different strategies are utilized by different enveloped viruses to mediate the process of membrane extrusion that we have termed budding. Envelopment by a lipid bilayer fulfills two functions for a virus: it provides a protective outer layer into which can be embedded the necessary machinery for target cell attachment and entry, and, in most cases, it releases the virus into an environment that is topologically equivalent to the exterior of the cell. The strategies used to drive the budding process can be classified into three general mechanisms.[81] In the first, membrane extrusion is driven by envelope glycoproteins alone. This is exemplified by the E protein of the coronaviruses that can induce the release of VLPs in the absence of an RNP. The second strategy is that used by the retroviruses where the capsid precursors, in the absence of the viral glycoproteins, can efficiently induce membrane extrusion and particle release. In this instance, it is hypothesized that the tight interaction between the MA domain of Gag and the lipid bilayer coupled with the force of Gag-Gag interactions in assembly drives the budding process. The third mechanism requires both the glycoproteins and capsid to drive budding. This strategy is used by alphaviruses, which involves interactions between the viral glycoprotein spikes and the assembled capsid, as well as *Flaviviridae* viruses where capsid assembly and budding occur simultaneously. It appears that lateral interactions between the glycoproteins, coupled with cytoplasmic domain-capsid connections, progressively bend the membrane to form the spherical particle.[82]

For all of these mechanisms, the final step of budding, the process of pinching off, requires a membrane fission event. For several viruses, it is now clear that this is a separable event that requires the involvement of both viral and host components. Experiments in HIV showed that deletion of the p6 domain at the C-terminus of Gag results in a block to virus release at the pinching off stage,[90] and it is now understood that diverse retroviruses encode functionally equivalent Gag “late function” or L domains that are required for efficient release of virions.[61,169] Viral L domains fall into three classes based on their characteristic tetrapeptide sequence motifs, Pro-Thr/Ser-Ala-Pro (PTAP, or PSAP), Pro-Pro-X-Tyr (PPXY), and Tyr-Pro-$(X)_n$-Leu (YP$(X)_n$L). In many instances, these viral L domains are functionally interchangeable and can mediate pinching off of the virion even when positioned at different locations in Gag.[199,294] Evidence has accumulated over the past several years that these motifs interact with components of a complex cellular machinery that is used in the biogenesis of an endosomal compartment known as the multivesicular body (MVB). Unlike other mechanisms used by the cell to form and pinch off vesicles into the cytoplasm, this machinery facilitates the pinching off into the MVB of exosomes that have the same topology as virus. This process is mediated by a complex and highly conserved protein network, the ESCRT (endosomal sorting complex required for transport) machinery, which exists in all eukaryotes and consists of 5 hetero-oligomeric complexes (ESCRT-0, ESCRT-1, ESCRT-II, ESCRT-III, and VPS-4).[130,158,283] Components of this complex also appear to be involved in the last stage of cytokinesis, termed abscission, where, as with virus release, a membranous stalk must undergo membrane fission to release the two daughter cells.[32,167] Recent studies have shown that the ESCRT-0 complex functions to concentrate ubiquitinated cargo on endosomal membranes, the ESCRT-I and -II complexes together induce bud formation, while remaining outside the vesicle, and the ESCRT-III complex mediates membrane scission from the cytosolic side of the bud.[286] Mammalian ESCRT-III is formed by charged multivesicular body proteins (CHMPs), a family of structurally related but highly divergent α-helical proteins that has 12 known members in humans.[283]

The initial indication that retroviral budding and this machinery were linked came from the observation that the ESCRT-I component Tsg101 interacted with p6 and that this interaction was dependent on the PTAP motif.[83] A Tsg101 interacting protein, ALIX, which can also interact directly with ESCRT-III, has been shown to interact with the YP$(X)_n$L motif in both equine infectious anemia virus and HIV.[255] The PPXY motif, which was first identified in Rous sarcoma virus, is utilized by several viruses including other retroviruses, filoviruses, arenaviruses, rhabdoviruses, and hepadnaviruses.[158] It plays a key role in recruiting host WW domain–containing proteins of the Nedd4 family, ubiquitin E3 ligases involved in the covalent attachment of ubiquitin to membrane-associated proteins.[231,290] Mono-ubquitination has been shown to direct the modified protein to the MVB and likely functions to link PPXY L-domain proteins to the ESCRT machinery.[169]

In addition to those L-domains that play a major role in virus release, it is becoming clear that in several viruses multiple auxiliary L-domains are present that can augment the process. In HIV-1, for example, there is evidence that the PTAP motif acts synergistically with ALIX-binding sequences at the C-terminus of p6 to optimize release.[147] Through these disparate mechanisms,[147,283] viruses recruit components of ESCRT-III to the site of budding to mediate the process of membrane scission. Only a subset of the 12 proteins known to make up the ESCRT-III complex may be involved since a recent study demonstrated that the codepletion of CHMP2 or CHMP4 family members profoundly impairs HIV-1 release, whereas siRNA knock down of other CHMPs had limited impact.[168]

The ATPase VPS4 (vacuolar protein sorting 4) acts at a late stage of ESCRT function, providing energy for ESCRT dissociation and membrane scission. Live cell imaging studies reveal that ESCRT-III and VPS4 are rapidly and transiently recruited before HIV-1 particle release, supporting the notion that VPS4 has a direct role in this stage of HIV-1 budding.[15,118]

Influenza virus is an exception to this widespread dependence on the ESCRT machinery.[31] Rossman and colleagues showed that for this virus, it is the viral M2 protein, rather than a host component, that mediates virus membrane scission.[224] During morphogenesis, the M2 protein localizes to the neck of budding virions, and a highly conserved amphipathic helix in the cytoplasmic tail appears to mediate a cholesterol-dependent alteration in membrane curvature. Mutation of the amphipathic helix results in failure of the virus to undergo membrane scission

and virion release.[225] Thus, it is possible that viral proteins such as M2 are able to mimic the functions of the ESCRT III machinery by constricting the viral membrane and inducing the scission events required for virus release.

Mechanisms to Facilitate the Release of Nascent Particles

If they are to efficiently travel to an uninfected target cell, viruses face one last hurdle following envelopment and release. This is the need to avoid rebinding to receptors on the producing cell. For viruses such as the ortho- and paramyxoviruses, which utilize sialic acid as a receptor on the cell surface, this problem is circumvented by the incorporation of a receptor-destroying enzyme, a sialidase, which can remove these residues during transit through the secretory pathway. For influenza virus, the neuraminidase is critical for virus release since in its absence nascent virus binds to both the cell surface and other virions in large aggregates.[136]

Retroviruses have similarly evolved mechanisms to facilitate release and thereby reduce superinfection of a cell. Cells infected with one retrovirus are generally resistant to subsequent infection by a second virus of the same receptor class. The presumed mechanism for this viral interference is the synthesis of viral glycoproteins in large excess over the levels that are incorporated into virions with the effect that cellular receptors that are transported to the cell surface are already occupied by their ligand. This results in removal or downregulation of the receptor from the cell surface. For HIV-1 downregulation of the primary receptor, CD4 seems to be crucial since the virus has evolved two additional mechanisms to ensure this. Two of the accessory proteins encoded by HIV, Vpu and Nef, act by binding CD4 in the ER and at the cell surface, respectively, and targeting the receptor for degradation.

Independent of this need to downregulate viral receptors, recent work has demonstrated that virus escape from the cell surface, the last step of the replication cycle, is effectively targeted by a host-cell restriction factor, tetherin (also known as BST2 or CD317). This protein was initially identified as the factor responsible for the block to virion release from certain cell types infected by HIV-1 mutants lacking the accessory gene *vpu*.[17,147,178,271] Tetherin can be induced by type I interferon and other proinflammatory stimuli and has an unusual topology in which the extracellular domain forms an extended parallel coiled-coil that is anchored at the N-terminus by a protein transmembrane domain and at the C-terminus by a glycosyl phosphatidylinositol GPI anchor. Biochemical and structural data favor a model where parallel tetherin dimers cross-link virions to the plasma membrane or the membrane of other virions.[17,147] Tetherin can restrict the release of all retroviral particles tested to date, including those of the spumavirus and betaretrovirus families, which preassemble capsids in the cytoplasm. In addition, mammalian tetherins block release of a variety of membrane viruses including filoviruses, arenaviruses, rhabdoviruses, and at least one herpesvirus.[71,116] In turn, viruses have evolved countermeasures that have allowed them to overcome this inhibition of release. The Vpu protein of HIV-1 is the prototypical antagonist to tetherin and interacts through the transmembrane region to mediate downregulation and lysosomal degradation of the host restriction factor. In the case of SIVs, this function is primarily carried out by the Nef protein, although in some instances, as in HIV-2 or Ebola virus, it can be mediated by the viral glycoprotein.[71] Given the diversity of mechanisms utilized to counteract tetherin, it is clear that this last step of the life cycle is critical to the virus. Indeed, the evolution of primate lentiviruses, particularly pandemic HIV-1, has been shaped by species-specific differences in this host-cell restriction factor.[236]

Cell-Associated and Noncanonical Spread of Infection

In addition to cell-free spread of virus infection that involves release of virions from infected cells, many virus infections are spread through directed processes that limit extracellular exposure.[43] Cell-associated spread provides several advantages for virus infection including limiting neutralization by extracellular immune responses and rapid movement of multiple genomes between cells. This can occur through the secretion of fully formed virions that are specifically targeted to uninfected cells, through secretion of virions in cellular exosomes or through the direct transfer of genetic material between cells without the formation of virus particles.

Several mechanisms have been described for selective targeting of virions to uninfected. Retroviruses utilize the close contact between lymphocyte cells to spread directly between cells through a “virological synapse.” For human T-cell leukemia virus type 1, contact between lymphocytes stimulate a microtubule polarization of the cell, which leads to recruitment of Gag and Env proteins to the cell contact site. This causes a rapid secretion of virus particles that are quickly taken up by the uninfected cell. Virus particles from numerous different species have also been observed to travel between cells along cellular extrusions such as actin tails or filopodia. Once outside the cells, vaccinia virus particles are propelled on virus-induced actin tails toward new cells. Virus infection often increases the formation of cellular filopodia, and filopodia-associated virus particles have been observed in several virus infections including murine leukemia virus (MLV), alphaviruses, and coronaviruses. In the case of MLV, viral particles move along the outside of filopodia to adjacent cells where they are taken up to initiate infection. On the other hand, alphavirus particles move along the interior of filopodia and bud from the tip in close contact to adjacent cells. In each case, virus particles retain cellular contacts or are released in a restricted space that limits the availability for neutralization.

In an alternative strategy for virus spread, several virus infections have been reported to spread directly between cells without the formation of virus particles. These mechanisms rely on the movement of viral genomic material to new cells through cellular channels or on the fusion of infected cells with uninfected cells. Influenza virus proteins and genetic material appear to transit on tunneling nanotubes that normally form channels between adjacent cells to allow cytosolic exchange.[42] Traveling along these intracellular pathways facilitates influenza virus cell to cell spread and genome reassortment. Paralleling this mechanism, measles virus infection leads to the formation of membrane pores between adjacent cells through which viral genomes are directly transferred. Alternatively, virus infections can spread through tissues by fusion of infected cells with uninfected cells to form large multinucleated syncytia. Respiratory syncytia virus, HIV, herpes simplex virus, and coronavirus infections can all lead to cell fusion mediated by the viral envelope proteins.[131] For coronaviruses, the fraction of S protein that localizes to the plasma membrane can interact with cellular receptor proteins on adjacent cells leading to an activation of the spike fusion peptide and subsequent cellular membrane fusion. In SARS-CoV-2 infections, large multinucleated cells are often observed in severe Covid-19 cases leading to the prediction that syncytia formation is involved in viral pathogenesis; however, the precise function of syncytia formation in coronavirus spread or pathogenesis is still poorly understood.

Finally, recent evidence demonstrates that assembled virus particles can be transferred between cells in host-derived extracellular vesicles (EVs). Notably, virions from several nonenveloped viruses are often found in EVs forming quasi-enveloped virus particles that are nonlytically released from host cells.[75] Examples include poliovirus, coxsackievirus, hepatitis A virus (HAV), and hepatitis E virus (HEV).[74,172] For enteroviruses such as poliovirus and coxsackievirus, the formation of virus-containing EVs is linked to the autophagosome secretion pathway.[172] Poliovirus virions are found inside LC3-II positive autophagosome-like double membrane vesicles, which traffic from the cytosol to the plasma membrane

and where the outer membrane fuses with the plasma membrane to release a single membrane EV containing multiple virions.[35] These enterovirus-containing EVs are enriched in phosphatidylserine (PS) lipids, which are thought to act both as a receptor for uptake in uninfected cells and as potent anti-inflammatory molecules. Similar mechanisms of secretion and spread through EVs have been observed for other enteroviruses as well as rotavirus, norovirus, and Zika virus.[235,297] Contrasting enterovirus-containing EVs that are enriched for autophagosome machinery, HAV-containing EVs are smaller, contain fewer virus particles, and have a protein composition comparable to exosomes. HAV budding into EVs is mediated by interactions between the C-terminal pX peptide of the viral VP1 capsid protein and components of the ESCRT machinery.[245,280] Although the site of budding is still unknown, the enrichment of endosomal proteins in HAV EVs argues for intracellular budding into multivesicular bodies followed by release at the plasma membrane.[74] Within infected individuals, HAV-containing EVs are the primary virion form found circulating in the blood.

Similar to other strategies for cell-associated spread, virion-containing EVs can provide efficient transfer of multiple viral genomes to uninfected cells while shielding viral epitopes from neutralizing antibodies. For RNA viruses that often accumulate mutations during replication, infection with multiple virus particles is an important avenue to overcome limiting mutations within individual genomes and decreases the barrier to establishing a productive infection. EVs have also proven more stable in harsh extracellular environments such as the GI tract and can be more resistant disinfectants.[296]

The fate of lipids and their catabolism

Regulation of lipid metabolism

Considerations regarding metabolic studies in virology

Metabolism in the host fight against virus infection

Summary and future outlooks

Acknowledgments

Viruses have evolved as master manipulators of cellular processes. Many examples are documented of viral effects on signaling pathways, stress responses, transcription, translation, innate immunity, and metabolism.[60,72,108,135,144,159] All these virally mediated changes in cellular processes establish a cellular milieu that is supportive of infection. Although host cell metabolism is a key target for viral manipulation, it has been among the last of the major cellular processes to catch the attention of the virology field. However, studies of viral interactions with host metabolism are rapidly increasing in number and revealing fundamental knowledge of virus biology and virus-host interactions. These increases are being accelerated by advances in metabolomics technologies and the availability of metabolic assays, thus lowering the barrier to studying metabolism.

In this chapter, we will present and discuss basic metabolic pathways with a focus on virology, to provide a conceptual framework necessary for any virologist who wants to initiate or interpret metabolic studies of virus-host interactions. But we must be circumspect; while it is easy to believe in the infallibility of the metabolic pathways that have so long been laid out in biochemistry texts, we should only consider them for guidance, not dogma, since metabolism is dependent on so many aspects of the cell, the cell type, and the cellular environment.

Over the past 15-20 years our concepts of metabolism and its mechanisms have changed due to intense studies of cancer metabolism using both cell and animal models.[114,155,195] Indeed, findings in cancer metabolism have challenged many classical views of general metabolism. Cancer metabolism has become an important source of guidance in examining metabolism in virally infected cells. Examples of viral alterations of metabolism that mimic those seen during oncogenesis have been documented.[105,154] However, we must be prudent with this comparison; while many RNA and DNA viruses may alter some of the same metabolic pathways affected during oncogenesis, they may do so by very different mechanisms and for the production of different outcomes. Thus the study of virus-host interactions involving metabolism must mature as a field complementary to, but independent of, cancer metabolism.

The broad term metabolism considers both the breakdown (catabolism) of biomolecules and the building up (anabolism), or biosynthesis, of biomolecules. Catabolism transforms polysaccharides, nucleic acids, proteins, and lipids into their basic subunits, monosaccharides, nucleotides, amino acids, and fatty acids. Nutrients derived from catabolism, or imported from the extracellular environment, can be used in two ways for anabolic metabolism. First, the catabolic products can be oxidized to produce the energy needed for biosynthesis. Second, the basic subunits produced by catabolism can be used to build complex biomolecules. These catabolically produced building blocks supplement those that can be synthesized *de novo* by the cell. These aspects of metabolism, as well as the *de novo* synthetic pathways, provide the basic needs for viral productive infection. Hence, they are potential targets for manipulation during infection.

The metabolic program of a cell reflects the cell's function and its environment, including the controlled coordination between anabolism and catabolism as the cell transitions from quiescence to a proliferative state. It is easy to imagine how an infecting virus may need to activate metabolism in quiescent cells or fine-tune active metabolism in proliferative cells. Viruses need to establish conditions that produce sufficient energy and biosynthetic precursors to maintain the level of biosynthesis that is appropriate to support the success of the infection. These conditions will undoubtedly vary depending on whether the infection is productive, persistent, or latent.

Viruses have proven to be excellent experimental tools for examining the intricacies of the cell, often uncovering aspects of normal cell biology heretofore unknown, or little understood. In this same vein, metabolism studies in virally infected cells will likely provide deeper insight into the complex world of cellular metabolism and the many interconnections between metabolism and all other cellular processes.

In this chapter, we will highlight the basic cellular metabolic pathways of glycolysis, the tricarboxylic acid (TCA) cycle, glutaminolysis, and lipogenesis. We are not going to attempt to review the vast virology literature to exhaustively document viral effects on metabolism. Instead, we will discuss the metabolic pathways in terms of why viruses may want to affect them and at what key points in metabolism these effects would be targeted. Since the study of viral effects on metabolism is still relatively new, we will discuss and speculate on potential ways viruses may manipulate metabolism. We hope to provide thoughts and ideas for future experimentation, a guide to potential mechanisms and targets that should be considered by any virologist with an interest in metabolism. In this regard we will discuss approaches to be considered when planning metabolic studies. In this way we hope to aid the reader in considering metabolism in their viral studies. Since a great amount of our present understanding of metabolism in infected cells comes from studies using herpesviruses, we will highlight these studies and supplement them with findings from other viruses. We will be focusing primarily on mammalian metabolism but will highlight some important differences in viral infection in other host systems, we apologize to the nonanimal virologist for our animal virus centrism; we hope that you still find interesting aspects in the chapter.

We will proceed by considering the basic pathways. For those who are not well founded in metabolism, we will try to go through the pathways in an educational way tailored for virologists and virus studies. For those more familiar with metabolic pathways we find that it never hurts to reacquaint oneself with the pathways, as it often provides new insight. We will start with glycolysis.

Glycolysis

Glycolysis occurs in the cytoplasm and is the process of fermenting (no oxygen is required) a 6-carbon glucose molecule to two 3-carbon pyruvate molecules. Subsequently, the pyruvates can either be converted to lactate, acetate, alanine, or oxaloacetate (OAA) or, alternatively, enter the mitochondrial TCA cycle for further oxidation and ATP synthesis. In Figure 7.1 the glycolytic pathway is shown using the abbreviated names of the glycolytic intermediates between glucose and pyruvate; the full names of each intermediate are in the figure legend. Each reaction is catalyzed by a specific glycolytic enzyme. Some of the glycolytic reactions are reversible, while others are not. Blue bidirectional arrows indicate that the enzyme for that reaction can catalyze both the forward and reverse reactions. Red unidirectional arrows indicate the three glycolytic reactions that cannot be reversed; these enzymes can catalyze only the forward glycolytic reaction because they utilize ATP or involve the hydrolysis of a high-energy bond. The enzymes that catalyze the irreversible reactions are shown in Figure 7.1 because they provide points where glycolysis can be regulated and, therefore, are potential sites for direct or indirect viral effects. This will be discussed below.

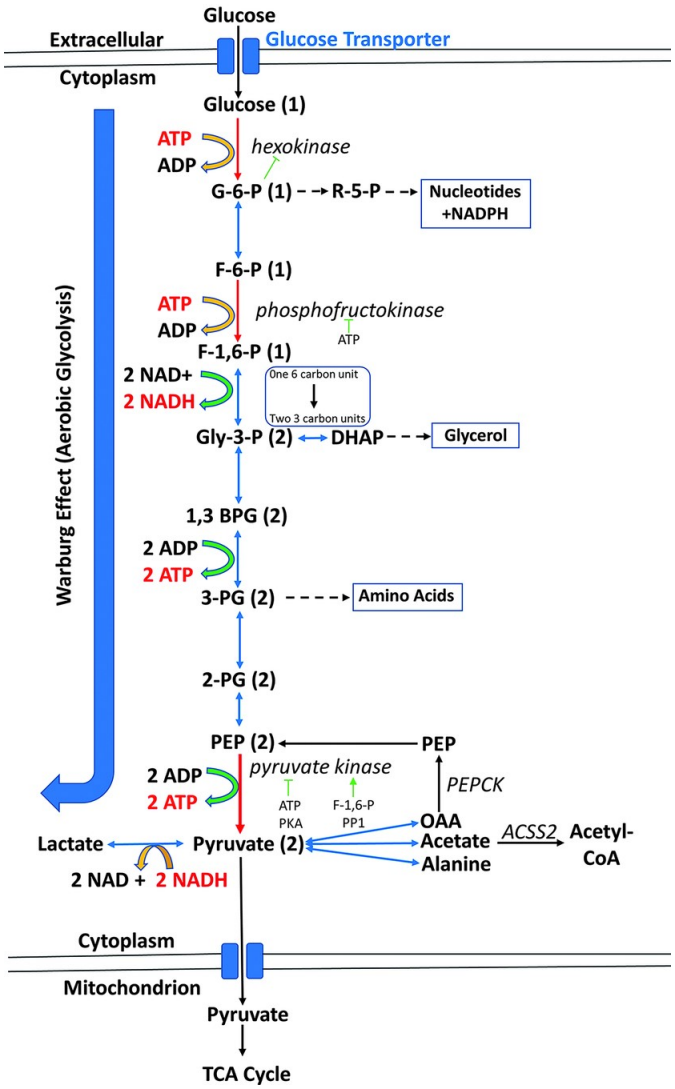

FIGURE 7.1 **The glycolytic pathway**. The steps converting glucose to pyruvate are indicated; each step is catalyzed by a specific glycolytic enzyme. *Blue bidirectional arrows* indicate that the enzyme can catalyze the forward and reverse directions to promote either glycolysis or gluconeogenesis. *Red unidirectional arrows* indicate where the enzyme can catalyze only the forward glycolytic reaction. The enzymes that catalyze the irreversible reactions (hexokinase, phosphofructokinase, and pyruvate kinase) are shown because they are targets for allosteric control or other types of control that modulate glycolytic activity. *Orange arrows* indicate the use of ATP or a reducing equivalent, NADH. *Green arrows* indicate the generation of ATP or NADH. Also shown are the glycolytic intermediates that can be drawn off for use in biosynthetic pathways, these are G-6-P, DHAP, 3-PG, and pyruvate. The *large blue arrow* indicates the Warburg effect or aerobic glycolysis, when the glucose-derived pyruvate is converted to lactate instead of entering the mitochondrion for further oxidation in the TCA cycle (Fig. 7.2). The gluconeogenic enzyme phosphoenolpyruvate carboxykinase (PEPCK) is shown and discussed in the text. The conversion of pyruvate-derived acetate to acetyl-CoA by ACSS2 is shown and discussed in the text. Abbreviations: G-6-P, glucose-6-phosphate; F-6-P, fructose-6-phosphate; F-1,6-P, fructose-1,6-bisphosphate; Gly-3-P, glyceraldehyde-3-phosphate; DHAP, dihydroxyacetone phosphate; 1,3-BPG, 1,3-bisphosphoglycerate; 3-PG, 3-phosphoglycerate; 2-PG, 2-phosphoglycerate; PEP, phosphoenolpyruvate; R-5-P, ribose-5-phosphate; ADP, adenosine diphosphate; ATP, adenosine triphosphate; NAD+, nicotinamide adenine dinucleotide (oxidized); NADH, nicotinamide adenine dinucleotide (reduced); NADPH, nicotinamide adenine dinucleotide phosphate (reduced); OAA, oxaloacetic acid; PKA, protein kinase A; PP1, protein phosphatase 1; PEPCK, phosphenolpyruvate carboxykinase; ACSS2, Acetyl-CoA synthetase short-chain family member 2.

In the process of gluconeogenesis, where glycolysis is reversed to make glucose from pyruvate, the three irreversible glycolytic reactions are catalyzed in the reverse direction by four gluconeogenesis-specific enzymes that are often expressed in a tissue-specific manner. It is not clear if, or why, a viral infection might induce gluconeogenesis. However, the gluconeogenic enzymes may play other roles in the cell which might be important for the viral infection. An example is phosphoenolpyruvate carboxykinase (PEPCK), which converts oxaloacetate (OAA) into phosphoenolpyruvate (PEP) (Fig. 7.1). PEPCK activity is greatly increased in human cytomegalovirus (HCMV)-infected fibroblasts,[18] suggesting that it may be used to convert cytoplasmic OAA to PEP (Fig. 7.1). However, PEPCK has another function; it activates the mechanistic target of rapamycin complex 1 (mTORC1) and this increases glycolysis.[98] HCMV infection dramatically increases mTORC1 activity and protects it from stress-induced inhibition[14,23-25,135]; thus PEPCK may be induced in HCMV infections to aid in mTORC1 activation. While this remains to be proven, the important consideration is that many of the metabolic enzymes may have other functions in the cell that may be important for viral infections. Another important point to consider is that the virally induced forms of metabolic enzymes may be tissue-specific isoforms that are not generally expressed in the infected tissue.[102] Their induction during infection may provide special functions or abilities that aid in the viral life cycle. We will return to the induction of tissue-specific isoforms when we discuss glucose transporters.

Returning to glycolysis, we can see in Figure 7.1 that it both uses and synthesizes ATP, as well as the reducing equivalent, NADH. NADH and its

oxidized counterpart NAD+ are co-enzymes used for either oxidation or reduction in many metabolic redox reactions, and they are needed for productive viral infections. Orange arrows indicate the use of ATP (ATP to ADP) or NADH (NADH to NAD+) in the ***forward glycolytic reactions, that is, glucose to pyruvate***. If the reaction can be reversed the opposite would occur (ADP to ATP or NAD+ to NADH). Green arrows indicate the generation of ATP (ADP to ATP) or NADH (NAD+ to NADH) in the forward reaction. Comparing the use and synthesis of ATP and NADH, we see that when one molecule of glucose is converted to two molecules of pyruvate there is a net gain of two ATPs and two NADHs. But there is so much more to this story.

Biosynthetic Pathways Using Glycolytic Intermediates

Not all of the glucose completes the pathway to pyruvate. Several glycolytic intermediates can be drawn off into important biosynthetic pathways. The products can be quite important during a productive viral infection:

1. *G-6-P (glucose-6-phosphate)* is converted to R-5-P (ribose-5-phosphate) in the pentose phosphate pathway that leads to nucleotide synthesis supporting cellular and viral RNA and DNA synthesis. Additionally, an important product of this pathway is the production of NADPH, another very important reducing equivalent used in many biosynthetic reactions, especially lipogenesis, which will be discussed in detail later in the chapter.

2. *Gly-3-P (glyceraldehyde-3-phosphate) and DHAP (dihydroxyacetone phosphate)* are the 3-carbon units that are produced by the breakdown of the 6-carbon F-1,6-P (fructose-1,6-phosphate). Gly-3-P and DHAP are easily interconverted. The important point is that DHAP can be drawn off for the synthesis of glycerol for lipid synthesis.

3. *3-PG (3-phosphoglycerate)* can be drawn off for the synthesis of nonessential amino acids (NEAAs), including l-serine. Besides its use as an amino acid, l-serine is a precursor for many other amino acids and metabolites, such as glycine, cysteine, tryptophan, phosphatidyl l-serine, sphingolipids, purines, porphyrins, glyoxalate, and glycine.

4. *Pyruvate* can be converted to alanine, lactate, acetate, and oxaloacetic acid (OAA) instead of entering the mitochondrial TCA cycle. As it turns out, all of these metabolites can be useful in productive viral infections. The conversion of pyruvate to acetate will be discussed further below since it is known to be used during HCMV infection.[167]

All of the products of glycolysis and its associated biosynthetic pathways (ATP, NADH, NADPH, nucleotides, glycerol, NEAAs, pyruvate, lactate, acetate, and OAA) are important for productive viral infections. Hence it is not difficult to see why glycolysis and its associated pathways are activated during infection by many viruses.[44,71,105,117,128] One of the first global analyses of metabolic flux, using ^{13}C-labeled glucose and mass spectrometry, examined glycolysis and the TCA cycle in cells infected with HCMV, a herpesvirus.[102,103] These data definitively showed that HCMV infection increased the uptake of glucose and increased glycolytic flux compared to mock-infected cells. In other words, labeled glucose was more rapidly converted into labeled glycolytic intermediates in HCMV-infected cells than in mock-infected cells. The data also suggested that the biosynthetic pathways using glycolytic intermediates are altered in infected cells: (1) Ribose-5-phosphate conversion into nucleotides was upregulated; (2) the intracellular pool of DHAP was increased, suggesting increased production of glycerol; (3) the intracellular pool of 3-PG was not dramatically increased, which left no clear prediction of whether this pathway to NEAAs was upregulated; (4) a significant amount of pyruvate was converted to alanine. However, an even greater amount of pyruvate was converted to lactate, a finding that we will discuss below. Additionally, a significant portion of the pyruvate entered the TCA cycle. In summary, these glycolytic flux data suggested that HCMV infection targets glycolysis and its associated biosynthetic reactions, and alters them to the advantage of the productive infection.

A Diversity in Metabolic Profiles

Several studies have found that related viruses may have widely divergent effects on the host metabolic profile, suggesting that virus-host metabolism interactions may be unique to each virus. Similar metabolic flux studies as described above for HCMV were done using a different herpesvirus, herpes simplex type 1 (HSV-1).[45,163] HSV-1 promotes the flow of carbons from glucose and glutamine to nucleotide synthesis,[45,163] while HCMV directs glucose towards lipid synthesis.[103,119,167,181,190] In another striking contrast, HCMV replication depends on argininosuccinate synthetase 1 (ASS1), but its enzymatic activity limits HSV-1 infection.[45] ASS1 pulls carbon and nitrogen atoms towards arginine synthesis and the urea cycle, limiting their flow to pyrimidine synthesis.[45] These observations suggest that nucleotide synthesis is a rate-limiting factor for HSV-1 infection but not HCMV. These studies in HSV-1 and HCMV were performed in lytic models and it is unknown how latent infection would influence metabolism. Further, Epstein-Barr virus (EBV) and Kaposi sarcoma herpesvirus (KSHV)—both gamma herpesviruses—alter host metabolism in ways that are also distinct from HCMV and HSV-1.[75] However, in comparing these studies we must consider the context in which these experiments were done. The metabolic effects of some herpesviruses, particularly the γ-herpesviruses, have mostly been studied in the context of latency. Latent γ-herpesviruses cause cancers, and oncogenesis requires host metabolic barriers that may limit proliferation to be overcome.[53,93] Some of the metabolic alterations are similar to metabolic profiles that happen in some cancers from nonviral etiology (eg, increase in aerobic glycolysis[11,31] and lipid synthesis,[32,171] and mitochondrial metabolism[127,170]). However, in one study of lytic replication of KSHV, infection one study of lytic replication of KSHV, infection promotes glycolysis similar to HSV-1 and HCMV infection, and enhances glutamine dependence and lipid metabolism like HCMV infection.[129] This highlighted work from the herpesvirus family demonstrates that the virus-host metabolism interaction is dependent on the virus, the cell type, and the type of infection (latent, persistent or productive).

It is important to remember that metabolic alterations that occur in virally infected cells reflect the natural history of both the virus and the host cell. Not only can related viruses have differing effects on metabolism, but cell types from the same host also have very different metabolic phenotypes. To highlight this point, consider how different tissues found in the human body have specialized metabolism. For example, while most cell types cannot make glucose from noncarbohydrate sources, hepatocytes can perform gluconeogenesis to produce glucose that can be distributed to other tissues.[153] In the brain, metabolism is partitioned by cell type reducing the competition for nutrients: neurons use glucose whereas other cells types in the brain consume lipids to generate energy.[66] Moreover, different cell types in the brain have intersecting metabolic networks. Astrocytes produce lactate that is released into the extracellular environment where neurons can import it to be fully metabolized via the TCA cycle after converting it to pyruvate.[86] This demonstrates that metabolism *in vivo* is a coordinated activity. During times of high energy demand, muscle cells will break down glycogen to lactate. The released lactate can be used to generate new glucose in the liver through gluconeogenesis, another example that tissues have coordinated metabolic activities. In the immune system different subtypes of T cells, B cells,

and macrophages have specialized metabolic profiles that are integral to their functions.[42,125,162]

It is important to remember that metabolism is also regulated by external signals including the nutrient environment that can be continuously changing in the body. As virologists, it is important to consider that not all cell types, especially in a given environment, will have metabolic phenotypes that are described in textbooks. Thus, continued studies of viruses, even related viruses, in relevant cell types are needed to understand how each virus uniquely interacts with host metabolism.

Controls of Glycolysis that may be Exploited by Viral Infections

Glycolysis, indeed, all the metabolic pathways in the cell, can be controlled at many levels.

Metabolic enzymes can be controlled at the transcriptional level by cell signaling pathways that may activate or inactivate transcription factors. Many of these signaling pathways are affected by growth factors. Viruses routinely alter aspects of cell signaling. Thus the effects that any specific virus has on growth factors and signaling must be considered for their potential effects on the metabolic transcriptome. These results can be correlated to metabolism and specific metabolic activation mechanisms predicted.

The ability of growth factors and their receptors to induce new transcription and translation led to the hypothesis that demands of cell growth were met through the replacement of nutrients as they are consumed during macromolecular synthesis, a demand-based system of nutrient uptake. However, this mechanism has been challenged.[156] There is increasing evidence from the cancer metabolism field to suggest a “supply side” mechanism where nutrient uptake is a “push mechanism.” In other words, there is direct stimulation of nutrient uptake in which growth factor signaling increases the uptake of glucose, lipids, and amino acids to levels that *exceed* a cell’s needs. This creates a pro-growth nutrient environment, which, together with signaling, can then push cells to grow. Under these conditions, adaptive changes in metabolism lead to the accumulation of anabolic precursors for the synthesis of protein, lipids, and nucleic acids. For some oncogenic viruses, metabolic alterations due to virus infection can help push cell growth and transformation. The metabolic changes that favor cell growth and oncogenesis may also stimulate virus replication as is the case for hepatitis C virus (HCV) or, alternatively, it may be independent of virus replication as is the case for EBV and KSHV, where the latent infection leads to changes in metabolism and oncogenesis.[118] A supply-side stiumlation of cell growt supply-side stimulation of cell growth could be an ideal mechanism to be exploited during viral infection to meet or exceed the energetic and biosynthetic needs of the infected cell. This may be particularly true for a virus with a very rapid productive lytic cycle. As an example of how a virus can attain nutrient excess to create a “pro-growth” state, let’s return to glycolysis and consider glucose uptake.

To initiate glycolysis, glucose must be brought into the cell. Figure 7.1 shows that this is accomplished by glucose transporters (GLUTs) located in the plasma membrane. GLUTs carry hexose sugars across the membrane without requiring energy. In eukaryotes GLUTs constitute a family of at least 13 members in three structural classes: GLUT1–4 (class I); GLUT5, 7, 9, and 11 (class II); and GLUT6, 8, 10, 12, and (H+)-myo-inositol cotransporter (class III).[70,160] Many of these are tissue specific or function best under specific conditions. Class I GLUTs are the best characterized, and for this discussion, we will consider two of them, the ubiquitously distributed GLUT1, which is abundant in fibroblasts, and GLUT4, which is very efficient and is the major GLUT in adipose tissue, skeletal muscle, and cardiac muscle.[62,76,100] During HCMV infection in fibroblasts, GLUT1 is quickly decreased to nearly undetectable levels and is replaced by the more efficient GLUT4, which is normally not detectable in fibroblasts.[189] This is mediated by the repression of GLUT1 gene transcription and activation of GLUT4 gene transcription. Thus the virus induces a more efficient transporter, but one that is not usually present in this cell type. The use of tissue-specific isoforms to support viral infections is a recurring theme as discussed above with respect to glycolysis. The evidence suggests that HCMV induces a tissue-specific isoform, GLUT4, that provides greater glucose uptake for the infected cell. It is an example of how supply-side stimulation can be accomplished, where the viral infection takes action to ensure increased nutrient uptake, making certain that levels meet or exceed the infected cell’s needs.

Protein modification is another way to affect the activity of metabolic enzymes. Activation of signaling pathways, or cell stress responses, induce kinases, phosphatases, and other protein modification enzymes. These enzymes modify metabolic enzymes to change their activity. A good example from glycolysis is pyruvate kinase (Fig. 7.1), which can be inactivated when phosphorylated by protein kinase A (PKA), and activated when dephosphorylated by phosphoprotein phosphatase 1 (PP1). Such enzymes can be influenced by many cellular signals and growth conditions affected by viral infection. The manipulation of such protein modification mechanisms during a viral infection provides another potential means for viral intervention in metabolic control.

Allosteric Regulation

Allosteric regulation is a very important concept in enzymology that is not always considered in virological studies, but we should consider why viruses might manipulate allosteric regulation in metabolism.

Many enzymes are regulated by the binding of an effector molecule at a regulatory site on the enzyme. The result of this binding is a conformational change in the enzyme that alters the enzyme’s activity. Effector molecules can activate or inhibit the enzyme’s activity. Allosteric regulation is a major means of controlling metabolic pathways; it also affects enzymes in nonmetabolic reactions, for example in cell signaling.[109,139]

Effector molecules are usually small molecules like ATP or a pathway-associated metabolite. Consider a metabolite in a metabolic pathway that is accumulating because it is not being readily used in the next step of the pathway. In order to slow this accumulation, the metabolite functions as an allosteric inhibitor of the enzyme that produces it. When the metabolite reaches a specific concentration, it can effectively bind the enzyme and change the enzyme’s conformation, inhibiting its enzymatic activity. This will slow the production of the metabolite and relieve its accumulation. Once the concentration of the metabolite decreases to a more homeostatic level, the allosteric inhibition is relieved and enzymatic activity returns. This is an example of feedback inhibition: the product of the reaction feeds back and controls the enzyme producing it. There are also examples of feedforward controls; examples of both feedback and feedforward controls will be discussed below.

It is important to keep in mind that allosteric controls can greatly activate or inhibit an enzyme without changing the amount of the enzyme in the cell. Thus, higher activity does not *necessarily* mean increased levels of the enzyme, and decreased activity does not *necessarily* mean lower levels. In most virology studies, it is routine to determine transcript and protein levels for a specific enzyme and correlate this with activity. In many cases this leap of faith is acceptable, but it may not be if the enzyme is allosterically controlled. For example, if one found that the level of an allosterically controlled enzyme decreased during a viral infection, one *could not* conclude that there would be less enzyme activity. Under the right allosteric conditions, the lower amount of enzyme may be capable of a great deal of enzymatic activity. Conversely, a high amount of

enzyme may have little activity under the influence of an allosteric inhibitor. At some point in the study of metabolic enzymes, the true enzymatic activity should be determined.

Allosteric Regulation of Glycolysis

The concept of allosteric regulation can be well demonstrated by its role in the regulation of glycolysis. As we discussed earlier, there are three irreversible reactions in the glycolytic pathway; these are the points of allosteric control. Figure 7.1 shows the three enzymes involved in these reactions: hexokinase, phosphofructokinase, and pyruvate kinase. Let's look at the allosteric control of each.

1. *Hexokinase* catalyzes the phosphorylation of glucose forming glycose-6-phosphate (G-6-P). It is controlled by feedback inhibition by the product of the reaction, G-6-P. If G-6-P levels increase because it is not being rapidly utilized in glycolysis or the pentose phosphate pathway, it will feedback and inhibit hexokinase, thereby allosterically inhibiting its production.

2. *Phosphofructokinase* (PFK) catalyzes the conversion of fructose-6-phosphate (F-6-P) to fructose-1,6-bisphosphate (F-1,6-P); it is considered the most important regulatory step in glycolysis. While the enzyme utilizes ATP it is also allosterically inhibited by ATP. Recall that ATP is a valuable product of glycolysis; thus it would be wasteful to overproduce ATP if it was not being used by the cell. What better way to avoid overproduction than by having the levels of ATP be sensed, allosterically, by PFK, slowing its activity and inhibiting glycolysis? Conversely, when ATP utilization is high, ADP, AMP, and inorganic phosphate (Pi) accumulate signaling the need for more ATP. Thus increased ADP and AMP counteracts the inhibition of phosphofructokinase by ATP, resulting in increased glycolysis. More broadly, the enzyme is being controlled by the cell's energetic environment. It senses the cellular ATP/ADP and ATP/AMP ratios; when the ratios are high, PFK activity is reduced, and when it is low, PFK activity is increased.

3. PFK is also allosterically inhibited by phosphoenolpyruvate (PEP), one of the last metabolites in the glycolytic pathway, just before pyruvate (Fig. 7.1). If PEP is accumulating at the end of the pathway it can feedback to control PFK at the beginning of glycolysis and turn down the entire pathway. Thus, PFK controls glycolysis allosterically by sensing not only the energic status of the entire cell but also the abundance of glycolytic metabolites.

4. *Pyruvate kinase* catalyzes the conversion of PEP to pyruvate with the production of ATP. It is allosterically inhibited by ATP, another example of an enzyme sensing the energetic environment of the cell. It is allosterically activated by F-1,6-P, an early metabolite in glycolysis. If F-1,6-P accumulates, it allosterically activates PK at the end of glycolysis, thus increasing the activity of the entire glycolytic pathway. This exemplifies a feed-forward allosteric mechanism.

The important point of this discussion, besides explaining allosteric controls, is that allosteric effects on enzymes have been little considered as a means of viral control. Yet a viral mechanism that alters allosteric controls may provide a great advantage for a viral infection. Viruses may have evolved means to block unwanted allosteric controls or enhance advantageous ones. Many viruses alter the compartmentalization of the infected cell, potentially protecting specific enzymes from allosteric inhibition or exposing them to advantageous allosteric activation.

Aerobic glycolysis, the Warburg effect

It is important to consider that the glucose flux analysis in HCMV-infected cells discussed above[102,103,163,172] showed that a significant proportion of the glucose-derived pyruvate was converted to lactic acid. Nearly a century ago, Otto Warburg observed that rapidly proliferating tumor cells consumed much more glucose than did most nontransformed tissues,[172] a condition now known as the Warburg effect or aerobic glycolysis (Fig. 7.1, large blue arrow). The conversion of glucose to lactate via pyruvate requires no oxygen; it is a fermentation reaction, and fermentation usually occurs under anaerobic conditions. The term aerobic glycolysis implies that the fermentation to lactate is occurring in the presence of abundant oxygen, specifically, at oxygen levels sufficient to support oxidative phosphorylation in the mitochondrion. If, instead of being converted to lactate, the pyruvate had entered the mitochondrion to enter the TCA cycle and oxidative phosphorylation, than much more ATP would have been produced from the original glucose molecule. This was the confusing aspect of the Warburg effect/aerobic glycolysis: why was the glucose not used to its full potential for ATP production in oxygenated, proliferating cells with an intact mitrochondrial functions? This question remains an important topic of study in cancer biology, normal cell biology, and now virology.

The other problem presented by aerobic glycolysis is the production of lactate, which must be secreted in order to maintain intracellular pH. Hence it was considered a waste product, and, again, a waste of the energy potential glucose could have supplied. It was thus confounding when it was discovered that aerobic glycolysis is actually a hallmark of proliferative metabolism in metazoan cells, not just a phenomenon of cancer cell proliferation.[84] This led many to consider that mitochondrial metabolism, the TCA cycle, and oxidative phosphorylation might not be as important for cell proliferation as previously supposed. This question remains, although more recent studies have shown that proliferative cells and tumor cells do increase flux through the TCA cycle, generating metabolites essential for biosynthesis.[36,131] Further, it was found that lactate can be taken up by many cell types, converted back to pyruvate, and used to fuel the TCA cycle in tumor cells as well as normal cells.[37,64] Given these findings, one can speculate that some viral infections may take advantage of the same processes. Excessive glycolysis leads to lactate production; the lactate is secreted to maintain intracellular pH but acidifies the infected cell microenvironment. This may aid in immune evasion and prepare surrounding cells for infection through uptake and utilization of lactate.

While the importance of both aerobic glycolysis and the TCA cycle could be established for proliferative cells, the question that arises is what is the division of labor between aerobic glycolysis and the TCA cycle. One possibility is that rapid aerobic glycolysis may be able to produce most of the ATP needed for rapid proliferation or viral infection,[99] leaving the major function of the TCA cycle to be the production of biosynthetic intermediated (discussed below) and not a major source of ATP. To make this mechanism successful, some ATP-expensive cellular processes may have to be curtailed. Many tumor cells dedifferentiate, thereby curtailing ATP-expensive processes, relieving the demands for ATP produced by aerobic glycolysis. In this regard, many viruses curtail cellular processes; for example, host shutoff mechanisms used by many viruses curtail the energy needs for host mRNA translation.[144] Additionally, some cells seem to survive and heal while dependent on aerobic glycolysis. After brain injury astrocytes inhibit the TCA cycle and initiate an aerobic glycolysis-like response as a restorative measure.[141] This is believed to be a protective mechanism to mitigate the oxidative damage that may result from reactive oxygen species (ROS) produced during mitochondrial oxidative phosphorylation. Perhaps viruses use a similar strategy; by relying on aerobic glycolysis rather than oxidative phosphorylation for ATP they limit the potential harmful effects of high levels of ROS on virus replication. This is a reasonable assumption since many viral infections increase aerobic glycolysis.[105,128,179,188] Many viruses, especially rapidly replicating ones, may rely completely, or in large part, on activated

aerobic glycolysis for their ATP needs under conditions of adequate glucose or glycogen availability. Thus leaving the TCA cycle to produce biosynthetic intermediates, possible utilizing glutamine instead of glucose (discussed below). Thus in virally infected cells showing increased aerobic glycolysis, the status of, or function of, the TCA cycle and oxidative phosphorylation should be determined. This will provide a more complete picture of how cellular metabolism has been altered to establish the energetic and biosynthetic milieu needed for the specific viral infection.

Finally, we are left with an intriguing question: Is there any virus that can rely completely on aerobic glycolysis to support its infectious cycle in the complete absence of the TCA cycle and oxidative phosphorylation? Recall that all of the products of glycolysis and its associated biosynthetic pathways (ATP, NADH, NADPH, nucleotides, glycerol, NEAAs, pyruvate, acetate, and OAA) are important for energy production and many aspects of biosynthesis. Is aerobic glycolysis, combined with other non-TCA/oxidative phosphorylation metabolic pathways, sufficient? It will be interesting to find out.

The Tricarboxylic Acid cycle

The TCA cycle (Fig. 7.2), also known as the citric acid cycle or the Krebs cycle, is a cyclic set of biochemical reactions that occur in the mitochondria. When glycolysis-derived pyruvate enters the mitochondrion, through the mitochondrial pyruvate carrier (MPC), it is converted to acetyl-coenzyme A (acetyl-CoA) by the pyruvate dehydrogenase multienzyme complex (PDH). At that point, the TCA cycle initiates when the two carbons of acetate from acetyl-CoA are combined with the four carbons of oxaloacetate (OAA) to form the six-carbon citrate molecule (Fig. 7.2).

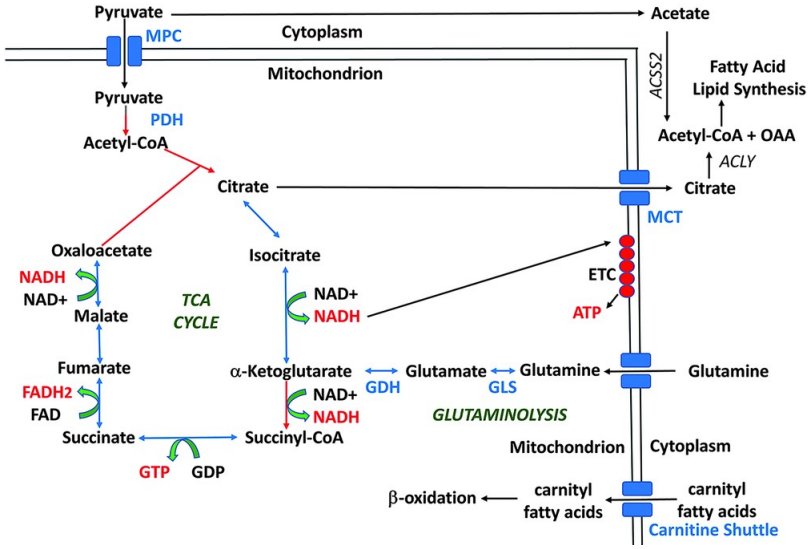

FIGURE 7.2 **The tricarboxylic acid cycle (TCA cycle)**. Glycolysis-derived pyruvate enters the mitochondrion through the mitochondrial pyruvate carrier (MPC) where it is converted to acetyl-coenzyme A (acetyl-CoA) by pyruvate dehydrogenase (PDH). The TCA cycle follows; all of the intermediates are shown; each reaction is catalyzed by a specific enzyme; irreversible reactions are shown by *red unidirectional arrows*, and reversible reaction are indicated by *blue bidirectional arrows*. The generation of reducing equivalents (NADH and FADH2) or GTP is shown by *green arrows*. All of the reducing equivalents can be used in the electron transport chain (ETC) for ATP production. Also shown is the transport of citrate from the mitochondrion to the cytoplasm by the mitochondrial citrate shuttle (MCS). In the cytoplasm citrate is converted into acetyl-CoA and oxaloacetate (OAA) by ATP-citrate lyase (ACLY). Also shown is the formation of acetyl-CoA from pyruvate-derived acetate by acetyl-CoA synthetase short-chain family member 2 (ACSS2). The steps of glutaminolysis indicate where glutamine is brought into the mitochondrion and converted to α-ketoglutarate by glutamine synthetase (GLS) and glutamate dehydrogenase (GDH).

Acetyl-CoA and Citrate

We should give some special consideration to acetyl-CoA and citrate because they define a critical branchpoint in the TCA cycle. Acetyl-CoA is the essential acetyl group donor in posttranslational acetylation reactions of proteins and other biomolecules; in addition, it is the source of acetyl groups for lipid synthesis. Thus acetyl-CoA is used in many parts of the cell. The problem is that mitochondrial acetyl-CoA cannot be exported from the mitochondria; however, citrate can be exported via the mitochondrial citrate shuttle (MCS, Fig. 7.2). There is an advantage and a disadvantage to this transport of citrate. The disadvantage is that a key metabolite for the TCA cycle is being removed and the forward progress of the TCA cycle is diminished; below we will discuss how this can be counteracted through the metabolism of glutamine. The advantage of the transport is that in the cytoplasm the citrate can be converted back to acetyl-CoA and OAA by ATP-citrate lyase (ACLY), providing cytoplasmic acetyl-CoA (Fig. 7.2).

Many studies have suggested that ACLY is the primary enzyme involved in making cytosolic acetyl-CoA.[7,56] However, it is important to note that there is another enzyme, acetyl-CoA synthetase short-chain family member 2 (ACSS2), that can make acetyl-CoA using free acetate (Figs. 7.1 and 7.2). Besides its important role in forming cytoplasmic acetyl-CoA, ACSS2 can also be transported to the nucleus where its acetyl-CoA synthetic activity can exert control on histone acetylation and, consequently, gene expression.[96] Clearly, control of this enzyme may be very important during a viral infection. In fact, it has been shown to be very important for HCMV infection.[178] ACLY and ACSS2 are both activated to produce acetyl-CoA for lipogenesis during HCMV infection. Interestingly, ACLY could be knocked out with no effect on lipogenesis or HCMV growth. Under these conditions, ACSS2 compensated for the loss of ACLY. Thus the viral infection can rely heavily on free acetate for acetyl-CoA synthesis. Free acetate has an important role in maintaining energy homeostasis in mammals, and it is known to be an essential carbon source for lipogenesis in cancer cells under stress conditions.[91,132] The sources of free acetate are many: it can be derived exogenously from foods or produced by the gut flora, it can be produced from ethanol metabolism, and it can be derived through the deacetylation of acetylated proteins

and acetylcholine, and through fatty acid β-oxidation. The latter two mechanisms could be exploited by viral infections for acetate production. Importantly, it had long been thought that there was no cellular metabolic mechanism for the production of acetate directly from glucose. However, in the HCMV study,[167] it was shown that glucose-derived pyruvate could be converted to free acetate and this mechanism was used in the infected cells. There are both a nonenzymatic[167] and an enzymatic means of performing this conversion.[83] Clearly, viruses that need an abundance of acetyl-CoA may be able to induce either of these mechanisms to allow ACSS2 to produce acetyl-CoA from acetate in the cytoplasm or the nucleus.

Besides a nuclear localization of ACSS2, it is important to note that PDH, the enzyme that produces mitochondrial acetyl-CoA, can also be found in the nucleus where it is also believed to provide acetyl-CoA for histone acetylation.[147] Although effects of viral infection on nuclear PDH or nuclear ACSS2 have not been examined, it is certainly intriguing to consider that a viral infection might manipulate the nuclear production of acetyl-CoA by either of these enzymes.

Reducing equivalents and oxidative phosphorylation. Let's return to the mitochondrion and think about the citrate that remains in the TCA cycle. The next step is its conversion to its isomer, isocitrate. This reaction is followed by two oxidative decarboxylation steps. First, the six-carbon isocitrate is converted into the five-carbon α-ketoglutarate and, second, to the four-carbon succinate unit in succinyl-CoA. The results of these reactions are the release of two molecules of CO_2 and the generation of two molecules of NADH.

The production of NADH marks the beginning of an important function of the TCA cycle, supplying reducing equivalents, redox factors, for the production of ATP by the electron transport chain (ETC) (Fig. 7.2). The ETC is a series of reactions that occur in the mitochondrial inner membrane. They are collectively known as oxidative phosphorylation, whereby the transport of electrons through the ETC generates a proton gradient across the inner mitochondrial membrane. The potential energy stored in the mitochondrial proton gradient is harnessed by ATP synthase to phosphorylate ADP to make ATP using oxygen.

All of the reducing equivalents made in the TCA cycle (NADH and FADH2, Fig. 7.2) can be utilized in oxidative phosphorylation in the ETC for ATP synthesis. The production of reducing equivalents in the TCA cycle continues in the reactions that follow from succinyl-CoA (Fig. 7.2). Succinyl-CoA is converted to succinate—producing CoA and GTP. The GTP can be converted to ATP without the loss of energy. The succinate is converted to fumarate with the production of flavin adenine dinucleotide (FADH2), another redox cofactor used by the ETC. In the final steps, fumarate is converted to malate and malate to OAA with the production of more NADH for oxidative phosphorylation. If we consider that all of the possible NADH and FADH2 molecules are produced in the TCA cycle from the two glycolysis-derived pyruvate molecules, then oxidative phosphorylation will generate 26 ATP molecules just from the reducing equivalents. This is why we made such a big deal about the apparent inefficiency of aerobic glycolysis; all of this ATP from oxidative phosphorylation would be lost. Again we must consider our above discussion, that high levels of ROS produced by oxidative phosphorylation may be too deleterious for some cellular and viral conditions. As mentioned above, the status and the importance of the TCA cycle and oxidative phosphorylation must be considered and determined on a virus-specific basis for it may vary greatly between different virus families and even between different viruses within a family.

Glutaminolysis

In the discussion of aerobic glycolysis, we noted that a consequence of converting glucose-derived pyruvate to lactic acid is that it lowers the amount of pyruvate that enters the mitochondrion, thus depriving the TCA cycle of glucose-derived carbon for the production of ATP. Similarly, the removal of citrate from the mitochondrion deprives the TCA cycle of an essential metabolite and again removes glucose-derived carbon from the cycle. Additionally, other TCA cycle metabolites can also be removed from the mitochondrion for a variety of purposes.[90] Each removal causes a loss of TCA cycle activity and reduced ATP production. However, there is a way to compensate by using exogenous glutamine, the most abundant amino acid in the body, and the second greatest source of carbon. As shown in Figure 7.2, glutamine can enter the mitochondrion where it is converted to glutamate by glutaminase (GLS) and glutamate to α-ketoglutarate by glutamate dehydrogenase (GDH). The resulting α-ketoglutarate then enters the TCA cycle. Thus glutamine fills the TCA cycle with glutamine-derived carbon to replace the lost glucose-derived carbon. The filling of a pathway in this way is called anaplerosis.

A number of viral infections are known to anaplerotically use glutamine to maintain the TCA cycle,[12,18,39,77,128,129,137] compensating for pyruvate being used in aerobic glycolysis and citrate being siphoning off for lipogenesis. For example, human cytomegalovirus is very dependent on glutaminolysis due to its upregulation of lipogenesis.[18]

The obvious use of glutaminolysis-derived α-ketoglutarate is for it to be converted to succinyl-CoA to continue the TCA cycle, thus supplying downstream TCA cycle intermediates and reducing equivalents for ATP synthesis. However, recall that the TCA cycle reactions that convert citrate to α-ketoglutarate (Figs. 7.2 and 7.3), catalyzed by aconitase 2 and isocitrate dehydrogenase 2, are reversible. Thus in the reverse reactions, α-ketoglutarate derived from glutamine could be converted back to citrate to support cytoplasmic acetyl-CoA production and lipogenesis. Importantly, this conversion of α-ketoglutarate to citrate can also be accomplished in the cytoplasm using cytoplasmic isoforms of the enzymes, aconitase 1 and isocitrate dehydrogenase 1 (Fig. 7.3). It is important to consider that this use of α-ketoglutarate, in either the mitochondrion or the cytoplasm, would be an ideal point for manipulation by a viral infection that requires increased lipogenesis, especially under conditions where aerobic glycolysis is depriving the TCA cycle of glucose-derived pyruvate.

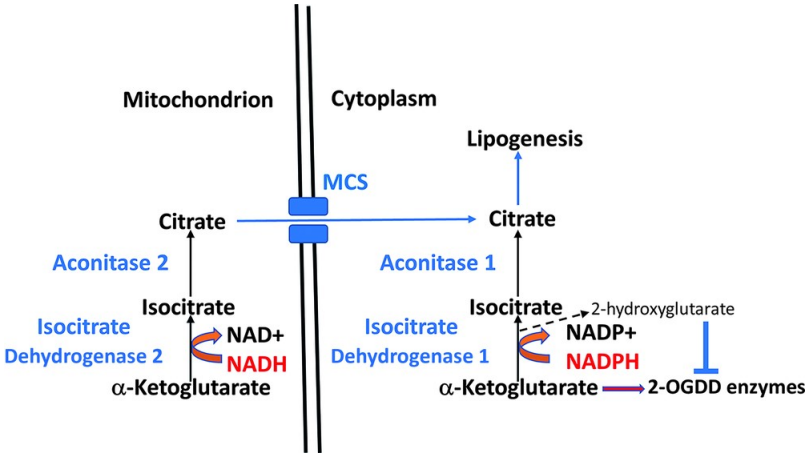

FIGURE 7.3 **The formation of citrate from α-ketoglutarate in either the mitochondrion or the cytoplasm**. Specifics are discussed in the text.

The α-ketoglutarate (also called 2-oxoglutarate) derived from either glutamine or glucose is important in a number of other cellular functions that may be important for viral infection.[90] For example, α-ketoglutarate is a co-substrate for 2-oxoglutarate-dependent dioxygenases (2-OGDDs).[67] The 2-OGDDs are a group of enzymes that catalyze hydroxylation reactions through the conversion of α-ketoglutarate to succinate. The 2-OGDDs have many substrates, including proteins, nucleic acids, and lipids. Importantly, α-ketoglutarate is a key modulator of the hypoxic response. Specifically, the prolyl-hydroxylases that regulate hypoxia-inducing factor-1α (HIF-1α), through proline hydroxylation, are 2-OGDD enzymes.[40] Further, α-ketoglutarate is a required substrate of some chromatin-modifying enzymes; thus, it has a role in epigenetic controls.[81]

Under some physiological conditions, isocitrate dehydrogenase can form 2-hydroxyglutarate from α-ketoglutarate (Fig. 7.3). Its formation is generally well controlled; however, it can accumulate to higher levels when there is a gain-of-function mutation in either the cytoplasmic or mitochondrial forms of isocitrate dehydrogenase.[30,173] The important point is that 2-hydroxyglutarate inhibits the 2-OGDD enzymes and thus functions in opposition to α-ketoglutarate for these enzymes. The production of 2-hydroxyglutarate has not been analyzed during viral infections, but one can imagine that for the life cycle of some viruses its production could be important, for example in altering epigenetic controls.

Other Functions of TCA Cycle Intermediates that May be Utilized by Viral Infections

We have discussed at length the non-TCA cycle functions of acetyl-CoA and α-ketoglutarate and how these should be considered as potential targets for manipulation during a viral infection. Other TCA metabolites also have non-TCA cycle functions.[90] Of note, increasing evidence suggests that the TCA cycle intermediates play crucial roles in regulating cellular immunity.[20] This would certainly be an aspect of the functions of TCA cycle intermediates that could be very useful for many viral infections.

We will look at a few examples of non-TCA cycle functions of TCA cycle intermediates that may affect viral infections:

- *Succinate*. Succinate plays an important role in inflammatory, hypoxic, and metabolic signaling[104]; it also has been reported to affect innate immunity.[90,150] Succinate can inhibit 2-OGDD enzymes, as it turns out it is an inhibitor of the proline hydroxylases that control HIF-1α levels, thus promoting the accumulation of HIF-1α in the presence of oxygen, also known as pseudohypoxia.[133] The control of HIF-1α is important in many viral infections.[80]
- *Fumarate*. Fumarate can function as an immunomodulator by controlling chromatin modifications and regulating protein succination.[4]
- *Malate*. Malate can be shuttled from the mitochondria to the cytosol where malic enzyme can use NADP+ to convert it to oxaloacetate and NADPH.[186] NADPH is an important reducing equivalent used in lipogenesis.

There are many more functions of TCA intermediates that we could discuss.[90] However, the important point is that the TCA cycle provides not only a means to make ATP but also valuable intermediates that have many other functions that could either support or inhibit a viral infection depending on the life cycle of the specific virus. They should be considered in any host-virus interaction study involving metabolism.

The Mitochondrion

In discussing the ETC and TCA cycle, we should stop to consider the organelle that contains them, the mitochondrion. Many viral studies have shown morphological (fission, fusion, expansion) and functional changes in the mitochondria during infection.[78,157] These studies often relate to the well-studied role of the mitochondria in apoptosis and immunity. Apoptotic signals that target mitochondria can affect morphology and increase permeability of the mitochondrial membrane, causing apoptotic effectors to leak out. Many viruses induce mechanisms to inhibit apoptosis. Cytomegaloviruses are a good example, encoding a mitochondria-localized inhibitor of apoptosis (vMIA), capable of suppressing apoptosis induced by diverse stimuli.[43,88] Additionally, under cell stress conditions, some of which may be induced by viral infection, the mitochondrial membrane may be disrupted and release the TCA cycle intermediates into the cytosol, which can activate mechanisms that impact cellular immunity.[20] All of these functions that affect mitochondria would be important for viral infections and may be manipulated during infection, either positively or negatively, depending on the virus's specific life cycle.

The effects of viral infection on the TCA cycle and ETC have been less studied; however, the examinations of HCMV metabolomics and glutaminolysis discussed above suggest that the bioenergetics of the mitochondrion are likely to be of key importance for many viral infections. Indeed, mitochondrial morphology changes during HCMV and KSHV infection, and disruption of ETC activity is quite deleterious to HCMV replication.[8,26,27,59] During HCMV infection the transcription and protein levels of ETC and ATP synthase proteins are increased[27,102]; similar

results have been reported with KSHV.[59] One must remember that many of the ETC proteins are encoded in the mitochondrial DNA. Transcription of the DNA requires a mitochondrial-specific RNA polymerase, which is quite different from nuclear RNAs polymerases, as it is believed to have evolved from a proteobacterium.[138] Likewise, translation requires mitochondrial-specific ribosomes and tRNAs.[48] Thus, it is interesting to consider that a virus may have evolved special mechanisms to interact with mitochondrial transcription and/or translation. However, the effects may be more indirect, possibly a general cellular response to many viral infections, or the result of stress responses induced by the infection. In any case, this will be an interesting area to watch as we learn more about the effects of viruses on cell metabolism and bioenergetics.

One last point about viral effects on mitochondria: it has been shown that an HCMV noncoding RNA (ncRNAβ2.7) stabilizes mitochondrial membrane potential, which assures ATP production during infection.[124] Up until now, we have not considered the potential effects that virally encoded lincRNAs, lncRNAs, and microRNAs may have on cellular metabolism because so little is known. It is known that cellular microRNAs affect metabolism,[164] often through their well-known controls of gene expression. Viral noncoding and microRNAs may do the same, but it is intriguing to consider that they may do more, consider the possibility that they have roles in allosteric regulation, effects on mitochondrial membranes, mitochondrial structure or function, or effects on transporter functions, for instance for glucose or glutamine transport. These are all important considerations as virologists delve deeper into the complex relationships between viruses and the metabolism of the cells they infect.

Lipid Metabolism

Lipids help form membranes and are a form of energy storage. Some lipids have more specialized functions such as being hormones or acting as signaling mediators. Lipids are structurally and chemically diverse. They can have different backbones, headgroups, and tails. Mammalian cells may have over 5000 different lipids.[55,136] They are organized into several classes, typically according to their backbone and headgroup structures. For example, glycerophospholipids contain a glycerol backbone, one of several types of phosphate-containing headgroups, and one to two tails of varying lengths and double-bond content while other lipids, including sterols, contain 5- and 6-carbon ring structures instead of a glycerol backbone. All lipids within a class are synthesized by the same pathways, which means a single enzyme in lipid synthesis may have several dozen to >100 products. This is different from many of the metabolic pathways that we have discussed where an enzyme may have only one product.

In general, lipids are synthesized from small metabolites, such as acetyl-CoA and amino acids. Fatty acids, cholesterol, and other sterols are made from acetyl-CoA. Most of the glycerol in the backbone is derived from DHAP redirected from glycolysis (Fig. 7.1). ATP provides the energy to make the fatty acids and attach them to the lipid backbone. It is noteworthy that CTP is also consumed during lipid synthesis. CTP is integral to making phospholipids via two general mechanisms: CTP is reacted with the metabolite that will become the head (eg, formation of CDP-choline or CDP-ethanolamine) or CDP is first conjugated to the backbone (eg, formation of CDP-diacylglyceride) (Fig. 7.4).

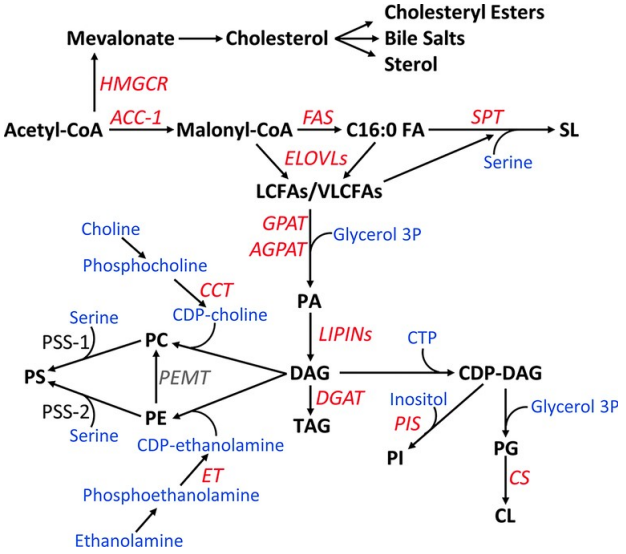

FIGURE 7.4 **Lipid Synthesis**. The *de novo* synthesis of lipids via different pathways starts with a common precursor: acetyl-CoA. Acetyl-CoA can be converted to mevalonate through the action of HMG-CoA reductase (HMGCR). This is the rate-limiting step of cholesterol synthesis. Mevalonate is the precursor to cholesterol. Cholesterol can be further metabolized to cholesteryl esters, bile salts, and sterols. Alternatively, acetyl-CoA can be converted to malonyl-CoA by acetyl-CoA carboxylase (ACC-1). This is the rate-limiting step in fatty acid synthesis. Fatty acid synthase (FAS) builds palmitic acid (C16:0) using carbon units from acetyl-CoA and malonyl-CoA. Fatty acids (FA) can be further elongated through the action of elongases (ELOVLs) to generate long-chain FAs (LCFAs) and very long-chain FAs (VLCFAs). FA can be used to generate sphingolipids (SL) via serine palmitoyl transferase (SPT). FAs can also be directed to acylglycerol lipid synthesis. Glycerol-3-phosphate acyltransferase (GPAT) and 1-acylglycerol-3-phosphate acyltransferase (AGPAT) add two FA tails to the glycerol 3-phosphate (glycerol 3P) to generate the simple phospholipid, phosphatidic acid (PA). LIPIN phosphatases (LIPINs) converted PA to diacylglycerol (DAG). A third fatty acid tail can be added to DAG by diglyceride acyltransferase (DGAT) to generate triacylglycerol (TAG). Alternatively, DAG can be converted to phosphatidylcholine (PC) via a *de novo* synthesis pathway involving choline metabolism. The rate-limiting reaction in PC synthesis is performed by CTP:phosphocholine cytidylyltransferase (CCT). Similar to PC synthesis, phosphatidylethanolamine (PE) is made from a pathway involving ethanolamine metabolism. In this case, CTP:phosphoethanolamine cytidylyltransferase (ET) is the rate-limiting enzyme. PC and PE can be converted to phosphatidylserine (PS) by the action of PS synthase-1 and -2 (PSS-1, PSS-2). Other phospholipids are made using CDP-DAG as a precursor. Phosphatidylinositol (PI) is made from CDP-DAG and inositol by PI synthase (PIS). CDP-DAG is converted to phosphatidylglycerol (PG) in multiple steps that consume glycerol 3P. In a final step, PG acts as a precursor for the synthesis of cardiolipins (CL) by CL synthase (CS).

Lipid synthesis occurs at several locations within a cell. Fatty acid synthase is in the cytosol, while fatty acid elongation and several other pathways of lipid synthesis occur in the ER. The Golgi, mitochondria, and peroxisomes serve as additional sites for lipid metabolism. Subcellular localization of enzymes involved in lipid metabolism can regulate activity through a pathway. As we will discuss later, viruses can take advantage of the regulation of lipid metabolism at several levels, including the subcellular localization of enzymes. We mentioned earlier that related viruses have divergent effects on host glycolytic and nucleotide metabolism. This is true for lipid metabolism as well. For example, flaviviruses are metabolically divergent as evident by the depletion of ceramides prior to infection suppresses West Nile virus (WNV) replication but enhances dengue virus (DENV) replication.[3] The metabolism of the major classes of lipids is defined, but the pathways involved in the synthesis of some lipids are poorly understood or only predicted. For this chapter, we will focus on what is known regarding the metabolic pathways for the major classes of lipids.

FA Synthesis, Elongation, and Desaturation

Fatty acids are built from acetyl-CoA and malonyl-CoA (Fig. 7.4). Acetyl-CoA carboxylase (ACC) adds a carbon from bicarbonate to acetyl-CoA to generate three-carbon malonyl-CoA in an ATP-dependent reaction. Fatty acid synthase (FAS) extends a growing fatty acid chain by adding two carbons from malonyl-CoA. The two carbons incorporated into the hydrocarbon are from the “acetate” unit of acetyl-CoA, while the carbon from bicarbonate is lost. As discussed earlier the two carbons that become part of the fatty acid chain are most often derived from glucose, acetate, or glutamine. FAS produces fatty acid chains 16 carbons (C16) in length. The newly produced fatty acid can be directed towards lipid synthesis to be incorporated as a tail in a lipid or can be further processed by acting as a substrate for fatty acid elongases or desaturases. Elongases extend fatty acid chains, again using malonyl-CoA as a carbon donor, to generate chains longer than 16 carbons. Like FAS, elongases added the new carbons to the carboxylic end of the growing chain. Each cycle where two carbons are added requires the reduction of two double bonds. Both FAS and elongases use NADPH as a cofactor to reduce the double bonds. Fatty acid desaturases catalyze the formation of carbon-carbon double bonds in the chain. Elongated and desaturated fatty acid chains can be used to form the tails of lipids. Once a chain becomes part of a lipid, elongases can no longer elongate it because the carboxylic end is no longer accessible since that is the end that is bound to the lipid glycerol backbone.

Virus infection creates a demand for fatty acids that is beyond the normal cellular demand. Several viruses are known to alter fatty acid metabolism. HCMV increases the flow of carbons from glycolysis and acetate through ACC, FAS, and elongation.[103,119,181,190–192] For this virus, the newly synthesized and elongated fatty acid chains are incorporated into lipids that function in the virus envelope and may likely support virus replication in other ways.[119] Vaccinia virus replication also requires *de novo* fatty acid synthesis to occur in the cytoplasm, but in contrast to HCMV fatty acids are imported into the mitochondria for breakdown for energy.[49] The synthesis and utilization of fatty acids in vaccinia virus may reflect the need for metabolic partitioning in organelles due to the nature of vaccinia's replication in the cytoplasm with little nuclear requirement. Viruses use several mechanisms to alter the activity in fatty acid metabolism. HCMV activates transcription factors that increase the expression of ACC, FAS, elongases, and desaturases.[119,143,190] Flaviviruses provide an example of how infection promotes the synthesis and desaturation of fatty acids and alters enzyme subcellular localization. Both FAS and stearoyl-CoA desaturase support dengue virus replication after being recruited to sites of replication.[51,57]

Fatty acids are not only directed toward lipid synthesis. Fatty acids can be used to modify proteins, both host and viral proteins. Saturated fatty acids with 14-carbon and 16-carbon chains are covalently attached to proteins via processes called myristoylation and palmitoylation. These types of modifications help viral proteins perform their functions. For example, HIV-1 Gag is myristoylated to increase its affinity for the plasma membrane for assembly, and palmitoylation directs glycoproteins to sites in the plasma membrane where the assembled immature virus will bud.[126,149] This example demonstrates how a virus can take advantage of the diversity in fatty acid modification performed by the host to coordinate its assembly and release.

Polyunsaturated fatty acids—ones that contain multiple double-bonds in the hydrocarbon chain—can be further metabolized via oxygenation to form a large class of bioactive molecules termed eicosanoids. Their synthesis can occur via three major pathways: cyclooxygenase (COX), lipoxygenase, and epoxygenase. The major precursor in these pathways is the 20-carbon polyunsaturated arachidonic fatty acid that has four double bonds (C20:4). Oxygenation by COX enzymes leads to prostaglandins and thromboxanes, which can be proinflammatory. Lipoxygenase products, including leukotrienes, and epoxygenase products also have potent proinflammatory signaling properties. Unsurprisingly, these proinflammatory responses can be detrimental to the virus and host if inflammation is severe.[22] However, for HCMV, COX-2 activity promotes virus replication,[194] demonstrating that viruses can use arachidonic acid metabolites to their advantage. Other polyunsaturated fatty acids can be oxygenated to form anti-inflammatory metabolites. These include eicosapentaenoic acid (C20:5) and docosahexaenoic acid (C22:6) that are used to generate bioactive molecules termed resolvins. Treatment with a resolvin promoted recovery from an ocular HSV-1 infection in an animal mode, suggesting that their anti-inflammatory properties can positively impact the outcome of infection.[121] This is a promising observation; however, anti-inflammatory fatty acid metabolites have not been well studied to understand if they have a direct impact on viral replication and if this impacts the outcome of virus infection more broadly.

Acylglycerol Lipids

Acylglycerol lipids contain a glycerol backbone to which one to three tails are esterified (Fig. 7.5). This class of lipids includes phospholipids that are major constituents in biological membranes and triacylglycerols, which efficiently store energy. Acylglycerol lipids are synthesized via pathways that have a shared beginning that starts with the generation of glycerol 3-phosphate from glycerol or DHAP (see Glycolysis).

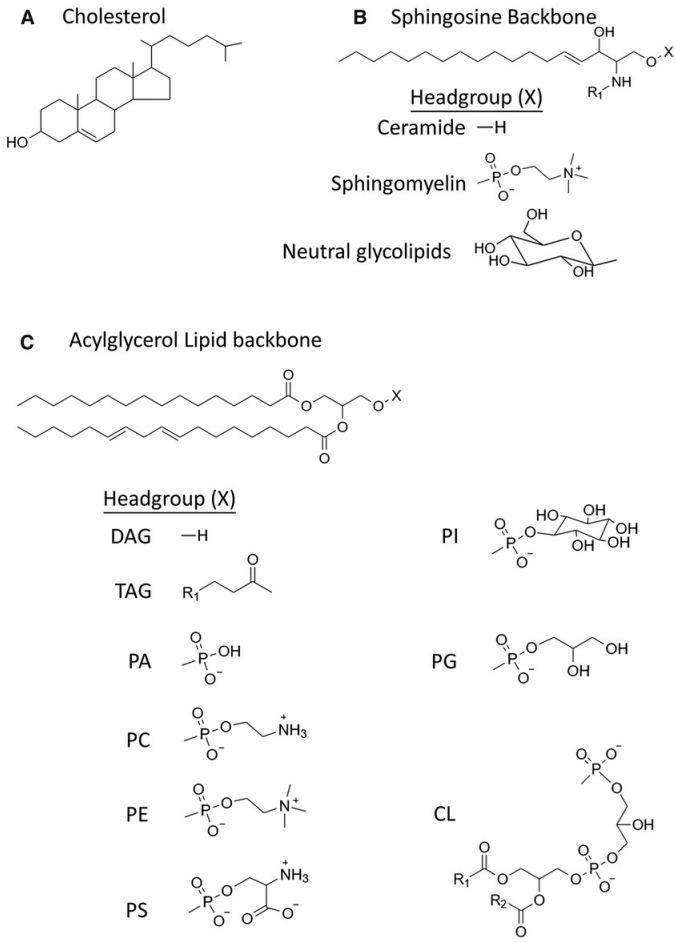

FIGURE 7.5 **Structure of the Major Classes of Lipids**. **A**. The structure of cholesterol is shown. **B**. The structures of sphingolipids are shown. Sphingolipids are characterized by a shared sphingosine backbone. Sphingolipids have an amide-linked fatty acid tail, typically saturated or monounsaturated (denoted as R1). They have variable headgroups (denoted as "X"). Ceramide is the most basic sphingolipid and "X" is a hydrogen (–H). Sphingomyelin has a phosphocholine head and glycolipids contain complex saccharides. **C**. The structures of acylglycerol lipids are shown. Glycerol functions as the backbone and two fatty acyl tails are attached via ester bonds. The composition of each fatty acid tail can vary in both carbon length and degree of saturation (shown is a saturated fatty acyl tail with no double-bonds, and a polyunsaturated tail with two double-bonds). "X" denotes the variable head-group. The simplest acylglycerol lipids is diacylglycerol (DAG), where "X" is a -H. Instead of a headgroup at "X", triacylglycerol (TAG) lipids contain a third fatty acyl tail denoted as R1. Phosphatic acid (PA) is the simplest acylglycerolphospholipid (ie, phospholipids) and only contains a phosphate headgroup. Phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylserine (PS) contain a phosphocholine, phosphoethanolamine, and phosphoserine as headgroups. Phosphatidylinositol (PI) and phosphatidylglycerol (PG) contain phosphoinositol and phosphoglycerol as headgroups. Cardiolipids (CL) are complex. Structurally, CL are two PA lipids connected together via a glycerol. This figure was made with the help of Ian Kline.

The attachment (ie, esterification) of fatty acids to the hydroxyl positions of glycerol 3-phosphate generates the first lipid in acylglycerol synthesis, phosphatidic acid (PA) (Fig. 7.4). The phosphate in PA lipids commonly comes from glycolysis via DHAP and is not further modified, making PA the simplest acylglycerolphospholipid (commonly called "phospholipid") (Fig. 7.5). PA is an early intermediate in the synthesis of other acylglycerols. Relative to other phospholipids, PA concentration in cells is low and most of it is further metabolized to other acylglycerol lipids. The next step in acylglycerol lipid synthesis is the formation of diacylglycerols (DAGs). DAGs are made by removing the phosphate from PAs through the action of lipin phosphatases. DAGs form a hub in acylglycerol synthesis. DAGs can be directly converted to triacylglycerol (TAG) lipids or some phospholipids (Fig. 7.4). Alternatively, DAGs can be activated to generate CDP-DAG for further metabolism to other phospholipids in a process that consumes CTP (Fig. 7.4). In addition to forming a metabolic hub, DAGs function as mediators of lipid signaling. Phospholipase cleavage of PIPs release DAG messengers that activate protein kinase C (PKC). The role of DAG signaling in virus infection has not been well studied, even though viruses exploit PKC to support replication.[97]

Triacylglycerols (TAGs) are formed following the addition of a third fatty acyl tail to DAGs (Fig. 7.4). Each of the three fatty acyl tails of TAGs can be oxidized to generate ATP via the TCA cycle as we will discuss in detail later. TAGs are a more efficient form of energy than carbohydrates and much of the energy stored in the body is in the form of TAGs in lipid droplets. TAGs are generated when energy needs of cells are low and consumed when demands for energy are high. The replication of some viruses stimulates the synthesis of TAG.[182] On the other hand, other viruses, like dengue virus, consume TAGs to generate energy.[58] Dengue virus stimulates the degradation of lipid droplets through autophagy; however, the energy generated via TAG breakdown and the TCA cycle may not be enough to sustain infected cells since the overall levels of ATP drop.[35]

Instead of being used for TAG synthesis, DAGs can be directed towards phospholipids. Synthesis of phosphatidylethanolamine (PE) lipids occurs via the transfer of a phosphoethanolamine group from CDP-ethanolamine to DAG (Fig. 7.4). The CDP-ethanolamine is formed from CTP and phosphoethanolamine in a reaction that "activates" CDP-ethanolamine to enable the transfer of the phosphoethanolamine group to DAG.

The final reaction produces PE and CMP. PEs are one of the most abundant phospholipids in many biological membranes and impart important biophysical properties. As such, it is unsurprising that PEs are enriched in enveloped viruses.[82,89,151] Moreover, PEs are necessary to form subcellular compartments that act as the replication site for positive-stranded RNA viruses.[183,184] It is likely that PEs are found in many membranes or membranous structures that are remodeled by viruses.

Phosphatidylcholines (PCs) are the most abundant phospholipids in many cellular membranes and can be made via multiple routes. In most tissues, PCs are synthesized via *de novo* synthesis, which involves adding a phosphocholine group to DAG, in a pathway that is analogous to PE synthesis (Fig. 7.4). In this pathway, the phosphocholine is donated by CDP-choline, which is generated from CTP and choline. Alternatively, PCs can also be generated from PE through the addition of three methyl groups to the ethanolamine headgroup to form a choline headgroup. The methylation is performed by phosphatidylethanolamine n-methyltransferase (PEMT) and occurs in the liver, fat, and a few other tissues.[28,34,175] It is unknown if animal viruses promote the PEMT pathway. Yeast and most plants are unable to methylate PE to PC. Instead, plants generate phosphocholine that can be incorporated into PCs by repeated methylation of the phosphoethanolamine precursor. This process of PC synthesis is targeted by plant viruses. Brome mosaic virus protein 1a recruits enzymes in PC synthesis to viral replication sites.[193] This finding further highlights that synthesizing lipids at sites where they can support virus replication—as opposed to transporting them to these sites—benefits the virus. Other RNA viruses, including HCV and poliovirus, may use a similar strategy of relocating lipid synthesis enzymes to replication sites.[193] It is unknown if negative-stranded RNA or DNA viruses relocalize enzymes in PC synthesis to make these lipids at sites of virus replication and assembly. However, since PCs are abundant in enveloped viruses it is possible that other viruses recruit PC synthesis enzymes to make PCs at the site of envelopment.

In mammals, phosphatidylserine (PS) lipids are made from PE or PC via head-group exchange where serine replaces ethanolamine or choline (Fig. 7.4). In yeast and plants, PS is synthesized from CDP-DAG. PS is found in several membranes and has important signaling functions, particularly in apoptosis. PS lipids are sequestered on the intracellular side of the plasma membrane in healthy cells. Their externalization during apoptosis stimulates macrophage phagocytosis. PS lipids contribute to apoptotic clearance, which can be triggered by viral infection. Additionally, viruses that infect macrophages can take advantage of their ability to recognize PS lipids. Macrophages express TIM and TAM family receptors to interact with PS. These receptors can interact with PS lipids that are incorporated in the outer leaflet of the envelope of flaviviruses.[95] This finding demonstrates that flaviviruses can take advantage of apoptotic signaling without inducing apoptosis through the inherent function of PS lipids and TIM/TAM receptors.

Next, we will focus on phospholipids made from the CDP-DAG precursor. Phosphatidylinositols (PIs), like PS, are a minor constituent of the inner leaflet of the plasma membrane. PI species are synthesized by the condensation of inositol with CDP-DAGs (Fig. 7.4). Phosphorylation of the inositol headgroup generates phosphatidylinositol phosphate (PIP). The phosphorylation can occur at several locations on the PI head resulting in several forms of PIPs, which are important mediators of signaling. Signal transduction at the plasma membrane activates phospholipase C to cleave PIP into DAG and an inositol phosphate (IP). As discussed earlier, DAGs activate protein kinase C and IP acts as a secondary messenger by activating Ca^{2+}-dependent enzymes. Like PI, phosphatidylglycerol (PG) lipids are synthesized from CDP-DAG (Fig. 7.4). In this case, glycerol 3-phosphate is added to CDP-DAG resulting in a PG-3-phosphate. In the final step, the phosphate is removed by a phosphatase resulting in the PG product (Fig. 7.5). PG lipids can be further metabolized to cardiolipins (CLs) using CDP-DAG as a substrate (Fig. 7.4). Structurally, CLs are complex and are essentially two phospholipids linked together through a third glycerol backbone (Fig. 7.5). CLs are enriched in the inner mitochondrial membrane. Given their importance to mitochondrial function, CLs are likely essential to the metabolic activity of viral infected cells.

Mevalonate and Cholesterol Metabolism

Cholesterol is one of the most studied lipids, including research into understanding its functions in viral infections. Cholesterol contains 27 carbons, each is derived from acetyl-CoA (Fig. 7.5). The rate-controlling enzyme of cholesterol synthesis is HMG-CoA reductase, which produces mevalonate (Fig. 7.4). Mevalonate is phosphorylated and decarboxylated to generate a 5-carbon activated isoprene. Successive condensation of 5-carbon isoprenes results in a 30-carbon intermediate that is oxygenated, decarboxylated, and reduced to yield cholesterol. As discussed later, viruses may utilize several mechanisms to alter cholesterol homeostasis. In membranes, cholesterol can enhance fluidity, reduce permeability, strengthen lipid bilayers, and assist in raft generation. Cholesterol is integrated into the envelope of diverse viruses (eg, influenza, herpesviruses, and others).[17,21,50,89,146] Proper cholesterol content in the host membrane and virus envelope is important for entry and virus infectivity.[50,61,142,146] Cholesterol is important for vesicle trafficking that is necessary for virus replication and the formation of RNA virus replication organelles.[65,107,145,176] DNA virus replication and production of infectious progeny also require cholesterol.[75,180] Cholesterol may support virus replication by being further metabolized to cholesteryl esters or bile acids.

A fatty acid tail can be attached to cholesterol at the hydroxyl position, generating a cholesteryl ester. Hepatitis C virus infection increases cholesteryl ester synthesis to enhance virus assembly demonstrating that cholesterol esterification is necessary for the replication of some viruses.[79,123] Alternatively, cholesterol can be metabolized to form other sterols or bile acids. Recently, bile acid binding to norovirus capsid was found to induce a structural shift in the shell that enhances receptor binding and aids escape from antibody recognition.[177] These observations demonstrate that cholesterol metabolism and its downstream metabolites can perform diverse and essential functions in virus infection.

In addition to being a precursor to cholesterol, mevalonate can alternatively be metabolized to form farnesyl and geranylgeranyl groups. These 15- and 20-carbon lipid structures can be attached to a cysteine residue of a protein in a process called prenylation. These posttranslation modifications increase the hydrophobicity of the target protein and are essential for the function of some proteins involved in signaling, including Rab family members. Geranylgeranyltransferase II (GGT-II) is increased by Epstein-Barr virus (EBV) infection, and its activity is essential to EBV-mediated B-cell growth.[171] Prenylation of host proteins is also important for Hepatitis C virus replication.[169] Although prenylation of viral proteins is not well studied, it is possible and may be essential to the function of some viral proteins.[110]

Sphingolipids

Sphingolipids (SLs) are primarily found on the outer leaflet of the plasma membrane. They are made through the condensation of a fatty acyl-CoA and serine through the action of serine palmitoyl transferase (SPT). SPT can, in some cases, utilize other amino acids in addition to serine, providing further SL diversity. At least two SLs, ceramide and sphingosine 1-phosphate (S1P), act as signaling messengers. Determining the importance of SL to viruses can be complicated since SL has multiple functions. Several extracellular signals or stimuli activate SL signaling,

including immune-related TNFα, IL-1α, IL-1β, and IFNγ factors. Since SL signaling can modulate immune-related factors, regulations of SL metabolism could be a mechanism viruses may use to favor infection. SLs are enriched in microdomains of plasma membranes and in the envelope of some viruses, suggesting that SLs participate in the assembly and release of enveloped viruses.[13] SLs interact with HIV gp120 and gp41 glycoproteins to assist entry.[54] SLs are also necessary for nonenveloped virus entry suggesting that the infection of some viruses is dependent on SLs enriched on the outer leaflet of the plasma membrane.[46,85] Furthermore, SL-dependent entry has also been noted for other enveloped viruses, suggesting that SLs may support virus entry by functioning within the viral envelope membrane or host plasma membrane.[54,166] It may be the case, as demonstrated by measles virus, that SLs are important for virus infection by functioning in the viral or host membrane and through SL-mediated host signaling.[166]

Discovery of Novel Lipids

It is estimated that only half of the lipids in cells can be identified using some of the most extensive lipidomic methods.[136] Just now, the large diversity of lipids is being revealed. There is a growing appreciation for new biological functions and physiological roles provided by newly discovered lipids. Like proteins that are posttranslationally modified, lipids too can be modified. Lipids can be oxygenated or nitrated. A free fatty acid can be modified with another free fatty acid. For example, a palmitic acid (C16:0) can be esterified to a stearic acid (C18:0) forming branched chain fatty acids.[187] Since these modified lipids regulate both metabolism and inflammation,[187] they may be targeted for synthesis or degradation by viruses.

As we discussed earlier, amino acids are important metabolites in the synthesis of lipid heads. In addition to being incorporated into the head of lipids, amino acids can be added to the methyl end of a fatty acid tail. In this case, the hydrocarbons from branched chain amino acids are added to the methyl end of fatty acids generating branched fatty acids with an even or odd number of carbons.[168] This happens in adipose tissue where lipogenesis activity is high. Since many viruses promote lipogenesis, they may increase the production of these branched fatty acids. HCMV infection promotes fatty acid elongation leading to the production of lipids with very long chain tails that are not observed using most standard lipidomic approaches.[119,181,182] As analytical and bioinformatic methods are developed to identify currently unknown lipids, we will likely see that viruses can have more profound effects on lipid metabolism and the host lipidome than we currently appreciate. Since viruses can shift metabolism in ways that we still do not understand, it may be possible that infection will increase the production of many unknown lipids. Continued lipidomic studies of virus infection may lead the way to identifying unknown lipids and virology-focused studies may reveal functions of lipids that have yet been discovered.

The Fate of Lipids and Their Catabolism

Both lipid synthesis and degradation can support virus replication. All lipids are catabolized via similar mechanisms, but specific types of lipids are broken down by different pathways and enzymes. Lipids are oxidized for energy, degraded to repurpose their heads or tails, or redirected to provide additional functions. Fatty acids are broken down in the mitochondria to generate energy. Fatty acids are transported into the mitochondria through the carnitine shuttle (Fig. 7.2). First, a carnitine group is added to the carboxyl end of a fatty acid by carnitine acyltransferase I (CPT-I). This is the rate-limiting step of fatty acid β-oxidation. Once in the mitochondrial matrix, the carnitine group is removed, and the fatty acid is degraded from the carboxyl end. If the fatty acid has an even number of carbons, then it is completely oxidized through multiple cycles that remove 2-carbon per cycle to generate acetyl-CoA. The acetyl-CoA is further consumed in the TCA cycle to generate ATP. If the chain has an odd number of carbons, then the final products are acetyl-CoA and 3-carbon propionyl-CoA that requires further processing for the conversion to succinyl-CoA, a TCA cycle intermediate (Fig. 7.2). Branched chain and very-long-chain fatty acids are oxidized in peroxisomes in an analogous process that breaks down the fatty acid chain by 2-carbons per cycle. Viruses can stimulate lipid breakdown to generate energy, as discussed earlier for dengue virus.[35] Additionally, virus infection can alter the activity of lipases that break down lipids. Coronaviruses stimulate a phospholipase that breakdowns PE by cleaving one tail to liberate it as a free fatty acid. The other tail remains attached to the PE head, creating a one-tailed lysoPE.[101,185] Inhibiting phospholipases reduces virus replication and pathogenicity for several viruses, including coronaviruses.[101,165]

Regulation of Lipid Metabolism

Like glycolysis and the TCA cycle, lipid metabolism is controlled through several coordinated mechanisms. The best-understood regulations of lipid metabolism pathways are fatty acid and cholesterol synthesis. Both fatty acid and cholesterol synthesis are regulated at several levels. The rate-limiting step of fatty acid synthesis is the production of malonyl-CoA by acetyl-CoA carboxylase (ACC-1). Since fatty acid synthesis is an energy expensive process, they are made when the energy demands of the cells are low. When energy demands of the cell are high, then fatty acid synthesis is disfavored. Since fatty acid synthesis and catabolism help balance the energy demands of a cell, their metabolism is regulated by AMPK, an energy sensor. When energy demands are high, AMPK phosphorylates ACC-1 to inactivate it. In its active form, ACC-1 multimerizes, but phosphorylated ACC-1 favors a monomeric state providing further loss of activity. ACC-1 is both allosterically activated and inhibited. Carbons from the TCA cycle are directed to fatty acid synthesis in the form of citrate. Citrate is shuttled to the cytosol to form acetyl-CoA and malonyl-CoA. Increased abundance of cytosolic citrate promotes ACC-1 activation. The product of fatty acid synthase, palmitoyl-CoA, acts as a feedback inhibitor to allosterically reduce ACC-1 activity.

Like fatty acid synthesis, making cholesterol is energy demanding. Cholesterol metabolism is tightly regulated through an elegant feedback mechanism. The expression of most genes that encode cholesterol synthesis enzymes, including the rate-limiting step catalyzed by HMG-CoA reductase, is transcriptionally controlled by sterol regulatory element–binding proteins (SREBPs). When cholesterol levels are sufficient, SREBPs are held in the ER membrane in an immature, inactive form. In the ER, SREBP is bound to SREBP cleavage-activating protein (SCAP), which interacts with insulin-induced gene 1 protein (INSIG). When cholesterol levels in the ER fall, INSIG releases the SCAP-SREBP complex allowing it to transit to the Golgi. Here, S1P and S2P protease cleave SREBPs releasing the mature, active transcription factor forms of SREBPs. There are three isoforms of SREBPs: −1a, −1c, and −2. In general, SREBP-1a stimulates the expression of genes encoding cholesterol and fatty acid synthesis, while SREBP-1c turns on fatty acid synthesis genes and SREBP-2 turns on cholesterol synthesis genes. SREBPs also regulate the expression of low-density lipoprotein (LDL) receptor (LDLR). LDLR binds to cholesterol-rich LDL particles to import them. Consuming LDL particles provide an inexpensive source of cholesterol.

As highlighted earlier, several viruses promote fatty acid and cholesterol metabolism. Again, HCMV provides a good example of the elaborate mechanisms viruses may use to regulate these lipid metabolic pathways. HCMV infection activates SREBPs leading to increased expression of

genes encoding ATP-citrate lyase, ACC-1, HMG-CoA reductase, and fatty acid synthase, and elongases.[119,143,181,190] Interestingly, HCMV infection activates AMPK causing an increase in the inactive phosphorylated form of ACC-1.[92,143,152] However, the overall metabolic activity of ACC-1 is increased to overcome this inhibition, in part by SREBP-dependent increased expression of ACC-1.[143] Consequently there is an increase in cholesterol levels in the early stage of infection, followed by an increase in fatty acid levels.[1,50,119] Further, HCMV infection reduces the ABCA1 cholesterol efflux transporter to retain intracellular cholesterol.[130] Notably, shortly after HCMV infection LDL related receptor 1 (LRP1), which decreases intracellular cholesterol, is upregulated as a possible host defense response to infection that the virus overcomes at a late stage in replication.[50]

In addition to SREBPs, lipid metabolism is transcriptionally regulated by liver X receptors (LXRs) and retinoid X receptors (RXRs). LXR and RXR restrict HIV-1 infection in activated CD4+ T cells by promoting cholesterol efflux via the ABCA1 transporter.[69] A similar mechanism may restrict HCV and Newcastle disease virus.[9,134] In contrast to promoting virus replication, LXR may have some antiviral potential in certain contexts. Interferon-mediated expression of LXR reduces murine herpesvirus 68 (MHV68) replication in primary macrophages by repressing the synthesis of lipids that support virus replication.[74]

Since many steps of lipogenesis occur in the ER, there is a significant connection between ER homeostasis and lipids. Stress and lipid metabolism have a complex relationship that is poorly understood but is important to nonalcoholic fatty liver disease, obesity, diabetes, and cancers. The relationship between stress and lipid metabolism can be exploited by viruses. HCMV uses the molecular mediators of ER stress to regulate metabolism to support virus replication.[68,192] Specifically, HCMV activates PKR-like ER kinase (PERK; also known as eukaryotic translation initiation factor 2-alpha kinase 3, EIF2AK3) to promote lipid synthesis, in part by increasing the levels of fatty acid elongase ELOVL7.[182,192] Interestingly, PERK is not required for HCMV-induced increases in ELOVL5.[182] The ability of PERK to regulate the differential expression of ELOVLs was unknown prior to this work and may also occur in conditions where stress promotes lipid synthesis. Furthermore, PERK may also regulate lipid synthesis by targeting the DAG hub between phospholipid synthesis and TAG synthesis. PERK may promote the flow of DAGs towards phospholipids instead of TAGs in HCMV-infected cells.[182] If true, this would be an example where studies of virus-host metabolism interactions increase our understanding of how stress responses regulate metabolism.

Considerations Regarding Metabolic Studies in Virology

At this point, we will turn our attention to a discussion of concepts a virologist should consider when studying metabolism. Many different types of experiments may lead a virologist to consider studying metabolism. Genomic, transcriptomic, and proteomic studies of virus-host interactions may suggest that infection reprograms metabolism. However, it is important to remember that metabolic conclusions must be reached using metabolic assays.

In regard to genomics, some viruses may contain genes that encode proteins with homology to known host metabolic enzymes. For example, HSV-1 encodes several proteins that can perform metabolic reactions, including deoxyuridine triphosphatase (dUTPase), thymidine kinase, and ribonucleotide reductase.[5,6,16,29,38,94,115,116] The enzymatic actions performed by these viral enzymes support pyrimidine synthesis required for DNA replication.[10] Although the viral dUPTase is not required for replication in cell culture[38], it is important for establishing a latent infection and reactivation in a mouse model.[120] While HSV-1 is an example where viral protein homology of host enzymes can faithfully predict metabolic activity that occurs in infected cells, other herpesviruses offer a cautionary tale. HCMV encodes enzymatically inactive homologs of HSV-1 uracil DNA glycosylase (UL114), ribonucleotide reductase (UL45), and dUTPase (UL72).[15,19,73,113,122] The fact that these homologs lack enzymatic activity demonstrates that these genes are conserved for nonmetabolic functions. Gamma-herpesviruses further encode a viral formyl-glycinamide-phosphoribosyl-amidotransferase (vFGARAT) that is a homolog of the cellular purine synthesis enzyme.[158,161] The vFGARATs lack enzymatic activity; instead they have evolved divergent functions to promote virus replication and pathogenesis.[41,158,161] As discussed earlier, virologists should be aware that any metabolic enzyme may have divergent or alternate functions that may be completely unrelated to metabolism.

Similar to genomic studies, transcriptomic and proteomic studies have limited predictive value for understanding metabolic activity. This is particularly true in conditions that perturb metabolism in ways that are not thoroughly investigated or not yet well understood, such as changes in metabolism triggered by virus infection. Systems-level analyses of model organisms demonstrate that measurements of enzyme abundance poorly predict regulation for many metabolic reactions.[52,111] Changes in metabolic flux can occur within minutes, while transcriptionally driven changes may require many minutes or several hours to change in response to metabolic stimuli. While the rate of some metabolic reactions is regulated by enzyme concentration, most enzymes are expressed in abundance and are regulated by the metabolite-substrate availability or allosteric regulation[52,111] (see the section on Allosteric Regulation).

Metabolomics and lipidomics provide a picture of how viruses may alter the host metabolic profile. These techniques offer a catalog of changes but do not describe the metabolic activity through a pathway. For example, if infection increases the abundance of citrate, this observation alone cannot lead to the conclusion that there is an increase in the activity of the TCA cycle or fatty acid synthesis. Supplementing metabolomic or lipidomic findings with measurements of metabolic activity is required to build a more complete picture of virus-host metabolism interactions. There are several approaches to experimentally define metabolic activity in a pathway. Measurements of extracellular acidification and glucose consumption can provide an understanding of glycolytic changes in response to infection.[27,31] Similarly, the oxygen consumption rate can be used as a measure of activity in oxidative-phosphorylation. These approaches led to the discovery that norovirus infection in macrophages increases ATP generated through glycolysis while slightly reducing mitochondrial production of ATP.[112] However, the best way to determine if a virus alters the flow of nutrients or the flux in additional metabolic pathways is through the use of metabolic tracers, typically isotopically labeled metabolites. In a 2008 paper, Munger et al used ^{13}C-labeled glucose and glutamine to determine the effects of HCMV infection on central carbon metabolism.[103] HCMV infection profoundly increased the metabolism of glucose, TCA activity, and the flow of carbons to fatty acid synthesis. This work demonstrated the power in metabolomics, isotopic tracers, and flux determination that has subsequently led to many additional findings. Afterward, it was demonstrated that HCMV also uses carbons derived from acetate to support lipid synthesis and virus replication using ^{13}C-acetate.[167] Additionally, these initial discoveries further led to the discovery that HCMV increases fatty acid elongation using ^{13}C-glucose and ^{13}C-acetate,[119,181] total lipid synthesis using ^{14}C-acetate,[190,192] UDP-sugar metabolism for glycosylation of viral proteins,[33] and many of the other findings regarding HCMV discussed in this chapter. Moreover, this work by Munger et al. provided a roadmap for studying other viruses.[93,148,163,170]

As discussed earlier, phosphoenolpyruvate carboxykinase (PEPCK) has nonmetabolic functions that may impact viruses. Several metabolites and enzymes similarly have functions outside of metabolism.[63] As another example related to glycolysis, phosphoglucose isomerase (PGI) functions in metabolism to convert glucose-6-phosphate (G6P) to fructose-6-phosphate (F6P). PGI also has a nonmetabolic function as an autocrine factor that promotes cell survival, migration, and proliferation.[174] Similarly, some metabolites have nonmetabolic functions. Kynurenine is a good example to highlight metabolic and non-metabolic functions of metabolites. Kynurenine is a metabolite in tryptophan degradation and an intermediate in NAD+ regeneration. Additionally, kynurenine is a ligand for the aryl hydrocarbon receptor (AhR) that acts as a transcription factor upon binding kynurenine. These nonmetabolic functions can impact the outcome of a virus infection and should be considered when studying metabolism in virology.[106,178] For those who want to further understand the noncanonical functions of metabolic enzymes, we recommend the review by Huangyang and Simon.[63]

Metabolism in the Host Fight Against Virus Infection

Much of this chapter focuses on the role of metabolism in the support of infection and virus replication, which reflects the focus of most studies in virus-host metabolism interactions. However, metabolism is also integral to the host antiviral response and can be used to suppress infection or virus replication. In recent years, the field of immunometabolism—the study of the role of metabolism in immunology—has grown into a mature field. Metabolism is essential in forming the immune response to cancers, self in autoimmune disorders, and pathogens including viruses. Rather than review the rapidly growing field of immunometabolism, we encourage any readers interested in learning more to read the following reviews regarding immunometabolism in general,[87] B cells,[125] T cells,[42] and myeloid cells.[162]

Furthermore, a few initial metabolic studies in virology have shifted our understanding of virus-host interactions to reveal that the host can use metabolism to limit virus-induced effects. A reduction in TCA activity and smaller nucleotide pools were associated with a growth arrest of B cells infected with EBV. In this case, metabolism creates a barrier to virus-induced cell immortalization.[53,93] Interventions to raise the metabolic barriers could provide benefits to reducing the oncogenic potential of EBV and other oncogenic viruses.[11] Herpesviruses provide an additional example where host metabolism is targeted to increase a barrier to virus replication. In response to HCMV infection, the host uses HIF-1α's metabolic regulatory activity to limit kynurenine levels.[178] Since kynurenine-mediated signaling promotes HCMV replication, HIF-1α suppression of its synthesis limits HCMV replication.[106,178] As more metabolic studies are performed in virology, it is likely that additional mechanisms the host uses to create barriers to infection and virus replication will be discovered.

Summary and Future Outlooks

We have attempted to provide reasons for the importance of metabolic studies in virology. Clearly, metabolism connects and interfaces with every function of the cell and vice versa. It is an ideal target for viruses to influence host cell functions and an ideal means for the host to fight back. Yet we have only scratched the surface of metabolism, glycolysis, TCA cycle, mitochondrial function, glutaminolysis, and lipid metabolism. There is so much more, so many more host metabolic and biosynthetic pathways with which viruses can interact.

Understanding the interactions between viral infections and host metabolism will provide many new avenues for the development of antiviral drugs through the inhibition of specific metabolic reactions or pathways. In the past, many have felt that metabolism was sacrosanct, that drugs targeting metabolism would be too deleterious. But this is not correct; there are many people who survive, albeit, with hardship, the loss of significant metabolic pathways due to mutations,[47] and cancer biology is showing how antimetabolic drugs may be effective cancer chemotherapy.[2] There is a great opportunity for antiviral drugs based on temporary metabolic interference; we just have to decipher and understand the intricate dance that goes on between the virus and host metabolism.

Future work in this field should strive to use models that best capture *in vivo* environments. For virus-host metabolism studies done in cell models, one should consider how the environment influences metabolism. Alterations in cell culture media, oxygen levels, confluency, cell-cycle and other physiological relevant conditions can have profound effects on both metabolism and virus replication. The natural history of the cell is also an important factor, especially in the case of studies performed in transformed or oncogenic cells where metabolism has already been altered to support proliferation regardless of the viral infection. These consideration are not unique to virology; they are challenging for all fields studying metabolism in health and disease. Moreover, additional work investigating how metabolic disease in the host may influence virus infection is much needed.[140] We hope that the rich history of virology may provide some advantages as the field continues to develop.

Acknowledgments

First, we would like to acknowledge the many researchers that are advancing our understanding at the interface of virology and metabolism whose work we were unable to discuss here. We are excited to see where the future of the field goes as you continue your work. Next, we would like to thank the editors, particularly Dr. Lynn Enquist, for helpful input as we discussed the ideas to cover in this chapter. We would like to thank Ian Kline of the University of Arizona for his assistance with making Figure 7.5. We would also like to thank Dr. Joshua Munger for providing critical feedback that helped improve this chapter. J.C.A. would like to acknowledge his many colleagues and friends who influenced his thinking over many years, especially Dr. Sherri Adams. J.G.P. is funded by the NIH NIAID under awards number AI162671 and AI155539. The content of this publication is solely the responsibility of the authors and does not necessarily represent the views of the NIH.

Viral pathogenesis as a series of sequential stages in infection

Viral genetic determinants can impact viral pathogenesis at multiple levels

Conceptualizing viral pathogenesis as the integrated effects of viral and host properties

Viral interactions with the host immune system have a major impact on viral pathogenesis

Viral pathogenesis research going forward

Introduction to Viral Pathogenesis

The term viral pathogenesis generally describes the processes by which a virus causes disease in a host. Different viruses cause distinct disease manifestations, due to factors such as virus-specific differences in the cell type or tissue targets of replication, the viral replication cycle, viral effects on the infected cell, and the host response to viral infection. Furthermore, infection with the same virus can result in outcomes ranging from asymptomatic infection to lethal disease across different individuals, further blurring the border between infection and disease. These differences in disease outcome are the result of many complex interacting factors that are unique to each specific virus, a particular host species, and the individual host. The interplay of these factors determines whether infection is successful, whether disease occurs, and if so, the severity and duration of disease.

The past two decades have seen a resurgence in interest in viral pathogenesis driven in large part by the emergence of several significant viral disease threats, including Ebola virus, Zika virus (ZIKV), and most notably, SARS-CoV-2. These outbreaks have led to the recognition that the development of safe and effective treatments and vaccines against these pathogens requires an understanding of their pathogenesis. The renewed interest in viral pathogenesis coincided with a molecular biology revolution that has seen the development and rapid deployment of new methods for quantifying viral and host gene expression (eg, advanced proteomics, RNAseq, spatial transcriptomics), high throughput methods for manipulating host gene expression (eg, CRISPR), as well as tools for rapidly engineering viral genomes through the application of synthetic biology and viral molecular clone technologies that have allowed the molecular manipulation of most clinically relevant virus families. These methods have provided the virology field with an unprecedented ability to manipulate both viral and host genomes and study the molecular events involved in every stage of the virus-induced disease process. These include the identification of entry receptors, pro and antiviral host factors, and polymorphic host genes that govern cell tropism, host range, and disease severity for a number of important viral pathogens, while also identifying key viral genetic determinants that interact with these host factors and regulate viral virulence. Furthermore, *ex vivo* systems for growing and manipulating primary host cells or even organ systems have led to significant advances in our understanding of how viruses interact with target cells. However, while these reductionist tools and systems have been invaluable for understanding the role that specific viral and host factors play in the virus-induced disease process, viral pathogenesis involves a complex set of interactions between viral and host factors, making it necessary to validate the results of these *ex vivo* studies in whole organisms.

Many aspects of virus-induced disease, including interactions with the host immune system, involve systemic responses and can therefore only be fully studied in the whole organism. Ideally, these responses should be studied in the natural host, and studies in virally infected natural hosts, including humans, have provided significant insights into the pathogenesis of a wide variety of clinically relevant viruses. However, for human viruses, it is often not possible to perform the types of highly invasive assays needed to mechanistically understand virus-induced disease processes within the infected individual. It is also difficult to control for the wide array of factors, such as viral dose, preexisting immunity, or other environmental factors that can significantly impact disease outcome during natural infection. Therefore, viral pathogenesis research is often conducted in model organisms of virus-induced disease. These model systems allow for better control of viral (eg, viral strain, dose) and host (eg, genetics, infection history, microbiome) factors that can confound analysis of natural infection, while permitting more mechanistic analysis through manipulation of the virus or the host. These model systems have proven to be invaluable for studying the pathogenesis of a wide range of viruses and have provided insights into how viral interactions with the host affect every aspect of the virus-induced disease process. There is also a growing recognition of the limitations of existing model systems and both the need for improved models that better reflect infection in the natural host and the necessity of confirming results in the natural host (eg, humans). Given the importance of understanding the pathogenesis of emerging viruses, and the rapid advances in molecular virology and animal models of disease, the study of viral pathogenesis continues to be an important and rapidly moving research area.

Goals of This Chapter

The focus of this chapter will be to utilize classical examples of viral pathogenesis, while discussing new insights into the molecular biology and molecular pathogenesis of disease-associated viruses to illustrate key concepts in viral pathogenesis. The large number of viral emergence events that have occurred over that past 40 years, first exemplified by human immunodeficiency virus (HIV), and including more recent outbreaks of ZIKV and Ebola virus, as well as the emergence of SARS-CoV-2 in 2019, have driven a significant expansion in our knowledge of how viruses cause disease. However, it is important to note that viral pathogenesis has been studied for well over 100 years, and this work has been covered in a variety of other authoritative texts that summarize many of the initial observations that form the foundation of our understanding of viral pathogenesis.[237,342] Not only do these early studies provide important context for understanding the evolution of the viral pathogenesis field, but they illustrate the importance of understanding viral pathogenesis for the development of effective public health interventions, including vaccines against human pathogens such as poliovirus, measles virus, hepatitis B virus (HBV), and SARS-CoV-2 or antiviral drugs against viruses such as HIV, hepatitis C virus (HCV), and SARS-CoV-2.

Because viral pathogenesis encompasses a wide variety of viruses and virus-induced disease states, it is not possible to provide a detailed description of the pathogenesis of all viral infections in a single chapter. Therefore, the goal of this chapter is to provide a conceptual framework for understanding viral pathogenesis. To achieve this goal, we will define common terms used in the study of viral pathogenesis, discuss research areas/tools for studying viral pathogenesis, and present key concepts using examples from a range of viral infections. Importantly, for details on the pathogenesis of specific viruses, the reader should refer to chapters in this book series that are devoted to these specific viruses. Furthermore, while viral infections impact a broad range of nonmammalian species, and much of our understanding of virus/host interactions has come from studies of viruses that affect plants or other nonmammalian species, this chapter will specifically focus on viruses affecting mammals, with an emphasis on viruses that are associated with human disease, or viruses that have served as robust model systems for human disease, or as models for studying foundational principals of viral pathogenesis.

Definitions and Concepts in Viral Pathogenesis

As noted above, the field of viral pathogenesis is over 100 years old and is associated with an extremely large body of literature. Due to the breadth of the field, many of the key terms used to discuss topics in viral pathogenesis have multiple definitions across the viral pathogenesis literature. Therefore, we will start by defining key terms and concepts as they are used in this chapter.

Productive, Abortive, and Latent Infection

Infection describes the processes whereby a virus introduces its genome into a host cell. Infection only occurs if the virus is able to bind to and introduce its genetic material into the cell. Infection is ***productive*** if the virus is able to complete its replication cycle to produce new virus, while no progeny virus is produced during ***abortive*** infection. A cell is described as ***susceptible*** if it has a functional receptor or receptors (multiple may be required) that supports viral entry and ***permissive*** if it is capable of supporting productive infection, and nonpermissive if infection is abortive. A susceptible cell may be permissive or nonpermissive. An infection is defined as ***latent*** if the virus infects a cell and does not immediately produce progeny virus but maintains the ability to produce progeny virus at a later time via a process termed reactivation. Importantly, latency is a unique stage in the virus life cycle with a distinct pattern of viral gene expression that differentiates it from productive infection. Productive infection can be ***cytolytic*** (cytocidal), resulting in death of the host cell, while ***noncytolytic*** infections produce progeny viruses without directly killing the cell. Individual viruses can produce cytolytic and noncytolytic infections depending on the cell type and context (eg, *in vitro* vs *in vivo*).

Acute vs Chronic Infection

Acute infection occurs when a virus first infects a susceptible host (Fig. 8.1), while ***chronic infection*** is defined as ongoing infection beyond the period when the host immune system would be expected to clear acute infection. Chronic infection is also referred to as "persistent" infection, and the terms can be used interchangeably. Chronic infection can involve continuous viral replication or latency/reactivation. During latent viral infection the virus has a distinct gene expression strategy, often involving restricted viral gene expression, which allows the genome to survive even when lytic replication is not occurring. Examples of chronic infections include the proviral form of retroviruses, or the circular episomal form with selective expression of viral genes observed for herpesviruses such as Epstein-Barr virus (EBV) and herpes simplex virus (HSV). Often latently infected cells express no viral proteins, making latency immunologically silent. For viruses like HIV, which persists in both a latent form while maintaining continuous replication,[187,510] the boundary between acute and chronic infection is defined as the period when the host immune response clears the initial burst of infection and a relatively stable viral load set point is established in the infected host. For some viruses, such as herpesviruses, infection of a permissive host almost always results in latency. However, there is significant variation in the development of persistent viral infection with other viruses. For example, while HBV frequently causes persistent infection, only a subset of individuals are chronically infected while others clear the infection.[211] Viral persistence can also occur for prolonged periods of time without the production of detectable infectious virus or reactivation competent virus. While the mechanisms underlying persistence of some RNA viruses are not completely understood, potential mechanisms include abortive infection, generation of defective viruses, or low levels of ongoing replication that fall below the sensitivity of standard detection methods. While these types of persistent infection do not result in the generation of infectious virus, they can be associated with significant pathology, such as subacute sclerosing panencephalitis (SSPE), a progressively lethal disease that is caused by hypermutated defective measles virus in the central nervous system (CNS).[178]

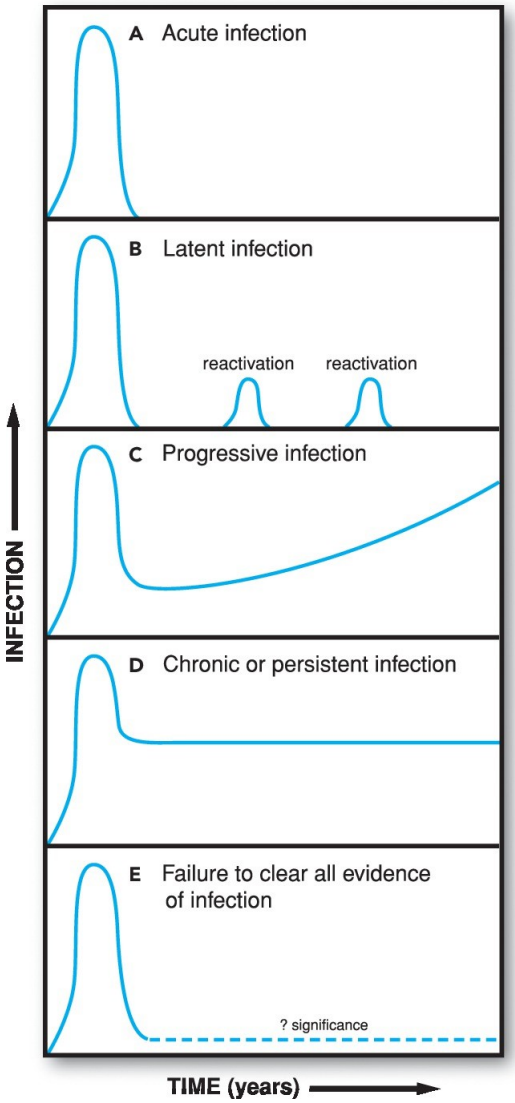

FIGURE 8.1 **Schematic of different patterns of viral infection**. **A**. Acute infection occurs when a virus first infects a susceptible host. All evidence of infection is cleared. **B**. Latent infection, characterized by intermittent viral reactivation, is a mechanism of chronic infection. **C**. Progressive infection is a form of chronic infection in which the viral burden continuously expands over time. **D**. Chronic or persistent infection is the continuation of infection beyond the time when the immune system is expected to clear acute infection. **E**. In some cases, viral nucleic acid can be detected in the host for prolonged time periods but the nature of the infectious process has not been defined. (This figure was adapted from Chapter 22 in Fields Virology, Third Edition by Herbert W. Virgin IV.)

Quasispecies

Viral variants arise due to errors that occur during viral RNA or DNA synthesis, and the population of variants constituting the virus population is referred to as a viral quasispecies (Fig. 8.2). While both DNA and RNA viruses exist as quasispecies, error-prone RNA dependent RNA polymerases (RdRp) can result in the rapid generation of genetic variants in an RNA virus population, and there is generally more genetic diversity in RNA viruses. Studies with poliovirus demonstrated that viruses with enhanced RdRP fidelity that limited the generation of viral mutants showed decreased virulence,[505] and viral variants in a population may exhibit altered cell or tissue tropism, affect host range through interactions with cellular receptors or other proviral factors, and facilitate escape from immune pressure. Therefore, while many areas within the virology and viral pathogenesis fields have focused on studying clonal, infectious clone derived viruses, it is important to consider the potential impact of quasispecies on viral fitness, host range, and pathogenesis.

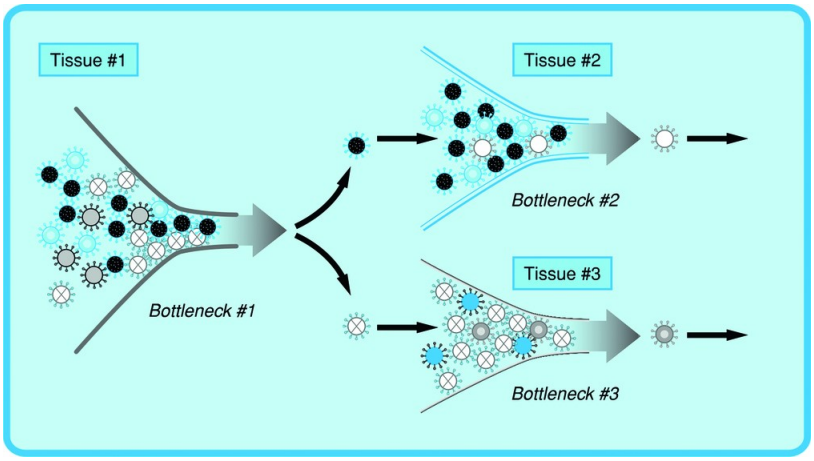

FIGURE 8.2 **Viral pathogenesis as stochastic events followed by selection by bottlenecks in infection**. Shown is a representation of a viral quasispecies, only two of which are fit to pass through an initial bottleneck in infection. Subsequent replication of these viruses in different tissues generates further quasispecies that are again acted on by selective forces at further bottlenecks in infection. (This figure was adapted from Chapter 22 in Fields Virology, Third Edition by Herbert W. Virgin IV.)

Host Response to Acute vs Chronic Infection

Some viruses (eg, herpesviruses) cause both acute and persistent infection in the same individual, while other viruses (eg, HBV, human papillomavirus [HPV]) may be cleared following acute infection in some individuals but progress to chronic infection in others. The host immune response plays a major role in controlling and clearing acute infection and maintains equilibrium during chronic infection. Therefore, knowledge of how the host immune response controls acute infections and regulates chronic infections is essential for understanding the pathogenesis of virus-induced disease. For many viruses, the immune effectors that mediate acute viral clearance are different than those that regulate chronic infection/latency. For example, interferon gamma is an essential regulator of murine gamma herpesvirus 68 (γHV68) latency, but is nonessential for control of acute infection.[33] These differences in immune control between acute and chronic infection may reflect the differential viral gene expression programs between acute replication and latency that characterize herpesvirus infections. However, for viruses that replicate continuously, maintenance of chronic infection generally involves evasion of host immune responses through other mechanisms. For example, both HIV and HCV generate large numbers of viral variants that evade the host immune response and prevent viral clearance.[70,223] Chronic infections with viruses, such as lymphocytic choriomeningitis virus (LCMV), HIV, and HCV, may overwhelm the capacity of the host immune system to clear the virus, leading to immune exhaustion and viral persistence.[229] Therefore, chronic infection should not be viewed as a simple extension of acute infection, since the two stages often involve very different interactions between the host immune system and the virus.

Disease

Virus-Induced Disease is defined as a harmful pathologic consequence of infection. Since viral pathogenesis is the study of virus-induced disease, for the purposes of this chapter we are only concerned with viruses where infection has the capacity to cause disease in at least a subset of infected individuals. With a few notable exceptions (eg, rabies virus), infection with most disease-associated viruses results in a range of outcomes spanning asymptomatic infection to severe disease or death. Some viruses, such as rabies virus, almost always result in lethal disease. However, even viruses such as Ebola virus that were thought to cause predominantly severe disease, similar to rabies virus, actually cause a spectrum of disease manifestations ranging from mild disease to hemorrhagic fever or multi-organ failure.[219] Often, the full spectrum of disease manifestations elicited by a particular virus is only revealed by outbreaks of substantial magnitude, such as the 2014-2016 Ebola virus outbreak in West Africa, the 2015-2017 outbreak of ZIKV in the Americas, and the 2019-present SARS-CoV-2 pandemic. Understanding the factors that drive these differential disease outcomes is a central theme of viral pathogenesis research.

Viruses can cause disease through several distinct mechanisms including direct virus-induced damage, virus-induced immune pathology, paracrine effects of viral infection, and virus-induced cellular dysfunction. Cytolytic viruses cause direct cell death, which can result in severe disease when the target cells perform an essential function and/or are nonrenewable, such as neuron destruction by rabies virus or Eastern equine encephalitis virus (EEEV). While the host immune response is essential for the control and clearance of most viruses, immune pathology due to overactive host immune responses can also cause virus-induced disease, as seen with HBV-induced acute hepatitis, which is largely mediated by the host immune response killing HBV infected hepatocytes.[141,482] Virus-induced disease can also be driven by viral proteins that alter the host cell, such as HPV driven tumor formation,[313] or through paracrine effects of secreted viral proteins, as illustrated by angiogenesis driven by secreted Kaposi sarcoma–associated herpesvirus (KSHV) derived proteins.[534] While most virus-induced disease states involve a combination of several or even all of these processes, understanding the major drivers of disease provides important insights into the biology of the specific virus, while also informing potential therapeutic strategies for that viral infection. For example, chikungunya virus (CHIKV) is

directly cytopathic for infected cells. However, overactive host inflammatory responses mediated by inflammatory monocytes and CD4 T cells contribute to CHIKV-induced arthritis,[477] and combining therapies that block viral replication while also inhibiting host inflammatory response shows promise for treating virus-induced disease.[324]

Virulence

Virulence, which is defined as the capacity of a virus to cause disease, determines the relationship between infection and disease. Avirulent or attenuated viruses are generally associated with mild or asymptomatic disease, while virulent viruses are associated with more frequent and more severe disease. Virulence can take on many forms that are dependent upon the virus-induced disease process. For example, virulent strains of variola virus, the causative agent of smallpox, resulted in rapid death with high case mortality rates, while certain highly virulent HPV strains are associated with high rates of tumor induction. Therefore, it is difficult to compare the virulence of two entirely different viruses (eg, influenza A virus and human cytomegalovirus [HCMV]), and comparisons of viral virulence should be restricted to related viruses. For example, the attenuated Reston strain of Ebola virus appears to be nonvirulent in humans, while Ebola Zaire is highly virulent, with high case mortality rates in infected humans.[538]

While virulence can often be linked to a virus's replication capacity, there are examples where viruses with reduced replication capacity show enhanced virulence[194] and multiple factors contribute to virulence, including the virus's cell and tissue tropism, the virus's ability to antagonize or evade the host innate immune response, and the virus's ability to replicate efficiently. Importantly, the host also plays a major role in determining whether a given virus is virulent, since normally avirulent viruses or even live attenuated vaccine strains can cause severe disease in individuals with highly compromised immune systems.

Although viral virulence genes are associated with a virus's capacity to cause disease, there are also examples of viral genes that actually dampen virus-induced disease. For instance, the vaccinia virus B15R protein is a secreted IL-1β receptor homolog that neutralizes IL-1β. Viruses carrying a mutated form of this gene induced fever and caused increased weight loss and disease signs compared with wild type virus.[8,9] This effect was due to B15R's effects on IL-1β, since administration of anti-IL-1β antibodies to mice infected with the mutant virus reversed the effects of the B15R mutation on fever.[8,9] Therefore, in certain situations, virally encoded genes may limit virus-induced pathogenesis.

Invasiveness

Invasiveness is the capacity of a virus to enter into and damage a tissue, a property that distinguishing viruses with high potential virulence but which differ in the efficiency with which they enter target tissues. For example, many strains of Sindbis virus cause severe neurologic disease in experimental animals if directly inoculated into the CNS, but are avirulent when inoculated into the periphery, while related neuroinvasive viruses with adaptive mutations that allow passage through the blood-brain barrier into the CNS can cause lethal disease following either peripheral or intracranial inoculation.[121]

Proviral and Antiviral Host Factors

Since all viruses are obligate intracellular parasites, they are by definition dependent upon the host cell for the production of all of the components comprising the virion (eg, nucleic acid, proteins). Cellular factors that are essential for or enhance viral infection, replication, or virion production are referred to as ***proviral factors***. Many of these factors are essential for all viruses (eg, ribosomes), while other factors, such as viral entry receptors or cellular cofactors that are co-opted by viruses to promote viral replication may be specific to virus families or even individual viruses. For example, the liver-specific host microRNA miR-122 is essential for robust HCV replication and inhibition of miR-122 in nonhuman primates limits HCV replication.[227,271] While the role of proviral factors has been recognized for decades, the development of high-throughput, whole genome methods for interrogating the importance for individual host genes, such as siRNA gene knockdown or CRISPR gene knockout screens, as well as more sensitive biochemical methods for identifying host proteins that interact with viral proteins, has led to significant advances in the identification of proviral host factors that facilitate viral replication, including new entry receptors, enzymatic pathways that are essential for viral growth, and cellular proteins that interact with viral replication complexes or facilitate the generation of viral replication compartments.[272,302,544] Not only has this knowledge led to new insights into how specific host factors regulate viral cell tropism or even host range, this information has also reinforced the idea that inhibiting essential cellular factors may have therapeutic benefit for treating virus-induced disease.[265]

While proviral factors are essential for successful viral infection, other cellular factors actively antagonize viral replication to prevent or limit infection. These ***antiviral factors*** include constitutively expressed restriction factors that can limit the ability of specific viruses to replicate efficiently in a species-specific manner, as well as inducible antiviral factors, such as interferon stimulated genes (ISGs). While some restriction factors show activity against a limited number of viruses, many antiviral genes have an essential protective role against a wide range of viruses.[233,234,266,432,433] In some cases, specific genes can determine the host range of highly pathogenic viruses such as ZIKV, yellow fever virus (YFV), or HIV.[168,306] Furthermore, naturally occurring variation in specific antiviral genes or their regulatory pathways can have a major impact on an individual's susceptibility to specific viruses.[91,92,288,409,542]

Viral Immune Evasion

Most viruses employ mechanisms to either actively antagonize or avoid detection by the host innate and adaptive immune systems or to bypass intrinsic cellular resistance molecules (also known as restriction factors) so that the virus can complete the infectious process and spread to a new host. These ***immune evasion*** strategies can take several forms. Large DNA viruses, including pox viruses and herpesvirus, encode proteins that mimic host cytokines, cytokine receptors, or cell death regulators to limit the host antiviral and inflammatory response.[15,346,459,512] Most RNA viruses that cause disease in mammalian hosts encode proteins that modulate aspects of the host type I interferon response either by antagonizing specific components of the interferon induction/signaling network or through generalized shutoff of host protein synthesis, which effectively limits the production of antiviral effector molecules.[5,6,148,149] Lentiviruses also encode immune modulatory proteins that antagonize specific intrinsic restriction factors, such as the HIV accessory protein Vif, which mediates inhibition of the cellular restriction factor APOBEC3G.[306,435] Due to the limited coding capacity of RNA viruses, many immune evasion activities are performed

by multifunctional proteins that may modulate multiple aspects of the host response (eg, influenza A virus NS1 protein) or even play essential roles in viral replication, such as the alphavirus nsP2 protein that mediates host cell shutoff of host macromolecular synthesis, modulates type I IFN signaling, and is also an essential component of the viral replication complex.[5,6,148,149] Although most of the known mediators of viral immune evasion are virally encoded proteins, there is a growing recognition that noncoding RNA elements of the genome can also modulate the host response, as illustrated by a stem loop structure on the extreme 5′ end of the alphavirus genomic RNA that allows virulent alphaviruses to avoid inhibition of viral protein synthesis by the host IFIT1 protein.[209,210] During acute infection, viral immune evasion strategies commonly focus on the host innate immune response, while evasion of adaptive immunity is more important for maintaining chronic infection. Therefore, viruses that cause chronic infection often employ mechanisms for evading antiviral T- and B-cell responses. These include limiting viral gene expression during latency (eg, herpesviruses), the rapid generation of viral mutants to outrun adaptive immunity (eg, HIV or HCV), or interfering with host cell antigen presentation to avoid detection by antiviral T cells (eg, herpesviruses).[261,423]

Tropism

Tropism is the capacity of a virus to infect specific cells, tissues, or species. Tropism is a fundamentally important contributor to viral pathogenesis and virulence as the capacity to induce disease is dependent on the cells and tissues infected. For example, a neurotropic virus such as West Nile virus (WNV) can cause encephalitis or paralysis while a virus with tropism for CD4 T cells such as HIV causes immunodeficiency.

Viral interactions with entry receptors are key determinants of tropism and are the major determinants for cell tropism and host range for numerous viruses (eg, coronaviruses). However, there are many additional factors that determine cell, tissue, and species tropism, including expression of essential proviral factors, the absence of restriction factors, or the virus's ability to evade these restriction factors. For example, the counteraction of viral restriction factors by accessory proteins encoded in primate lentiviruses occurs in a species-specific manner and dictates cross-species transmission of these viruses.[124] Other factors, such as cellular differentiation state, can affect a virus's ability to replicate, as illustrated by the impact of cellular differentiation on HPV replication (Fig. 8.3). The comprehensive identification of both proviral and antiviral factors and the role that they play in either promoting or limiting the replication of specific viruses has provided important new insights into the regulation of cell tropism for a number of medically important human viruses.

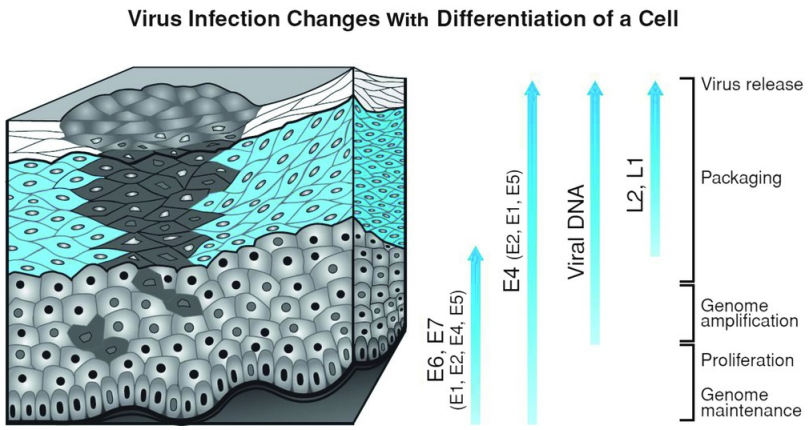

FIGURE 8.3 **Cellular differentiation plays a critical role in papillomavirus pathogenesis**. Shown are the relationships between stages in cell differentiation on the replication of a papillomavirus on the far right, the nature of the progressions of infection through the layers of the skin on the left, and the patterns of papillomavirus gene expression as shown by the labeled *blue arrows* in the center. Virus-infected cells in the skin are designated in *dark gray*. (This figure was adapted by H.W. Virgin IV from Doorbar J. The papillomavirus life cycle. *J Clin Virol*. 2005;32:S7-S15. Virulence Determinants

Virulence is determined by the capacity of a virus to grow, be invasive, infect vulnerable cells, evade the immune system, subvert cellular processes, and cause tissue damage. While virus extrinsic factors, such as mosquito saliva–mediated enhancement of arbovirus infection,[430] or the immune-competence of the infected host can affect virulence, virally encoded factors play a major role in determining whether a given virus is virulent. It is well established that viral genotype has a major impact on virulence,[20,103,121,129,204,235,303,311,462,488-490,492] and the availability of molecular clone technologies, and recent advances in synthetic biology have allowed for the rapid generation of molecularly cloned viruses and the identification of viral genetic determinants of virulence.[235,294,319,320,380,382,488-490] Subsequent studies have shown that different viral genes can confer capacities for infection in different tissues, indicating that viral virulence genes can be tissue specific,[189,310] and viral variants that arise during chronic infection are often cell and tissue specific.[2,3,188,245,338]

A ***virulence determinant*** is a virally encoded feature that contributes to viral virulence and where variation in that determinant affects the virulence of related viruses. Since viral replication is generally required for a virus to induce disease, any viral gene (or noncoding RNA element) that is essential for viral replication contributes to virulence, and variants in a gene that affects viral replication can be virulence determinants. Replication independent functions, such as immune evasion or alterations in cell tropism, can also affect viral virulence, and viral variants that affect these activities are considered to be virulence determinants. Genes that are not essential for viral replication, which are also referred to as ***accessory genes***, are often required for *in vivo* virulence and can therefore also act as virulence determinants. There are numerous examples of accessory proteins acting as virulence determinants, including the HSV γ34.5 gene, which is dispensable for viral replication, but which is required for virulence due to its role in modulating multiple aspects of the host antiviral response.[104,307,362] While large DNA viruses such as herpesviruses and pox viruses encode large numbers of virulence-associated accessory genes due to their large genome size, RNA viruses and retro/lentiviruses also encode accessory proteins that contribute to viral virulence. Examples include the previously mentioned HIV Vif protein that is dispensable for viral replication in cells lacking APOBEC3G but is essential for counteracting the antiviral effects of APOBEC3G,[306,435] as

well as the NS1 protein of influenza virus, which is essential for viral virulence in animals with an intact type I interferon system.[152,522] However, it is also important to remember that many viral proteins are multifunctional, and proteins that may be essential for viral replication, such as the alphavirus nsP2 protein, may also regulate aspects of the host innate immune response or modulate cellular functions.[5,149,159,321] Therefore, it is sometimes difficult to separate out these essential enzymatic processes from the accessory functions of these proteins, and it is important to recognize that allelic variations in the function of essential genes can be important determinants of viral virulence. In this case, the specific property associated with a given alleles effect on virulence is considered a virulence determinant. For example, allelic variants in the PB2 protein, which is an essential component of the H5N1 avian influenza virus RdRp, regulate viral host range, are associated with enhanced replication in mammalian cells, affect viral spread in tissues, and promote enhanced *in vivo* virulence in mouse models of virus-induced disease.[192,284,444,470]

Virulence Genes and Determinants May Not Encode Proteins

While virulence is often mediated by viral proteins, noncoding promoters or elements in the viral genome can also regulate viral virulence. For example, EBV infection is associated with the development of B-cell lymphomas. The EBV EBNA1 protein, which plays an important role in the maintenance of latent EBV infection, can be expressed from four different promoters termed Cp, Wp, Fp, and Qp, each of which is regulated in distinct ways by viral and host proteins.[461] These finely tuned promoters, which ensure appropriate EBNA1 expression and regulation in B cells, are therefore properly considered virulence determinants for EBV-associated malignancies. Another example of nonprotein coding virulence determinants are virally encoded microRNAs, which are expressed by a number of mammalian viruses, including herpesviruses, adenoviruses, and polyomaviruses.[169,293,453] These noncoding RNAs target multiple cellular processes, including cell cycle regulators, apoptotic machinery, or virus-encoded transcripts and play a role in promoting viral persistence. An interesting example are the tRNA-like noncoding RNAs found in the left end of the murine gammaherpes virus γHV68 genome.[57] Remarkably, these tRNA-like RNAs are cotranscribed with viral miRNAs to generate tRNA-miRNA-encoded RNAs or TMERs[115] (Fig. 8.4) and TMER-deficient γHV68 strains are attenuated *in vivo*.[116,134] Noncoding functions within RNA virus genomes can also contribute to virulence. Mutations within a stem loop structure found in virulent alphavirus strains are associated with increased sensitivity to IFIT1 (Fig. 8.4), and viruses encoding these mutations are attenuated in their ability to replicate and cause disease *in vivo*.[209,210] The 3′ UTR of flavivirus genomes contain numerous RNA structural elements including a class of structured RNAs termed exoribonuclease-resistant RNAs (xrRNAs) that have recently been identified in a broad range of animal and plant viruses[504] (Fig. 8.4). During flavivirus replication, xrRNAs resist degradation by the 5′-to-3′ exoribonuclease Xrn1 due to the presence of a ringlike structure through which the 5′ end of the RNA threads.[7,82,225] XrRNA-mediated inhibition of Xrn1 results in the production of flavivirus subgenomic RNAs (sfRNAs) that are derived from the 3′ end of the viral genome.[377] These sfRNAs have been shown to modulate multiple aspects of the host response, including the siRNA and type I IFN response.[455] Mutations that prevent the generation of sfRNAs have been shown to be attenuating for multiple pathogenic flaviviruses, and this subgenomic RNA is considered to be a flavivirus virulence determinant.[455] Noncoding RNAs can also affect cell tropism, as illustrated by EEEV, where microRNA target sites in the viral 3′ UTR that are targeted by miR-142-3p prevent the virus from replicating in myeloid cells, limiting detection by the host immune system and promoting viral neuroinvasion and disease.[485]

The Study of Viral Pathogenesis

The study of viral pathogenesis takes advantage of a scientific tool kit that includes standard assays for quantifying infectious virus, measuring virus-induced pathology in infected tissues, and measuring virus-induced disease. However, recent advances in molecular biology, as well as areas such as synthetic biology, genomics, tissue engineering, imaging, and animal models have enhanced investigators' ability to probe the specific viral and host factors that impact virus-induced disease. Understanding these tools and how they can be applied to viral pathogenesis research is essential for anyone interested in viral pathogenesis or viral pathogenesis research. In this section, we will discuss some key examples of the types of research tools that are employed in viral pathogenesis research.

Epidemiology

Epidemiology plays an important role in understanding the pathogenesis of most viruses. Epidemiology research often plays an essential role in linking specific viruses to disease outbreaks, or even specific disease manifestations, while identifying disease patterns and characterizing mechanisms of viral transmission. Epidemiology studies can also provide insight into factors that put individuals at risk of developing disease, including prior immunity, comorbidities, and demographic factors (eg, age, gender), and this information provides strategies for reducing viral spread or protecting individuals who are at highest risk for developing disease. This information can then inform which questions are pursued by viral pathogenesis researchers to mechanistically understand how these factors contribute to the pathogenesis of a specific virus. The importance of epidemiology research for guiding viral pathogenesis can be illustrated by the following examples.

Kaposi sarcoma (KS) was recognized as a common manifestation of HIV-induced acquired immune deficiency syndrome (AIDS).[78] However, epidemiology work indicated that HIV status did not accurately predict risk of developing KS, suggesting that other factors contributed to KS risk.[39] The discovery of Kaposi sarcoma herpesvirus (KSHV)[79] was followed by additional epidemiologic studies, which provided additional evidence linking KSHV to KS.[39,151,329] These discoveries spurred numerous studies focused on understanding the pathogenesis of KS, as well as other KSHV-associated cancers, and understanding how KSHV interacts with the host to promote tumor development.

A second example of the importance of epidemiology in pathogenesis research is provided by ZIKV, which was discovered in 1947 in Uganda.[114] Although initially considered to be largely innocuous, during a series of outbreaks starting in 2006, the virus was associated with febrile illness and arthralgia.[123] ZIKV infection was also associated with an increase in the incidence of Guillain-Barre syndrome, a neurologic disease of peripheral nerves that can result in ascending paralysis and even respiratory failure.[72] The capacity of ZIKV to cause serious disease was further illustrated by a massive ZIKV outbreak in South America that occurred in 2015. During this outbreak, a cluster of cases of fetal microcephaly was noted in Northern Brazil, and subsequent epidemiologic studies demonstrated a strong association between ZIKV seropositivity and fetal birth defects.[60,99] Follow-up studies found that infection early in pregnancy was associated with increased risk of congenital birth defects.[290,502] This association between congenital ZIKV infection and the development of birth defects sparked a significant amount of research focused on understanding the pathogenesis of ZIKV-associated birth defects. These included studies focused on developing small animal and nonhuman primate models of ZIKV infection[59,196] and using these models to understand how ZIKV crosses the placental barrier and causes disease. Other topics of investigation have included the identification of viral virulence determinants[24,73,97,283,341,388,439,440,460,540] and elucidating host factors that play either protective or pathologic roles during viral infection.[76,221,351,486] While the pathogenesis of ZIKV-induced congenital birth defects is still not completely understood, the rapid pace of this research is in part due to the guidance provided by early epidemiologic studies that defined key parameters associated with the disease.

Clinical Research

Clinical virus disease research, which involves the study of control and infected patients or samples derived from those patients, also plays a key role in understanding the pathogenesis of viruses that cause disease in humans. Historically, clinical observations have involved the careful documentation of disease signs, the use of diagnostic markers such as liver enzyme levels and white blood cell counts/composition in the blood, characterization of viral isolates, and analysis of tissue biopsies or autopsy specimens. This information has been essential for defining key aspects of virus-induced disease and guiding the direction of basic science approaches for understanding the pathogenesis of virus-induced disease. However, with advances in molecular diagnostics, including methods for systematically measuring host gene expression (eg, RNAseq), as well as high-resolution *in vivo* imaging techniques, such as magnetic resonance imaging (MRI), it is now possible to obtain a more comprehensive picture of the molecular signatures associated with the response to specific classes of viral pathogens or specific disease outcomes.

One of the major limitations of studying clinical outcomes during natural infection in humans is the difficulty in controlling for variables that can affect disease outcome, such as viral dose, viral genotype, time post exposure, and underlying health conditions. While it is difficult to control for these variables during natural human infection, controlled human challenge studies using defined viral challenge stocks with close monitoring of virus-induced disease have provided important insights into virus-induced disease processes. While these types of studies are often restricted to viruses that cause self-limited or mild disease, they still have the potential to provide important insights into how these viruses cause disease. For example, human challenge studies with seasonal influenza A virus have provided information on the disease course following exposure,[315,316] the impact of biological sex on disease outcome,[166] and correlates of immune protection[205,530] and have been used to study viral transmission.[243,345] Likewise, human norovirus challenge studies have provided information on the impact of the microbiome on susceptibility to norovirus-induced disease,[369] and for studying the role of blood histo-group antigen secretor status on susceptibility to virus-induced disease.[144] This information, along with the molecular insights provided by more advanced readouts of virus-induced gene expression, metabolic changes, and imaging of tissues from infected patients can then be used to draw conclusions about how viruses or the host response affect specific aspects of the disease process, while also guiding downstream pathogenesis studies using animal models or cell culture systems (see below) to further define the mechanisms driving the pathogenesis of virus-induced disease.

Cell Culture Systems

The development of methods for culturing mammalian cells *in vitro* represents one of the most significant advances in the history of the virology field. Prior to the availability of continuous cell lines, maintenance and detection of disease-associated viruses relied on passage of the virus through permissive animal models. However, the development of cell culture enabled the generation of high-titer virus stocks and methods for quantifying viral titers (eg, plaque assays and tissue culture infectious dose [TCID50] assays) based on the seminal work of Renato Dulbecco.[125] These techniques revolutionized the virology field and are now routinely used for growing, quantifying, and characterizing a wide variety of mammalian viruses and even viruses affecting other species. Furthermore, these techniques have been essential for the development and production of live-attenuated and inactivated vaccines such as the polio vaccine.[26,128,416]

While continuous cell lines are an essential tool for modern virology, these cell lines have limitations. Many cell lines lack key innate immune system components, such as an intact type I IFN system,[111,113,363] and the immortalization process used to generate continuous cells often results in changes in cell cycle regulation or other metabolic processes that make these cells quite different from normal cell types. Therefore, the virology field often utilizes nontransformed cells or even primary cells such as primary fibroblasts, neurons, airway epithelial cells, or dendritic cells[29,87,150,381] to more closely model viral interactions with the infected host. However, even primary cell cultures fail to reproduce the complex interactions that occur within virally infected organs. Therefore, the development of organoid cultures, which better mimic the

architecture and cellular interactions that occur within intact organs, provide the field with new systems for studying how viruses interact with infected organs *ex vivo*. These types of systems have already been used to model viral infection for enteric, pulmonary, and neurologic pathogens.[49]

Viral Molecular Clone Technologies

The ability to manipulate viral genomes using infectious clone technologies has become an important tool for identifying and characterizing viral virulence determinants. As noted above, cell culture methods have enabled the production, maintenance, and study of a wide variety of viruses. Prior to the modern molecular biology era, studies using reassortment of segmented viruses such as reovirus and influenza viruses allowed investigators to link specific pathogenesis phenotypes (eg, viral spread or transmissibility) to specific viral genes[240,471,492] while the use of mutagens, the development of temperature-sensitive mutants, and complementation studies allowed viral enzymatic processes or functions to be attributed to specific virus genes in a wide variety of DNA and RNA viruses including HSV,[426,427] alphaviruses,[69,308,429] and picornaviruses.[386] However, the development of recombinant DNA technology[96,218] greatly facilitated the virology field's ability to identify and molecularly characterize the specific genetic determinants that affect virulence, or prove the causality of a gene for a specific phenotype through deletion or mutagenesis of that gene. Reverse genetics technologies, which include using recombination to generate DNA viruses with mutations in specific genes,[457] as well as infectious cDNA clone technology, where the viral genome is introduced into a DNA molecule (eg, plasmids or bacterial artificial chromosome) that is then used to launch the production of infectious virus, allowed for the targeted manipulation of viral genomes. These tools then allowed investigators to use standard molecular biology approaches to mutagenize specific regions or introduce specific nucleotide substitutions into the virus. For RNA viruses, infectious clone technology was initially developed using bacteriophage.[475] The technology was then used to study molecular determinants of replication and pathogenesis for positive sense RNA viruses such as poliovirus or alphaviruses due to the infectious nature of their RNA genomes.[382,392,400] However, infectious clone technology has now been extended to all of the major classes of viruses, including DNA viruses,[301,322] retroviruses,[299] negative sense RNA viruses,[14,64,274,344,431,526] and double-stranded RNA viruses.[253] Therefore, it is possible to use this technology to genetically manipulate almost every pathogenic virus and to use these techniques to test the role of specific viral genes or even single nucleotide variants in regulating different stages of the viral infection process or their role in disease pathogenesis. Moreover, these technologies also facilitate broad genetic approaches including deep mutational scanning and the use of bar-coded viral libraries to track and determine the influence of viral diversity in viral pathogenesis.[47,498]

Synthetic biology, where DNA molecules are chemically synthesized, allowing for the *de novo* generation of DNA clones without access to physical viral genomes as templates, has also proven useful for the generation and manipulation of viral infectious clones. This technology was initially used to generate an infectious clone for poliovirus[77] but is now routinely used to generate clones for a wide variety of viruses.[203,332,436] Since the *de novo* synthesis of viral genomes requires only sequence information, this approach has allowed for the rapid generation of infectious clones of newly discovered viruses, or even for viruses where the viral genome sequence has been identified through field studies but the actual virus has not been isolated.[319] These synthesized viruses have been used to test whether zoonotic coronaviruses have the capacity to replicate in human cells and thus have the potential to infect and cause disease in humans.[319] Furthermore, these synthetic biology approaches can be used to generate large numbers of viral mutants, allowing investigators to perform saturation mutagenesis studies across regions of the viral genome to identify potential viral virulence determinants or functional domains in viral proteins.[71,464,465] Therefore, synthetic biology provides a powerful set of tools for manipulating viral genomes and the identification and study of virally encoded virulence determinants.

Functional Genomics Technologies

The host response to viral infection plays a major role in determining whether an individual is susceptible to virus-induced disease, or even what type of disease an individual develops. For example, signaling by NF-kB plays a major role in regulating which organ systems are affected by reovirus infection, where deficiency in the nfkb1/p50 gene results in reduced virus-induced apoptosis in the CNS but an increase in viral replication and damage in the hearts of reovirus-infected mice.[352] Therefore, understanding how individuals respond to viral infection at the molecular level can provide important information on the gene expression profiles that are associated with specific disease outcomes or how responses differ when individuals are infected with viruses of differing virulence. The application of functional genomics approaches, which span a wide variety of methods for analyzing host genes or gene products, has had a major impact on our understanding of viral pathogenesis. Given the breadth and rapid developmental pace of this field, we will focus on a few key examples of how these approaches can be used to study how viruses interact with the host, or to determine the functional impact of specific host gene products on viral infection.

Prior to the availability of whole genome sequence information, most analysis of virus-induced host gene expression was limited to analyzing a limited number of host genes or gene products using targeted assays such as Northern blot, reverse-transcriptase polymerase chain reaction (RT-PCR), ELISA, or protein-specific bioassays. However, the availability of whole genome sequence information for humans[215,501] and key laboratory species, such as the mouse,[90,239,336] combined with the development of high throughput platforms for measuring host gene expression, such as microarrays and high throughput RNA sequencing technologies, made it possible to measure genome wide changes in host gene expression.[68,523] These technologies have enabled investigators to address a wide variety of questions, including the study of how host cells or tissues respond to specific viral infections, compare the host response to different viral pathogens that target the same tissue,[317,318] and analyze the role of specific viral proteins in modulating host transcriptional responses.[449] More recent advances, including the development of single cell RNA sequencing technologies, and methods for measuring host gene or protein expression *in situ*,[206,484] such as spatial transcriptomics and mass cytometry, allow investigators to differentiate responses of virally infected vs uninfected cells, account for heterogenous responses during an infection, or analyze the response of specific immune or nonimmune cells in an infected tissue.

High throughput analysis of virus-induced changes in transcriptional responses, protein expression, or other metabolic processes provides important information on how the host or even specific cell types respond to a given viral infection. This information can then be used to test what role specific host genes or gene products with altered expression play in the virus-induced disease process. However, in addition to these gene-by-gene approaches, the virology field has also taken advantage of high throughput methods for interrogating the role of entire classes of genes or even across the entire genome for their role as pro- or antiviral factors. These screens can be generally divided into two categories involving either the overexpression of libraries of genes or the knockdown or knockout of host genes to test their role in viral replication. Overexpression libraries have proven useful for testing the role of specific genes in inhibiting replication (antiviral factors) against a variety of viruses.[234,266,432,434] The development of multiplexed, barcoded short interfering RNA (siRNA) libraries for knocking down the expression of

thousands of host genes[43,367] provided an opportunity to functionally test genes across the entire genome for their role in promoting or antagonizing replication by a wide variety of viruses, including early studies with HIV, flaviviruses, and influenza virus.[61,191,197,259,262,473,548] The availability of high throughput CRISPR-based methods for knocking out, knocking down, or even upregulating gene expression has provided additional tools for identifying host genes with antiviral or proviral activity.[89] While the number of viruses studied using these methods are too numerous to discuss in this chapter, these approaches have and continue to provide important insights into the role of specific host genes in every stage of the viral life cycle, including the identification of host genes that regulate viral tropism or host range. For example, siRNA and CRISPR based screens have identified a number of entry receptors for different alphaviruses,[94,302,408,544] and these results have set the stage for downstream *in vivo* studies evaluating how these molecules affect viral cell tropism or host range.[244,543]

High throughput analysis of host gene function (eg, knockdown or knockout screens) in cell culture has been useful for identifying genes that act at the cellular level. However, many genes impact viral pathogenesis at the systemic level through regulation of complex biologic processes that cannot be easily replicated in cell culture, such as complex interactions regulating the systemic immune response. Whole organism high throughput genetic screens can be readily performed in genetically tractable organisms with rapid reproduction times such as the roundworm *Caenorhabditis elegans*,[231] the fruit fly *Drosophila melanogaster*,[231] and the zebrafish *Danio rerio*,[421] and these systems have been useful for identifying and characterizing host genes that regulate the replication and pathogenesis of viruses that naturally infect those species or related organisms as well as for human pathogens.[23,228,410,472] However, while nonmammalian models have provided important insights into genetic factors that regulate virus-induced disease, those models do not recapitulate many of the organ systems or complex immune regulation in mammals and therefore cannot model more complex virus/host interactions that occur in humans. While homologous recombination and enzyme-based genome editing methods (eg, CRISPR) make it relatively easy to knock out or modify mammalian genes *in vivo* using laboratory mice,[4,257] high throughput genome-wide whole organism genetic screens are more difficult in mammalian species due to longer reproduction times and challenges associated with knocking out or knocking down genes in the whole animal, as well as the logistical challenges and costs associated with conducting virus susceptibility assays in the thousands of animals required for such a screen. Therefore, the majority of *in vivo* studies have focused on the characterization of individual host genes or small sets of genes in virus-induced disease using gene-specific knockout mice. However, approaches such as *N*-ethyl-*N*-nitrosourea (ENU) mutagenesis of the whole genome have been used to screen for genes that regulate virus susceptibility,[101,532] and the availability of large libraries of gene-specific mutant mice generated by homologous recombination, CRISPR gene editing, or ENU mutagenesis[19,454,496,519] makes it possible to screen large numbers of host genes for their impact of viral pathogenesis using mouse models.

Animal Models

Animal models are another important set of tools for understanding viral pathogenesis. As noted above, human clinical studies can provide insights into multiple aspects of pathogenesis. However, human infection outcomes can be influenced by a variety of factors, including viral dose, exposure route, and underlying medical conditions that can be difficult to control for during natural infection. While tightly controlled human challenge studies can account for many of these variables, due to safety concerns, these types of studies are generally limited to viruses that cause mild or self-limited disease and are conducted in healthy individuals lacking many of the risk factors that might lead to poor disease outcomes during natural infection. Furthermore, the types of highly invasive studies needed to study virus-induced pathology or define the role of specific host factors in disease pathogenesis are often not possible in humans. Therefore, animal models, which allow invasive experiments and where it is feasible to control many of the experimental variables that confound human studies, have been an essential tool for studying viral pathogenesis. Animal models of virus-induced disease can make use of either nonhuman viruses that are related to pathogenic human viruses, but which naturally infect an animal host, or human viruses that are capable of infecting and causing disease in a permissive animal species. Both of these approaches have provided important information on viral pathogenesis in general and have informed our understanding of how viruses cause disease in humans.

Natural Infection Models of Viral Pathogenesis

Natural infection models are particularly useful for *in vivo* pathogenesis studies when the analogous human pathogen is restricted to replicating in human cells. Examples of natural animal pathogens as models of human disease include simian immunodeficiency virus (SIV) and murine cytomegalovirus (MCMV).[142,323] There are multiple SIV strains circulating in old world nonhuman primate (NHP) species, and phylogenetic studies indicate that both HIV-1 and HIV-2, the causes of AIDS, originated from SIV strains that were transmitted to humans through zoonotic spread.[200,207,370,442] While SIV strains often cause little disease when infecting their natural NHP hosts, infection of a different NHP species can result in disease. For example, SIV derived from sooty mangabeys causes AIDS-like disease in rhesus macaques,[242] and this model has been important for studying the pathogenesis of AIDS and as a resource for the development and testing of vaccines and antivirals against HIV-1 and HIV-2.[323]

Human cytomegalovirus (HCMV) latently infects a large fraction of the human population without causing significant disease but is a major cause of birth defects when primary infection occurs during pregnancy and also causes severe disease in immune compromised individuals.[179] Cytomegaloviruses (CMV) are generally species specific, and while HCMV can be studied in humanized mouse models,[515] these models do not yet fully recapitulate viral pathogenesis or interactions with the host immune system. Therefore, the majority of studies of cytomegalovirus pathogenesis have used CMV strains that naturally infect rodents (eg, MCMV or rat CMV) or NHPs (rhesus CMV).[142,384] MCMV, which is a natural mouse pathogen, has allowed investigators to take advantage of the wide variety of genetic and immunology tools that exist for working with laboratory mice to study MCMV pathogenesis. Although there are important differences between HCMV and MCMV in terms of their genome organization/gene conservation and specific aspects of their pathogenesis, such as congenital infection,[142] MCMV has been an important model for studying specific HCMV-induced disease states, such as HCMV-associated cardiovascular disease.[50] The MCMV model has also provided important insights into mechanisms regulating immune control of acute infection and maintenance of viral latency,[13,102,195,300] and for understanding how virally encoded genes modulate immune cell populations.[132]

Human Viruses in Animal Models

While infection models with natural animal pathogens are powerful tools for studying viral pathogenesis, the viruses used in these models are often genetically distant from the analogous human viruses and may have evolved to interact with the infected host in ways that are significantly

different from the human virus. Therefore, in cases where the actual human pathogen is able to replicate and cause disease in a relevant animal model, it is often preferable to utilize the human virus. While there are often important differences between the pathogenesis of these viruses in animals compared to human infection, these model systems have provided important insights into the pathogenesis of a wide variety of human pathogens, including Ebola virus, influenza A virus, SARS-CoV-2, HSV, and VEEV.[422]

Some human viruses, such as Ebola virus, HSV, and VEEV can replicate and cause disease in animal models without adaptation, allowing human clinical isolates to be directly evaluated in models such as laboratory mice or nonhuman primates. For example, clinical isolates of Ebola virus causes disease in macaques that is very similar to human disease, including disseminated intravascular coagulation,[162-164] and these models have been important for the development and testing of vaccines and therapies against filoviruses.[162-164,226] However, not all human viruses can directly replicate and cause disease in animals, and several strategies have been used to overcome this problem.

1. If a virus is able to replicate in the animal, but is attenuated or does not cause disease, it is often possible to adapt the virus through repeated passage to generate an animal adapted virus that replicates efficiently in the animal host and causes disease signs that are similar to those seen in humans. These approaches have been used to generate mouse-adapted influenza A virus strains, SARS-CoV-1 and SARS-CoV-2 strains, and Ebola virus strains that are capable of causing disease in mice.[56,63,230,402]

2. While blind passage is often used to generate mouse-adapted viruses, if the specific determinants of host range are known, it is also possible to engineer viruses to permit replication in an animal host. Early pandemic strains of SARS-CoV-2, which utilizes ACE2 as a cellular receptor, are unable to utilize mouse ACE2 and are therefore unable to infect or cause disease in mice.[117] Mutating two amino acid positions in the viral spike protein confers the virus with the ability to utilize mouse ACE2, and this virus replicates efficiently in the lungs of wild-type mice.[117] However, this virus was nonpathogenic in mice, and additional adaptive mutations generated through serial passage were needed to confer virulence and generate a mouse model reproducing SARS-CoV-2 disease signs similar to those observed in SARS-CoV-2 infected humans.[277]

3. Some viruses are unable to replicate in animal hosts due to the lack of appropriate cell entry receptors, and the transgenic expression of the human receptor either in the germline or through the transient delivery of the receptor through a viral expression vector can result in the development of a permissive model of virus-induced disease. These approaches have been used to generate mouse models for viruses such as polio virus, measles virus, MERS-CoV, and SARS-CoV-2.[256,438,546,547] It is also possible to either replace the mouse gene with the functional human receptor by homologous recombination or use CRISPR-mediated gene editing to introduce specific coding changes into the mouse gene to create a functional, humanized, viral receptor.[95,282,368] While transgenic or gene knock in mice is commonly used to express functional viral receptors, these approaches can also be used to modify host genes that regulate aspects of the host immune response, such as the type I interferon system, that act as viral restriction factors. For example, the NS5 protein of ZIKV promotes proteasomal degradation of human STAT2 to antagonize the host type I IFN system,[168] but ZIKV does not antagonize mouse STAT2, which restricts the virus's ability to replicate efficiently and cause disease in immunocompetent mice. However, replacement of murine STAT2 with human STAT2 resulted in a mouse model where a mouse adapted ZIKV strain was able to replicate to higher levels in the placenta and more efficiently cause fetal infection compared to wild-type mice, thereby generating an immunocompetent mouse model of ZIKV transplacental infection.[168]

4. Some viruses are unable to replicate in nonhuman hosts due to multiple incompatibilities or restriction factors that make it difficult to generate animal models by genetically engineering the virus and/or the host genome. For viruses such as HCMV, HIV, HCV, and varicella-zoster virus that are restricted to humans, mice carrying allografts of the human immune system, and/or specific organ systems have provided useful models for studying the pathogenesis of these viruses.[27,160,276,424,515,541]

5. For some human restricted viruses, such as hepatitis B virus (HBV), it is also possible to express the viral genome as a transgene, which leads to production of infection virus in specific cell types.[182,184] This system has provided important insights into the role of specific components of the host immune system in clearing HBV infection and driving virus-induced immune pathology.[183]

Selection of Appropriate Animal Models

Despite their importance for viral pathogenesis research, it is important to remember that all animal models have limitations and no model completely recapitulates all aspects of virus-induced disease in humans. Furthermore, different model systems have strengths and weaknesses, both for modeling specific aspects of virus-induced disease and for mechanistically studying the viral and host factors that contribute to virus-induced disease. For example, of the commonly used vertebrate animal models, NHPs are most closely related to humans, and therefore share similarities in both their physiology and genetics, which often leads to disease outcomes that more closely reflect those seen in humans. For this reason, NHPs are considered to be the gold standard for studying the pathogenesis of several important human pathogens, including filoviruses (eg, Ebola virus).[452] However, NHPs also have several limitations, including high cost, the need for specialized facilities, limited availability, and a lack of robust genetic tools for studying the role of specific host genes in disease pathogenesis. Therefore, a variety of other models for studying filovirus pathogenesis have been developed, including hamsters, guinea pigs, and mice.[63,98,127,452] Although these models require the use of adapted viruses,[63,98,127,452] or the use of type I IFN deficient animals,[62] they do recapitulate key aspects of the virus-induced disease process and have been useful systems for studying filovirus tissue tropism or performing detailed studies of virus-induced pathology.[452] Furthermore, mouse models provide access to a wide range of genetic tools, including gene-specific knockout mice and genetically diverse reference populations (eg, the Collaborative Cross [CC]) that can be used to study the role of specific host genes or host genetic variation in the pathogenesis of filovirus-induced disease.[395,452] These small animal models can then be viewed as complementary tools that can be used to address questions that either cannot be readily addressed in NHPs, such as the role of specific host genes in virus-induced disease susceptibility, or as low-cost alternatives that can be used for initial discovery studies where results are confirmed using NHPs or human data sets. As we will discuss in more detail below, it is important to weigh the strengths and weaknesses of any animal model when considering how well it models virus-induced disease, whether that model can provide useful information on the pathogenesis of a given infection, or whether it might be necessary to use different model systems to address various aspects of the virus-induced disease process.

Selection of an animal model for studying virus-induced disease is partly driven by how well that model reproduces the virus-induced disease process; however as noted in the previous paragraph, factors such as ease of use, cost, availability, experimental tractability, and the availability of research reagents also influence model selection. For these reasons, the laboratory mouse, which fulfills all of these criteria, has played a dominant role in studying the pathogenesis of a wide variety of viruses[309] (Fig. 8.5). While all of these factors contribute to the popularity of the mouse as a model system, the large panel of genetic tools in the mouse, including inbred mouse strains where every mouse in a strain is

genetically identical, and the ability to easily knock out or modify specific genes in the mouse genome, has made the mouse a particularly powerful resource for understanding how viruses interact with the host.[422] Inbred mouse strains allow investigators to use large numbers of genetically identical mice for studying the response to specific viruses, allowing investigators to control for host genetic effects when studying how other viral or host factors, such as viral genetics, viral dose, microbiome, prior immunity, or environmental influences affect virus-induced disease. Knowledge of the whole genome sequence of these strains combined with gene knockout and gene editing technologies (eg, CRISPR gene editing), has allowed investigators to knock out or modify specific host genes while controlling for genetic effects across the rest of the genome.[4,257] These technologies and the subsequent availability of large panels of gene-specific knockouts on defined genetic backgrounds allow investigators to interrogate the role of host genes in the pathogenesis of any virus that is capable of replicating and causing disease in the mouse.[19,454,496,519] In addition to allowing investigators to study the role of specific genes in viral pathogenesis, genetically modified mice have allowed for the development of new model systems. As discussed above, mice can be modified to express functional receptors or to ablate specific host antiviral factors to make mice permissive for a variety of viral pathogens.[95,168,256,282,368,438,496,546,547] Furthermore, knockout mice with severely compromised immune systems have been essential for developing humanized mice engrafted with human immune systems or specific tissues to generate small animal models for viruses that are only capable of replicating in human cells.[160,515] The dominance of the mouse as a model system, not just for virology but for biomedical science as a whole, has also led to the development of a wide array of reagents for studying biological processes in the mouse, including the immune system, thereby providing the virology community with a variety of tools for studying the host response to viral infection in the mouse.[422]

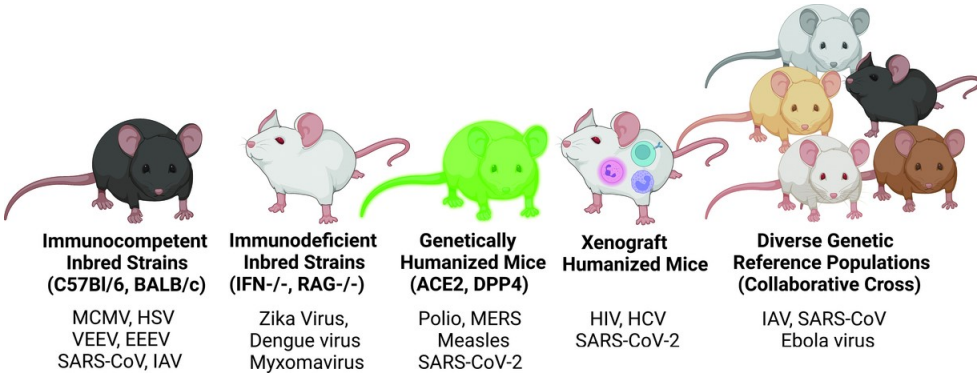

FIGURE 8.5 **Mouse models for viral pathogenesis studies**. Examples of different types of mouse models, and their utility for studying representative viruses discussed in this chapter. (Created with BioRender.com.)

It is important to consider the limitations of a model organism both when selecting a model and when interpreting data generated in that model. Using mice as an example, while mouse models have played a major role in the study of viral pathogenesis, they do have significant limitations. Mice are genetically distant from humans, and although many genes and gene functions are conserved between mice and humans, there are abundant examples of differences in specific genes or gene expression between mice and humans.[90,270,291,336] Therefore, it is important to keep these differences in mind when choosing a model system and if a nonconserved gene or pathway is being studied, it may be necessary to consider using more closely related species such as NHPs or humanize mouse models.

As detailed above, the use of inbred mouse strains has allowed virologists to control for host genetics in their studies; however, the reliance on a limited number of inbred mouse strains fails to account for impact of genetic diversity on virus-induced disease outcomes in humans.[348] This can be partly addressed by the use of genetically diverse inbred mouse populations, such as the CC mouse genetic reference population, which was derived from 8 founder strains and capture 90% of the genetic diversity in laboratory mice, while maintaining the advantages associated with fully inbred (eg, genetically reproducible) and genetically defined standard inbred mouse strains[348] (Fig. 8.5). The genetic diversity in the CC and the genetic reassortment of the original eight founder strain genomes resulting in new allele combinations across the CC strains often results in CC strains presenting with new phenotypes not seen in the original eight founder mouse strains.[348,463] The virology community has taken advantage of this aspect of the CC both to map host genes associated with variation in virus-induced disease[172,349] and to develop new models of virus-induced disease that more closely reflect disease outcomes in humans infected with viruses such as Ebola virus, SARS-CoV, and WNV.[140,171,172,258,395]

The physiology of a species can also have a major impact on whether that species should be used for studying the pathogenesis of a virus-induced disease or even specific aspects of the virus-induced disease process. For example, mouse models have been used extensively to study the pathogenesis of respiratory viruses such as influenza A virus (IAV), SARS-CoV, and SARS-CoV-2, and they have provided key insights into the role of specific host genes or immune cell populations in either limiting or exacerbating virus-induced disease.[56,250,277,481,547] However, mice do not efficiently transmit these viruses.[56,481] For this reason, transmission studies for influenza virus primarily rely on ferret or guinea pig models,[56,481] while SARS-CoV-2 transmission studies have predominantly used ferret or hamster models.[445,447] These types of differences may also be relevant to other aspects of virus-induced disease, such as congenital viral infection. HCMV is a common cause of congenital birth defects in humans,[179,401] but while the MCMV model has been useful for studying multiple aspects of CMV pathogenesis, this model is less useful for studying congenital infection in part due to structural differences between the mouse and human placenta.[142] In contrast, both rhesus CMV and guinea pig CMV are capable of crossing the placenta and causing congenital infection and are therefore useful models for studying the pathogenesis of congenital CMV infection.[401] Additional differences between the mouse and human placenta,[16] including placental development and timing of perfusion with maternal blood, can limit the utility of mice for the study of other viruses with known teratogenic effects (eg, ZIKV, HSV).

Key Concepts in Viral Pathogenesis

Virus-induced disease represents a complex series of interactions between the virus and the host. For any given virus, disease outcome can be influenced by a variety of virus-associated factors, such as viral genotype, viral variants that arise over the course of the infection, viral dose, and route of inoculation. Likewise, host factors, including genetic variation, underlying medical conditions (eg, diabetes), immune status, and

microbiome, as well as sex and age, affect susceptibility to disease or even the type of disease that develops. Given this complexity, it can be daunting to consider how to deconvolute these processes to understand specific mechanisms that contribute to viral pathogenesis. However, it is still possible to conceptualize virus-induced disease processes into discrete stages, mechanistically study the viral and host factors that regulate each of those stages, and even define aspects of those stages that are common between viruses. While the specific virus/host interactions that drive disease will be unique to any given virus, and even vary between individual hosts infected with the same virus, similar methodologies can be used to study the pathogenesis of different viruses and even define general principles that are common aspects of viral pathogenesis. There are a wide range of approaches for studying viral infection and disease, and we will discuss a few of these approaches to illustrate how these types of studies can inform our understanding of viral pathogenesis. Importantly, we will also discuss some of the limits of these approaches, while illustrating the importance of not overgeneralizing findings from one virus to others.

Clinical Observations Can Provide Fundamental Insights into Viral Pathogenesis

While much of our understanding of viral pathogenesis comes from experimental model systems, including animal models of virus-induced disease, fundamental insights are often provided by clinical observations of naturally infected individuals. For example, much of our understanding of measles virus–induced disease, including the incubation period between exposure and disease onset, the enhanced susceptibility of young individuals, and the concept of lifelong immunity following prior infection came from studies of a measles outbreak in the Fareo Islands in 1886[175,176] at a time when the viral cause of measles had not yet been identified. Likewise, during the modern era, the massive amount of clinical and epidemiological data generated by the SARS-CoV-2 pandemic has provided insight into the role of underlying heath conditions (eg, diabetes) and advanced age in disease susceptibility, while the success of anti-inflammatory treatments in reducing disease severity has illustrated a role of pulmonary inflammation as a driver of disease in some SARS-CoV-2 infected individuals.[38,107,252,396,468] Importantly, over the past 15 years the availability of more advanced analysis techniques for studying disease processes and host responses in patient populations, such as high throughput methods for quantifying genome wide gene expression (eg, proteomics and RNA sequencing), it is now possible to generate a more detailed picture of the molecular events occurring in an infected patient or tissue. However, as noted above, it is often difficult to fully dissect these disease processes at the mechanistic level through clinical analysis alone, and therefore, clinical findings often serve as a starting point for more detailed analysis using in *vitro* and *in vivo* model systems. Through the careful analysis of human clinical data and the use of appropriate cell culture based systems and animal models, it is often possible to define the molecular mechanisms underlying specific virus-induced disease processes.

Viral Pathogenesis as a Series of Sequential Stages in Infection

One approach for studying viral pathogenesis is to divide the virus-induced disease process into a series of stages, including initial infection, viral dissemination, invasion of the target tissue(s), and disease induction, followed by outcomes such as disease resolution/viral clearance, viral persistence/chronic disease, or even death of the host. By dividing these processes into discrete stages, it is often possible to understand how different viral and host variables affect each stage of the infection and disease process.

The pathogenesis of poliovirus represents a classic example of how viral pathogenesis can be broken down into several discrete, sequential stages. The poliovirus epidemics of the first half of the 20th century led to a concerted effort to understand the pathogenesis of poliovirus infection and disease. This analysis was key to understanding both the mechanisms of poliovirus transmission and why some individuals remained symptom free while others progressed to meningoencephalitis and paralysis. Importantly, this work also set the stage for the development of vaccines that have nearly eliminated poliovirus as a global disease threat.[325,391,393]

As illustrated by Figure 8.6, poliovirus infection consists of several distinct stages that help explain viral disease pathogenesis. Poliovirus transmission occurs via the fecal-oral route and enters Peyer patches from the intestine, where the virus replicates in lymphoid cells. The virus then spreads to secondary replication sites via the blood, where the virus replicates and seeds a second round of viremia that can lead to CNS infection in some individuals through either viral transit across the blood-brain barrier or infection of peripheral nerves that mediate viral entry into the CNS.[46,180,325,355,391,393,399] Upon entering the CNS, the virus replicates in and kills motor neurons, leading to paralysis. These studies also identified an important role for the immune system in determining whether an individual progresses to CNS infection and disease. The host immune response is initiated at the time of viral replication in lymphoid tissue, and the host antibody response is involved in clearing poliovirus from the circulation, which can limit the virus's ability to transit into the CNS.[325,399] Antibody has also been shown to mediate clearance of poliovirus and other viral pathogens from neurons.[280,325,340,491,493] Therefore, the kinetics and quality of the host immune response can have a major role in determining whether individuals remain asymptomatic, or develop neurologic disease.

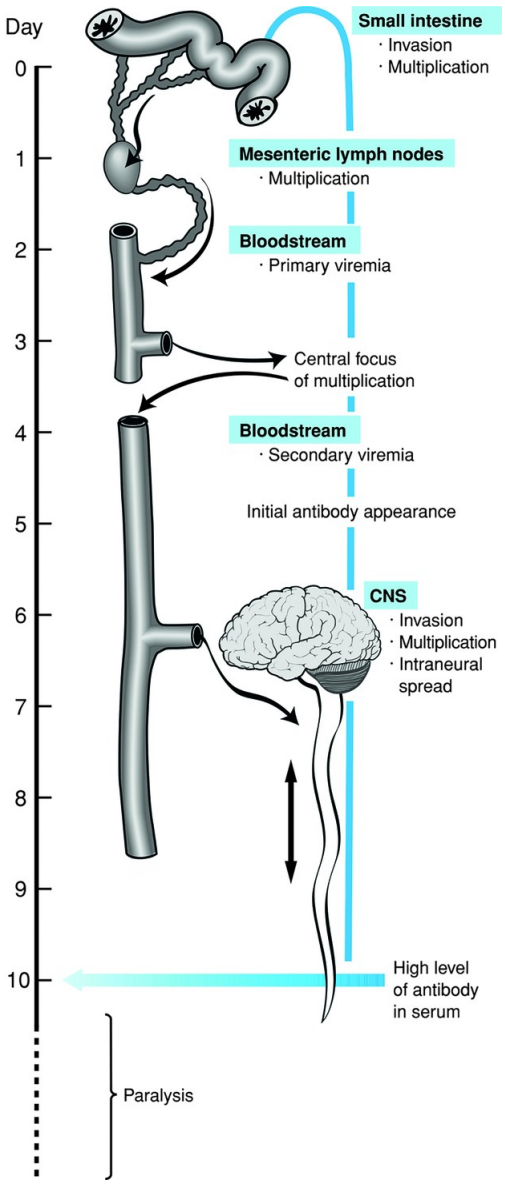

FIGURE 8.6 **Model of poliovirus pathogenesis as a series of sequential stages**. The steps in poliovirus infection of a human are schematized. (This figure was adapted from Chapter 22 in Fields Virology, Third Edition by Herbert W. Virgin IV.)

It is important to note that unrelated viruses that cause similar disease manifestations may go through a similar set of disease stages. For example, encephalitic viruses ranging from DNA viruses such as HSV, to RNA viruses, including polioviruses, rabies virus, WNV, or Venezuelan equine encephalitis virus (VEEV) must all invade the CNS to cause neurologic disease. While neuroinvasion is a common step in the disease process for all encephalitic viruses, the specific mechanisms or even routes of neuroinvasion vary greatly between viruses. HSV enters the CNS through retrograde neuronal transport via peripheral nerves such as olfactory nerves.[37,287,330] Rabies virus also enters the CNS via retrograde transport in peripheral nerves following virus uptake at neuromuscular junctions.[249] WNV can utilize olfactory nerves to enter the CNS[347]; however, the initial invasion of the CNS is mediated by disruption of the blood-brain barrier by inflammatory cytokines in the periphery.[18,517,520] VEEV initially enters the CNS via either olfactory nerves or the trigeminal ganglion[83]; however, a second round of neuroinvasion occurs via disruption of the blood-brain barrier; inhibition of blood-brain barrier disruption results in delayed onset of VEEV-induced disease.[425] As noted above, poliovirus can also enter the CNS either by directly crossing the blood-brain barrier or via infection of peripheral nerves.[46,180,325,355,391,393,399] Therefore, while viruses that cause similar disease states (eg, neurologic disease) may go through similar stages in the disease process, the specific molecular mechanisms used by each virus to complete each stage may be quite different. Recognizing how these virus-specific aspects of the disease process affect disease outcome is essential for understanding the pathogenesis of a given virus.

Mosquito-borne arboviruses, which include members of the order *Bunyavirales*, and the *Flaviviridae* and *Togaviridae* families, further illustrate the point that viral infection can be divided into discrete stages that share features across many viruses, while also demonstrating that viruses that cause very similar disease outcomes may do so through different mechanisms. These arboviruses all initiate infection via transcutaneous delivery in arthropod saliva, and while their initial target cells differ, initial viral infection and amplification occurs in resident cells in the skin.[41,289,304,469] Local viral replication seeds serum viremia, which facilitates transmission to new mosquito vectors if a sufficiently high viral load is achieved in the blood.[374,398,480] This viremia also facilitates viral dissemination to secondary sites of viral replication, including downstream targets of virus-induced disease. The disease states and target tissues associated with different arboviruses can also be quite similar. A wide variety of arboviruses from all three viral families cause neurologic disease, and as noted above, neuroinvasion therefore represents a key disease stage for each of these viruses. Likewise, unrelated viruses, such as YFV and Rift Valley fever virus (RVFV) can target

similar tissues (eg, the liver) and cause similar disease manifestations, such as hepatitis and hemorrhage.[213,328,389,390]

Comparing and contrasting the disease processes induced by phenotypically similar viruses can be useful for identifying common mediators of specific stages in pathogenesis, while also illuminating aspects of pathogenesis that are unique to a given viral pathogen. Advances in molecular virology, high throughput genetic screening, genomic technologies, and other experimental tools, as well as the use of animal models that reproduce key aspects of virus-induced disease, have allowed detailed analysis of the viral and host factors that regulate the various stages in the infection process for a wide variety of viruses at the molecular level. These approaches have identified cases where viruses that cause similar disease outcomes utilize common pathways. For example, arthritis-associated alphaviruses, including CHIKV, Ross River virus (RRV), and Mayaro virus (MAYV) all utilize Mxra8 as a cellular entry receptor,[544] while similar components of the host immune response, such as inflammatory monocytes/macrophages, contribute to the tissue pathology and rheumatic disease signs caused by these virus infections.[106,158,285,286,413] However, it is often the case that viruses that cause very similar disease outcomes interact with the host in very different ways to establish infection, avoid or suppress the host immune response, and ultimately cause disease. This is illustrated by VEEV and EEEV, mosquito-borne alphaviruses that cause severe neurologic disease. Although VEEV and EEEV must both establish infection after mosquito delivery, disseminate systemically, and invade the CNS to cause disease, the two viruses differ greatly in their interactions within the host at the molecular level. Following introduction into the skin via mosquito bite, VEEV infects Langerhans cells and/or dermal dendritic cells[304] through interactions with DC-SIGN,[247] which binds high mannose N-linked glycans on the surface of the mosquito-derived virus, and the viral entry receptor low-density lipoprotein receptor class A domain containing 3 (LDLRAD3).[42,302,304] The virally infected dendritic cells then migrate to the draining lymph node where VEEV replicates and spreads to secondary lymphoid tissues, while seeding a serum viremia that facilitates neuroinvasion via infection of olfactory nerves or the trigeminal ganglion.[83] In contrast, EEEV does not infect dendritic cells or other myeloid cells and instead initially infects skin fibroblasts and muscle cells. Unlike VEEV, EEEV does not utilize LDLRAD3 as an entry receptor[153] but instead uses VLDLR and ApoER2, two other lipoprotein receptors.[94] While receptor differences may influence VEEV and EEEV tropism, EEEV tropism is largely mediated by the presence of micro-RNA binding sites in the EEEV in the 3′ UTR that are targeted by miR-142-3P micro-RNAs expressed in myeloid cells.[485] Disruption of these miRNA target sites allows EEEV to replicate in myeloid cells, but these mutant viruses are attenuated and induce high levels of type I interferon, indicating that EEEV evades the host innate immune response by limiting viral replication in myeloid cells to promote viral dissemination and virus-induced disease.[157,248,485] EEEV and VEEV also differ significantly in other mechanisms related to the virus-induced disease process. The presence of positively charged mutations in the E2 glycoprotein of VEEV, as well as other alphaviruses such as CHIKV that arise through cell culture adaptation and promote binding to heparan sulfate and other charged glycosominoglycans, are associated with viral attenuation.[22,42,414] In contrast natural isolates of EEEV exhibit heparan sulfate binding activity, and this heparin binding activity contributes to EEEV neurovirulence in mouse models of EEEV-induced encephalitis.[154,155]

These examples illustrate several important points when thinking about viral pathogenesis. It is important to remember that even viruses from the same family that exhibit similar disease outcomes may do so through very different mechanisms. Understanding these mechanisms and how they differ between viruses has important implications both for understanding virus-induced disease processes and the development of antiviral therapies or vaccines. For example, blocking VEEV entry receptor LDLRAD3 has therapeutic benefit against VEEV in animal models,[302] since EEEV does not use LDLRAD3 as an entry receptor, this approach would be unlikely to have clinical benefit against EEEV. Likewise, introduction of heparin binding mutations is a common strategy for developing live attenuated vaccines against alphaviruses such as VEEV and CHIKV.[156] However, since heparin binding promotes EEEV pathogenesis,[154,155] this approach would not be beneficial in EEEV vaccine development.

Viral Genetic Determinants Can Impact Viral Pathogenesis at Multiple Levels

Viral genetic factors play important roles in the pathogenesis of all disease-associated viruses. These include viral genes and noncoding elements that regulate fundamental aspects of the viral lifecycle, including genome replication, receptor interactions, and virion assembly and that modulate the host response to viral infection. While many viruses are genetically stable, viral genetic adaptation plays an important role the pathogenesis of a wide variety of viruses. These adaptive mutations can affect the virus-induced disease at the population level, such as adaptive mutations affecting virus host range, or within individuals by driving immune evasion or selecting for viruses with enhanced tropism for specific organ systems. Understanding how these adaptive mutations affect virus-induced disease can provide important insights into the role of specific viral genes in the disease process, illuminate key interactions between the virus and the host, and even predict which viruses represent the greatest risk for zoonotic emergence.

Viral adaptation frequently occurs when viruses infect a new species and may even be a driver of zoonotic emergence. For example, both the original SARS-CoV and SARS-CoV-2 utilize angiotensin converting enzyme 2 (ACE2) as a cellular entry receptor.[217,263] Comparison of SARS-CoV isolates from early vs late stages in the 2003 outbreak identified adaptive changes in the receptor binding domain (RBD) of the viral spike protein that improved interactions with the human ACE2 receptor, thereby enhancing viral infectivity for human cells.[232,443] Similar adaptive changes have been observed during the SARS-CoV-2 pandemic, where viral variants that either enhanced virion stability[380] or improved ACE2 binding affinity resulted in enhanced transmissibility, increased viral replication efficiency in the lungs, and enhanced virulence. Moreover, these variants have emerged to become the dominant viral strain either regionally and/or globally.[327,417] Therefore, these types of adaptive changes can have major effects on viral pathogenesis and even enhance the virulence of newly emerging viruses as they adapt to a new host species.

While viral genetic changes can promote adaptation to a new host, and thereby enhance viral transmission or pathogenesis, there are also examples of viruses becoming less virulent as they adapt to new host species. This is illustrated by classic studies conducted by Fenner and colleagues on the pathogenesis and epidemiology of the myxomatosis virus in Australian rabbit populations.[136,137,139] European rabbits (*Oryctolagus cuniculus*) are an invasive species that causes significant ecological damage in Australia due to a lack of natural predators. Myxomatosis virus is a pox virus that causes mild disease in its natural host (*Sylvilagus brasiliensis*) but causes severe systemic disease with >99% mortality of infected European rabbits and was therefore introduced into the Australian rabbit population in 1950 as a biological control effort. The virus caused high mortality in rabbit populations at the time of its introduction, with initial mortality rates in excess of 99%. However, within a year mortality dropped to < 90%.[136,137,139] While there was clearly selection for resistance within the Australian rabbit population (Table 8.1), the virus also exhibited significant changes in virulence.[138,139] Myxomatosis virus isolates could be classified into five virulence grades based on their case mortality rate,[137] with grade 1 causing >99% mortality, while grade 3 causes 70%-90% mortality (Table 8.2). Although the virus introduced into the Australian Rabbit population was a Grade 1 virus, Grade 3 viruses quickly became the predominant circulating virus.[136,137,139] A second myxomatosis introduction in Europe in 1952 resulted in a very similar pattern, where the initial highly

virulent viruses were replaced by attenuated strains with reduced mortality rates and extended survival times.[137] Further studies also found that when a virulent strain was introduced into an area where viruses of intermediate virulence were circulating, the attenuated strains outcompeted the more virulent virus[136] as illustrated in Figure 8.7. However, there is also evidence that as rabbit populations became more resistant to myxomatosis virus, there was selection for increased viral virulence in some populations.[241] This led to the conclusion that the virus achieved equilibrium with its host, where highly virulent viruses may spread less efficiently due to the rapid death of the host, while overly attenuated viruses may not achieve sufficient viral loads for efficient transmission via direct contact or to arthropod vectors. Therefore, viruses of intermediate virulence would have a transmission advantage leading to these viruses outcompeting both highly virulent and highly attenuated viruses.[241]

TABLE 8.1 The susceptibility of nonimmune wild rabbits after successive epidemics of Myxomatosis

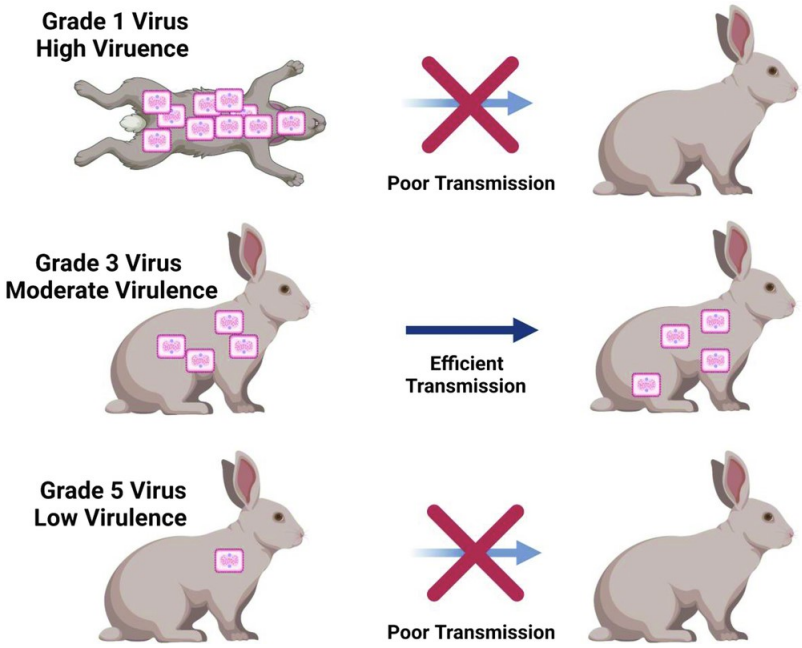

FIGURE 8.7 **Changes in viral virulence can affect transmission efficiency and lead to the establishment of equilibrium within a host population**. Highly virulent myxomavirus strains (Grade 1) result in the rapid death of the host, which limits the opportunity for viral transmission to new, susceptible hosts **(Top Panel)**. Likewise, viruses with significantly reduced virulence (Grade 5) produce less virus resulting in less efficient transmission **(Lower Panel)**. Viruses with intermediate virulence (Grade 3) result in sufficiently high levels of virus production, but delayed death in the host, which increases the likelihood that the virus will be transmitted to a new host **(Middle Panel)**. (Created with BioRender.com.)

The availability of high throughput, whole genome sequencing methodologies has allowed analysis of the genetic differences between the originally introduced Grade 1 myxomatosis viruses and the subsequent less virulent viruses that arose over the course of the outbreak.[241] These studies demonstrated that myxomatosis virus had undergone extensive evolution, and that less virulent viruses acquired mutations in a variety of virulence genes.[241] Importantly, the data also indicated that attenuation was not associated with specific mutations or even mutations in the same sets of genes between viruses, illustrating the stochastic nature of viral evolution during a major outbreak, and the possibility that different mutations or mutations in different genes may result in very similar pathogenesis phenotypes.

While coronaviruses and myxomatosis virus provide excellent examples of how viral genetic changes can impact virus-induced disease across populations, viral adaptive changes can also influence disease outcomes within individuals. This is illustrated by viral immune escape variants, where viruses avoid clearance by mutating T-cell and B-cell epitopes. Studies with LCMV in transgenic mice whose T cells were specific for a LCMV epitope in the viral glycoprotein demonstrated the rapid selection for viruses with mutations in this epitope that allowed for immune escape.[378] Similar results have been observed for other viruses. Lentiviruses such as HIV and SIV acquire mutations in $CD8^+$ T-cell epitopes, and these mutations are associated with escape from virus-specific T cells and progression to AIDS.[12,30,31,53,130,170,254,378] HIV also acquires resistance to neutralizing antibodies via adaptive mutations. Although individuals can mount neutralizing antibody responses against HIV, the neutralization-sensitive viruses are replaced by successive populations of neutralization-resistant viruses.[524] Importantly, unlike evasion of T-cell responses, which involves mutations that disrupt protective T-cell epitopes, HIV can escape virus-specific neutralizing antibodies through mutations that alter glycosylation sites on the viral envelope protein, where the glycans block antibody interactions with neutralizing epitopes.[524]

Conceptualizing Viral Pathogenesis as the Integrated Effects of Viral and Host Properties

Viral genetic factors clearly play a major role in determining viral virulence and can affect aspects of the disease process such as host range, tissue tropism, and immune evasion. However, variation in a wide variety of host factors also have a major impact on viral pathogenesis, and the interactions between these host factors and viral genetic determinants shape the virus-induced disease process (see Fig. 8.8).

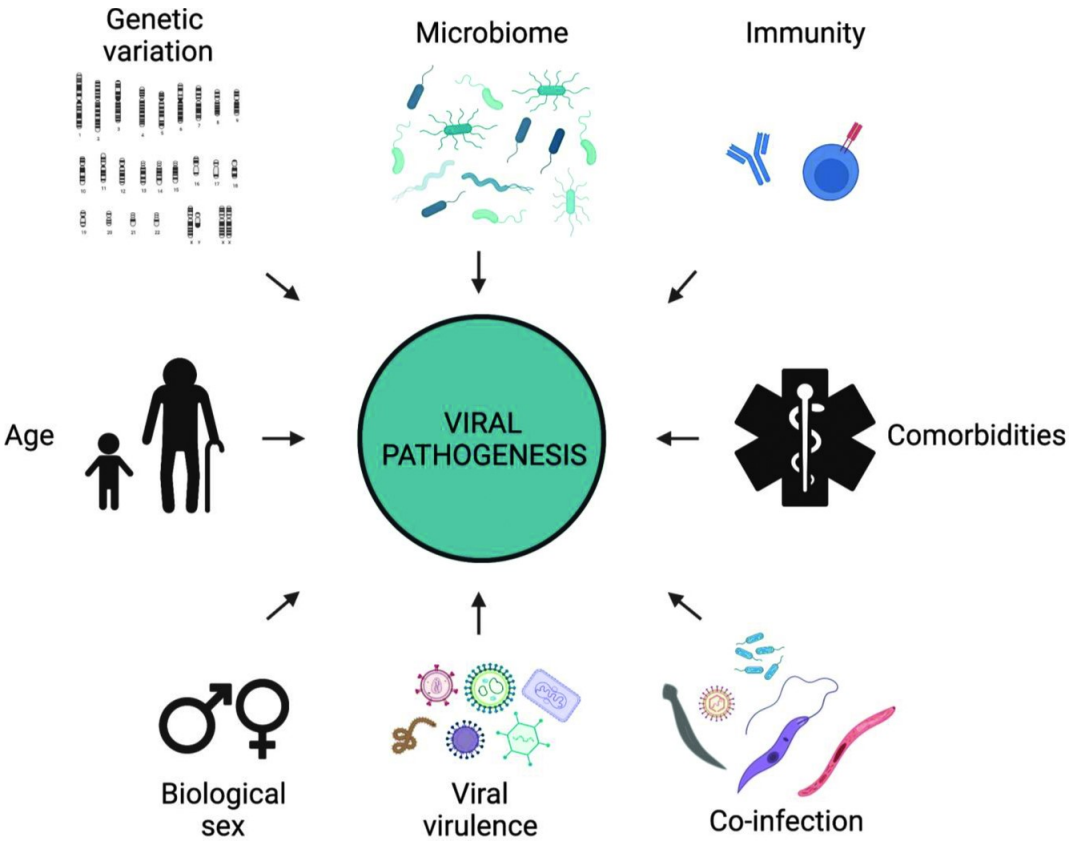

FIGURE 8.8 **Multiple viral and host factors interact to shape the pathogenesis of virus-induced disease**. In addition to virus-derived factors (eg, viral virulence, viral dose); host factors, including age, sex, genetic variation, microbiome composition, and underlying disease states (eg, comorbidities or coinfections); as well as host immune status (eg, preexisting immunity, immunodeficiency) can influence an individual's susceptibility to virus-induced disease. Different combinations of these host factors can contribute to variation in disease outcomes across a population infected by the same virus. (Created with BioRender.com.)

Effects of Host Genetic Variation on Susceptibility to Viral Infection

Major host determinants of viral virulence and pathogenesis are innate and adaptive immunity (discussed in more detail below), but host genes not involved immunity also play a role. Thus, allelic variations in host genes can alter viral pathogenesis. A powerful demonstration of this is the identification of inborn errors of immunity that are associated with severe outcomes of viral infection. For example, life-threatening encephalitis is a rare complication of herpes simplex virus-1 (HSV-1) infection.[379] Genetic studies of HSV-1 encephalitis patients revealed that this rare but severe outcome is associated with allelic variation that impairs type I and type III IFN-mediated immunity, including genetic mutations in STAT1,[126] a transcription factor activated downstream of the type I IFN receptor; NF-kappa B essential modulator (NEMO),[387] a protein that regulates the activation of IKKα and IKKβ; UNC-93B, a protein required for TLR3, TLR7, and TLR9 activation; TRIF[419] and TRAF3,[373,545] proteins required for TLR3 signaling; and TLR3,[545] a pattern recognition receptor that elicits induction of type I and III IFN. Loss-of-function variants in genes that regulate type I IFN immunity, including *IFNAR1*, *IRF7*, *IRF9*, *TLR3*, *TLR7*, and others, also have been associated with life-threatening COVID-19,[21,542] a rare complication following SARS-CoV-2 infection.

Among additional examples, some are well established while others come from single studies and await confirmation. Mutations in CCR5, which is a co-receptor for HIV entry,[11] confer resistance to HIV infection.[105,292,418] Human noroviruses (type virus Norwalk) are responsible for more than 90% of the epidemic nonbacterial gastroenteritis in the world.[119,167] Norwalk virus susceptibility is determined by blood group secretor status conferred by the presence of the FUT2 fucosyltransferase.[208,292] Among human norovirus strains there are multiple patterns of norovirus viruslike particle (VLP) binding to blood group carbohydrates suggesting that allelic variation in human blood groups contribute to susceptibility to a variety of norovirus strains. Patients with mutations in the IFN-γ receptor have been reported to have unusual viral syndromes.[376] Autosomal dominant mutations in the chemokine receptor CXCR4 have been associated with severe warts,[273] and mutations in *EVR1* and *EVR2* have been associated with an unusual clinical presentation of papillomavirus infection called epidermodysplasia verruciformis.[394] Allelic variations in mannose binding lectin (MBL) and FcγRIIA have been linked to the severity of SARS-CoV-1.[216,539] A relationship between expression of certain KIR genes, encoding NK cell receptors, and severity and chronicity of infection with HIV, HCV, and EBV have been reported.[74] Responsiveness to hepatitis B vaccine may be linked to allelic variations in complement genes.[48,201] Thus, a significant number of allelic variations in humans are important determinants of viral pathogenesis.

Though many studies have focused on the impact of variation in a single gene on viral pathogenesis, it is clear that susceptibility or resistance to viral infections is a complex phenotype regulated by multiple interacting genes and gene networks. For example, studies designed to identify genes that regulate resistance to influenza A virus infection between two mouse strains identified multiple quantitative trait loci (QTL) that contribute to disease susceptibility.[51] Though the full number of host genes that vary between susceptible and resistant hosts for a single virus is incompletely understood, it is likely that variation in hundreds of different genes may contribute to disease resistance or susceptibility.[75,511] Advances in the area of host genetics, including the application of Genome Wide Association Studies (GWAS), which scan the genome for allelic variants, such as single nucleotide polymorphisms (SNPs), associated with specific phenotypes, as well as whole exome and whole genome

sequencing, promise to further enhance our understanding of how different polymorphic genes contribute to disease susceptibility. For example, application of GWAS approaches to identify genes that associate with HIV control identified a major association between polymorphisms in the HLA locus that affect class I peptide presentation to CD8 T cells and an individual's ability to control HIV.[214] These approaches have also been extended to HCV, and identified a polymorphism within the IL28B gene (interferon λIII) that associates with viral clearance following interferon therapy.[161] These types of GWAS studies have proven useful for identifying susceptibility loci for some viral pathogens and hold promise for predicting treatment outcomes for infection in patient populations as has been suggested for inflammatory diseases.[509]

The examples outlined above illustrate that allelic variants in host genes can have a significant impact on the pathogenesis of infection. As multiple independently segregating genes contribute to the susceptibility or resistance to a viral pathogen, many human genotypes exist that may vary significantly in their resistance to even a single viral infection. Therefore, even without considering the impact of viral virulence determinants or other environmental factors, much of the variation in viral pathogenesis within a diverse population could be explained by polymorphisms in host genes. This has implications not only for viral pathogenesis in human populations but also for studying viral pathogenesis in animal models. Though GWAS and candidate gene studies in humans can establish an association between a polymorphic gene and susceptibility to a viral infection, the investigation of the mechanisms by which a polymorphic gene or genes affect pathogenesis requires additional tools, including appropriate animal models (As Described Above in the Section on Animal Models).

Age as a Determinant of Viral Infection Outcomes

The age of the host can have a major impact on susceptibility to virus-induced disease, with both very young and very old individuals often being at increased risk of developing severe disease. Very young individuals often have increased viral tissue burdens, higher levels of viral dissemination, and increased susceptibility to viral invasion of target tissues, which correlates with disease severity or outcome.[448] For example, neonatal exposure to viruses such as HSV or CHIKV frequently results in severe neurologic disease that is less frequently observed in adults.[32,165] Furthermore, while the majority of adults clear HBV infection, HBV exposure in neonates commonly results in chronic infection.[528] These differences in susceptibility may be partly due to infants being immunologically naïve, and the lack of preexisting adaptive immunity leads to increases disease susceptibility. There is also evidence that the innate immune response is less robust in the very young compared to adults, and these differences in innate immunity lead to increased risk of developing severe disease for viruses such as HSV.[165] However, other developmental changes can also contribute to the enhanced susceptibility of the very young to infection. For example, studies with Sindbis virus, which shows age-dependent virulence in mouse models, have demonstrated that undifferentiated neurons are susceptible to virus-induced apoptosis, while differentiated neurons are resistant.[281]

Age dependence of virus resistance does not always favor older hosts. For example WNV encephalitis is more common and more severe in older hosts,[193] and lethality after SARS-CoV and SARS-CoV-2 infection is highly age dependent, with risk of severe disease being significantly higher in people older than 60 years of age compared to younger people.[120,181,371] This is also the case in mouse models of SARS-CoV and SARS-CoV-2 infection.[277,403,404] Alterations in the immune response in older individuals at least partly explain the increased susceptibility of aged individuals to severe virus-induced disease. Age-dependent immune senescence in older individuals can lead to waning of preexisting immunity, poor ability to mount adaptive immune responses,[67,100] as well as defects in key innate immune pathways, such as the type I IFN system, where dampened innate immune responses or even autoantibodies against type I IFN (eg, autoantibodies against type IFN account for up to 20% of fatal COVID-19 cases) can impact host antiviral responses.[35,135] Although the very young and the very old are often at increased risk of viral infection compared to healthy young adults, there are also instances where young adults are at increased risk of enhanced disease. For example, mumps virus is generally associated with painful swelling in the parotid glands (parotitis) but can cause swelling in the testis (orchitis) that can affect male fertility. Orchitis is considered to be rare in prepubescent males, but more than 30% of infections in postpubescent males can result in orchitis.[36] During the 1918 H1N1 influenza A virus pandemic, very young and old individuals exhibited increased death rates normally associated with influenza A virus infection. However, young adults in the 15- to 40-year age range also had more severe disease signs than did older children and teenagers.[366] While the mechanisms responsible for the increased susceptibility of young adults to 1918 influenza A virus are not fully understood, younger individuals had not previously been exposed to H1N1 influenza strains, and this lack of prior immunity would have left them susceptible to infection, while their more robust inflammatory responses may have resulted in so-called cytokine storms that contributed to pathogenesis.[108,235,366]

Biological Sex as a Determinant of Viral Infection Outcomes

Sex differences can influence the outcome of viral infections, and this has been highlighted by the COVID-19 pandemic. Severe COVID-19 is more commonly observed in males compared with females.[85,122,181,437] This male bias in severe disease also has been observed for the other highly pathogenic coronaviruses, SARS-CoV-1[279] and MERS-CoV.[10] The precise reason(s) for these observations is not well understood but could reflect sex-specific differences in steroids, chromosomes, and immune responses.[437] For example, male COVID-19 patients were found to have higher levels of cytokines such as IL-8 and IL-18, higher activation of monocytes, and less activation of T cells, which correlated with disease severity.[474] Studies in mice also demonstrated sex-based differences during CoV infection. Male mice are more susceptible to SARS-CoV-1 infection, which is characterized by elevated lung viral burden and enhanced lung inflammation and injury compared with age-matched female mice.[81] The less severe infection outcomes in female mice were linked with sex steroids as treatment of female mice with an estrogen receptor antagonist increased virus-induced mortality.[81] Similar findings were observed in SARS-CoV-2-infected hamsters in which male animals developed more severe lung pathology.[112] Sex-based differences in infection outcomes also have been observed for a variety of other viral infections, including WNV,[222] CHIKV,[44,65,220,503] and influenza A virus.[503]

Effects of Variation in the Host Microbiome on Susceptibility to Viral Infection

The host microbiota regulates immunity and thus functions as an additional host property that influences susceptibility to viral infection. Mice treated with oral antibiotics display differential outcomes to a variety of viral infections, including influenza A virus,[212,466] HSV-2,[353] CHIKV,[466] poliovirus,[268] reovirus,[268] norovirus,[28,224] rotavirus,[494] and numerous others. In the case of enteric viruses including poliovirus, reovirus, and rotavirus, antibiotic-treated mice are less susceptible to viral infection and virus-induced disease, indicating that in these cases the host microbiota promotes viral replication and pathogenesis. Mechanistically, poliovirus and reovirus infectivity is enhanced in the presence of intestinal bacteria or bacterial products.[40,268] Antibiotic treatment of mice also reduces replication of murine norovirus in the intestine during

acute infection[224] and prevents persistent enteric murine norovirus infection.[28] Additional studies revealed complex interactions between norovirus and the host microbiota. During acute murine norovirus infection, the intestinal microbiota limits viral replication in the proximal small intestine but promotes viral replication in more distal regions of the small intestine and the colon.[174] The inhibition of viral replication in the proximal small intestine was found to be due to microbiota-mediated transformation of bile acids (ie, deconjugated), which promote induction of type III IFN to locally restrict norovirus replication.[174] Intestinal bacteria–generated bile acids also can influence infection outcomes with nonenteric viruses. Depletion of the microbiome increases dissemination and tissue burdens of CHIKV due to impaired type I IFN induction in plasmacytoid dendritic cells (pDC).[531] Control of CHIKV infection and normal pDC type I IFN responses were restored in antibiotic-treated mice reconstituted with *Clostridium scindens* or treated with the secondary bile acid deoxycholic acid, which can be generated by *Clostridium scindens*. Although the mechanism(s) is not known, the gut microbiota also can regulate type I IFN responses in lung epithelial cells to limit influenza A virus infection.[58] These findings highlight how microbiota-generated metabolites can regulate immunity to viral infection, including at distal sites, and function as a determinant of viral pathogenesis.

Coinfection as a Determinant of Viral Infection Outcomes

An additional host property that can determine the susceptibility to virus infection is the presence of coinfection. For example, coinfection with *Mycobacterium tuberculosis* (TB) can accelerate the progression of disease during HIV-1 infection by a number of proposed mechanisms including T-cell exhaustion and TB-activated inflammation.[269,535] Enteric helminths commonly infect humans, and these infections can cause profound alterations in host metabolism and immunity that influence the outcomes of viral infection.[109] Prior infection of mice with the enteric helminth *Trichinella spiralis* diminished the development of antiviral immunity and enhanced the intestinal viral burden following murine norovirus infection.[364] These effects were independent of the host microbiota and were instead mediated by IL-4- and STAT6-dependent signaling stimulated by helminth infection. HSV-2 infection in the murine female genital tract also is more severe during helminth coinfection, likely due to helminth-induced recruitment of eosinophils and induction of a type 2 immune profile in the female genital tract.[86] Enteric helminth infection also can influence systemic viral infections as coinfection of mice with the intestinal roundworm *Heligmosomoides polygyrus bakeri* increased disease severity following WNV infection again by an IL-4 and STAT6-dependent mechanism.[110] In contrast, induction of IL-4 and its effects on $CD8^+$ T cells during infection with the flatworm *Schistosoma mansoni* or the intestinal roundworm *Nippostrongylus brasiliensis* enhanced control of a subsequent respiratory infection with murine γHV68,[407] and helminth coinfection has been shown to protect against other respiratory virus infections including influenza A virus.[428] Coinfection with protozoan parasites also can dictate susceptibility to virus infection. In clinical studies conducted during the Ebola outbreak in West Africa, Ebola virus–infected patients who had *Plasmodium* parasitemia were found to be more likely to survive.[411] In a mouse model, prior exposure of mice to *Plasmodium yoelii* protected from a subsequent infection with mouse-adapted Ebola virus.[406] These protective effects were mediated by *Plasmodium*-mediated induction of IFN-γ. Similarly, prior exposure of mice to *Plasmodium* species suppresses CHIKV replication and joint disease by the induction of IFN-γ.[478] These examples and many others demonstrate that coinfections can profoundly impact viral pathogenesis.

Effects of Comorbidities on Susceptibility to Viral Infection

Similar to coinfection, the presence of underlying noninfectious diseases and disorders at the time of virus exposure can impact the pathogenesis of viral infection. Perhaps the most common condition linked with altered viral pathogenesis is immunosuppression. For example, immunocompromised hosts, including induced immunosuppression for transplant recipients, autoimmunity, and other reasons, are highly susceptible to severe HCMV infection that can be characterized by pathology in a variety of tissues (eg, retinitis, pneumonitis, and hepatitis) not typically observed during HCMV infection of immunocompetent individuals.[179] As mentioned above, the COVID-19 pandemic has revealed that individuals with neutralizing autoantibodies against type I IFNs, another form of immunosuppression, are more susceptible to life-threatening SARS-CoV-2 infection.[34,35,297]

Obesity was identified as a risk factor for severe influenza during the 2009 influenza A H1N1 pandemic.[298,487,536] In animal studies, genetic and diet-induced obese mice develop more severe disease following infection with mouse-adapted influenza A virus and 2009 H1N1 influenza A virus.[350,458] The worse disease was characterized by differences in the pulmonary inflammatory response (ie, composition of lung infiltrates); more severe injury in lung tissue, including protein exudates and edema; and poor reconstitution of damaged airway epithelium. Similarly, mice with diet-induced obesity and type 2 diabetes are more susceptible to severe MERS-CoV infection characterized by poor wound healing and delayed recovery from virus-induced lung damage.[264] The impact of obesity and metabolic diseases on respiratory virus infection has been further highlighted during the COVID-19 pandemic; obesity, diabetes, and hyperglycemia are associated with an increased risk of severe SARS-CoV-2 infection.[133,375,385,451,467,468,518,537] Collectively, these limited examples illustrate that preexisting comorbidities are important host properties that determine viral pathogenesis.

Viral Interactions With the Host Immune System Have a Major Impact on Viral Pathogenesis

The host immune system, which can be broadly divided into innate and adaptive (eg, antigen specific) immune responses, has a major impact on the pathogenesis of most viral infections. At a fundamental level, the innate immune system initially limits viral replication, while adaptive immunity mediates viral control and clearance. Therefore, poor innate and/or adaptive immune responses may lead to adverse outcomes such as uncontrolled viral replication and severe disease or failure to clear infection and chronic disease. However, while robust immune responses are needed for viral control and clearance, an overactive or dysregulated immune response can lead to immune pathology characterized by excess tissue damage and disease (Fig. 8.9). Therefore, understanding how a virus interacts with the immune system can provide important insights into the pathogenesis of virus-induced disease. Given the complexity of the host immune system and its regulation, a comprehensive discussion of the host immune system, or even specific aspects of the innate or adaptive immune system, is beyond the scope of this chapter. We will therefore provide some key examples to illustrate the importance of virus/immune system interactions in viral pathogenesis. For readers who are interested in a more in-depth discussion of the host immune system and its role in the response to viral infection, please consider the following resources.[1,339]

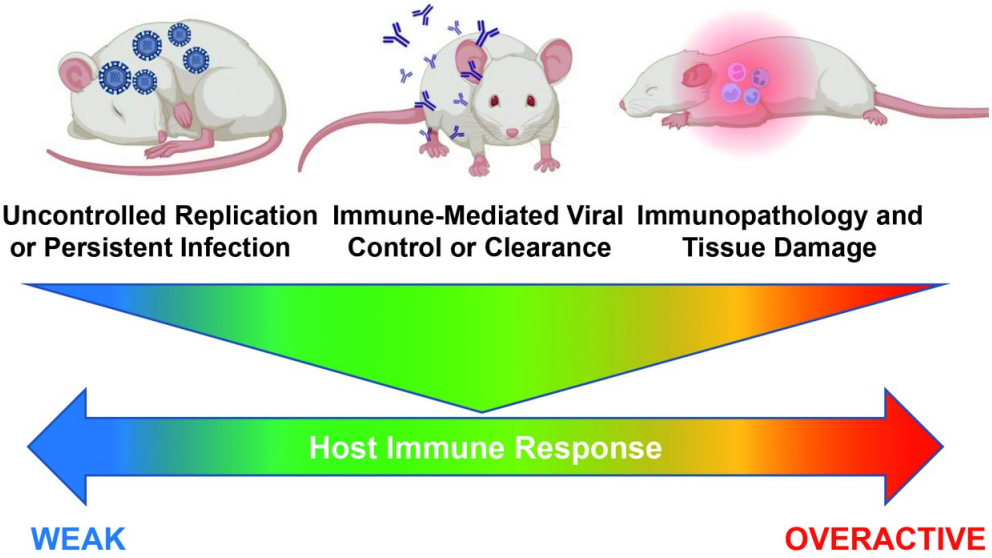

FIGURE 8.9 **Host immune responses mediate control of virus infection and immunopathology**. The strength of the host immune response can impact viral infection outcome. Individuals who mount weak or suboptimal immune responses may suffer from uncontrolled viral infection or persistence. Likewise, individuals who mount overactive or dysregulated immune responses can develop excess tissue damage and immune pathology. (Created with BioRender.com.)

The Host Immune System Plays an Essential Role in Controlling Viral Infection

The mammalian innate antiviral immune response consists of a variety of cell intrinsic antiviral restriction factors (eg, APOBEC3G), cytokines (eg, type I interferons), cell extrinsic defense pathways (eg, the complement cascade), and effector cells (ie, natural killer cells, neutrophils, and monocytes) that protect from viral infection through direct inhibition of the virus's ability to infect or replicate in cells, the induction of other antiviral molecules (eg, interferon stimulated genes of ISGs), or the killing of virally infected cells. The importance of these innate immune pathways for specific viruses has been demonstrated both in humans and in animal models. As discussed above, people with inborn genetic errors that result in defects in the induction of type I interferon responses, such as IRF7, exhibit enhanced susceptibility to a variety of viruses, including SARS-CoV-2 and Influenza A virus.[92,542] Likewise, NK cells play an important role in controlling herpesviruses, as demonstrated in mice infected with MCMV,[326] while humans suffering from NK cell deficiency or a loss of NK cell effector function are predisposed to recurrent herpesvirus infections.[361] In addition to directly controlling viral infections, innate immunity also influences the adaptive immune system by recruiting immune cells, promoting efficient antigen presentation and co-stimulation, and shaping the nature of antiviral antibody and T-cell responses. Therefore, the quality of the innate immune response to a virus can influence the efficacy of the adaptive immune response and thereby determine whether a viral infection is cleared or results in persistent infection and chronic disease.[551]

The innate immune system is composed of multiple effector molecules, signaling pathways, and cell types that play important roles in the host response to viral infection.[551] For example, the type I interferon system, as well as the related type II (IFNγ) and type III (IFNλ) interferons, plays a particularly important role in the response to viral infection. Interferons (IFN), which can act in both an autocrine and a paracrine manner, stimulate a wide array of IFN-stimulated genes (ISGs), which exhibit antiviral and immune modulatory activity.[432,434,495] As noted above, humans with genetic defects in key genes that regulate interferon induction or signaling are at significantly increased risk of developing severe virus-induced disease.[92,542] Likewise, studies in animal models have demonstrated that type I IFN signaling is essential for controlling a wide variety of viruses[533]; can regulate the tissue tropism or even host range of viruses such as Sindbis virus, myxoma virus, and ZIKV[415,516,533]; and also modulates the host adaptive immune response to influence viral clearance and protection from persistent infection.[551] The importance of the type I IFN system in controlling viral infections is further illustrated by the fact that most, if not all pathogenic human viruses have evolved strategies for evading detection by the host IFN system or actively antagonize key components of the IFN system to block type I IFN induction, IFN receptor signaling, or the activity of specific IFN-induced antiviral effector molecules. As discussed above, these virally encoded IFN antagonists are often essential for viral virulence. For example, the NSs protein of RVFV antagonizes the host type I IFN response by interfering with host transcription.[45,275] RVFV strains carrying mutations that disrupt NSs function are attenuated in wild-type animals, but these viruses regain full virulence in mice lacking a functional type I IFN system, demonstrating the importance of NSs-mediated IFN antagonism for the virus-induced disease process.[54]

The adaptive immune system also plays an essential role in the pathogenesis of most mammalian viruses. Although a comprehensive review of the adaptive immune system is beyond the scope of this chapter, virus-specific T-cell and antibody responses are essential for viral clearance, contribute to the control of persistent and/or latent viral infections, and protect from reinfection through the maintenance of long-term immune memory. Individuals with inborn immune deficiencies that affect T-cell function, HIV-induced acquired immunodeficiency syndrome (AIDS), or immune-suppressed individuals exhibit increased susceptibility to virus infections. For example, functional T-cell responses are essential for control of pox viruses, where vaccinia virus infection results in little or no disease in immunocompetent individuals, but T cell –deficient individuals are at risk of progressive vaccinia that can be fatal.[506] These individuals are also susceptible to certain virus-induced cancers, such as Kaposi sarcoma; suffer from recurrent herpesvirus infections; and exhibit defects in clearance of viruses such as noroviruses and SARS-CoV-2.[412] Although T cell–mediated immunity is generally thought to be more important for control and clearance of viral infections, and persons suffering from B-cell deficiencies or agammaglobulinemia (antibody deficiency) are at lower risk of severe viral infection than those suffering from T-cell deficiency, humoral immunity plays roles in the control of infections and is often the main correlate of immune protection from reinfection following either natural infection or vaccination.[173] B-cell or antibody deficiency, as well as treatment with B cell–depleting therapies, has been associated with persistent infection or severe disease outcomes for viruses such as WNV, human norovirus, and SARS-CoV-2.[88,202,251,365,479]

Heterologous Immunity

Heterologous immunity, or immunity to prior infections that impacts the outcome of subsequent infection with a distinct infectious agent, can have profound effects on viral pathogenesis that range from complete protection to severe immunopathology and disease enhancement. Heterologous immunity is typically mediated by cross-reactive T cell or antibodies, but other effectors of immunity also can contribute. Mechanisms of heterologous immunity include direct cross-reactivity between unrelated viruses, nonspecific activation of bystander cells, cytokine-mediated activation of cells that engage residual antigen from prior infections, and virus infection mediated induction (eg, via cytokines or cell injury) of self-antigen. All of these mechanisms can alter T and B cell memory responses, repertoires, and immunodominance leading to variation in the outcome of viral infection.[525]

A prominent example of heterologous immunity impacting viral pathogenesis is observed with DENV infection (Fig. 8.10). A major risk factor for clinically severe dengue (ie, dengue hemorrhagic fever/dengue shock syndrome) is prior infection with a distinct DENV serotype.[93,420,529] In addition, DENV infection in infants born to dengue-immune mothers when maternal antibodies wane to subneutralizing levels also is associated with increased risk of severe dengue.[84,246,450] A number of studies suggest that the immunological mechanism for these observations is antibody-mediated enhancement (ADE) of DENV infection and disease[190,238] in which heterotypic antibodies, at specific concentrations, bind but do not neutralize DENV virions during the secondary infection. These antibody-coated virions are recognized by Fcγ receptors that mediate virus internalization and thus enhance DENV replication in leukocytes. This idea is further supported by studies showing that patients with DENV-specific afucosylated IgG1 with enhanced affinity for FcγRIIIA had more severe disease.[55,521]

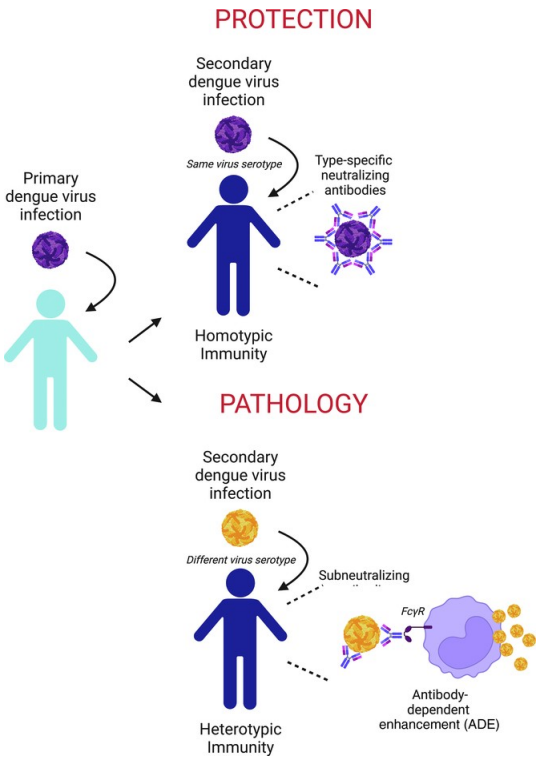

FIGURE 8.10 **Heterologous immunity affects outcomes of dengue virus infection**. The outcome of a secondary infection with dengue virus is dictated by the preexistence of homologous or heterologous immunity, with the latter associated with protection and the former associated with pathology due to the enhancement of dengue virus infection and disease by cross-reactive subneutralizing antibodies (nonneutralizing antibodies that bind the virion or neutralizing antibodies below the threshold concentration for neutralization). (Created with BioRender.com.)

During the SARS-CoV-2 pandemic, an important question has been whether prior infection with a common seasonal human CoV (ie, HKU1, OC43, 229E, and NL63) alters the outcome of SARS-CoV-2 infection. Indeed, some clinical studies found that patients with a previous seasonal human CoV infection developed less severe COVID-19, although there was no difference in the rate of SARS-CoV-2 infection.[55a] These data suggest that preexisting immunity against a seasonal hCoV can protect against severe SARS-CoV-2 infection. Additional studies found that some individuals possess nonneutralizing antibodies that cross-react with SARS-CoV-2 spike and nucleocapsid proteins[17]; however, these antibodies were not associated with protection against SARS-CoV-2 infection or severe COVID-19, suggesting that other immunological mechanisms such as cellular immunity may mediate heterologous protective immunity.

These are just two examples from a variety of studies indicating that heterologous immunity influences resistance and susceptibility to viral infection and disease.[441,525]

Viral Clearance and Chronic Viral Infection

The host immune system plays an essential role in the clearance of viral infections. These interactions can be roughly broken down into four categories: (1) clearance of acute infection with lifelong sterilizing immunity, (2) clearance of acute infection with transient immunity and reinfection, (3) viral latency, and (4) viral persistence with active viral replication. The immune system plays a fundamental role in each of these viral infection outcomes. Many viruses, such as YFV, Venezuelan equine encephalitis, and variola virus, the cause of smallpox, are associated with acute infection, and provided the host survives the infection, the immune system rapidly clears the virus and confers lifelong immunity to

reinfection. Other viruses, such as respiratory syncytial virus (RSV), noroviruses, and seasonal coronaviruses also cause acute infection and are cleared by the immune response. However, antiviral immunity against these viruses is often transient, allowing viral reinfection to occur as immunity wanes.[131] For example, RSV is a common respiratory infection in children that can cause serious respiratory disease, especially in preterm infants or young children with underlying medical conditions.[497] While the host immune system clears acute RSV infection, adaptive immune responses to the initial infection are weak, allowing reinfection to occur. Although subsequent infections result in more robust immunity and reduced disease susceptibility, RSV can continue to reinfect individuals into adulthood and is a common cause of severe respiratory infection in the elderly as antiviral immunity wanes.[497]

Many viruses are associated with chronic disease in the form of either viral latency or persistent infection with ongoing viral replication, and the host immune response plays an important role in regulating these types of infections. Herpesviruses have both lytic and latent phases in their replication cycle, and following the establishment of viral latency, herpesvirus can undergo frequent reactivation events leading to lytic replication and virus production. The host immune system plays an important role in regulating both lytic and latent stages of the herpesvirus life cycle. For example, NK cells and cytotoxic T cells are essential for controlling acute herpesvirus infection, such as MCMV, and individuals with defects in NK-cell or T-cell function are at increased risk of recurrent herpesvirus infection.[13,102,195,300,361,397] Importantly, these viruses have evolved a wide variety of mechanisms for modulating both NK-cell and T-cell recognition to allow the virus to avoid immune clearance during acute infection, while viral latency limits or eliminates production of viral proteins, allowing herpesviruses to avoid immune detection during latency.[361] Other viruses, such as HIV and HCV, cause persistent infection characterized by continuous viral replication. Although the host immune response controls the initial burst of viral replication, the immune response is unable to clear infection due to the viruses' high mutation rate, which results in the rapid generation of viral escape variants that are able to evade antiviral T cells or antibody-mediated neutralization and maintain viral persistence.[70,223] The failure of the immune system to clear these types of persistent infections can have significant consequences for the host, including organ failure or cancer. For example chronic HBV infection is associated with increased rates of cirrhosis, can lead to liver failure, and significantly increases the risk of developing hepatocellular carcinoma.[183]

Immune Clearance of Viral Infection Can Lead to Tissue Damage and Disease

The host immune system employs both cytolytic and noncytolytic strategies for clearing viruses from infected cells and tissues. Noncytolytic mechanisms, which preserve the virally infected cell while clearing the virus, are important for minimizing tissue damage or preserving nonrenewable cell types such as neurons. Virus-specific antibodies play an important role in the clearance of Sindbis virus,[280] and nonneutralizing antibodies that bind to the viral E2 glycoprotein on the surface of infected neurons act in combination with IFN-γ to suppress viral replication without killing the cell.[177,280] Antibodies can also enter infected cells to inhibit replication of viruses such as reovirus and WNV without killing the infected cell,[483,507,508] and the tripart motif containing-21 (TRIM21) protein acts as an intracellular antibody receptor that can bind viruses opsonized with nonneutralizing antibody and promote viral degradation while inducing the activation of antiviral pathways.[143,305]

The immune system also employs a number of cell extrinsic mechanisms to initiate cell killing via apoptosis or other cell death pathways. These effectors include cytokines such as TNF and the complement cascade. NK cells and cytotoxic T cells also kill virally infected cells via cytotoxic granule components that are introduced into virally infected cells via perforin, and which have been shown to be important for the control of a variety of viruses, including herpesviruses, coronaviruses, arenaviruses, picornaviruses, and flaviviruses.[236,295,296,337,372,446]

Certain viruses, including HBV and LCMV, can persistently replicate without killing the infected cell. Therefore, viruses such as HBV can infect cells and replicate within tissues without causing significant cell death, tissue destruction, or disease for several weeks. However, liver damage and disease, as defined by release of serum alanine aminotransferase (sALT), a marker of hepatocyte lysis, occurs at later stages in the infection process in concert with the appearance of CD8 T cells and the expression of IFN-γ in the liver (Fig. 8.11).[527,528] Studies using HBV transgenic mice have demonstrated that these cytolytic CD8 T cells lyse infected cells via perforin and FAS dependent cell killing pathways. These CD8 T cells are essential for viral clearance but also contribute to acute liver damage through both direct cell killing and the recruitment of other inflammatory cell populations into the liver.[141,482] Therefore, while the immune response plays a key role in clearing virus from the liver, inflammatory damage and acute hepatitis are a consequence of this protective immune response.

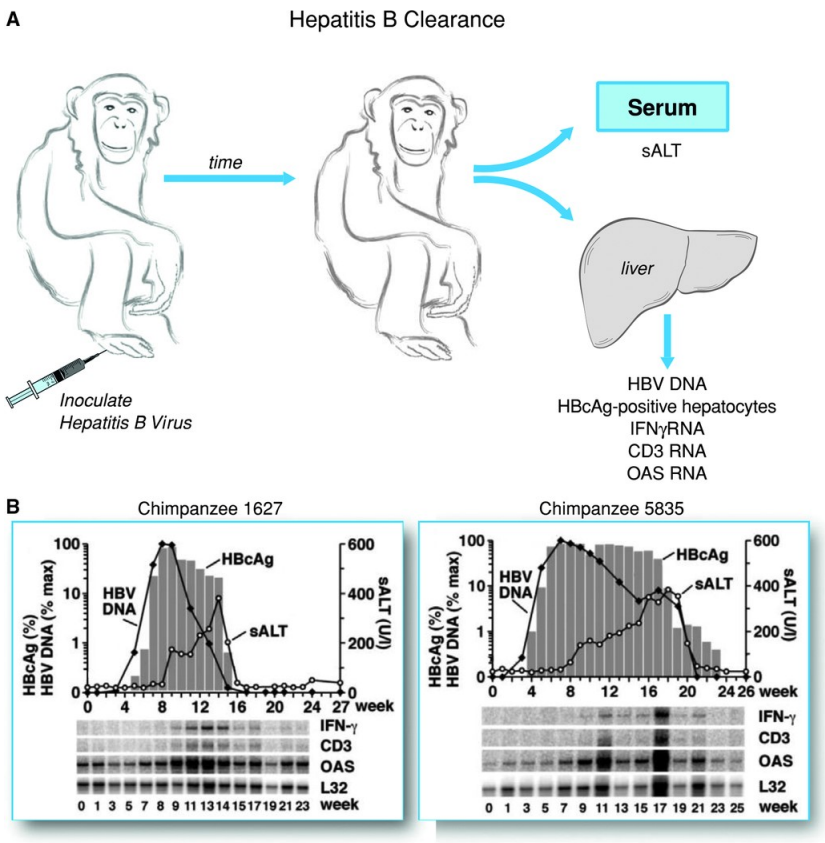

FIGURE 8.11 **Clearance of hepatitis B virus is associated with liver damage**. Chimpanzees were infected with HBV as illustrated in **panel A**, and at various times after infection serum samples or liver biopsies were taken and analyzed for serum alanine aminotransferase (sALT) and various parameters of HBV infection **panel B**. Intrahepatic HBV DNA (*black squares*, Panel B) is expressed as a percentage (% max) of the peak HBV DNA levels in the liver of each animal. Hepatitis B core antigen-positive (HbcAg) hepatocytes (*gray bars*) are expressed as percentage of the total number of hepatocytes. sALT (*open circles*) is expressed in units per liter. Intrahepatic expression profiles for IFN-γ, CD3, and 2′5′-OAS were determined by RNase protection assay. (Adapted by H.W. Virgin IV from Wieland S, Thimme R, Purcell RH, et al. Genomic analysis of the host response to hepatitis B virus infection. *Proc Natl Acad Sci U S A*. 2004;101(17):6669-6674. Copyright © 2004 National Academy of Sciences, USA.)

Overactive or Dysregulated Immune Responses Can Result in Immunopathology

As discussed in the previous section, tissue damage and disease are common consequences of the immune response to viral infection, and these processes are often referred to as immune pathology. However, it is important to differentiate between damage that occurs during clearance or resolution of the viral infection vs instances where an overactive or dysregulated response results in tissue damage or disease that is disconnected from viral clearance or may even result in enhanced viral replication.[52,549] These processes can be driven by dysregulated innate immune or inflammatory responses,[267] as well as adaptive antibody- or T cell–dependent immune responses.

The adaptive immune system is frequently associated with virus-induced immunopathology, with B- and T-cell responses both contributing to disease. As discussed above, ADE of DENV by nonneutralizing heterologous antibody responses resulting in severe DENV-induced disease is an example of antibody-mediated immunopathology. Antibody immune complexes, which are generated during persistent infections with a number of viruses, including LCMV, HBV, and HCV, are another example of how antibody-mediated immunopathology can contribute to virus-induced disease. These complexes, which consist of virus-specific antibody bound to viral antigens, can be deposited in the kidney and induce complement activation and inflammation, leading to kidney damage.[118,198,356-358,383,499,500] T cells have also been demonstrated to play an important role in promoting immunopathologic tissue damage and disease. This is clearly illustrated by studies with LCMV. Although LCMV is noncytolytic for infected cells, intracranial infection of adult, immunocompetent mice induces fatal choriomeningitis (inflammation of the choroid plexus and meninges).[52,66,312] This disease process is mediated by virus-specific CD8 T cells killing virally infected cells in the CNS, and depletion of these cells protects against disease, demonstrating that the virus-specific T cells are driving virus-induced immunopathology.[52,66,278,335,550]

The host innate immune system can also contribute to immunopathology independently of adaptive immunity. Although the complement cascade plays a protective role against a wide variety of viruses, including WNV, VEEV, DENV, and Sindbis virus,[25,199,314] complement activation can also contribute to virus-induced immunopathology. RRV causes debilitating arthralgia and myalgia in humans, and the virus infects skeletal muscle and causes severe myositis in infected mice that is characterized by inflammatory cell infiltration and complement activation.[286,331,334] MBL binding to N-linked glycans on the RRV E2 glycoprotein expressed on the surface of virally infected muscle cells[185,186] activates complement and promotes cell killing by inflammatory macrophages leading to myositis and limb weakness.[333] Mice lacking key complement components, such as MBL or C3, are resistant to virus-induced disease, but viral replication and clearance are largely unaffected,[186,331,333] indicating that complement activation is driving nonprotective immunopathology in this model.

Other aspects of the innate immune system that normally play protective roles against viral infection can also contribute to virus-induced

immunopathology in certain situations, including the type I IFN response. As discussed above, type I IFN is normally essential for controlling many viral infections, however, in some situations type I IFNs can exacerbate disease and drive immune pathology. For example, mouse adapted strains of SARS-CoV-1 cause severe respiratory disease in BALB/c mice,[402] and disease pathogenesis is in part driven by type I IFN and inflammatory monocytes.[80] Type I IFN responses are delayed in SARS-CoV-1 infected mice and do not contribute to viral control,[147] possibly due to the wide variety of IFN evasion strategies employed by this virus.[145,146,260] Instead, type I IFN promotes the recruitment and activation of inflammatory monocytes into the SARS-CoV-1 infected lung, and loss of functional type I IFN receptor signaling or depletion of inflammatory monocytes results in decreased virus-induced disease and a reduction of virus-induced pathology within the lung.[80] Type I IFN signaling can also contribute to immune pathology during chronic viral infection. For example, type I IFN contributes to early control of LCMV infection, but during chronic infection type I IFN suppresses CD4 T-cell function through the upregulation of negative regulators, thus inhibiting T cell–mediated viral clearance to promote viral persistence.[476] Therefore, dysregulation of normally protective immune mediators can also promote immune pathology and/or interfere with viral clearance.

Virus-induced immunopathology is most often associated with direct interactions between the immune system and the virus (eg, ADE) or virally infected cells. However, there is also the possibility that viral infection will lead to autoimmunity where the host immune response targets self-antigens to induce diseases such as diabetes and neurologic disease. Although the immune system is tightly regulated to avoid the generation of autoreactive immune responses, viral infections might break tolerance to induce autoimmunity through several mechanisms, including molecular mimicry (cross-reactivity between viral antigens and host antigens), unmasking host antigens through the infection of immune privileged tissues or cells, or bystander reactivation of anergic autoreactive immune cells through the actions of virus-induced cytokines or inflammatory signals.[456] Experimental models provide support for molecular mimicry as a potential driver of autoimmunity. Studies of LCMV infection in transgenic mice expressing LCMV proteins in insulin-producing islet cells demonstrate that viral infection can trigger diabetes by triggering a T-cell response against the self-like antigens expressed in the transgenic pancreas.[354,359,360,513,514]

Importantly, while infection by a variety of viruses, including enteroviruses, herpesviruses, and influenza viruses has been associated with the onset of type I diabetes or other autoimmune diseases in humans,[456] a direct causal role for viruses initiating these disease processes through molecular mimicry or bystander activation has not yet been demonstrated. Although the role of viral infections in driving human autoimmunity is still largely undefined and requires additional investigation, there are clear examples of virus-induced autoimmunity, including Guillain-Barré syndrome (GBS), an autoimmune disease where the immune system targets the myelin sheath on peripheral nerves, that can result in limb weakness that can progress to breathing problems in severe cases. GBS onset is often associated with infection by a number of viruses, including CMV, VZV, EBV, HSV, SARS-CoV-2, WNV, ZIKV, and CHIKV.[255,405] While GBS induction by bacterial infections, such as *Campylobacter jejuni*, is associated with molecular mimicry where antibodies against bacterial lipo-oligosaccharides cross-react with gangliosides on peripheral motor neurons,[255,405] the mechanisms underlying virus-induced GBS are not currently understood. Therefore, further investigation into the pathogenesis of virus-induced GBS is required to understand how infection initiates autoimmune responses against peripheral nerves.

Viral Pathogenesis Research Going Forward

Over the past 40 years, the world has suffered three major pandemics (HIV, 2009 H1N1 Influenza A virus, and SARS-CoV-2), as well as multiple regional outbreaks and epidemics by emerging or reemerging viruses such as CHIKV, ZIKV, and Ebola virus. These viruses have caused significant human suffering, millions of deaths, trillions of dollars in economic loss, as well as significant social disruption and in some cases, the near collapse of public health systems. Importantly, these outbreaks appear to be occurring with increased frequency, and despite advances in vaccine and antiviral development, virus-induced disease represents an ongoing and growing threat to human health. Viral pathogenesis research to understand the mechanisms that drive virus-induced disease and the factors that determine an individual's susceptibility or resistance to a given viral infection represents a key part of the response to these viral threats. This information is essential for the development of safe and effective vaccines or therapies against existing virus-induced diseases, while also laying the groundwork to guide responses to newly emerging pathogens.

The viral pathogenesis field has benefited from advances in research areas such as molecular biology, synthetic biology, systems biology, functional genomics, and genome engineering to gain unprecedented insights into the biology and pathogenesis of a wide variety of viruses. The impact of these advances is illustrated by the rapid pace of research on SARS-CoV-2 pathogenesis, where many of the research areas and technologies discussed in this chapter, including epidemiology, clinical research, synthetic biology, systems biology, functional genomics technologies, and advanced animal models have informed the field's understanding of the pathogenesis of SARS-CoV-2-induced disease. In addition to providing important new insights into the pathogenesis of SARS-CoV-2-induced disease processes, this work, in combination with prior pathogenesis studies on the original SARS-CoV and MERS-CoV, has guided the rapid development and deployment of highly effective and safe SARS-CoV-2 vaccines and therapeutics. Given the threat posed by new emerging viruses, and the availability of increasingly powerful techniques for studying both the viral and the host side of the disease process, the viral pathogenesis field is likely to continue to thrive and provide new insights into virus-induced disease processes that inform public health responses to new and existing viral diseases.

Conclusion

The innate immune system provides a universal form of host protection from infectious pathogens. Viruses enter the host either through the mucosal surfaces or transmitted by blood-feeding arthropods. Consequently, there are natural intrinsic immune defense mechanisms that block invading viruses at the mucosal surfaces and in blood. Even before the virus can enter the host cell, it faces barriers at the entry surfaces. The cornified epithelia of the skin provide a formidable barrier against viruses. At the surfaces of respiratory, gastrointestinal, and genitourinary tracts, the virus must penetrate the mucus layer coating to reach host target cells. The mucus is an aqueous secretion containing inorganic salts, antimicrobial enzymes, immunoglobulins, and glycoproteins such as lactoferrin and mucins. Viruses caught inside the mucus layer can be destroyed by antimicrobial enzymes. Mucus also assists in the removal of trapped viruses through mucociliary clearance mechanisms.

If the viruses manage to attach to the host cell epithelia lining the mucosal membranes, they must utilize cell surface molecules as viral entry receptors to enter the cell. Upon successful entry, viruses will be detected by a variety of pattern recognition receptors (PRRs) that sense unique features of viruses, mostly through the recognition of viral nucleic acids. Because viruses can infect most cell types of the host organism, every cell is equipped to detect and initiate immune responses against viruses. A key set of molecules induced by signaling downstream of PRRs are interferons (IFNs) and cytokines. IFNs induce hundreds of genes, known as IFN-stimulated genes (ISGs), that act on multiple stages of the viral life cycle to stop the production of viruses and prevent the spread of viruses. At the same time, both IFNs and cytokines induce the production of

chemokines that attract circulating immune cells to the site of infection. Recruited cells further contribute to host defense, by fortifying innate antiviral defenses, and by inducing adaptive immune responses. One of the main host innate immune defense strategies against viral pathogens is the elimination of the infected cells. This can be achieved by the effects of IFNs that promote the death of infected cells, or with the help of cytotoxic lymphocytes. Many additional antiviral defense mechanisms are mediated by ISGs to interfere with viral entry, replication, gene expression, virion assembly, and exit from the infected cells.

This chapter describes innate immune responses against viruses, with a primary emphasis on humans and other mammals. While many other innate antiviral functions are preserved throughout evolution, such as RNAi and xenophagy, this chapter will focus mostly on interferon and cytokine-induced antiviral defense mechanisms. It describes various host sensors that detect DNA and RNA viruses, signaling downstream of PRRs leading to IFN production. We will describe how these IFNs trigger the synthesis of ISGs and how they mediate their effector functions to provide an antiviral defense. We will describe viral evasion mechanisms against various host defense mechanisms. Finally, key cell types that are specialized to respond to viral infections are discussed.

Sensing Viral Infections

Viral Sensing Through Pattern Recognition Receptors

The mammalian immune system detects the presence of viruses through multiple mechanisms. The best-understood mechanisms involve various PRRs. The most common molecular patterns associated with virus infection are the features associated with viral nucleic acids. Innate immune recognition can be cell-intrinsic or cell-extrinsic, depending on whether it is mediated by infected or noninfected cells. Cell-intrinsic innate immune recognition is mediated by cytosolic sensors, including the RIG-I–like receptors (RLRs), cGAS, and NOD-like receptors (NLRs). Activation of these receptors generally occurs in infected cells. Accordingly, PRRs involved in cell-intrinsic recognition are broadly expressed because viral pathogens target a variety of cell types for replication. In contrast, cell-extrinsic innate immune recognition is mediated by transmembrane receptors, including Toll-like receptors (TLRs) and C-type lectin receptors (CLRs); their activation does not require the cells expressing these receptors to be infected. Cell-extrinsic recognition is mainly mediated by specialized cells of the immune system, such as macrophages and dendritic cells (DCs).

PRRs involved in microbial recognition have modular structures and share several structurally related domains for innate recognition, multimerization, interaction with adaptor molecules, and signaling (Fig. 9.1).

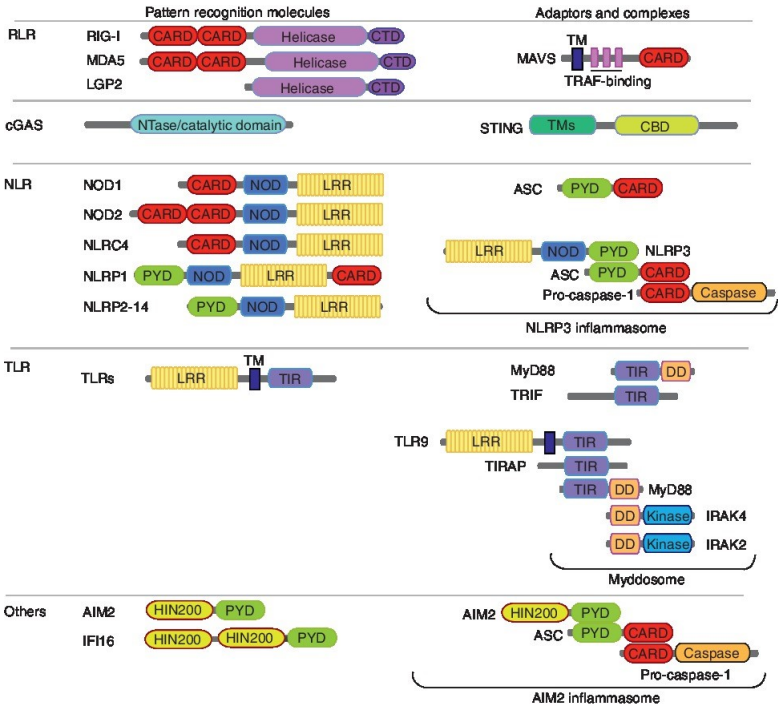

FIGURE 9.1 **Domain structure of viral sensors and adaptor molecules**. Pattern recognition molecules involved in viral sensing contain distinct domains, some of which are shared by different classes of receptors. These domains include CARD, caspase activation, and recruitment domain; CTD, C-terminal domain; DD, death domain; HIN200, hemopoietic IFN-inducible nuclear proteins is a 200-amino acid motif; LRR, leucine-rich repeat; NOD, nucleotide-binding oligomerization domain; NTase, nucleotidyltransferase; CBD, cGAMP-binding domain; PYD, pyrin domain; caspase domain; TIR, Toll/interleukin-1 receptor; TM, transmembrane region. Many of these domains can be used for homotypic oligomerization. Examples of molecular complexes are depicted for NLRP3 and AIM2 inflammasomes.

Cell-Autonomous Virus Recognition

RIG-I–Like Receptors

RNA viruses are recognized by the cytoplasmic RNA helicases, retinoic acid–inducible gene-I (RIG-I), and melanoma differentiation–associated gene 5 (MDA5).[246] The RLRs are expressed by most cell types. Both RIG-I and MDA5 recognize viral RNA through their helicase domains and the C-terminal domains (CTDs). Binding to viral RNA induces a series of conformational changes that include oligomerization of the helicase

domain and a caspase activation and recruitment domain (CARD) to initiate antiviral signaling[195,247] (Fig. 9.1). Both RIG-I and MDA5 utilize a common adaptor molecule called mitochondria antiviral signaling protein (MAVS),[207] which localizes to the mitochondrial membrane[207] and the peroxisomes.[59] MAVS directly recruits multiple TRAF E3 ligases (TRAF2, 3, 5, and 6) and activates TBK1-IKKi and IKKα/IKKβ/IKKg complexes, leading to activation and nuclear translocation of transcription factors IRF3 and NF-kB, respectively[62,136,211] (Fig. 9.2). MAVS can also activate IRF3 and NF-kB through mechanisms involving FADD-caspase-8/10,[222] TANK-NAP1,[196] and MEKK1.[248]

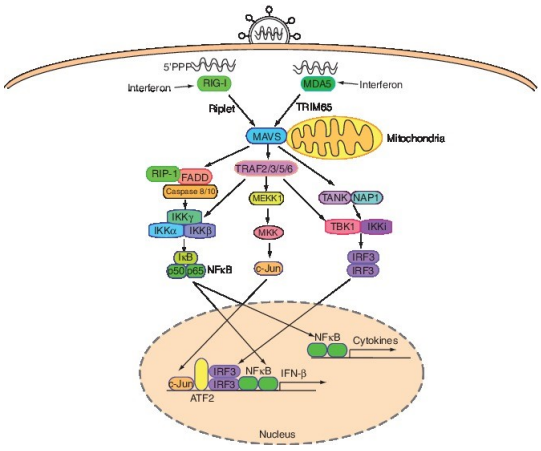

FIGURE 9.2 **RIG-I and MDA5 virus recognition pathways**. In a virally infected cell, RNA structures that are unique to viruses are recognized by RIG-I and MDA5. RIG-I detects dsRNA containing 5′ triphosphate, while MDA5 recognizes a long stretch of dsRNA. RNA binding to RLRs induces conformational changes, enabling their binding to MAVS adaptor protein expressed on the surface of mitochondria and peroxisomes. MAVS activates signaling to activate NF-kB, MAP kinases, and IRF3, leading to target gene expression including IFN-b and cytokines. Type I IFNs increase the levels of RLRs in bystander cells, enabling robust antiviral signaling upon infection.

RIG-I

RIG-I consists of two N-terminal CARDs, a central DExH box RNA helicase/adenosine triphosphatase (ATPase) domain and a zinc-binding CTD (Fig. 9.1). RIG-I functions as a critical PRR for many viruses including Sendai virus (SeV), vesicular stomatitis virus (VSV), influenza, hepatitis C virus, Japanese encephalitis virus, and Epstein-Barr virus.[110] RIG-I recognizes double-stranded RNA (dsRNA) that contains 5′-triphosphate or 5′-diphosphate ends, but not 5′-monophosphate, 5′-OH, or a 2′*O*-methyl group (as in the cellular mRNA cap structure).[78,187,199,204] While short (20 bp) dsRNA can bind and activate RIG-I when the duplex structure resides within a stem-loop,[118] duplex length >30-40 bp is generally optimal for robust activation of the RIG-I signaling.[32,177] RIG-I has an ATP-powered dsRNA translocation activity,[167] which enables its assembly into filamentous oligomers along the length of the dsRNA.[177,181] RIG-I oligomers then recruit the essential E3 ligase Riplet in an avidity-dependent manner (Fig. 9.2), allowing only the oligomeric RIG-I to be conjugated with K63-linked ubiquitin chains (K63-Ub_n).[32] In the presence of K63-Ub_n, RIG-I CARD domains from adjacent subunits form a homotetramer, serving as a seed to nucleate filament formation of MAVS.[180,243,249] MAVS filament functions as a signaling platform to recruit and activate further downstream signaling molecules.[90,137] This model suggests that RIG-I utilizes two distinct features of viral RNA simultaneously, the chemical structure of the 5′ end and duplex length. This mode of recognition can explain why RIG-I is more potently activated by SeV defective interfering (DI) particles than by wild-type virus.[20,216] However, for many other viruses, such as the influenza A virus, RIG-I ligands remain highly controversial and require future investigation.

MDA5

MDA5 senses many positive-strand viruses, such as picornaviruses and coronaviruses, and can be activated by cytosolic synthetic dsRNA, such as polyinosinic-polycytidylic acid (poly I:C).[75,110] There appears to be some level of redundancy in RIG-I and MDA5 in recognition of certain viruses. Dengue virus and West Nile virus are recognized by both MDA5 and RIG-I, and either of these sensors alone can induce type I IFN production.[144] Comparison of synthetic and viral dsRNA of various lengths revealed that MDA5 preferentially recognizes longer dsRNA that is at least ~1-2 kbp in length.[109] But this length threshold is not absolute—rather, it is dependent on dsRNA and MDA5 concentrations and other factors that together determine the stability of the MDA5 multimeric assemblies on dsRNA. MDA5 cooperatively assembles filaments along the length of the dsRNA.[22,179] MDA5 filament then recruits the essential E3 ligase TRIM65 (Fig. 9.2), which conjugates MDA5 with K63-Ub_n and activates CARD in a manner analogous to how Riplet activates RIG-I.[103,111] Unlike RIG-I, MDA5 filament formation does not require a triphosphate group at dsRNA 5′-end. Also unlike RIG-I, MDA5 does not translocate along dsRNA and does not require ATP hydrolysis to assemble filaments. These differences in assembly and disassembly mechanisms likely explain their distinct viral RNA specificity.

Studies also showed that both MDA5 and RIG-I can be aberrantly activated in the absence of viral infection, causing a spectrum of inflammatory disorders. Certain gain of function mutations in these receptors or loss of function mutations in their regulators (such as an RNA-modifying enzyme, ADAR1) lead to misrecognition of cellular RNAs by MDA5 and RIG-I and constitutive activation of the antiviral signaling pathways.[4,65,101,189,190] Environmental stress, such as certain chemotherapeutic agents or ionizing radiation, can also activate MDA5 and RIG-I through induction of virus-like cellular RNAs.[40,63,185,193]

LGP2

The third member of the RLR family, LGP2, harbors the helicase domain and CTD that are highly homologous to those of RIG-I and MDA5. However, LGP2 lacks a CARD and is unable to directly activate MAVS and downstream antiviral signaling pathways. LGP2 plays seemingly

complex regulatory roles for RLR signaling; LGP2 can either suppress or enhance RIG-I signaling depending on the context, while LGP2 enhances MDA5 signaling in response to both poly I:C and EMCV infection.[41,198,238] At least two distinct mechanisms have been proposed for how LGP2 stimulates MDA5 signaling. First, LGP2 was found to assist MDA5 filament nucleation, which is the rate-limiting step of MDA5 filament formation, thereby assisting the MDA5 signaling.[30] Second, LGP2 was shown to suppress Dicer's ability to process long viral dsRNA into siRNAs, thereby preserving MDA5 ligands and increasing the MDA5 signaling potential.[236,254] On the other hand, LGP2 was also shown to bind and sequester Ubc13, a subunit of the primary E2 conjugating enzyme for K63-Ub_n synthesis in the cytoplasm.[129] Considering both RIG-I and MDA5 signaling require K63-Ub_n, this could potentially function as a mechanism for their negative regulation. These multiple activities of LGP2 that can both positively and negatively affect different steps of the RLRs signaling pathway may explain the context-dependent effect of LGP2.

cGAS

cGAS is a sensor for cytoplasmic DNA. Upon double-stranded DNA (dsDNA) binding, cGAS undergoes a conformational change in the nucleotidyltransferase domain and joins ATP and GTP to synthesize cyclic GMP-AMP adduct (cGAMP).[3,58,72,218,252] cGAMP is then released from cGAS and functions as a second messenger to activate the downstream adaptor molecule STING, which is located on endoplasmic reticulum (ER) membranes[97] (Fig. 9.3). cGAMP binding triggers a conformational change in STING and induces STING oligomerization,[60,208,250,257] which enables recruitment and activation of TBK1 and IRF3 (Fig. 9.3). STING activation is accompanied by translocation of STING from ER to Golgi via the ER-Golgi intermediate compartment (ERGIC)[81] (Fig. 9.3). STING's redistribution to the ERGIC/Golgi compartment is required for STING signaling. While cGAS can be located in both the cytoplasm and the nucleus, only cytoplasmic cGAS is active because nuclear cGAS is tightly bound by the nucleosome in the inactive conformation, which prevents cGAS activation by the cellular DNA.[26,33,178,240,258] Cytoplasmic cGAS recognizes foreign DNA in a manner independent of DNA sequence, but dependent on double-stranded DNA (dsDNA) structure and length.[147] DNA length recognition is mediated by the cooperative assembly of ladder-like cGAS oligomers along DNA length.[9,132,253]

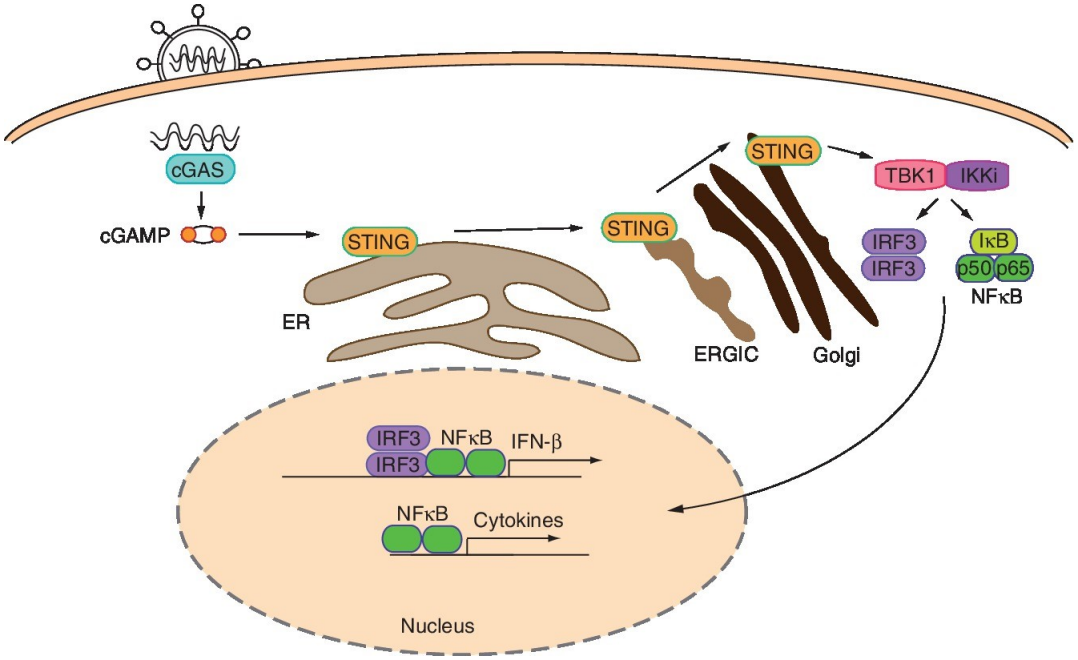

FIGURE 9.3 **cGAS virus recognition pathway**. Cytoplasmic DNA is recognized by cGAS. Upon dsDNA binding, cGAS joins ATP and GTP to synthesize cGAMP. cGAMP is then released from cGAS and activates STING localized on the ER membrane. cGAMP binding induces conformational changes in STING, enabling recruitment of TBK1 and activation of NF-kB and IRF3 to induce transcriptional activation of type I IFNs and proinflammatory cytokines. STING activation is coupled to and dependent on its translocation from ER to Golgi via the ERGIC intermediate.

Similar to RLRs, cGAS-STING signaling pathways can be activated in the absence of infection. For example, deficiencies in enzymes responsible for turning over endogenous DNA (eg, TREX1 and SAMHD1) can lead to autoimmune diseases due to the accumulation of cytosolic DNA and activation of the cGAS.[49,188,214] Gain-of-function mutations in STING also can result in aberrant activation of antiviral signaling and pathogenesis of inflammatory diseases.[102,140]

In addition to cGAS, other sensors can recognize viral DNA and activate antiviral innate immune responses. These include IFI16, DAI, and RIG-I (through Pol III–mediated RNA synthesis), which can play important roles depending on the DNA location and sequence composition.[2,43,223,234]

NOD-Like Receptors

NOD-like receptors (NLRs) comprise a large family of intracellular PRRs that regulate innate immunity in response to various pathogen infection and environmental stress.[155] The NLR family consists of multidomain proteins that contain a C-terminal LRR domain, a central NOD domain (a.k.a. NACHT domain), and an N-terminal effector domain. NLR proteins can be subdivided into three subfamilies depending on the structure of N-terminal domains—CARD-containing subfamily (NOD1, NOD2, NLRCs, CIITA), pyrin domain (PYD)-containing subfamily

(NLRPs) (Fig. 9.1), and BIR domain–containing subgroup (NAIPs) (not shown). Both NOD and NLRP members contribute to antiviral defense. The PYD subfamily of NLRPs consists of 14 members. Although the functions of many of the NLRPs are largely unknown, several NLRPs play a key role in the activation of caspase-1 by forming a multiprotein complex known as the "inflammasome" using the adaptor protein ASC[154] (Fig. 9.4). Caspase-1 is an essential mediator of the inflammatory response through its capacity to cleave and generate active forms of IL-1β and IL-18. IL-1β and IL-18 are potent proinflammatory cytokines. Activated caspase-1 also cleaves the pore-forming protein Gasdermin D, which releases the C-terminal repressor domain from the N-terminal pore domain and allows the formation of the multimeric pores in the plasma membrane[139,210] (Fig. 9.4). Gasdermin D pore facilitates cytokine release and induces an inflammatory form of cell death, namely pyroptosis. Formation and secretion of mature IL-1β and IL-18 require a two-step activation mechanism: first, transcriptional and translational upregulation of the pro-forms of these cytokines are induced by TLR and other cytokine stimulation (signal 1, priming), and a second signal that leads to the assembly of inflammasome and proteolytic activation of caspase-1 (signal 2, activation) (Fig. 9.4). Inflammasome complexes that are important in antiviral defense, in particular those activated by viral nucleic acid, are described below.

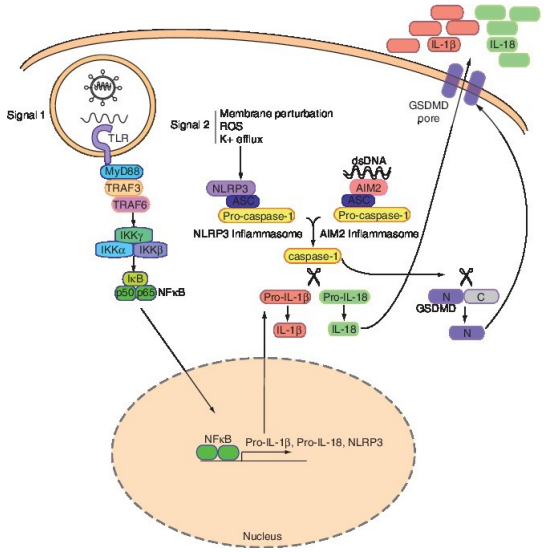

FIGURE 9.4 **Inflammasome activation by virus infection**. Virus infection can lead to inflammasome activation through two separate pathways. NLRP3 inflammasome is activated upon infection by adenovirus or influenza virus. This pathway is initiated by membrane perturbation, K^+ efflux, and reactive oxygen species (ROS). The second pathway involves AIM2, which is activated by dsDNA in the cytosol. Both NLRP3 and AIM2 form complex with ASC and pro-caspase-1 (inflammasome), leading to the self-cleavage and activation of caspase-1. Pro-forms of IL-1bβ and IL-18 induced by TLR signals are cleaved by activated caspase-1. Gasdermin D (GSDMD) is also cleaved, resulting in the formation of Gasdermin D pores in the plasma membrane. Mature forms of IL-1β and IL-18 are then released to the extracellular space through the Gasdermin D pore.

NLRP3-ASC Inflammasome

NLRP3 forms an ASC-dependent inflammasome (Fig. 9.4).[230] In the resting state, NLRP3 forms a cage-like assembly that is pre-localized on membranes within the trans-Golgi network.[8] The cage structure shields the PYD domains from activating ASC, but at the same time is a necessary state for activation. Upon stimulation, NLRP3 relocalizes to the microtubule-organizing center (MTOC) and engages with NEK7 kinase, which then triggers the assembly of the active disc-like complex.[209] This assembly stimulates NLRP3 PYD oligomerization, which seeds nucleation of the ASC filament through the PYD-PYD interaction and ASC CARD oligomerization. Oligomerized ASC CARD in turn recruits caspase-1 through the CARD-CARD interaction, which induces the oligomerization and activation of caspase-1.[145]

The NLRP3 inflammasome can be activated by a variety of stimuli including endogenous signals from dying cells (uric acid), crystals (asbestos, silica, alum) as well as microbial signals such as whole bacteria, bacterial RNA, pore-forming toxins, and fungal infection.[155] It is unclear whether microbial ligands can directly activate the NLRP3 inflammasome. Instead, the NLRP3 inflammasomes may sense signs of cellular damage, such as disruption in membrane integrity (through detection of K^+ efflux),[165,182] extracellular ATP released from stressed or damaged cells,[153] or disruption of mitochondria or trans-Golgi structure.[38,261] Virus infection also results in the activation of inflammasomes. Both SeV and influenza virus activate the NLRP3 inflammasome.[7,107,229] DNA viruses such as adenovirus also stimulate the NLRP3 inflammasome.[166] However, NLRP3 inflammasome is not activated by transfection of naked viral RNA, poly I:C, or infection with reovirus (dsRNA virus) or VSV (ssRNA virus),[115,166] indicating that viral RNAs are insufficient to trigger inflammasome activation. In the case of the influenza A virus, the NLRP3 inflammasome can be activated through the activity of the M2 ion channel[95] or the viral RNA sensor ZBP1.[124] Note that ZBP1 can also function independently of the NLRP3 inflammasome in a RIP1/3- and MLKL-mediated manner upon infection with influenza virus.[260] *In vivo*, *Nlrp3* deficiency resulted in increased susceptibility to high-dose influenza virus challenge.[7,229] In addition, after a sublethal dose of influenza virus, ASC-dependent inflammasome activation is required to elicit adaptive protective immunity to influenza virus, indicating the importance of NLRs in linking innate viral recognition to adaptive immunity.[94]

AIM2-ASC Inflammasome

Not all inflammasomes are activated by NLRPs. Recent studies showed that AIM2 couples cytosolic dsDNA recognition to ASC-caspase-1 inflammasome.[31,64,88,192] AIM2 is a HIN200 family of proteins that contains a dsDNA binding domain (HIN domain) and the PYD domain, which promotes interaction with the PYD domain of ASC (Fig. 9.1). AIM2 recognizes dsDNA in the cytosol and forms a filament-like structure along the length of dsDNA, detecting both dsDNA structure and length as key viral signatures.[104,163] Filamentation of the AIM2 HIN domain is

accompanied by oligomerization of AIM2 PYD, which then seeds ASC PYD filament[156] and in turn caspase-1 filament, leading to activation of caspase-1 (Fig. 9.4). Vaccinia virus, which contains a dsDNA genome, was shown to require AIM2 for recognition and activation of caspase-1 inflammasomes.[88] It is interesting to note that different classes of dsDNA viruses are recognized by NLRP3 (adenovirus) or AIM2 (vaccinia virus) for inflammasome activation. This likely depends on both the accessibility of the dsDNA genome to intracellular sensors, as well as the viral-induced cellular stress responses. While cytosolic dsDNA can bind AIM2 directly and activate inflammasomes, how and where exactly NLRP3 becomes activated by dsDNA viruses is yet to be determined.

IFI16

IFI16 is another DNA sensor that contains PYD and HIN domains. Similar to AIM2, IFI16 also forms filaments on DNA in a sequence-independent manner.[164] Unlike AIM2, however, IFI16 contains a nuclear localization signal and can function in both the nucleus and the cytoplasm, depending on the cell type and viruses.[131,237] IFI16 was shown to detect viral DNA within the nucleus and suppress its transcription by recruiting epigenetic silencing factors, such as PML, Sp100, and ATRX.[158,159] In the nucleus, IFI16 forms filaments on DNA to measure the length of the exposed stretch of DNA and to discriminate between chromatinized host genome vs naked viral DNA. Consistent with this idea, IFI16 restricts gene expression from the naked transfected SV40 DNA but not from prechromatinized SV40 DNA introduced into cells by viral infection.[174] Accordingly, viruses with unchromatinized DNA, such as HSV-1, can be detected by IFI16, which then promotes loading of nucleosomes and the addition of heterochromatin marks for silencing of viral genes.[174] IFI16 can also induce cytosolic innate immune signaling pathways, for example, by activating ASC inflammasomes, presumably through a mechanism similar to that of AIM2.[114] IFI16 was also reported to stimulate a type I interferon signaling pathway through STING.[175,234] It remains unclear whether IFI16 is exported to the cytoplasm and directly activates cytoplasmic STING and ASC.

Cell-Extrinsic Virus Recognition

Toll-Like Receptors

Toll-like receptors (TLRs) are one of the first mammalian PRR families to be characterized in depth. There are 11 functional TLRs in mice (TLR1-7, 9, 11-13) and 10 functional TLRs in humans (TLR1-10). All TLRs are type I transmembrane proteins with ectodomains containing leucine-rich repeat (LRR) that mediate the recognition of PAMPs. Some TLRs recognize bacterial, fungal, and protozoan pathogens, while others are dedicated to the viral recognition.[225] This chapter will focus on the TLRs that recognize viral pathogens.

The transmembrane domains of TLRs dictate the localization of the receptor, and the cytosolic domain contains a Toll/interleukin-1 receptor (TIR) domain, which binds to adaptor proteins and ultimately leads to the expression of a variety of genes.[5] TLR activation by viruses triggers a complex signaling cascade that bifurcates into two main pathways, culminating in the synthesis of proinflammatory cytokines (NF-kB dependent) and antiviral cytokines, type I interferons (IFNs) (IRF dependent). In addition, TLR signaling results in the activation of the mitogen-activated protein kinases (MAPKs) (Fig. 9.5). TLR recognition by DCs, the most potent antigen-presenting cells, enables their activation and antigen-presenting function, effectively linking innate recognition to the induction of adaptive immunity.[100]

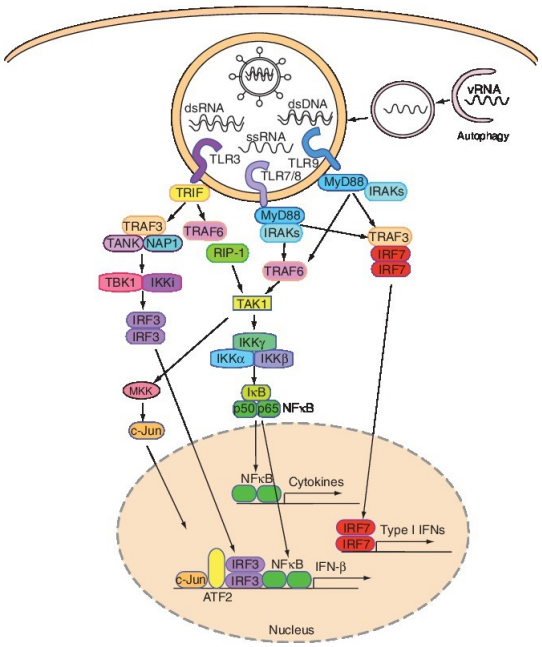

FIGURE 9.5 **Endosomal TLR virus recognition and signaling**. Viruses or virus-infected cells are endocytosed, and signatures of virus infection become accessible to TLRs upon digestion of membranes and nucleocapsid. TLR3 recognizes dsRNA, TLR7 and TLR8 recognize ssRNA, and TLR9 recognizes DNA. In addition, autophagy delivers TLR7 ligand (cytosolic viral replication intermediate) by fusion with the endosomes containing TLR7. Proteolytically activated TLRs in the endosomes recruit adaptor proteins and induce downstream signaling to activate a variety of transcription factors. IRF3 in combination with NF-kB, c-Jun, and ATF bind to the promoter and induce IFN-b expression. IRF7 homodimer binds to promoter regions of IFN-a genes and induces IFN-a expression. In addition, NF-kB activates transcription of a large number of genes including cytokines.

TLRs are distributed on specific subcellular locations and are specifically expressed by different cell types. TLRs can be categorized into two

major types, those that are expressed on the cell surface (TLR1, 2, 4, 5, 6, 11, 12) and those that are expressed in the endolysosomes (TLR3, 7, 8, 9). Although virus-TLR interaction can occur with both types of TLRs, many of the virus interactions with surface TLRs represent a viral invasion mechanism (beneficial to the virus) rather than PAMP recognition by TLRs (beneficial to the host). In this section, we will discuss the latter type of TLR-virus PAMP recognition leading to antiviral defense.

Viruses are recognized by a group of TLRs that reside in the endosomal membrane, namely, TLR3, 7, 8, and 9, where they can gain access to viral nucleic acids upon endocytosis of virions or nucleic acids released from infected and dead cells. A major advantage of this strategy of viral recognition is that the viral sensing and subsequent induction of type I IFN genes can occur in uninfected cells (thus called cell-extrinsic sensing) and, therefore, are not subjected to viral evasion mechanisms. In addition, since all viruses contain a genome consisting of RNA or DNA, such molecular patterns can be surveyed by a very limited number of receptors. These endosomal TLRs require trafficking by the endoplasmic reticulum (ER) membrane protein, UNC93B1,[29,221] and further regulation by UNC93B1.[150,151] Mutations in the *Unc93b1* gene were found in two patients with severe HSV encephalitis,[34] indicating the importance of transport of endosomal TLRs via UNC93B1 in antiviral defense. Within the endosome, TLR3, 7, and 9 additionally undergo processing by endolysosomal proteases cathepsins, which is required for receptor activation and downstream signaling.[61,108,176,232] Dependence of TLRs activation upon proteolytic processing in the endolysosomes provides an additional mechanism to ensure that aberrant activation of TLRs from the cell surface or other cellular location by self ligands is avoided.

TLR3

TLR3 is expressed by a variety of cells in humans and mice, including conventional DCs, B cells, fibroblasts, and epithelial cells but not in plasmacytoid DCs (pDCs). Upon PAMP recognition, TLR3 recruits TRIF via its TIR domain (Fig. 9.5). TRIF activates both NF-kB and IRF3, leading to proinflammatory cytokines and type I IFN gene expression, respectively. TLR3 recognizes dsRNA that is often generated during replication of RNA viruses (except for retroviruses).[6] DNA viruses also produce dsRNA by convergent transcription of their genomes.[241] TLR3 responds to the artificial dsRNA mimic, poly I:C, when it is provided extracellularly.[75,110] Structures of TLR3 in complex with dsRNA showed that TLR3 utilizes LRRs to recognize dsRNA structure,[130] binds dsRNA as a dimer, and possibly higher-order oligomer,[130,251] leading to a graduated response that increases with dsRNA length.[135] However, evidence supporting TLR3-mediated recognition of authentic viral replication intermediates remains elusive, possibly due to overlapping recognition pathways that can compensate for the loss of TLR3. TLR3 may also recognize virus-produced dsRNA in the context of phagocytized apoptotic cells.[205] Humans with dominant-negative mutations in the *TLR3* gene suffer from neonatal herpesvirus infection,[251] indicating the importance of this receptor in protection against HSV-1 in the CNS.

TLR7/8

In humans, TLR7 is expressed in plasmacytoid DCs and B cells, while TLR8 is expressed by myeloid DCs and monocytes. In mice, TLR7 is expressed by pDCs, conventional DCs (except for DC1s), and B cells. The function of the mouse TLR8 is still poorly understood. However, TLR8-deficient mice develop autoimmunity due to hyperstimulation of TLR7.[52] TLR7, 8, and 9 are all expressed in the endosomes and share similar signaling pathways. Upon cognate ligand engagement, these receptors recruit TIRAP via their TIR domains.[25] This interaction triggers oligomerization of TIRAP TIR domains, which in turn nucleates polymerization of MyD88 filament through TIR-TIR interactions.[45] The oligomer of MyD88 subsequently recruits IRAK2 and 4 through their death domains (DDs), resulting in the formation of a macromolecular assembly termed the myddosome.[133] Within the myddosome, IRAK2/4 triggers the downstream signaling cascades for activation of the NF-kB and IRF7 (Fig. 9.5).

TLR7 and TLR8 both induce innate immune responses to ssRNA-viruses. TLR7 signaling induces type I IFN and cytokine responses to influenza, SeV, and VSV.[56,148] While the influenza virus is recognized upon endocytosis by TLR7, other viruses such as VSV and SeV require replication in the cytosol before recognition by TLR7. These viruses are recognized by TLR7 in the endosome upon delivery of cytosolic viral replication intermediates through the process of autophagy.[128] Human TLR8 appears to function as a bacterial RNA sensor,[121] similar to the murine TLR13.[173] At the molecular level, TLR7 and TLR8 recognize degradation products of ssRNA.[227,255] Both TLR7 and TLR8 contain two distinct ligand-binding sites. Site 1, which is highly conserved between TLR7 and TLR8, recognizes nucleosides (G for TLR7 and U for TLR8). Unlike site 1, site 2 of TLR7 differs from that of TLR8, recognizing distinct degradation products of ssRNA. TLR7 site 2 binds successive U-containing ssRNA,[256] while TLR8 site 2 binds purine-2′3′-cyclophosphate generated by RNase T2-mediated cleavage.[80] Ligand binding at site 2 further stabilizes the ligand binding at site 1 and TLR dimerization.

TLR9

TLR9 is expressed in pDCs and B cells in humans. Mice express TLR9 in pDCs, B cells, macrophages, and conventional DCs. TLR9 is located in the endosome and mediates the recognition of viral DNA. Bacterial DNA sequences containing hypomethylated CpG motifs were shown to activate TLR9,[86] but the sugar-base-backbone, 2-deoxyribose, of phosphodiester DNA also plays an important role.[82] Crystal structures of TLR9 in complex with DNA showed that TLR9 binds ssDNA as a dimer.[170,171] As with TLR7/8, two sites are used to recognize both CpG DNA and 5′-TCG/TCC. Ligand engagement of both sites is important for TLR9 activation. Interestingly, a TLR9 molecule “retargeted” to the plasma membrane was unable to respond to viral nucleic acids, however, now responded to self DNA which did not stimulate wild-type TLR9.[19] These results suggest that not only is endosomal localization important to trigger TLR-viral nucleic acid interactions but that endosomal TLRs may limit access to non-viral nucleic acids via an active sequestering mechanism in the endosome.

C-Type Lectins

In addition to TLRs, CLRs expressed on the plasma membrane can bind to certain viruses. Classical CLRs contain a carbohydrate recognition domain responsible for the $Ca2^{+}$-dependent binding to their ligands. However, carbohydrate-recognition domains of many CLRs do not bind to $Ca2^{+}$.[12] CLRs can be classified into those that are used solely for endocytosis of pathogens, and those that are used for inducing signaling. The endocytic CLRs include mannose receptor, DEC205, and langerin, which are expressed on DC1s and Langerhans cells, respectively. Langerin on Langerhans cells is capable of clearing HIV by receptor-mediated endocytosis and degradation in Birbeck granules.[51]

The signaling CLRs include Dectin-1 and DC-SIGN.[53] Dectin-1, which is a receptor for fungal β-glucans, contains an ITAM motif in the cytosolic domain and engages Syk tyrosine kinase and CARD9, leading to NF-kB activation.[113] Dectin-1 plays an important role in antifungal defense, but it is not known to have antiviral functions. DC-SIGN binds to HIV-1 and Ebola virus. Signaling through DC-SIGN alone does not lead to the activation of NF-κB or expression of cytokines, but it can modulate signaling through other PRRs. DC-SIGN engagement by viruses leads to serine/threonine kinase Raf-1 activation. After translocation of NF-κB by TLR-stimulation, DC-SIGN–activated Raf-1 mediates the phosphorylation of NF-κB subunit p65, which in turn leads to p65-acetylation. Acetylation of p65 both prolongs and increases IL-10 transcription, resulting in increased IL-10 production. However, the majority of C-type lectin-virus interactions reflect the viral invasion mechanism. A clear example of this is DC-SIGN signaling by HIV-1. This interaction results in impaired DC maturation, enhanced T-cell proliferation, and transmission of HIV-1 to T cells, thereby promoting systemic infection of the host. DC-SIGN and a related C-type lectin, DC-SIGNR, also enhance infection by Ebola virus.[17] Another example is the dengue virus, which binds to CLEC5A and induces signaling through DAP12 to induce proinflammatory cytokines. This leads to lethality in infected mice.[39]

Innate Antiviral Cytokines

Interferons

Antiviral mechanisms in vertebrates are highly dependent on the action of interferons, a group of cytokines that are induced when a cell senses a viral infection. There are three types of interferons: type I (a, b, e, k, w, t), type II (g), and type III (l) (Fig. 9.6). The type I IFNs are the best studied for antiviral activity. Type III IFNs are also emerging as key players in innate immunity, primarily at mucosal surfaces, as described below. Type II IFN is often considered an antibacterial cytokine, though it also has bona fide antiviral properties. This section will focus primarily on the antiviral actions of type I and III IFNs, and type II IFN will be discussed below.

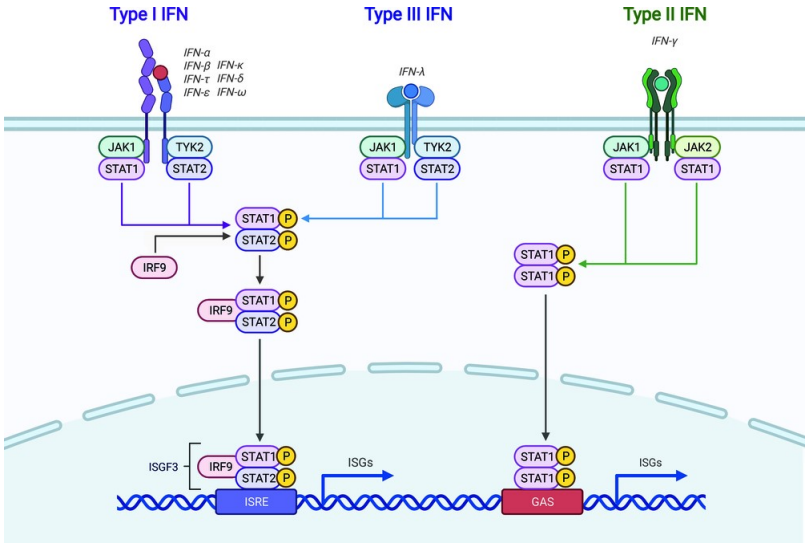

FIGURE 9.6 **IFN receptor signaling.** Type I, II, and III IFNs initiate signaling by binding their cognate receptors IFNAR, IFNGR, and IFNLR. Engagement of the receptors induces activation of prebound kinases (JAK1 and TYK2), leading to phosphorylation of STAT proteins. Phosphorylated STAT molecules form dimers, which translocate into the nucleus to initiate the transcription of genes. STAT1/STAT2 dimers recruit IRF9, forming ISGF3, which binds to ISRE sequence found in the promoter of many ISGs. STAT1 homodimer binds to the GAS sequence to induced transcription of a set of ISGs that partially overlaps with the ISGF3-dependent genes.

Type I IFN Overview

Type I IFNs are key cytokines for inducing an antiviral state in infected and uninfected neighboring cells,[96] and for promoting adaptive immune responses.[215] In humans, the type I IFNs consist of 13 α-genes coding for 12 IFN-α subtypes and single genes encoding IFN-β, IFN-ε, IFN-κ, and IFN-ω. IFN-β is a central cytokine in antiviral immune responses, as it can be produced by all nucleated cells upon infection. IFN-α subtypes are also critical in antiviral defenses, and many of the genes encoding IFN-α are directly induced by IFN-β signaling, resulting in amplification of the antiviral response. Other type I IFNs listed above have a tissue-specific expression (IFN-κ, IFN-ε), or they are expressed exclusively in certain lineages of mammals (IFN-τ, IFN-δ).

Type I IFN Induction

As described in detail above, stimulation of various PRRs including TLRs, RLRs, and cytosolic DNA sensors leads to the production of type I IFNs. Most virally infected cells trigger the cell-intrinsic pathway of type I IFN production through activation of RLRs or DNA sensors, which leads to phosphorylation of IRF3 and induction of IFN-β. Antigen-presenting cells additionally recognize viral genomes within the endosome via TLR7 or TLR9 and induce robust secretion of IFN-a and IFN-β. pDCs express high constitutive levels of IRF7 and are thought to be the only cells capable of coupling TLRs to IRF7 directly, thereby leading to rapid and robust transcription of type I IFN genes. IRF7 is also involved in amplifying the interferon response. The *IRF7* gene is induced by IFN-β, and IRF7 transcriptionally stimulates the production of additional IFN genes. Additionally, IFN signaling also increases the expression of some RLRs and TLRs, further augmenting the response.

Type I Interferon Signaling

The type I IFN receptor, herein referred to as IFNAR, is a heterodimeric receptor composed of chains encoded by IFNAR1 and IFNAR2 genes (Fig. 9.6). The canonical pathway for type I IFN signaling is depicted in Figure 9.6. Upon engagement of type I IFNs with the receptor, the receptor subunits dimerize resulting in phosphorylation of Tyk2, which is associated with the IFNAR1, by Janus kinase (JAK) 2. Activated Tyk2 subsequently phosphorylates JAK1, which is coupled to the IFNAR2 chain. Signal transducer and activator of transcription (STAT) 1 and 2 are prebound to the IFNAR2 chain. Activated JAK1 binds to STAT2 and phosphorylates it, creating a binding site for STAT1, and resulting in dimerization of STAT1 and STAT2. The STAT1-2 heterodimer forms a transcription complex, ISGF3, with IRF9 to facilitate transcription of ISGs by binding to sequences called interferon-simulated response elements (ISREs). In contrast to type I IFNs, type II IFN (IFN-g) signaling results in STAT1 homodimers that bind to the IFN-g–activated site (GAS) sequence motif (Fig. 9.6).

Type II Interferon

IFN-γ is secreted mainly by activated lymphocytes, such as T cells and NK cells, though other immune cells can also produce IFN-γ under certain conditions. The interferon-gamma receptor (IFNGR) is analogous to other IFN receptors and consists of two subunits: IFNGR1, the ligand-binding chain, and IFNGR2, the signal-transducing chain (Fig. 9.6). Receptor assembly leads to activation of JAK-STAT signaling, with STAT1 homodimers being the principal transcription factor that binds GAS elements in the promoters of responsive genes. IFN-γ is not as well known for its antiviral properties as other antiviral interferons, but it does exert antiviral activity by inducing the transcription of a set of ISGs that overlap with those induced by type I IFN.[55]

Type III Interferons

In humans, there are 4 type III IFN genes: *IFNL1*, *IFNL2*, *IFNL3*, and *IFNL4*. All have antiviral activity and loss of IFNL4 expression in certain human populations correlates with viral diseases, most notably hepatitis C.[184,228] Type III IFNs share many similarities with the type IFNs, though there are notable exceptions.[119,127,160,245] A major difference is that type III IFNs use a different receptor, IFNLR, which is a heterodimer IFNLR1 and IL-10Rb (Fig. 9.6). The intracellular JAK-STAT signaling cascade triggered by IFNL engagement with the receptor is mostly identical to the type I IFN–induced cascade, leading to the induction of similar sets of ISGs. In addition to distinct receptor utilization, IFNLR is also not as widely expressed as IFNAR. It is primarily expressed in mucosal tissues such as lung and intestinal epithelial cells. Thus, type III IFNs are emerging as key antiviral defense molecules at barrier surfaces. Type III IFNs are generally also less potent than type I IFNs, with slower signaling kinetics, and less induction of inflammatory signature due to the limited tissue distribution of the receptor.

Inflammatory Cytokines

In addition to type I IFNs, many inflammatory cytokines play an important role in antiviral defense, by either directly inducing antiviral effector molecules, or indirectly by stimulating cellular recruitment, phagocytosis of infected cells, and activating adaptive immune responses such as cytotoxic T lymphocytes and neutralizing antibodies. Cytokines can act locally through autocrine and paracrine mechanisms, or, if produced at high enough levels, they can gain access to the circulation and induce systemic effects, such as acute phase response or fever. The major inflammatory cytokines IL-6, IL-1β, and TNF-α are produced by virally infected DCs and macrophages and act systemically with a wide spectrum of biological activities that help to coordinate the body's response to infections. These cytokines are responsible for causing fever by inducing prostaglandin E2, which acts on the hypothalamus. This increases heat production from brown fat and induces vasoconstriction to prevent heat loss through the skin. Fever is thought to be generally beneficial to host defense, because some pathogens may replicate less efficiently at high temperatures. However, the role of fever in host defense is still incompletely understood. IL-6, IL-1β, and TNF-α also stimulate the acute phase response in the liver. Acute-phase proteins secreted by hepatocytes can have direct antiviral effects, for example, by promoting their killing by complement or phagocytes. Finally, IL-6, IL-1β, and TNF-α induce a leukocytosis, leading to an increase in circulating neutrophils, which are phagocytes that help to clear virally infected cells. When these inflammatory cytokines are overstimulated or chronically induced, however, they can lead to cytokine storm and immunopathology.

Interleukin-6

IL-6 is induced by virus infections downstream of most PRR signaling. IL-6 binds to IL-6R, which belongs to the hemopoietin family of receptors, which are tyrosine kinase–associated receptors that form dimers upon binding their cytokine ligand. IL-6R consists of IL-6Ra and gp130 chains. IL-6 bound to the IL-6Ra chain causes the association of the complex with gp130, resulting in the activation of Jak1, Jak2, and Tyk2, followed by the phosphorylation of Stat3. Phospho-Stat3 dimerizes and translocates into the nucleus, where it activates the transcription of target genes. IL-6 is a pleiotropic cytokine with a wide range of biological activities in immune regulation, hematopoiesis, inflammation, and oncogenesis.[117] IL-6 is induced by a variety of signals including TLR, NLR, and RLR signaling and is a key cytokine that triggers the acute phase response, as well as activation of T cells and antibody-producing plasma cells.

Interleukin-1-Beta and Interleukin-18

As described above, secretion of IL-1β and IL-18 requires the activation of inflammasomes. Both IL-1R and IL-18R are heterodimers of a ligand binding a chain and a coreceptor accessory protein (AcP). Both chains contain a TIR domain in the cytoplasmic tail. As such, these receptors recruit MyD88 and induce NF-kB signaling (Fig. 9.7). IL-1β through binding to IL-1R induces the expression of hundreds of genes, including cytokines (IL-6 and TNF-α), chemokines (eg, IL-8), and adhesion molecules that are important for the leukocyte trafficking.[57] In adaptive antiviral immunity, IL-1β plays an important role in the antigen-driven expansion and differentiation of CD4 T cells.[21] While IL-1R is widely expressed by many cell types, IL-1β is mainly produced by the sentinel cells of the innate immune system including macrophages and DCs, although fibroblasts and keratinocytes can also synthesize this cytokine in response to tissue injury or stress signals.[57,212] On the other hand, IL-18, which is expressed mainly by macrophages and DCs, works alone or in combination with IL-15 prime natural killer (NK) cells to produce IFN-γ and enhance their cytolytic activity.[67,92,226] IL-18 in combination with IL-12 or IL-2 can also induce differentiation of either Th1 or Th2 cell types depending on the cytokine milieu.[89,172] IL-18 is also required for optimal cytokine production by CTLs including IFN-γ, TNF-α, and IL-2.[54]

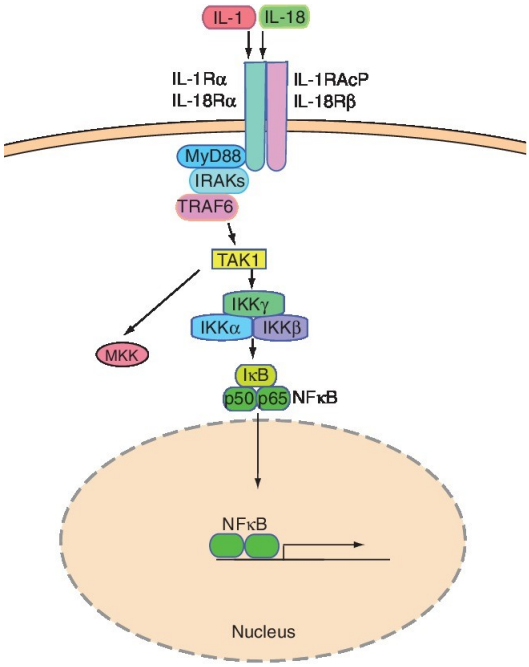

FIGURE 9.7 **IL-1R and IL-18R signaling**. IL-1R consists of the IL-1Ra chain and IL-1RAcP chain, while IL-18R consists of the IL-18Ra chain and IL-18Rb chain. Each chain contains a TIR domain in the cytoplasmic region, and upon receptor engagement by IL-1 or IL-18, recruits MyD88 and induces signaling resulting in NF-kB and MAPK activation.

IL-1β plays an integral role in antiviral immunity against influenza A virus infection. IL-1R$^{-/-}$ mice infected with influenza virus have impaired leukocyte recruitment to the lung, diminished CD4 and CD8 T-cell responses, impaired immunoglobulin responses, and succumb to virus-induced fatality.[94,200] On the other hand, mice deficient in IL-18 were found to have a transient increase in viral titer due to defective NK cytotoxicity after influenza A virus infection but otherwise had normal adaptive immunity to influenza infection.[134] Excessive levels of IL-1β and IL-18 produced during viral infection are associated with mortality from SARS-CoV-2.[146]

Tumor Necrosis Factor-Alpha

TNFR belongs to a group of receptors known as the TNFR family, characterized by a cysteine-rich common extracellular binding domain. Upon engagement of the ligand TNF, TNFR forms a trimer (Fig. 9.8). TNFRI contains a cytoplasmic death domain, which recruits the adaptor TRADD through its death domain. TRADD can assemble two different signaling complexes, involving FADD pro-caspase-8 or RIP1 and TRAF2. RIP1 activates IKK, resulting in the activation of NF-κB, while TRAF2 stimulates the JNK signaling pathway. Like IL-1β and IL-6, TNF is involved in the induction of a stereotypic inflammatory response that promotes host defense from a broad range of pathogens, including viruses. Recent studies revealed an additional pathway activated by TNFR—the induction of cell necrosis via the protein kinase RIP3. This TNF-induced necrosis was shown to be important for immune defense against vaccinia virus and CMV.[44,235] TNF blockers widely used to treat rheumatoid arthritis and other chronic inflammatory diseases have revealed the importance of TNF in the prevention of infection and reactivation of various viruses such as varicella-zoster virus, Epstein-Barr virus, cytomegalovirus, human papillomavirus, and JC virus.[116] However, the incidence of these infections in TNF blockade remains uncommon.

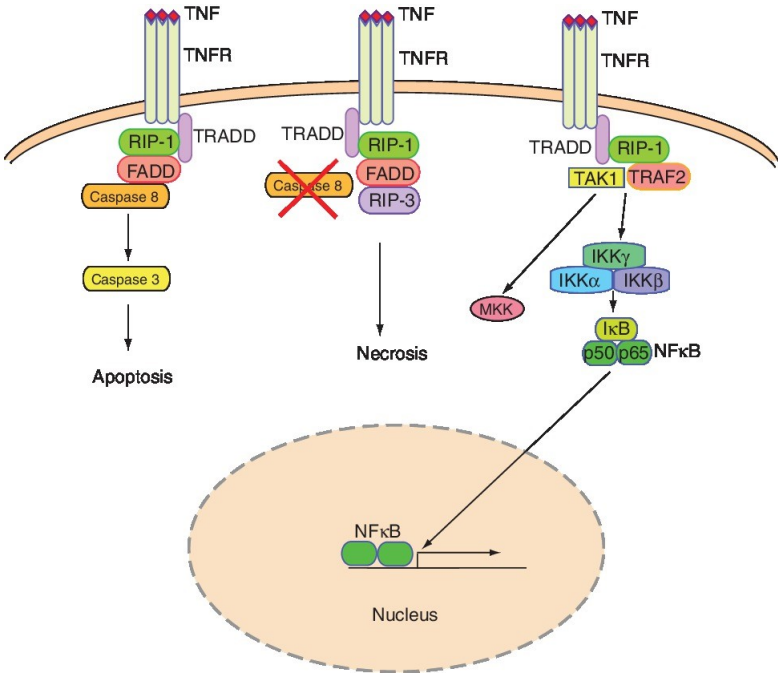

FIGURE 9.8 **TNFR signaling leads to three distinct cell fates**. TNF binding trimerizes the TNFR. Through the cytoplasmic death domain, TNFR recruits TRADD, which also contains a DD. TRADD can assemble different signaling complexes. TRADD can recruit FADD through DD-DD interaction, which results in caspase-8 activation, leading to apoptosis. In cells in which caspase-8 is rendered nonfunctional, RIP-3 is recruited to the complex to induce necrosis. In addition, TRADD can also recruit RIP-1 and TRAF2, resulting in signal transduction and activation of NF-kB and MAP kinase pathways.

Interleukin-15

IL-15 is produced by DCs and macrophages upon viral infection. IL-15R is a trimer of the IL-15Rα chain, which is specificto IL-15, the β chain, and the common γ chains that are shared with IL-2 and other cytokines. An unusual feature of the IL-15R complex is that the IL-15Rα chain is expressed on the cells that produce IL-15, rather than on the target cell that responds to IL-15. IL-15 forms a complex with the IL-15Rα chain in the ER and the two proteins are transported to the cell surface where they remain associated and function as a ligand for the IL-15Rβ and the common γ chains expressed on target cells. IL-15R induces activation of STAT5, resulting in the expression of antiapoptotic and growth-promoting genes in target cells.[152] The main target cell types of IL-15 are cytotoxic lymphocytes: IL-15 is an important growth and survival factor for CD8 T cells, NK cells, and a subset of NKT cells. Importantly, IL-15 can function downstream of type I IFNs in antiviral immune responses.[169]

Cell-Intrinsic Antiviral Defense Mechanisms

Interferon-Induced Antiviral Defense

IFN signaling leads to the induction of hundreds of ISGs, as demonstrated by many transcriptome profiling studies over the past 20+ years.[55] While a small fraction of the induced genes is noncoding, the vast majority encode specific proteins that together exert the antiviral, antiproliferative, and proinflammatory activities typical of an IFN response. Genetic screens have begun to catalog which ISGs encode antiviral effectors.[138,203] The picture emerging from many studies is that although IFN induces hundreds of ISGs, a relatively small fraction of them has antiviral activity. Indeed, IFN induces many proteins such as MHC molecules, cytokines, chemokines, and their receptors, all of which help stimulate adaptive immunity but do not have intrinsic antiviral activity.

Antiviral ISG effectors have specific mechanisms that usually target viruses at some stage of their replication cycle. Many reviews have covered this topic[37,201,202]; therefore, rather than present an exhaustive list of known antiviral effectors, general themes will be presented, with certain effectors mentioned as notable examples (Fig. 9.9).

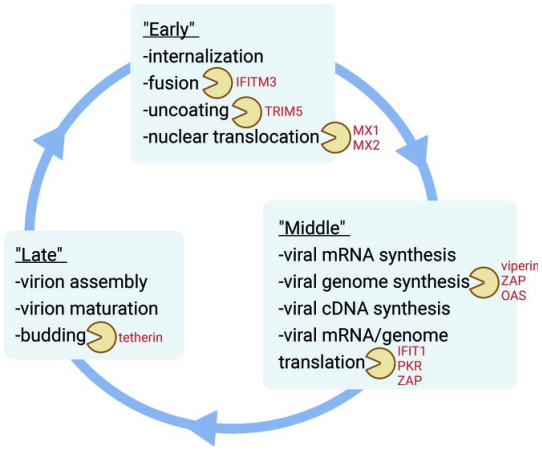

FIGURE 9.9 **Type I IFN–induced antiviral mechanisms**. Antiviral IFNs induce hundreds of genes, many of which encode effectors that establish an antiviral state. ISG-encoded effectors can target the viral replication cycle at any stage, including entry, translation, replication, and egress. Selected examples are depicted in the figure.

Inhibition of Viral Entry

Viruses must enter cells as a first step in the replication cycle, and this step is a key target of ISG-mediated defense. A family of ISGs that inhibits viral entry is the interferon-induced transmembrane (IFITM) protein family, encoded by genes *IFITM1*, *IFITM2*, and *IFITM3* as well as two other genes with no known roles in immunity. The best characterized of these is IFITM3, which suppresses infection of numerous viruses, including flaviviruses and influenza A virus. IFITM3 inhibits these endocytic viruses by preventing the fusion of their membranes with the endosomes.[27,259] This prevents the release of the genome into the cytosol, effectively halting replication.

In a unique mechanism of postentry inhibition, TRIM5α, an E3 ligase, forms a lattice on the surface of retrovirus capsids and mediates proteasome-dependent destruction of the virus.[70,217] Interestingly, TRIM5α from Old World monkey confers potent resistance to HIV-1, but not SIV, while the human ortholog of TRIM5α is unable to specifically target HIV. The differential ability of the human and monkey TRIM5α to restrict HIV hinges on a single amino acid difference between the two proteins. HIV and SIV have likely evolved in their natural hosts to evade interaction with TRIM5α.

Inhibition of Viral Protein or Synthesis

Translation of viral genomes or virally encoded mRNAs is one of the major antiviral strategies used by various ISG effectors. The classic example is protein kinase R (PKR, gene *EIF2AK2*), a serine/threonine kinase that phosphorylates the α-subunit of eukaryotic translation initiation factor 2 an (eIF2α). This results in inhibition of translation and a decrease in total cellular and viral protein synthesis, effectively impairing viral production. In addition to its translational regulatory function, PKR has roles in signal transduction, transcriptional control, apoptosis, and autophagy, all of which can contribute to curbing viral replication and spread.[123,194]

The interferon-inducible tetratricopeptide (IFIT) proteins are also key ISG regulators of viral protein synthesis. Most mammals have five IFIT genes: *IFIT1*, *IFIT1B*, *IFIT2*, *IFIT3*, and *IFIT5*, many of which are among the most highly induced ISGs during an IFN response. In general, the IFIT proteins bind and sequester the 5′ ends of the viral RNA.[1,183] They outcompete eIF4F for binding to the RNA, effectively inhibiting translation. These proteins accommodate viral RNAs with unique structures that signal to the host cell that the RNAs are nonself. For example, human IFIT1 recognizes uncapped triphosphate RNA or capped RNAs lacking 2′*O*-methylation, which is the hallmark of most cellular RNAs.[50] Indeed, many viruses encode their own 2′*O*-methyltransferase as a mechanism to evade IFIT1-mediated restriction.

Inhibition of Viral Genome Nuclear Translocation

Many double-stranded DNA viruses, retroviruses, and certain RNA viruses like influenza A virus replicate their genomes in the nucleus. These genomes must translocate from the cytosol to the nucleus, and this process is the known target of ISG effectors MX1 and MX2. These proteins have a large N-terminal GTPase domain, a central interacting domain (CID), and a C-terminal leucine zipper (LZ) domain. Both the CID and the LZ domain are required to recognize target viral structures. MX1 inhibits nuclear translocation of influenza A virus genome, whereas MX2 analogously inhibits retroviruses and herpesvirus genomes from entering the nucleus.[79,84,87,106] It is interesting to note that most inbred strains of mice harbor a defective Mx1 gene.[83] Therefore, studies using inbred mice must be interpreted with the caveat that they are Mx1-deficient.

Inhibition of Late Stages

As with the early stages of the viral replication cycle, late stages can also be targeted by antiviral effectors. The classic example of a late-stage inhibitor is the GPI-anchored protein tetherin (gene *BST2*). Tetherin was first identified as a restriction factor that inhibits retroviral budding by physically tethering the outgoing virion to the viral membrane.[168] Tetherin has since been found to inhibit the egress of other viruses including influenza A virus, vesicular stomatitis virus, and hepatitis B virus.[37]

Multifunctional Antiviral Effectors

Not all ISG effectors fall neatly into the categories listed above. Some effectors have been reported to have antiviral effects at multiple steps in the viral replication cycle, or their mechanisms are indirect, or they are insufficiently clarified. Examples of seemingly multifunctional and or

“indirect” antiviral effectors are the zinc antiviral protein ZAP, viperin, OAS (2′-5′ oligoadenylate synthetase) proteins, and ISG15.

In humans, ZAP (gene *ZC3HAV1*) is expressed as two isoforms, one long (ZAP-L) and one short (ZAP-S). ZAP-L is longer due to the presence of a nonenzymatic PARP (poly ADP-ribose polymerase)-like domain and is considered the more antiviral of the two isoforms. ZAP proteins have broad activity against diverse viruses, including alphaviruses, filoviruses, and retroviruses. Multiple mechanisms of action have been reported for ZAP, including (1) targeting viral RNA to exosomes for degradation, (2) inhibiting translation of viral RNA, and (3) indirectly amplifying interferon induction pathways.[71,244] Notably, ZAP has specificity for viral RNAs enriched with CG dinucleotides, which are suppressed in vertebrate host genomes.[224]

Viperin (gene *RSAD2*) contains a radical *S*-adenosyl- l-methionine (SAM) domain and exhibits antiviral activity against a range of viruses including cytomegalovirus, influenza A virus, flaviviruses, and bunyaviruses.[42,191] One mechanism of action of viperin is to catalyze the formation of the small molecule 3′-deoxy-3′,4′-didehydro-CTP (ddhCTP), which functions as a chain terminator of the viral RNA-dependent RNA polymerase (RdRP).[76] Other studies report that viperin can inhibit viral replication by interfering with viral nonstructural proteins or interfere with egress by perturbing cellular membranes. Remarkably, viperin is not specific to eukaryotes. Ancient homologs of viperin have been identified in bacterial and archaeal genomes, and these molecules exert antiviral activity against phage.[23]

The oligoadenylate synthetases (encoded by *OAS1*, *OAS2*, *OAS3*) are three enzymes that are activated upon sensing viral RNA. The enzymes use ATP as a substrate and convert it into 2′-5′-linked oligoadenylates (2-5A). The 2-5A then activates latent RNAseL, which directly degrades viral genomes.[91,265] Notably, OAS1 exists predominantly as two major isoforms (p46 and p42) in the human population, due to genetic variation that results in differentially spliced transcripts. The p46 isoform is targeted to membranes via prenylation and inhibits viruses that co-opt host membranes to form their replication organelles (eg, flavivirus, coronavirus, etc.).[213,242] A fourth member of this family, OASL (gene *OASL*), does not have oligoadenylate synthetase activity, but rather modifies the activities of viral sensors by augmenting RIG-I or impairing cGAS pathways.[73,264]

ISG15 (gene *ISG15*) is a ubiquitin-like molecule that has many diverse functions related to the antiviral defense.[66] Like ubiquitin, ISG15 can be covalently attached to target proteins in a process called ISGylation, using E1 activating enzyme (UBE1L), E2 conjugating enzyme (UBCH8), and E3 ligases (HERC5, EFP, or TRIM25). The ubiquitin-specific protease USP18, also an ISG, can remove ISG15 modifications. ISGylation can occur on a variety of host and viral proteins, modifying the targets in a manner that generally disfavors some critical steps of the viral replication cycle. ISG15 can also be found in a free form that negatively regulates IFN induction and signaling, and a secreted form that functions as a signaling molecule to induce other cytokines such as IFN-γ.

Cell Types Involved in Innate Immune Responses to Virus Infections

In addition to the cell-intrinsic host defense mechanisms described above, mammals are equipped with many local and circulating immune cells that can provide further support to antiviral resistance mechanisms. Embedded in tissues are resident lymphocytes, dendritic cells, and macrophages that monitor the environment for invading pathogens. They provide local antiviral defense within minutes to hours of infection. In addition to the red blood cells and plasma, the peripheral blood contains white blood cells such as neutrophils, eosinophils, basophils, monocytes, dendritic cells, plasmacytoid dendritic cells, natural killer (NK) cells, and T and B lymphocytes. These cells can be called into the site of infection by chemokines produced by the local cells. T and B lymphocytes provide immune defense specific to the pathogen and are covered by Chapter 10. The circulating cells strengthen the innate immune response to viruses by inducing high levels of IFNs or killing virally infected cells.

Tissue-Resident Innate Immune Cells That Support Antiviral Defense

Within most peripheral tissues, there are lymphocytes and myeloid cells that are situated to monitor invading pathogens. This section discusses the relative roles of such tissue-resident leukocytes that confer antiviral immunity at the site of viral entry and replication.

Tissue-Resident Lymphocytes

These tissue-resident lymphocytes consist of both adaptive lymphocytes (conventional T cells) and innate or innate-like lymphocytes. They perform very similar functions of eliminating infected or damaged epithelial cells, but the initiating triggers differ. While conventional T cells detect viral antigens through their T-cell receptor (TCR) that recognize viral peptides presented on MHC molecules, innate and innatelike lymphocytes detect virus-infected cells through invariant TCR or TCR-independent manner through cytokine activation. Innate lymphocytes and innate-like lymphocytes are located either within or beneath the epithelial layer and detect signs of stress by the epithelial cells. These include cells with TCRs, such a γΔ T cells with invariant TCRs, mucosal-associated invariant T cells (MAIT cells), and NKT cells. Innate lymphocytes without TCRs include natural killer (NK) cells and innate lymphoid cells (ILC) (Fig. 9.10). MAIT cells express unique TCR and are restricted to the nonpolymorphic MHC class I–related 1 molecule (MR1), which recognizes vitamin B–based antigens. However, the response of MAIT cells to viruses does not rely on MR1 but the cytokines (especially IL-18, IL-12, IL-15, and type I IFNs) induced by myeloid cells in response to the virus.[77] Upon cytokine stimulation, MAIT cells, in turn, secrete IFN-γ and TNF and mediate cytotoxic effects, which may aid in the clearance of infected cells. ILCs consist of heterogeneous groups of innate lymphocytes that do not express antigen receptors. Group 1 ILCs consist of both mature NK cells and type 1 innate lymphoid cells (ILC1). They are further defined based on the production of the signature cytokine IFN-γ in response to the proinflammatory cytokines IL-12 and IL-18. Group I ILCs exert antiviral functions through the action of IFN-γ that induce hundreds of ISGs as discussed above. ILC1 is tissue resident and serves as a local source for IFN-γ early during infection (Fig. 9.10).

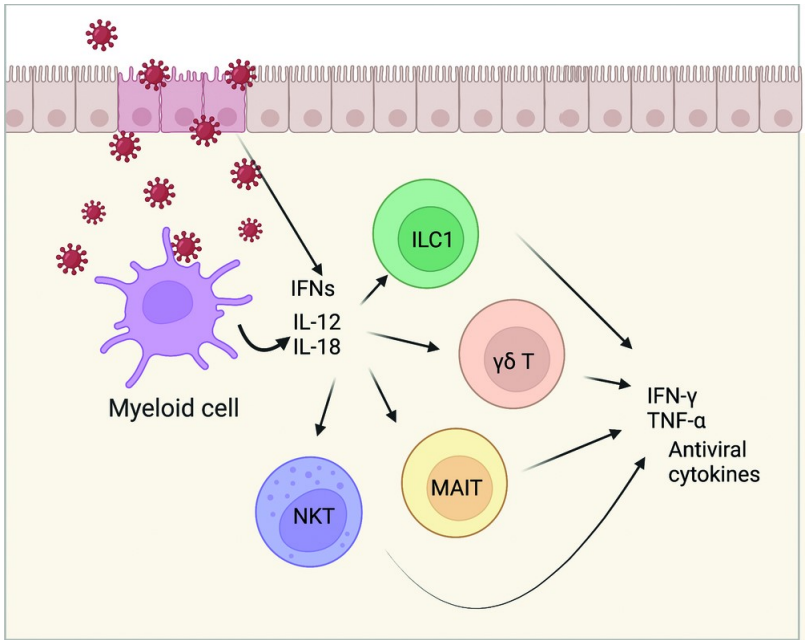

FIGURE 9.10 **Tissue-resident innate lymphocytes that contribute to antiviral defense**. Within peripheral tissues, several innate and innatelike lymphocytes, including ILC1, γΔT cells, MAIT, and NKT cells, are present. Upon stimulation by cytokines such as IL-12, IL-18, and type I and type III IFNs, these local innate lymphocytes secrete antiviral cytokines such as IFN-γ and TNF. These cytokines induce downstream antiviral genes to block the further spread of the virus before the adaptive immunity can be engaged.

Macrophages

Macrophages are tissue-resident myeloid cells that play central roles in host defense, inflammation, wound healing, tissue homeostasis, and tissue remodeling. Macrophages are professional phagocytes, clearing dying cells and pathogens. Macrophages can be found in most organs as specialized cell types, such as Kupffer cells (liver), microglia (neuronal tissue), and osteoclasts (bone). Macrophages are well known in their defense against bacterial and protozoan pathogens, as they are the chief phagocytes that engulf and degrade these types of pathogens upon activation with IFN-g.

Macrophages also play crucial roles in antiviral defense. Macrophages are situated at the forefront within mucosal barriers. In the lung, alveolar macrophages sample and degrade incoming pathogens. In addition, alveolar macrophages become highly infected with respiratory viruses such as Newcastle disease virus (NDV) and produce the highest levels of type I IFNs locally that prevent other cells from becoming infected.[122] Not only do macrophages provide the initial type I IFNs in infected tissue, but they also serve as a “viral sink” to prevent more vulnerable cell types from becoming infected. Subcutaneous injection of VSV results in a selective and productive infection of subcapsular sinus macrophages in the draining lymph nodes. These macrophages secrete high levels of type I IFNs that prevent infection of neurons. In mice depleted of such macrophages, local injection of VSV results in infection of innervating neurons in the lymph node leading to neuropathogenesis and death of mice.[93] Subcapsular macrophages also prevent systemic dissemination of lymph-borne pathogen by initiating an inflammatory immune response in the subcapsular region to activate and recruit innate and adaptive immune cells.[162]

Dendritic Cells

Dendritic cells are professional antigen-presenting cells capable of stimulating naïve antigen-specific lymphocytes in secondary lymphoid organs. Dendritic cells play an important role in immune responses at multiple levels. First, they are situated at various sites of pathogen entry and are among the first cells to recognize the incoming pathogens through a set of PRRs. Engagement of PRRs upon viral recognition induces the expression of genes required to both eliminate the pathogens (innate effectors) and to initiate adaptive immune responses.[157] Second, DCs are the only cell type capable of initiating adaptive immune responses by activating naïve T lymphocytes. Pathogen recognition through PRRs activates DCs to increase their expression of the chemokine receptor, CCR7, which enables them to migrate from the site of infection to the secondary lymphoid tissues, where naïve lymphocytes recirculate (Fig. 9.11). On transit, DCs undergo a maturation program that results in the upregulation of costimulatory molecules and translocation of their MHC class II to the cell surface.[233] Once in the lymph node, DCs can present antigens derived from the pathogens to naïve T cells and induce their activation (through costimulation) and differentiation (through secretion of appropriate cytokines)[15] (Fig. 9.11). A naïve T cell requires three kinds of signals for activation and differentiation. First, a T cell must recognize the viral peptide presented by the MHC molecules. CD4 T cells bind to peptides presented by MHC class II, while CD8 T cells bind to peptides presented by MHC class I. Second, T cells must receive signals from costimulatory molecules on APCs. PRR stimulation of APCs results in the expression of costimulatory molecules including CD80 and CD86, which bind to CD28 on naïve T cells and provide this second signal that allows optimal clonal expansion. The third signal dictates the differentiation of a naïve T cell into different effector types. CD4 T cells can differentiate into Th1, Th2, and Th17 cells depending on the cytokines provided by the APCs or other accessory cell types. Antiviral responses are mediated by Th1 cells, as they are uniquely capable of secreting IFN-γ.

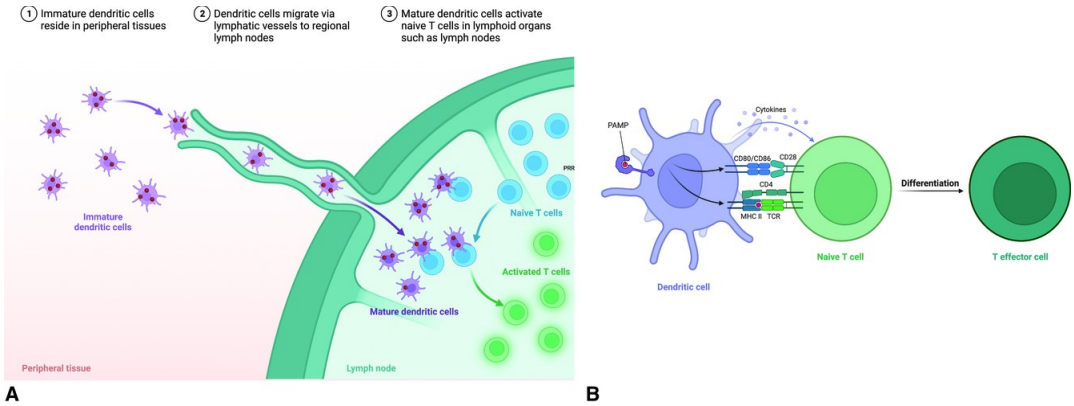

FIGURE 9.11 **Innate instruction of adaptive immunity**. **A**. Dendritic detect and phagocytose pathogens. DCs migrate to the lymph node, where they present viral antigenic peptides on MHC class I and MHC class II to activate naïve CD8 T and CD4 T cells whose T-cell receptors (TCR) are specific to the peptide presented by MHC molecules, respectively. **B**. PRR engagement (shown here for a TLR) by viral PAMPs induce expression of costimulatory molecules CD80 and CD86, as well as cytokines that stimulate naïve T cells, providing second and third signals needed for robust T-cell activation and differentiation. T cells receiving all three signals can proliferate and differentiate to become effector T cells. Depending on the cytokines secreted by DCs, CD4 T cells can become various effector T-cell types.

DCs can be broadly divided into two types, those that reside in the peripheral tissues (mucosa, skin, internal organs) and those that reside in the blood and lymphoid tissues.[98] Different DC subsets orchestrate innate and adaptive immune responses to viruses, depending on the type of PRR engaged by a given virus infection (see Chapter 10, The Adaptive Immune Response to Viruses).

Recruited Innate Immune Cells for Antiviral Defense

In addition to tissue-resident leukocytes, circulating immune cells are called into the site of infection to prevent further spread of the virus.

Natural Killer Cells

Unlike ILC1, NK cells are circulating and are recruited to the sites of infection to mediate antiviral defense. NK cells are activated by cytokines, as well as cells that express NK-activating receptor ligands and those that express lower levels of MHC class I. NK cells express two classes of receptors, known as activating and inhibitory receptors. These receptors induce or inhibit the target cell lysis and IFN-γ production upon recognition of their cognate ligands on target cells (Fig. 9.12). The ligands for activating NK receptors are induced in virally infected cells. The ligands for NK inhibitory receptors are MHC class I molecules and other molecules constitutively expressed on most cells and downregulated upon viral infection. The ligands for inhibitory receptors can be downregulated either as a result of sensing the viral infection in the cell or, in the case of MHC I, as a result of viral downregulation of MHC I. Many DNA viruses encode molecules dedicated for evasion of MHC I processing and presentation of viral antigens, to avoid recognition by CD8 T cells.[85] Through their ability to detect missing self (reduction in MHC class I molecules on the cell surface), NK cells fulfill the gap in immunosurveillance by CD8 T cells. Thus, NK cell recognition of infected cells relies on both the sensing of “induced self” (by activating receptors) and the “missing self” (by inhibitory receptors)[186] (Fig. 9.12). The net effect of these changes is detected by NK cells. Only when positive signals dominate, NK cells induce apoptotic death of target cells by unleashing their cytotoxic granules.

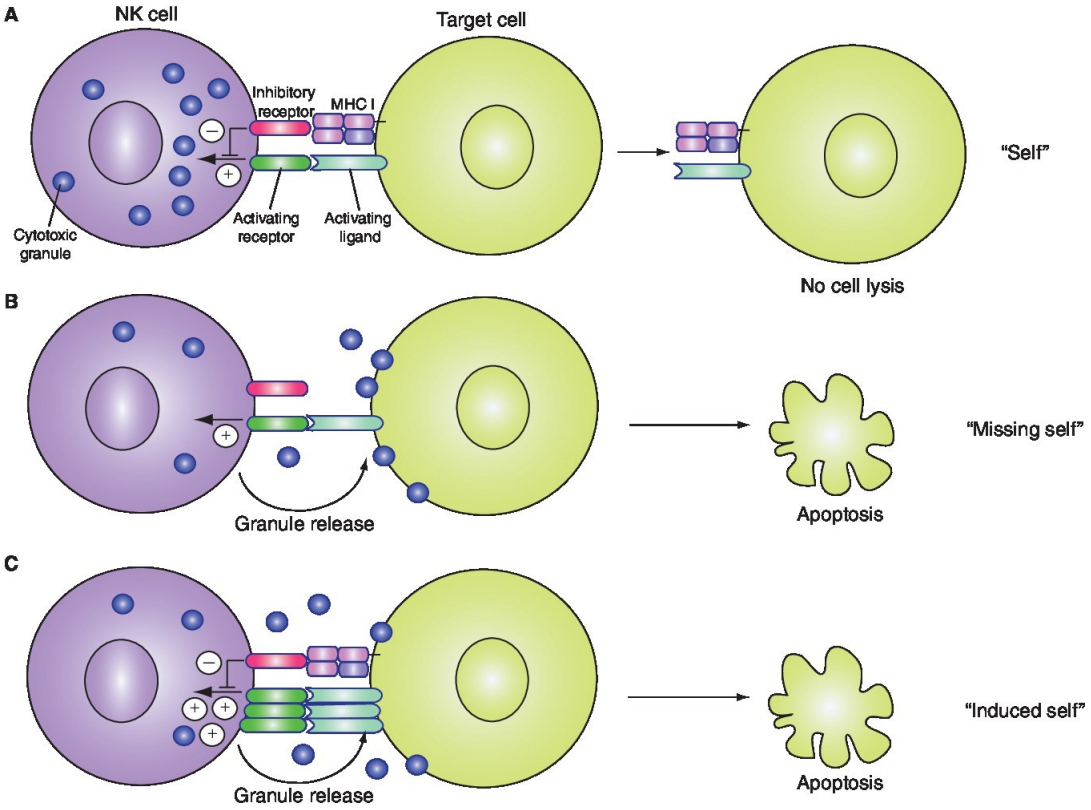

FIGURE 9.12 **Natural killer cell activation and inhibition**. NK cell recognition of infected cells relies on both the sensing of "induced self" (by activating receptors) and the "missing self" (by inhibitory receptors). NK cells contain cytosolic lytic granules that mediate apoptosis in target cells. **A**. When an NK cell recognizes a healthy cell, the NK cell lysis of the target cell is prevented by engagement of the inhibitory receptor by normal level of MHC class I on the target cell. **B**. When an NK cell interacts with virally infected cells that have reduced MHC class I on the cell surface ("missing self"), NK cells induce apoptosis in the target cell. **C**. When an NK cell recognizes stressed virally infected cell expressing high levels of stimulating ligands ("induced self"), negative signals from the inhibitory receptor is overridden by the activating signal, leading to lysis of target cells.

The ligands for NK activating receptors are generally absent or expressed at a low level on normal uninfected cells. Their expression is upregulated in response to viral infection and cellular stress. The best characterized activating ligands are recognized by NKG2D.[126] Human ligands for NKG2D include MHC class-I-chain–related protein A (MICA) and MICB, which are nonclassical MHC I molecules. In mice, NKG2D binds to several ligands including retinoic acid early transcript 1 (Rae1), a glycosylphosphatidylinositol (GPI) anchored protein, histocompatibility 60 (H60), and mouse UL16-binding proteinlike transcript 1 (Mult1). While Rae1, H60, and Mult1 only share 20% amino acid sequence homology, they share a structurally related domain, which is distantly related to MHC I a1 and a2 domains. Inducible expression of these ligands can overcome inhibitory signals provided by recognition of normally expressed MHC class I molecules, resulting in target cell lysis (Fig. 9.12C).

NK inhibitory receptors sense the level of MHC class I molecules on target cells. The CD94:NKG2A heterodimers recognize nonpolymorphic MHC class I molecules HLA-E in humans and Qa-1 in mice, which present leader peptides from classical MHC class I proteins. Thus, when the MHC I levels decrease as a result of viral manipulation, it is reflected in the decreased level of HLA-E/Qa-1 expression, resulting in disengagement of the CD94:NKG2A inhibitory receptor. Not surprisingly, several viruses mimic the activity of HLA-E. UL40 of HCMV confers protection in infected cells by encoding the same leader sequence that can be presented on HLA-E,[231] while HIV-1 selectively avoids downregulation of HLA-E and HLA-C to prevent NK-mediated lysis.[46] Mouse Ly49 family of inhibitory receptors recognizes the polymorphic MHC class I molecules. There are 18 Ly49 proteins in mice that have specificity to different MHC class I haplotypes. This mechanism of NK inhibition has been co-opted by the MCMV protein m157, which stimulates Ly49I to inhibit NK activation.[11]

Plasmacytoid Dendritic Cells

Plasmacytoid dendritic cells are considered professional viral sensors for several reasons.[141] First, pDCs are equipped with special cellular machinery to endocytose many types of viruses and transport them to the endolysosomal compartment, whereupon uncoating of viral envelope and capsid, viral genomic DNA, or RNA can be detected through TLR9 or TLR7, respectively. Second, pDCs constitutively express molecules involved in signaling to induce type I IFN genes. For instance, these cells express constitutively high levels of IRF7[112] and utilize various signaling proteins downstream of TLRs to induce IFN transcription. Third, pDCs form specialized lysosome-related organelles from which TLR9 and TLR7 can engage IRF7 activation to trigger the transcription of type I IFN genes.

Consequently, pDCs were originally known as IFN-producing cells (IPC), characterized by their potent ability to secrete type I IFNs in response to viruses.[13,28,74,99] Whereas DCs as a class are thought to be the professional antigen-presenting cells specializing in antigen uptake, processing, and presentation to T cells, the predominant role of the pDCs appears to be the secretion of type I IFNs. In particular, pDCs can be induced to secrete large amounts of IFN-α when stimulated with many DNA and RNA viruses. However, this situation may not be universal, as inflammatory monocytes and alveolar macrophages are the predominant IFN producers after vaccinia virus or NDV infection, respectively.[16122]

The pDCs express both L-selectin and CCR7 and can enter from the blood vessel into secondary lymphoid tissues.[35] At a steady state, these cells are not found in peripheral tissues. However, they can be induced to migrate into peripheral tissues and secrete antiviral IFNs *in situ*.[149] In mice that are depleted of pDCs, virus infections with MCMV and VSV resulted in reduced early IFN-I production and increased viral burden leading to impaired survival.[219] Given the location of pDCs, these cells likely serve as the initial source for type I IFNs in response to systemic viral infections, and as a secondary source of type I IFNs in response to localized viral infections restricted to the peripheral tissues.

Monocytes

Circulating monocytes also play an important role during viral infection. Monocytes patrol the bloodstream and peripheral tissue for infection. Once inside the tissue, monocytes can give rise to macrophages and dendritic cells. Circulating monocytes can be broadly categorized into two types, inflammatory monocytes and patrolling monocytes.[14] Inflammatory monocytes ($Ly6C^+$ $CCR2^+$ in mice and CD14 hi CD16lo in humans) are selectively recruited to inflamed tissues and lymph nodes, producing high levels of TNF-α and IL-1 during infection. Mouse inflammatory monocytes express TLR2 and recognize dsDNA viruses such as vaccinia virus and MCMV and secrete large amounts of type I IFNs.[16] Interestingly, monocyte recognition of viruses by TLR2 requires endocytosis while recognition of bacterial TLR2 ligands does not. While the exact viral ligands for TLR2-dependent detection by monocytes is unclear, TLR2 is known to be triggered by a variety of viruses including human cytomegalovirus,[47] mouse cytomegalovirus (MCMV),[220] herpes simplex virus types 1 and 2,[125,197] hepatitis C virus,[36] lymphocytic choriomeningitis virus,[262] measles virus,[24] and vaccinia virus.[263]

The other subset of monocytes ($Ly6C^-$ in mice and $CD14^{dim}$ CD16hi in humans) patrols the blood vasculature, can differentiate into macrophages after extravasation into tissues, and may promote tissue repair.[14] The human $CD14^{dim}$ monocytes do not express cell surface TLRs but express endosomal TLR7 and TLR8 and after recognition of viral nucleic acids produce TNF, IL-1β, and CCL3, but not type I IFNs.[48] Thus, monocytes as a class of cells promote antiviral resistance through the secretion of IFNs and other cytokines that induce antiviral genes in neighboring cells, as well as promote the recruitment of adaptive immune cells for viral clearance.

Viral Evasion of Innate Immunity

The innate immune response is a formidable evolutionary pressure on viruses. Accordingly, virtually all viruses have evolved mechanisms to counteract the induction, signaling, or antiviral effector functions induced by antiviral IFNs.[239] As a vast literature covers this topic, only key concepts with select examples will be presented here.

Viruses can interfere with initial host sensing at the level of PRRs. For example, paramyxovirus V protein prevents MDA5 dimerization,[10] whereas influenza A and B viruses express an NS1 protein preventing the activation of RIG-I.[69] Notably, NS1 also has other evasion mechanisms including inhibition of host mRNA processing and export, blockade of IFNAR signaling, and antagonism of innate effectors PKR and OAS.[239] PRR adaptors can also be targeted, with hepatitis C virus NS3 protease-mediated cleavage of MAVS serving as a prime example.[132,161]

A common viral strategy to interfere with IFN gene induction is represented by viral inhibitors of IRF3 and IRF7. Examples include KSHV vIRF3 that blocks the host IRF7 activity[105] and rotavirus NSP1 that blocks IRF3 and IRF7.[18,206] Even if the infected cells can produce type I IFNs, many viruses encode factors that inhibit signaling through the IFNAR. SARS-CoV and SARS-CoV-2 ORF6 protein prevent nuclear translocation of STAT1 by sequestering nuclear import factors on the ER/Golgi membrane.[68] Lastly, ISG effectors themselves can also be targets of viral evasion. For example, certain viruses can antagonize tetherin-mediated inhibition of viral egresses, such as HIV-1 with its Vpu protein.[168]

Differences Between Evasion Strategy Mechanisms of DNA vs RNA Viruses

Even though all viruses encode factors that interfere with host antiviral defense mechanisms, different classes of viruses appear to target different stages in antiviral defense. Nearly all viruses with (−)ssRNA genomes interfere with the innate sensors themselves. By contrast, (+)ssRNA and dsDNA viruses target the downstream IRFs as the means to interfere with IFN induction.[239] Another intriguing feature shared among the dsDNA viruses, particularly poxviruses, is that they encode soluble decoy molecules that antagonize antiviral signaling to prevent neighboring cells from becoming resistant to viral infection. Large dsDNA viruses can also accommodate multiple genes to specifically inhibit pathways that are useful for their replicative niche. By expressing soluble IFN-binding proteins that compete with the cellular IFN receptor for its ligand, dsDNA viruses allow for infection and spread to cells that would otherwise be prevented from infection. Another feature associated with dsDNA viruses is their ability to establish latency. To this end, almost all herpesviruses encode molecules that specifically block PKR and its downstream target to block the cell-mediated arrest of translation. This strategy is particularly important to ensure the survival of the latently infected cells. Other dsDNA viruses have narrow targets such as a single NK receptor ligand. MCMV encodes three proteins, m152, m145, and m155, that reduce surface expression of NKG2D ligands, RAE-1,[142] MULT-1,[120] and H60,[143] respectively, in infected cells. Chronicity of virus infection may result from the ability of dsDNA viruses to manipulate the host immune response by interfering with specific effector mechanisms of various host cell types.

Conclusion

In the past 10 years, there has been tremendous progress in the characterization of the innate immune recognition of viral pathogens. The role of type I IFNs, NK cells, TLRs, cGAS, and RLRs in antiviral defense is now well appreciated and understood in considerable detail. Many IFN-induced antiviral gene products still have to be functionally characterized. These proteins likely interfere with multiple steps in viral infection cycles. This functional redundancy makes the analysis of their contribution to antiviral defense particularly challenging. Other outstanding questions include the impact of host-intrinsic factors, such as aging and biological sex, as well as the impact of the host-extrinsic factors, such as the environment and diet, on antiviral innate immune defense. Finally, how a viral infection could lead to chronic disease conditions, such as autoimmunity and neurodegenerative disease, remains a fruitful area of research. Ultimately, the greatest challenge lies with the application of the accumulating knowledge to the management of emerging pandemics and the ultimate eradication of major viral infections that continue to threaten our well-being.

CHAPTER 10

The Adaptive Immune Response to Viruses

Dennis R. Burton • Shiv Pillai • Young S. Hahn • Thomas J. Braciale

Introduction

Overview of the adaptive immune response to virus infection

Development and architecture of the adaptive immune system

Generation of T and B lymphocytes: primary lymphoid organs

Secondary lymphoid organs: structure and function

Genes and molecules that mediate adaptive immunity

The CD1 family of class Ib genes and lipid recognition

T-cell receptor, coreceptor, and costimulatory genes and proteins

Antigen-presenting cells and the induction of adaptive immune responses

Dendritic cells activate naive T lymphocytes in secondary lymphoid organs

Activation of T and B lymphocytes in secondary lymphoid organs

Viral antigen recognition by B cells

Nature of B-cell epitopes

Antigenicity and immunogenicity

Generation of the primary B-cell repertoire

B-cell activation by viral antigens

Viral antigen recognition by T cells

Antigen processing and presentation to T cells

Antigen presentation by the major histocompatibility complex class I pathway

Antigen presentation by the major histocompatibility complex class II pathway

Induction of T-cell responses to antigen

Effector activities of B cells

Antiviral activities of antibody *in vitro*

Antiviral activities of antibody *in vivo*

Effector activities of T cells

$CD8^+$ effector mechanisms

$CD4^+$ T_E effector mechanisms

The phenomenon of $CD8^+$ T-cell exhaustion/dysfunction

Regulatory T-cell function in antiviral adaptive immune responses

Adaptive immune memory

B-cell memory

T-cell memory

Viral strategies to evade the adaptive immune response

Viral evasion of humoral (B-cell) immunity

Viral evasion of cellular (T-cell) immunity

Escape by subverting antigen processing and presentation

Interference of cytokine functions

Virus-induced immune dysregulation and autoimmune disease

INTRODUCTION

Viruses have been part of human ecology since the human species first evolved on the plains of East Africa. As humans moved out of Africa to populate the continental land masses, viruses, already adapted to the human species, were carried along with other microorganisms as part of the human ecological baggage. With the migration of humans around the world, we were exposed to new viruses present in the animal species that humans encountered. Some viruses, such as the herpes family members, Epstein-Barr virus (EBV), and herpes simplex virus (HSV) have co-evolved with humans and have developed complex mechanisms (eg, latency) to subvert the host defense mechanisms and sustain themselves in the human population. These viruses generally produce mild disease, except where host defenses are absent or weakened (eg, in immune-deficient or immune-suppressed individuals). Other human viruses (eg, measles virus) appear to have evolved mechanisms to persist at low levels in some infected individuals and sustain themselves by infecting previously unexposed individuals (typically children) who then go on to develop mild to severe illness and, in turn, serve as reservoirs for further virus propagation. Animal viruses can also *jump* from their host reservoir to infect humans and produce devastating diseases of potentially pandemic proportions. Three notable examples of zoonotic viral diseases are (1) the acquired immune deficiency syndrome (AIDS) pandemic produced by the human immunodeficiency virus (HIV), (2) the coronavirus disease 2019 (COVID-19) pandemic caused by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), and (3) the periodic outbreaks of highly pathogenic avian influenza infection in poultry since 1997 in Asia and more recently in Africa and Europe, which have resulted in sporadic direct infections of humans with mortality rates approaching 50%. Indeed, the reconstruction and analysis of the genome of the influenza virus that caused the 1918 *Spanish flu* pandemic indicates that this virus was an avian influenza virus that spread directly to humans (without modification of virus in an intermediate host or the acquisition of genetic information from then-circulating human influenza strains).[193]

Virus infection can result in acute or chronic disease in virtually any organ and tissue of the body. Furthermore, infection with human papillomavirus (HPV), human herpesvirus 8 (HHV8), and hepatitis B (HBV) and C (HCV) viruses have been directly linked to the development of cervical cancer, Kaposi sarcoma, and hepatocellular carcinoma, respectively. As the devastating effects of HIV infection and the COVID-19 pandemic have taught us, virus infections are a continuing threat to human health. We can point to some notable successes in the struggle against viruses including the eradication of smallpox in the 1970s, the effectiveness of the live attenuated oral polio vaccine in eliminating paralytic polio in the developed world heralding the prospect of eradicating polio worldwide, and the successes of vaccines against SARS-CoV-2. These vaccination successes rely on the mobilization of the body's major defense against virus infection—the adaptive immune system. Our enthusiasm about these *successes* must be tempered, however. Because of the success of smallpox eradication, mandatory smallpox vaccination was discontinued in the United States in the early 1970s, making a large fraction of the population (ie, those under age 35 years) now susceptible to smallpox. This fact, along with the advances in poxvirus genetics and genetic engineering, now make smallpox a major bioterrorism threat. Similarly, administration of live oral polio vaccine to children in third world countries whose immune function is suppressed by malnutrition or HIV infection can result in outbreaks of paralytic polio caused by infection with virulent mutants (revertants) of the live attenuated vaccine strain. This realization has prompted a reevaluation of the prospect of global polio eradication using current vaccination strategies. Vaccines against SARS-CoV-2 protect against severe disease but cannot yet protect us from infection by antigenically altered viral variants. Strain-specific vaccines that minimally cross-react antigenically with previously employed vaccines, or pan-coronavirus vaccines, might be necessary. To counter the continuing threat posed by viruses, it is essential to understand the body's primary defense against virus infection in the immune system.

Overview of the Adaptive Immune Response to Virus Infection

Viruses are obligatory intracellular parasites; that is, they replicate within cells of the infected host and utilize the cell's biosynthetic machinery for replication and production of progeny virions. Furthermore, most viruses replicate rapidly in infected cells (ie, within hours) producing progeny virions capable of infecting additional cells, thereby propagating and sustaining infection in the host. These properties of infection by viruses dictate how the immune system must respond to counter infection. In acute virus infection, the race between the replication of the virus and the host response will result either in the death of the host or in virus clearance and the termination of infection. The tissue injury produced by viruses at the site(s) of infection results both from the cytopathic effects of virus replication and, equally importantly, from the host immune response to infection. In general, therefore, the greater the extent of virus replication in the infected host, the greater the tissue injury and illness severity.

In chronic infection, the time scale of virus replication in the host is not measured in days (as in acute infection) but in weeks, months, or even years, with the host immune response likewise continuing over the same prolonged time scale. Viruses that produce chronic, persistent infection have evolved mechanisms to suppress or alter the immune response (allowing these viruses to persist in the infected host). The tissue injury produced by the immune response to virus infection (termed, *immunopathology*) occurs with both acute and chronic virus infection; in many chronic virus infections (eg, HCV infection), however, immune-mediated tissue injury predominates (rather than direct virus-mediated injury).[96] Furthermore, the clinical manifestations of virus infection (eg, fever, headache, myalgia, anorexia) are primarily caused by inflammatory mediators (eg, cytokines) released by cells of the immune system in response to infection. Finally, the triggering of the immune system by virus infection can result in the induction of aberrant immune responses directed both to the virus and to self-cellular constituents, resulting in autoimmune disease.[16,108]

The primary host defenses against virus infection are physical/chemical barriers to infection and the immune system. The immune system can be divided into two components: the innate immune system and the adaptive immune system. This division is based on the properties of the immune cell types and molecules involved in the response to infection and the tempo of the response (Table 10.1). The response of the innate immune system to virus infection is either immediate (ie, constitutively active) or rapidly induced (ie, within hours of infection). The innate immune response is triggered in two ways: first, through recognition of viral constituents (eg, viral nucleic acids) by a limited set of cellular pattern recognition receptors for foreign molecules displayed on innate immune cells and, second, through the activation of intracellular signaling mechanisms following virus entry into cells and the initiation of virus replication. Importantly, a defining feature of the innate immune

response is that repeat exposure to a particular virus generally evokes an identical response from the innate immune system, although some epigenetic "memory" may partly strengthen some responses.

TABLE 10.1 Cells of the immune system

Type	Subtype	Onset of Effect
Innate immune cells		
Granulocytic	Neutrophils, basophils, eosinophils	Immediate/ inducible (h)
Monocytic	Macrophage, DC	Immediate/ inducible (h)
Lymphocytic[a]	Innate lymphoid cells, NK cells, NK T cells	Immediate/ inducible (h)
Somatic cell (nonhematopoietic)	Epithelial, endothelial cells, etc.	Immediate/ inducible (h)
Adaptive immune cell		
B lymphocyte	—	Inducible (d)
T lymphocyte	$CD4^+$, $CD8^+$, T_{reg}	Inducible (d)

[a]Specific subtypes of T lymphocytes (eg, γδ T cells and intraepithelial [IEL] $CD8^+\alpha\alpha$ T lymphocytes) are considered to be part of the innate immune system. These cell types with lymphocytic morphology employ a TCR-type antigen recognition system but differ in this function and strategy of antigen recognition from conventional T cells. Plasmacytoid dendritic cells are now considered to be of lymphoid origin.
DC, dendritic cells; NK, natural killer; h, hours; d, days.

By contrast, the response of the adaptive immune system to a first encounter with a virus takes days to evolve. The response of the cells of the adaptive immune system (ie, B lymphocytes and T lymphocytes) is triggered by viral constituents, through the engagement of highly specific cell surface recognition receptors displayed by a minuscule fraction of the total repertoire of adaptive immune cells for any given virus. These receptors only recognize the constituents (antigens) of that particular virus. Importantly, this arm of the immune system *adapts* to repeat exposure to a particular virus or viral protein; this results in a more rapid response of higher magnitude by the specific adaptive immune cells on repeat exposure/infection—a phenomenon called *immunological memory*, the basis for vaccination.[2,51,74,134,147,152,157,179]

Circulating molecules of the innate immune response include proteins of the complement system and circulating agglutinins, including pentraxins and lectins of the collectin and ficolin families. These molecules are present in the blood and tissue fluids and can bind or be covalently attached (in the case of complement proteins) to certain viruses, thereby inhibiting virus infection. Leukocytes, in particular, neutrophils, blood monocytes, tissue macrophages, dendritic cells (DCs), and innate lymphoid cells including natural killer (NK) cells are the dominant, innate immune cell types that respond to virus infection. They are triggered/activated through the engagement of pattern recognition receptors (eg, Toll-like receptors [TLR]) expressed on the cell surface, in endosomes, or in the cytosol, that recognize viral constituents (eg, viral nucleic acids). Some of these cells reside in the tissues, and they respond there while others are recruited to sites of infection from the bloodstream in response to cytokines and chemokines released during infection.

Nonhematopoietic body cells (eg, epithelial cells, endothelial cells, fibroblasts) that are targets of virus infection must also be considered part of the innate immune response because, on infection, they are triggered to secrete antiviral proinflammatory mediators such as type 1 interferons and certain cytokines/chemokines (the production of which can initiate and amplify the innate immune response to infection). The induction of the innate immune response and the role of innate immune cells and molecules in controlling virus infection are discussed in detail elsewhere (Chapter 8). One of these innate immune cell types, the conventional DC, however, bridges the innate and adaptive immune response, and its role in the initiation of the adaptive immune response is discussed in a later section of this chapter.

A hallmark of the adaptive immune response is the exquisite specificity of adaptive immune cells for a particular foreign viral antigen and the capacity of this system to recognize and respond to a myriad of viruses (or other antigens). This remarkable property of the adaptive immune cells is achieved by the generation of a correspondingly diverse array of cell surface recognition receptors, which are randomly generated within the lymphocytes of every individual and clonally distributed among the adaptive immune cells. As a consequence, in a nonimmune individual, only an extremely small fraction of the adaptive immune cell repertoire (eg, one cell in a million) may have an antigen receptor capable of recognizing a specific viral antigen. Understanding how this diverse array of clonally distributed antigen receptors is generated during lymphocyte development and how rare adaptive immune cells specific for particular viral antigens find infected cells in a peripheral site of infection (eg, the skin or lungs) is critical to the understanding of the adaptive immune response to virus infection.

Viruses, because they exist as extracellular virion particles and replicate/assemble within infected cells, pose a unique recognition problem for the adaptive immune system (ie, how to recognize the virus [viral proteins or genome] both outside of the cell and within the infected cell). The elegant solution to this problem employed by the adaptive immune system is the partitioning of the adaptive immune system into two distinct cell types: B and T lymphocytes (Table 10.2). B lymphocytes displaying a receptor specific for a particular virus will, on encounter with the virus and activation, release their antigen receptor in a soluble form (ie, as antibody molecules) capable of binding free (extracellular) virions in a highly specific matter. This interaction typically results in virus neutralization/elimination. Antiviral B lymphocyte responses are exquisitely sensitive to the three-dimensional confirmation of the virus (and its constituents), and they play a dominant role in clearing virus during infection, in preventing or limiting reinfection (after previous infection with a virus), and in vaccination against a specific virus.

TABLE 10.2 Properties of T and B lymphocytes

General Properties	B Lymphocytes	T Lymphocytes
Origin	Bone marrow	Bone marrow
Self/ non–self-discrimination	Bone marrow and periphery	Thymus and periphery
Activation	BCR and other ligand receptors	TCR and other ligand receptors
Antigen recognition	Native (3-D) conformation	Nonnative fragments
Antigen receptor	**B Lymphocytes**	**T Lymphocytes**
Somatically generated	+	+
High specificity	+	+
Clonally represented	+	+
Localization	Cell surface/ secreted (Ab)	Cell surface only

BCR, B-cell receptor; TCR, T-cell receptor; Ab, antibody.

Activated antiviral T lymphocytes retain their antigen-specific receptors on the cell surface and are responsible for recognizing and eliminating virus-infected cells. T lymphocytes, however, do not recognize viral proteins in their native conformation. Rather, the antigen receptors on the T lymphocytes recognize *processed* peptide fragments of viral proteins displayed on the infected cell surface bound to cell surface molecular recognition platforms (ie, the major histocompatibility complex [MHC] locus gene products). Activated virus-specific T lymphocytes halt the spread of infection through direct cell-to-cell contact with virally infected cells, which may then be killed by these T cells. They also contribute to clearance or containment by the release of soluble mediators that include cytokines such as interferon gamma (IFN-γ) and tumor necrosis factor (TNF). By releasing cytokines and chemokines, activated T lymphocytes can recruit and orchestrate the activation of innate immune cells, which can also facilitate viral clearance. Understanding how and where B and T lymphocytes are activated, the mechanism of antigen presentation to these cells, and the range of effector activities that these cells use to control and eliminate virus is essential for understanding the adaptive immune response to virus infection. These important topics are reviewed in this chapter.

Finally, the importance of the immune system in general and the adaptive immune response in particular in controlling virus clearance and promoting recovery from infection is exemplified by the fact that viruses have evolved a variety of mechanisms to inhibit or alter the host immune response. Whereas these viral immune evasion strategies are best considered in the context of viral pathogenesis (Chapter 11) and are addressed in chapters dealing with individual viruses, this chapter highlights some of the viral strategies that contribute to the evasion of adaptive immune responses.

Development and Architecture of the Adaptive Immune System

Generation of T and B lymphocytes: Primary Lymphoid Organs

Unlike the cells of the innate immune system, T and B lymphocytes possess one unique and profoundly important property. On their surfaces, these cells also display a receptor complex capable of recognizing foreign (nonself) structures—with exquisite specificity. The extraordinary diversity of adaptive immune cells is generated by a process of somatic recombination of antigen receptor gene segments. These gene segments are randomly selected and joined together in individual developing lymphocytes. The recombination-based creation, in each developing lymphocyte, of a different antigen receptor contributes to tremendous clonal diversity. Thus, of the ~10^9 naive T and B lymphocytes in the human adaptive immune system, each cell may, in principle, display a unique receptor directed to a specific foreign antigenic structure. This common property of the antigen receptor on T and B lymphocytes (ie, random generation by somatic DNA recombination and clonal receptor display) immediately raises some important questions. If these antigen receptors are stochastically generated, how is the generation of lymphocytes with receptors to self-structures (eg, tissue proteins) avoided? And if the frequency of lymphocytes with a receptor directed to a specific foreign antigen (eg, the coat proteins of an invading virus) is extremely low (1 in 10^7 lymphocytes), how can those rare lymphocytes locate the antigen quickly enough to respond before the infection is beyond control? As will be discussed below, it is the unique structure of the primary (central) lymphoid organs where lymphocyte progenitors develop into mature T and B lymphocytes, and of the secondary (peripheral) lymphoid organs where mature T and B lymphocytes respond to invading microorganisms, that provide some of the answers to these questions.

Mature T and B lymphocytes are derived from lymphoid progenitors that emerge prenatally in the fetal liver and subsequently, after birth, in the bone marrow, through a process of differentiation and selection linked to, and driven by, the antigen receptors displayed by these cells.[2,51,74,134,147,152,157,179] As outlined in Table 10.2, B lymphocyte development occurs after birth in the bone marrow (and prenatally in the fetal liver) and follows a well-defined sequential program. Initially lineage-defining transcription factors commit common lymphoid progenitors to the B lineage and induce the expression of genes whose products initiate the sequential rearrangement of immunoglobulin (Ig) D_H and J_H, heavy chain genetic elements (by random somatic recombination), at the pro-B stage. This is followed by V_H to DJ_H rearrangement. Combinatorial rearrangements between about 45 V_H segments, 23 J_H segments, and 6 J_H segments contribute to a different fusion VDJ exon in each developing B cell that encodes the V domain of an Ig heavy chain protein.[2] Downstream C region exons encode the Ig heavy chain constant domains. IgH gene rearrangement, transcription, RNA splicing, and protein expression are followed by a checkpoint at the transition between the pro-B and the large pre-B stages that ensures that only developing pre-B cells with productive IgH gene rearrangements capable of yielding a complete IgH protein (initially the IgM μ protein) are preserved; this checkpoint also ensures allelic exclusion—the process that maintains clonal

specificity by ensuring that only one (maternal or paternal) IgH locus is productively rearranged in each developing B cell. This is followed, at the small pre-B stage, by rearrangement of the Ig light chain kappa locus (or later the lambda locus) involving V_L to J_L rearrangements, thus yielding diverse "immature" B cells in the bone marrow, each now expressing a surface IgM molecule that serves as the B-cell receptor. A large proportion of these surface IgM-expressing immature B cells in the bone marrow are specific for self-molecules (ie, proteins, lipids, carbohydrate, nucleic acid) and undergo a process of negative selection called receptor editing that involves replacement of the existing rearranged light chain gene with a new V_L to J_L rearrangement (first at the kappa locus, and if that fails, at the lambda Ig light chain locus), that yields a non–self-reactive BCR. B cells that do not bind to self-antigens leave the bone marrow as transitional B cells and eventually seed peripheral lymphoid organs as naive follicular B cells. At the transitional B-cell stage and beyond, self-reactive B cells can still be tolerized by an apoptotic clonal deletional process or by a process of induced dysfunction called anergy.

The rearranged IgH gene produces two types of related transcripts; one encodes an Ig H-chain protein with a transmembrane anchor that associates with a L-chain to form the BCR while an alternatively spliced version that is shorter, encodes the Ig H-chain of soluble, secreted antibodies. The membrane-bound Ig H-L tetramer (the BCR) is transported from the endoplasmic reticulum (ER) to the cell surface by two proteins that associate with it called Igα and Igβ; these proteins are also essential for BCR signal transduction and for the endocytic internalization by the BCR of specific antigens. The ability of each B cell to express a surface BCR initially and to later, after activation, secrete antibodies that bind the same antigen as the original BCR, has two important implications for the recognition of viruses by B lymphocytes: (1) the B lymphocyte response to viruses will be particularly effective when interacting with free/extracellular virus constituents (eg, virions) and (2) the BCR and the secreted antibody generated after B-cell activation will be sensitive to the conformation of the viral constituent recognized.

T lymphocyte lineage development follows a program similar to that of B lymphocytes. The T-cell antigen receptor (TCR) is also a heterodimer consisting of two polypeptide chains, each of which is formed by somatic recombination of variable (V), diversity (D), and joining (J) segments encoding the variable portion of one chain (or V and J joining for the other chain). This process generates a VDJ exon or a VJ exon encoding the variable (V) domain of each TCR polypeptide, while a downstream unrearranged exon contributes to the constant (C) domain. Like the BCR, the TCR is an integral membrane protein but no alternative secreted antibodylike form of the TCR exists in nature. Unlike the BCR, the TCR does not recognize intact or fragmented microbial products directly but rather recognizes small fragments of molecules—typically, short peptide fragments of microbial or self-proteins bound to and exhibited on cell surfaces by protein products of the mammalian MHC genetic locus (eg, the classically defined major human transplantation antigens). These cell surface MHC gene products serve as molecular platforms, both selecting and displaying the self-peptides involved in TCR selection during T lymphocyte development in the thymus and also presenting microbial peptides to mature T lymphocytes that respond to microbial entry or infection of host cells. Consequently, T lymphocytes are uniquely suited to recognize host cells that harbor microorganisms (eg, viruses and intracellular bacteria). The steps in the processing (proteolytic fragmentation) and presentation of both self and microbial gene products by MHC locus proteins, and the structure of the major classes of MHC proteins (ie, MHC class I and II proteins), are discussed below.

T lymphocyte development occurs primarily in the thymus (Fig. 10.1). Lymphoid progenitors from the bone marrow enter the thymus from the blood, where they differentiate into T lymphocytes that then leave the thymus, enter the circulation, and ultimately populate secondary lymphoid organs (SLOs). Two classes of mature T lymphocytes are produced in the thymus. The major population (~80% of the peripheral T lymphocyte pool) are αβ T cells (so-called because their heterodimeric TCR express two chains encoded by TCR-α and β loci). The second minor population of mature T lymphocytes is called γδ T cells (because they express a related two-chain TCR derived from the TCR-γ and δ loci). Much of our current information on T lymphocyte development comes from analysis of αβ T-cell development. These T lymphocytes represent the T-cell subset that primarily responds to viral infection, and the selection process of these T cells in the thymus will be emphasized here. The γδ T-cell subset likely plays a limited role in the adaptive response to virus infection, and the properties and functions of this subset are summarized below.

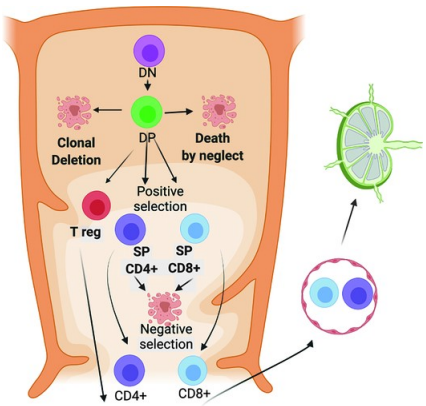

FIGURE 10.1 **T lymphocyte development and selection in the thymus**. In the thymic cortex, $CD4^-/CD8^-$ double-negative (*DN*) thymocytes mature into $CD4^+$ $CD8^+$ double-positive (*DP*) thymocytes. DP thymocytes with T-cell antigen receptors that interact with moderate avidity for self-MHC (major histocompatibility complex) class II or class I molecules presenting self-peptides are, respectively, *positively selected* into $CD4^+$ or $CD8^+$ single-positive (*SP*) thymocytes, which migrate into the thymic medulla. DP thymocytes that fail to bind self-MHC die by apoptosis (death by neglect), while those that bind very tightly to self-MHC-peptide complexes in the cortex are *negatively selected* (marked in the figure as clonal deletion). Positively selected single-positive thymocytes undergo further clonal deletion in the thymic medulla and surviving single-positive $CD4^+$ and $CD8^+$ T cells as well as regulatory T cells (Treg) egress the thymus into the bloodstream. Naive T cells home to secondary lymphoid organs and recirculate.

T lymphocyte development proceeds in a stepwise fashion with the sequential gene rearrangement and expression of one (ie, TCR-β or TCR-δ), then the other (ie, TCR-α or TCR-γ TCR chain) TCR genes as thymocytes mature. For TCR-β chains, one of ~50 V_β gene segments recombines with a single diversity (D_β) segment and one of 6-7 J_β gene segments to give rise to the rearranged $V_\beta D_\beta J_\beta$ exon encoding the V domain of the TCR-β chain (the D, J, and C region of the TCR-β locus in humans is duplicated and rearrangement occurs randomly in one of these duplicated regions in any given developing T cell). For human TCR-α chain formation, one of ~45 distinct V_α genes recombines with one of ~55 joining (J_α)

gene segments and the associated downstream C gene segment to produce the rearranged gene $V_\alpha J_\alpha$ exon encoding the V domain of the TCR-α chain. Further, TCR diversity is generated by the enzymatic addition/deletion of nucleotides during and e V_β-D_β-J_β and V_α-J_α recombination. The TCR on γδ T cells is generated by an identical process involving the rearrangement of V_γ-J_γ and V_δ-D_δ-J_δ segments. Four cell surface molecules including three CD3 proteins (CD3 γ, δ, ε) and the ξ protein noncovalently associate with the TCR (analogous to Igα and Igβ for the BCR), transport it to the cell surface and are critical for signaling through the TCR. Each TCR dimer associates, initially in the ER membrane with a CD3 γε heterodimer, a CD3 δε heterodimer, and a ξξ homodimer, with a total of eight polypeptides making up the TCR complex. This complex must form for the TCR to be transported to the plasma membrane. Specific antigen recognition by the TCR-αβ (or γδ) heterodimer results in signaling that is dependent on the CD3 and ξ components of the TCR complex.

Because the TCR does not recognize foreign molecules directly (but rather small fragments of proteins bound to MHC molecules), the TCR generated and expressed on developing thymocytes must recognize both MHC molecules and the peptide fragments bound to these molecules. The source of these peptides bound by MHC class I and class II molecules in the thymus are self-proteins expressed by several different cell types in the thymus. The selection of the thymocytes that ultimately become mature *single-positive* T lymphocytes ($CD4^+$ or $CD8^+$) and populate the SLOs is a two-step process in the thymus: first positive selection followed by negative selection.

The most immature T-cell progenitors commit to the T lineage and differentiate after being triggered by Notch ligands on thymic cortical epithelial cells (cTECs). Initially, they do not express the CD4 or CD8 coreceptor proteins and are therefore called *double-negative* (DN) thymocytes. These cTECs also provide the IL-7 cytokine that supports the proliferation and survival of DN thymocytes. DN thymocytes begin to rearrange their T-cell receptor genes in an ordered fashion. In the case of αβ T cells, TCR Dβ to Jβ gene rearrangement is followed by Vβ to DJβ rearrangement and a checkpoint ensues whereby signaling ensures that only cells able to express an intact TCR-β chain protein are selected, and allelic exclusion at this checkpoint ensures that each T-cell clone will eventually only express one TCR-β chain protein. Selected cells then make the TCR-α locus accessible to randomly recombine TCR Vα and Jα gene segments. As a result, T cells with a complete αβ TCR and that now simultaneously express both the CD4 and CD8 coreceptors emerge. These *double-positive* (DP) T cells are still in the thymic cortex where they undergo positive selection by self-MHC and peptide presented on cTECs.

The "purpose" of positive selection is to assign to each T-cell the coreceptor that matches the class of self-MHC molecules that its TCR recognizes. There is an intrinsic structural bias of all αβ TCRs to recognize MHC molecules, and a very small fraction of DP T cells have randomly generated TCRs that are unable to bind to self-peptide/MHC molecular complexes, and they are not positively selected. In the absence of a signal delivered through the TCR, these thymocytes will die by apoptosis (a process called "death by neglect" for these cells). Those DP thymocytes whose TCRs can bind specific self-peptide/MHC complexes above a threshold avidity, augmented by either a CD4 or a CD8 coreceptor binding to the MHC molecule, will undergo positive selection and survive. If the DP thymocyte TCR binds a peptide bound to MHC class II, this interaction results in the silencing of the CD8 coreceptor gene and preservation of CD4. This signaling event thus results in the development of a $CD4^+$ single-positive thymocyte whose TCR recognizes (is restricted to) peptides bound to MHC class II molecules. Similarly, the DP thymocytes whose TCRs recognize MHC class I-self-peptide complexes with sufficient avidity to survive (ie, those that are positively selected) will give rise to MHC class I–restricted $CD8^+$ single-positive thymocytes by a broadly similar silencing mechanism but of the CD4 gene. Although in the cortex the major selection event is positive selection, the recognition by any TCR of MHC-self-peptide complexes on cTECs with very high avidity results in apoptotic death or negative selection of those developing T cells. However, negative selection also occurs in the thymic medulla at the single-positive (SP) thymocyte stage.

After undergoing positive selection, the surviving SP thymocytes migrate into the medulla. They are all intrinsically autoreactive (ie, directed to self-peptide/MHC complexes), but these cells had not encountered self-MHC-peptide complexes of really high avidity in the thymic cortex. A process of negative selection must ensue to eliminate self-reactive SP T cells that can recognize self-peptides, especially from different part of the body, presented on self-MHC molecules and that have high avidity for TCRs on developing T cells. Failure to eliminate or eventually suppress such strongly self-reactive T cells could result in autoimmunity. Most negative selection in the medulla is mediated either by circulating professional APC, particularly plasmacytoid DCs (pDCs) and conventional DCs (DCs), or by medullary thymic epithelial cells (mTECs). Both pDCs and DCs can capture self-proteins that originate in different organs and tissues and enter the circulation either as soluble proteins or shed in exosomes. Some of these proteins will be processed in late endosomes, and resultant peptides are presented on MHC class II molecules, while other proteins are processed in proteasomes and peptides so derived are presented on MHC class I molecule (as discussed later in this chapter). Consequently, when SP thymocytes encounter these self-peptide/MHC complexes displayed by professional APC in the medulla with high avidity, these T cells will be eliminated (ie, undergo negative selection—death by apoptosis).

Another very important process of negative selection that is mediated by mTECs occurs in the thymic medulla. Individual mTECs turn on entire batteries of genes that characterize specific peripheral cells. This differentiation of mTECs into partial phenocopies of many different types of peripheral cells is dependent on a protein called AIRE that is mutated in a rare single gene human autoimmune disorder.[14,130] This differentiation process allows the expression, processing, and presentation by mTECs of peptides that are representative of tissue-specific peripheral proteins expressed across many different tissues and cell types. As a result, many self-reactive SP T cells with TCRs that have a high avidity for a wide range of self-peptides are deleted in the medulla.

Only about 2%-5% of immature thymocytes will survive the positive and negative selection processes. These remaining thymocytes emerge as mature naive $CD4^+$ or $CD8^+$ T lymphocytes with TCRs that recognize peptide/MHC complexes but will only interact with the MHC molecules with sufficient avidity to be activated when the appropriate foreign (microbial) peptides are bound to the MHC molecule. These naive single-positive αβ T lymphocytes will leave the thymus to populate SLOs and recirculate (Fig. 10.1). $CD4^+$ and $CD8^+$ αβ T cells represent 70%-80% of the circulating extrathymic T-cell population—they are the primary T cells that respond to virus infection.

The second (minor) population of thymus-derived cells that populate peripheral sites are the γδ T cells, which are so named because they employ a heterodimeric TCR whose variable (and constant) region are encoded by a distinct set of genetic loci (the γ locus and the δ locus) homologous to the α and β TCR loci[2,51,74,134,147,152,157,179] (Table 10.3). They are sometimes referred to as innatelike T cells. These TCR genes rearrange in the thymus in a manner analogous to that of the dominant αβ TCR T-cell homolog. The generation of γδ T cells in the thymus precedes αβ T-cell development. The γδ T cells are generated in two waves during T-cell development in the fetus. The first wave of maturing thymocytes consists of cells with limited TCR V gene diversity (ie, utilize one or few Vγ and Vδ rearrangement in their TCR). After selection, these γδ T cells leave the thymus, traffic through the circulation, and preferentially localize to epithelial surfaces, particularly the skin, gut, and urogenital tract. The second wave of γδ T cells, as with αβ T cells, displays a highly diverse TCR array, and these cells localize to the secondary lymphoid tissues. Unlike the αβ TCR, however, the γδ TCR does not recognize peptides bound to the MHC class I or II proteins. These γδ T cells either directly recognize structures such as heat shock proteins displayed on the surface of the infected cells or recognize lipids or

phosphorylated metabolites bound to MHC-like molecules (eg, nonpolymorphic MHC Ib molecules) on the surface of stressed (infected) cells. Intraepithelial γδ T cells function like cells of the innate immune system, recognizing not a specific pathogen but alterations in epithelial cells induced by infection with microbes such as bacteria. At present, no direct role for γδ T cells in the control of virus infection has been established.

TABLE 10.3 T lymphocyte subsets

αβ T	Dominant T-Cell–Type Responding to Virus Infection		
	$CD8^+$	Recognize major histocompatibility complex (MHC) class I viral peptide complexes, and are important adaptive immune antiviral effector cells	
	$CD4^+$	Recognize MHC class II viral peptide complexes, and regulate B-cell differentiation and host inflammatory responses to infection	
		T_H1	Effector $CD4^+$ T cells that produce IFN-γ
		T_H17	Effector $CD4^+$ T cells that secrete IL-17 and IL-22
		T_H2	Effector $CD4^+$ T cells that produce IL-4, IL-5, and IL-13
γδ T	Play a prominent role as "innatelike" effector cells • Express the CD3 complex, but usually not CD4 or CD8 • The generation process of γ:δ TCR chains in the thymus is similar to that of the dominant TCR-α:β T-cell TCR • Present in the circulation and lymphoid organs and prominently expressed at body surfaces (eg, gut, skin) • Recognize products of stressed cells—no restriction in recognition by major histocompatibility complex (MHC) class I/II molecules but can recognize lipid complexed to MHC class Ib molecules		
NKT	Act as "innatelike" immune effectors early in immune responses • Express conventional TCR-αβ chains, but use a restricted number of possible TCR genes • Express CD4 molecules (most NK T cells) and NK cell markers but not CD8 molecules • Recognize products of stressed cells and can recognize lipid moieties displayed by MHC class Ib–related molecules on cell surfaces • Activation of TCR triggers release of regulatory cytokines (eg, IL-4)		
T_{reg}	Conventional TCR-αβ T cells that control the response of T and B lymphocytes to foreign (eg, viral) antigens and self-proteins • Dominant population expresses CD4 and CD25 • May occur spontaneously during T-cell differentiation or after exposure to foreign (eg, viral) antigen • Regulates (usually suppresses) the response of $CD4^+$ T cells and $CD8^+$ T cells to infectious agents and self-constituents		

IFN, interferon; TCR, T-cell receptor; IL, interleukin; NKT, natural killer T cells.

Among the other T lymphocyte subsets (Table 10.3) generated during development are invariant NK T cells, so-called because these αβ TCR–expressing T cells display cell surface markers shared with NK cells and, similar to γδ T cells, they utilize a limited number of TCR V genes in receptor generation. Other NK T cells exist that are not invariant, but all NK T cells recognize lipid antigens presented on a family of MHC class I–like molecules called CD1 molecules. They are also, like γδ T cells, sometimes considered to be innatelike T cells. Another type of innatelike T-cell population with an invariant TCR, called mucosa-associated invariant T cells or MAIT cells, recognize fungal or bacterial metabolites derived from the riboflavin synthesis pathway that presented on an MHC class I–related protein (MR1). MAIT cells are abundant in the gut and liver, express CD8, secrete cytokines upon encountering infected cells including virally infected cells, and have been implicated in controlling some viral infections.

During T lymphocyte development, the thymus also generates cells called regulatory T cells or (Tregs), a subset of $CD4^+$ T cells that are critical regulators of adaptive immune responses to infectious agents, self-molecules, and allergens. These Tregs are often called "natural" or "thymic" Tregs to distinguish them from very similar cells that are generated in the periphery from mature $CD4^+$ T cells. Tregs suppress the activity of conventional $CD4^+$ and $CD8^+$ T cells responding to viral infection. They prevent the development of excessive injury during T-cell responses to infection and suppress the development of autoimmune responses during viral infection.

Secondary Lymphoid Organs: Structure and Function

Mature naive (resting) B and T lymphocytes egress central lymphoid organs (the bone marrow and thymus, respectively) and acquire the ability to recirculate through the blood to and from SLOs. The major SLOs are the lymph nodes (LN), the spleen, and the so-called mucosal-associated lymphoid tissue (MALT). Recirculation of naive B and T cells refers to the homing of naive (and some categories of memory) lymphocytes to SLOs through the blood, then egress into efferent lymphatics that drain into the thoracic duct, and then reentry into the blood for the next homing event. This recirculatory process continues throughout the lifespan of each naive lymphocyte, unless this cell encounters a specific antigen in an SLO and is then activated.

SLOs play a critical role in the initiation of the adaptive (T- and B-cell) immune response to viruses and other microbes. LN are highly organized structures located at vessel convergence points in the lymphatic system, a system that collects fluids and cells from the tissues of most internal organs (eg, liver, stomach) and body surfaces (eg, skin, mucosa of the gastrointestinal [GI], genitourinary [GU], and respiratory tracts). The capacity of lymphatic vessels to collect antigen (eg, virus, viral constituents) from the body surfaces/tissues and deliver them to the LN (where antigen is concentrated) is essential for the efficient triggering of the adaptive immune response to microbes. The spleen plays a similar role as the LN network; however, the spleen is uniquely suited to collect antigen (virus) directly from the bloodstream, because of its unique architecture and extensive blood circulation. The third class of SLO, the MALT, is composed of specialized lymphoid aggregates associated with major mucosal surfaces and sites of microbial invasions (eg, the GI, GU, and respiratory tracts). The gut-associated MALT (also called GALT) includes the tonsils, adenoids, appendix, and Peyer patches in the small intestine. In the respiratory tract, there are similar but more diffuse aggregates of lymphoid tissues associated with the epithelium of small/medium airways (ie, bronchial-associated lymphoid tissue [BALT]). As with the other SLO, the MALT are sites of antigen localization where the initiation of the adaptive immune response occurs.

The common feature of SLO is the localization of adaptive immune cells (ie, T and B cells) to distinct regions of the SLO. For example, most B cells are localized in distinct follicles within the LN cortex. Activation of B cells specific for a pathogen/antigen by protein antigens and with T-cell help can lead to their proliferation and formation of germinal centers (GCs) within the LN cortex. T cells within the LN localize to, and are diffusely distributed within, the LN paracortical areas. Other cell types are also distributed within the outer cortex and central medulla of the normal LN. These include stromal cells and cells of macrophage and DC lineage. These cells (particularly DC) play a crucial role in the induction of the adaptive immune response, and some stromal cells serve to direct T-cell/B-cell localization to distinct LN regions through the constitutive release of small (low molecular weight) chemotactic proteins or chemokines. A similar segregation of B cells/T cells to distinct regions occurs within the white pulp of the spleen and the MALT (likewise, under control of chemokines elaborated by SLO-resident cells).

Homing of Naive Lymphocytes to Secondary Lymphoid Organs

The body's complement of B and T cells consists of more than 10^9 cells, each of which may display a unique antigen receptor directed to a specific epitope. Thus, the frequency of B or T cells directed to a specific pathogen is extremely low (eg, a frequency of 1 of 10^4-10^6 naive B or T cells). The problem faced by the adaptive immune systems is that these rare, antigen-specific cells are randomly distributed throughout the body and must be rapidly mobilized to respond to invading organisms. These rare antigen-specific cells must first contact antigen, then activate, and generate effector cells capable of eliminating the pathogen. The solution to this problem is achieved through the process of lymphocyte recirculation through the SLO.

Lymphocyte recirculation of naive T cells and naive follicular B cells is controlled by the expression of distinct homing receptors (adhesion molecules) whose ligands are expressed on cells within the SLO. Naive $CD4^+$ and $CD8^+$ T cells within the bloodstream express on their surface the adhesion/homing receptor, CD62L (L-selectin). T cells entering the blood vessels encounter the CD62L ligand, a tetrasaccharide called Sialyl Lewis x, that decorates the mucinlike CD34 and GlyCam-1 proteins on the endothelium of specialized high endothelial venules (HEV) within the LN cortex. The interaction of CD62L (on the T or B cell) with its endothelial cell ligands induces the rolling of the lymphocyte. CCR7, a chemokine receptor (found at higher levels on naive T cells but present on naive B cells as well) is then triggered by the chemokines CCL21 and CCL19, which results in the activation of the $\alpha_L\beta_2$ integrin (LFA-1) and the arrest of lymphocyte migration. This arrest results in transmigration (diapedesis) of the lymphocyte across the HEV into the T-cell zone of the cortex. A little CCL19 and CCL21 is produced by the HEV cells, but these chemokines are mainly derived from fibroblastic reticular cells (FRCs) in the T-cell zone of the lymph node and then transcytosed by and displayed on the surface of endothelial cells of the HEV. The interaction between the CCR7 receptor on the arrested T cells and its chemokine ligand triggers the migration of the naive T cells through the HEV and into the LN cortex (parafollicular T-cell region). Naive B cells express CD62L and sufficient CCR7 to be first drawn in across HEVs into the T-cell zone, but because they express high levels of CXCR5, they are rapidly drawn into lymphoid follicles along a gradient of the CXCL13 chemokine made by stromal cells in the follicle (B-cell zone) including cells of nonhematopoietic origin called follicular DCs. If naive lymphocytes do not encounter antigen, they traffic through the LN cortex to the medulla, then exit the LN though efferent lymphatic vessels, and ultimately return to the bloodstream where the process of recirculation though the SLOs begins again. Lymphocyte trafficking through the spleen and MALT is likewise regulated by the interplay of adhesion receptor/ligand interactions and chemokines constitutively expressed in these SLOs. In the case of MALT, a set of unique receptor/ligand interactions (restricted to these sites) guide the trafficking of adaptive immune cells to these specialized mucosal sites.

Afferent lymphatic vessels are localized in all body surfaces/tissues, and they drain into the subcapsular sinus of the LN. Virus infection of a body surface/tissue triggers the innate immune system—the initial defense against infection. Innate immune cells located peripherally encounter pathogen, take up virus/viral antigen, are activated, and then migrate through afferent lymphatics to the draining LN. In the draining LN, these migrating cells (along with resident DC in the LN cortex) serve as APC to the naive B and T lymphocytes trafficking through the LN. As a result of encounter with antigen displayed on the APC, the lymphocytes with antigen receptors specific for the antigen or pathogen will no longer traffic through the LN, but rather will be retained in the LN and initiate the process of activation and differentiation leading to the generation of specific effector B and T cells directed to the pathogen. Thus, the SLO concentrate antigen in a specific site where the rare antigen-specific, naive B and T cells circulating through the body can encounter and respond to the pathogen. Once fully activated, effector T cells exit the lymph node, enter the blood, and instead of homing to SLOs, specifically migrate to the site of viral infection.

If infection by a virus is localized to the body surface (eg, papillomavirus infection of the skin or influenza virus infection of the respiratory tract), then the adaptive immune response to that pathogen will be primarily induced in the LN draining these sites. Virus infections that result in systemic spread (ie, viremia) will also induce adaptive immune responses in the spleen. Viruses that infect sites where MALT are prominent (eg, rotavirus infection in the Peyer patches of the small intestine) will trigger the local induction of the adaptive immune responses at the site of MALT localization.

Genes and Molecules That Mediate Adaptive Immunity

With genome sequencing of the human and other species (eg, the mouse), the overall organization and fine structure of most genetic loci that regulated adaptive immune responses are now well defined. Furthermore, the molecular structure of MHC molecules, T- and B-cell antigen receptors, and many other molecules essential for the adaptive immune response have been elucidated through analytical techniques (eg, x-ray crystallography). It is useful to briefly review the properties of certain genes and molecules—in particular, the MHC locus genes and proteins and the components of antigen receptors, costimulatory ligands, and receptors and coreceptors. Antibodies and the B-cell receptor will be discussed in a later section of the chapter. Cytokines and chemokines are frequently products of innate immune system cells but are also secreted by adaptive immune cells. Several of the cytokines that control adaptive immune responses will also be mentioned later in this chapter.

The Major Histocompatibility Complex Locus Genes/Products

The genes within the MHC locus are classified as class I (Ia and Ib), class II, and class III. The class I and class II proteins are intrinsic to the presentation of antigens to T cells. The MHC class I proteins are made up of a transmembrane α (heavy) chain and an associated β2-microglobulin (β2-M) protein. The MHC class II proteins are transmembrane αβ heterodimers. The class III genes encode proteins, some of which have important functions in immunity (eg, the complement proteins, C2, C4, and factor B [Bf]), but have no sequence structural homology to the MHC class I or II genes or products. Class III genes encoding cytokines of the TNF family (eg, TNF, lymphotoxin α and β [LT-α and LT-β]) also play a critical role in innate immunity. In the case of LT-α and LT-β (and related TNF family members), these gene products also play a role in the development of the SLO, because genetic deficiency in either LT-α or LT-β results in defective lymphoid tissue formation during development. The linkage of these and other class III genes to the MHC locus suggests a strong evolutionary pressure to retain these

genes in close proximity to the genes encoding the conventional MHC locus products. The importance of this linkage is evident considering that the class III genes encoding tapasin, the TAP1 and TAP2 transporter, and immunoproteasome subunits (b1i-LMP2, b5i-LMP7) all map within the MHC and regulate the induction of $CD8^+$ T-cell responses and the expression of $CD8^+$ T-cell effector activity. The other class III genes within the locus, however, encode proteins with no obvious immunologic function (eg, the gene for the steroid biosynthetic enzyme 12-hydroxylase, which when deficient causes adrenal hypoplasia). Unlike class Ia and class II genes, the numerous class III genes exhibit minimal polymorphism (ie, have few/no allelic forms), and the function of many of their products have yet to be defined.

The class Ib genes encode proteins whose overall structure is similar to the highly polymorphic class Ia gene products, but these genes display minimal polymorphism. The class Ib genes also encode cell surface molecules that are associate with β-2M. The number of class Ib genes varies among species, and the expression of these β-2M–associated class Ib gene products varies among class Ib products, both in magnitude and in tissue distribution. Many class Ib gene products serve as ligands for receptors on NK cells and/or γ:δ T cells.[45] The HLA-G molecule, for example, is expressed on fetal-derived placental cells along the uterine wall and provides an N-terminal leader sequence (signal peptide) that binds to the groove of HLA-E, which can then ligate an inhibitory receptor on maternal NK cells, CD94/NKG2A, to inhibit NK cell killing of fetal cells. These placental lining cells are also devoid of classic MHC class Ia molecules and are not recognized by $CD8^+$ αβ T cells; unlike other class Ia–deficient cells, these placental cells are not susceptible to killing by NK cells as a result of HLA-G (and HLA-E) expression. The class Ib HLA-E molecule is relevant for both NK cell activation and inhibition. HLA-E molecules bind a limited set of peptides derived from the signal peptides of class Ia molecules and HLA-G. These peptide/HLA-E complexes can not only bind to an inhibitory receptor on NK cells and prevent NK cell–mediated lysis, as mentioned above, but can also contribute separately in different contexts to NK cell activation through a distinct activating receptor. In contrast, the expression of products of the MHC class I chain–related (MIC) family of class Ib genes is controlled by a novel mechanism. These molecules, MIC-A and MIC-B, are selectively expressed on the surface of epithelial cells (and fibroblasts) undergoing stress (eg, heat shock and viral infection). The MIC-encoded molecules interact with receptors on NK cells, γδ T cells, and rare $CD8^+$ αβ T cells, activating these cells to kill MIC-expressing cells. At least one class Ib gene, HFE, has no apparent immune-related function. It encodes a protein expressed on the intestinal epithelium that is involved in iron metabolism. Deficiency in HFE gene expression results in the iron storage disease, hereditary hemochromatosis. As these examples suggest, the full spectrum of class Ib gene function is complex and not yet elucidated.

The hallmark of the class Ia genes, the genes encoding the classic transplantation antigens, is the extensive polymorphism of the HLA-A, B, and C locus genes. Approximately 3500 HLA-B locus alleles alone and a total of about 6000 HLA class I alleles at the A, B, and C loci have so far been identified. Because class Ia genes are codominantly expressed, individuals can express up to six different HLA class Ia gene products on their cells (ie, two alleles each of HLA-A, B, and C). X-ray crystallographic analysis of HLA class Ia molecules has demonstrated that most amino acid differences associated with individual class Ia alleles are localized to the outer two domains (α_1 and α_2) of the heavy chain molecule that encloses the peptide-binding groove and thus contribute to interaction with the TCR-αβ heterodimer on $CD8^+$ T cells.

Allelic variation in the α_1 and α_2 domains of the class Ia molecules is clustered within specific sites in the outer two domains; that is, in the floor of the peptide-binding cleft (consisting of a β-strand structure contributed by both the α_1 and α_2 domains) and along the two walls of the bivalve, clamshell-like peptide-binding cleft, demarcated by two α helical walls (ie, halves of the clamshell) contributed by the α_1 and α_2 domain, respectively, with polymorphic amino acid side chains pointing into the groove from the walls. The floor of this bivalve, clamshell cleft demarcates *pockets* defined by the polymorphic residues surrounding the pockets, which allow antigenic peptides with the appropriate amino acid side chains to be *anchored* in the groove. The location of these pockets in the groove (typically, two to three pockets in the floor of the class Ia–binding cleft), and the allele-specific residues of the α_1 and α_2 domain lining the pockets in the floor of the groove, defines the anchor residues of peptides capable of binding to the groove and, therefore, the MHC class I allele–specific, peptide-binding motif of antigenic peptides (and self-peptides) that bind to a specific class Ia allele. The interaction of other residues in the 8-10 amino acid antigenic peptide with the side chains of residues lining the wall of the groove further defines (limits) the range of peptides capable of stable interaction with a particular class Ia allele. Finally, once stably bound to the class Ia–binding cleft, the side chains of one or more amino acids of the bound peptide extend up and out of the surface of the groove and, therefore, are accessible to the TCR. X-ray analysis of crystals of TCR-αβ heterodimers and specific peptide/class I complexes indicates that the TCR interacts with a surface composed of amino acid along the α helical walls contributed by the class I α_1 and α_2 domains, and amino acid side chains of the bound peptide. Thus, both the class Ia molecule and the bound peptide contribute to the structure recognized by the TCR on $CD8^+$ T cells, either during T-cell development in the thymus (with self-peptides bound to the MHC) or in response to viral infection in the SLO or the site of infection.

Because each allelic class Ia molecule can only bind a limited range of peptides, dictated by the structure of the peptide-binding cleft, polypeptides encoded by a virus must contain one or more strings of amino acid in a precise linear arrangement to stably bind to a particular MHC class Ia allele and be recognized by $CD8^+$ T cells. Why then is the $CD8^+$ T-cell recognition of a foreign antigen by any individual limited to six possibilities (ie, the peptides captured by the two alleles of HLA-A, B, and C inherited from one's parents)? Why do we not express on our cells multiple versions of each HLA antigen to increase the chances of capturing an antigenic peptide and stimulating a $CD8^+$ T-cell response? The explanation for these questions likely comes from the process of $CD8^+$ T-cell selection in the thymus. The greater the number of MHC alleles expressed in the thymus (ie, displaying self-peptides), the greater the chance that the developing $CD8^+$ T cells will undergo negative selection (deletion in the thymus in response to TCR recognition of self-peptide/MHC complex), thereby decreasing the number of potential naive $CD8^+$ T cells capable of responding in the periphery to infection. The compromise is at the species level (ie, express a diverse array of MHC alleles within an outbred population). Consequently, although any particular individual displaying a particular set of MHC class Ia alleles may not be able to mount a response to a particular virus, sufficient allelic diversity exists within the population for most individuals to display an MHC allele capable of presenting at least one antigenic peptide to $CD8^+$ T cells and clear infection.

The MHC class II genes, HLA-$DP_{\alpha:\beta}$, $DQ_{\alpha:\beta}$, and $DR_{\alpha:\beta}$, also express a high degree of polymorphism (with the exception of the DR_α gene, which has a limited allelic polymorphism, for reasons that are not fully understood).[129] The six alleles of the codominantly expressed human MHC class II genes inherited by any individual may be further diversified by the ability of the α chain of the class II allele (eg, DR) to pair with the β chain of another class II gene product (eg, $DQ_{\beta1}$) forming a hybrid class II molecule with a new (additional) peptide-binding capacity. The polymorphism of class II genes, as with class Ia genes, is largely restricted to the gene segments encoding the domains forming the peptide-binding groove (ie, the α_1 and β_1 domains of the class II α and β chains, respectively). Unlike the ends of the peptide-binding groove of the class I molecule (which is *closed* and, therefore, capable of accommodating peptides of a restricted length—8-10 amino acids), the ends of the class II–binding cleft are open, allowing the class II cleft to accommodate peptides of variable lengths of 13 or more amino acids, containing N- and C-terminal amino acid extensions of the 8-9 amino acid internal residues representing the internal core of the antigenic peptides. As with the class I groove, the interaction of anchor residues of the peptides with pockets in the floor of the class II–binding groove is essential for the

selection of peptides with the proper binding motif by a particular class II allele. The amino acid residues in the N- and C-terminal extensions of the core peptide sequence, however, stick out of the ends of the clamshell groove and interact with regions of the α_1 and β_1 domains of the class II molecule outside of the binding groove to stabilize overall peptide/class II interaction. Therefore, the binding motifs of peptides that bind to particular MHC class II alleles is not as clearly defined and not as rigid as the motifs for peptides that bind MHC class I molecules.

The CD1 Family of Class Ib Genes and Lipid Recognition

The recognition of lipids as well as peptides is an important feature of the host response to infection (and possibly in tumor immunosurveillance and autoimmunity). One family of MHC class Ib–like molecules that are encoded by genes outside of the MHC locus is the CD1 family of glycoproteins. The CD1 family consists of five genes and proteins in the human (ie, CD1a-e). These molecules have the unique feature of binding lipids and presenting those bound lipids to T cells. As with most class Ib molecules, they associate with β-2M and are encoded by genes with limited polymorphisms, and display the domain structure (α_1, α_2, α_3 domains) typical of class I molecules. The binding cleft of the CD1 molecule, however, is deep and extremely hydrophobic (267). Thus, these molecules can efficiently bind and present lipids/glycolipids to T cells, with several exceptions; however, they do not bind peptides. These molecules are not retained in the ER after synthesis awaiting peptide loading (ie, do not require TAP transporter function for cell surface expression), but likely traffic to the cell surface, and then capture lipids, either at the cell surface or after recycling into endosomes. Therefore, lipid uptake by CD1 molecules is similar to the peptide capture mechanism employed by MHC class II molecules. Different CD1 family members bind distinctly different lipid moieties as dictated by the structural constraints of their hydrophobic binding groove.[17] They can bind both lipids of microbial origin (with mycobacterial lipids representing the best characterized moieties examined to date) and lipids/glycolipids of cellular (self) origin. The mechanism of lipid presentation by CD1 family involves the assembly in the ER of newly formed CD1 molecules with endogenous lipids, their transport to the cell surface, internalization into endocytic compartments where they can, with the help of saposins, exchange the endogenous lipid in the groove for exogenous lipids that may be pathogen-derived, or for other endogenous lipids derived from other cellular compartments. CD1 molecules are expressed on DCs, monocytes, thymocytes, and some B lymphocytes. Conventional TCR-αβ–displaying T cells can recognize certain glycolipids (eg, CD1d/mycobacterial mycolic acid complexes), and these lipid-specific T cells may play an important role in the host defense against infection with intracellular bacteria. Recognition of lipid-bound CD1 molecules appears, however, to be a major focus of NK T cells (T cells that do not express CD4 or CD8 coreceptors but do express characteristic NK cell surface markers and whose TCRs contain an invariant TCR-α chain).[80] The lipid/CD1 interaction, with the invariant TCR on NK T cells, induces the rapid production of cytokines (eg, IFN-γ, IL-4) by the NK T cells. The CD1 recognition system and the T cells responding to CD1 molecules appear to comprise an important evolutionary mechanism for responding to nonviral microbial infections. The contribution of the CD1 family and most other MHC class Ib molecules in the host response to virus infection may be limited.

T-Cell Receptor, Coreceptor, and Costimulatory Genes and Proteins

Specific antigen recognition by T cells is carried out by a heterodimeric disulfide-linked cell surface glycoprotein, the TCR. The TCR heterodimer is similar in overall structure to the F_{ab} portion of Ig molecules, reflecting that the TCR chains are members of the Ig gene superfamily. Thus, antigen recognition by conventional $CD4^+$ or $CD8^+$ αβ T cells is carried out by variable V_α and V_β domains of the TCR. Unlike the constant domains of antibody heavy chain genes that include many different constant regions genes that each give rise to a different antibody isotype or class, all αβ T cells utilize a single C_α gene segment and one of two virtually identical C_β gene segments downstream of two different sets of (duplicated) D and J gene segments. The same C region domains are utilized in the TCRs of both $CD8^+$ T cell and $CD4^+$ αβ T cells.

Coreceptors in the immune system bind the antigen receptor complex and assist in the initiation of antigen receptor signaling. They should be distinguished from costimulatory receptors, which do not participate directly in antigen receptor signaling. CD4 and CD8 are the two coreceptors, respectively, on helper and cytotoxic phenotype αβ T cells. CD4 is a single chain, glycosylated molecule containing four extracellular domains, the outermost of which binds MHC class II molecules. The CD8 molecule exists primarily as a disulfide-linked heterodimer glycoprotein consisting of an α and β chain, each containing a single extracellular Ig domain. Interaction with MHC class I is mediated primarily by the CD8α chain though the β chain of CD8 helps orient the heterodimer to appropriately bind MHC class I molecules. A subset of $CD8^+$ T cells express CD8 α/α homodimers and are localized primarily to the gut epithelium. These $CD8^+$ T cells may play a role in the recognition and destruction of stressed (eg, infected) epithelial cells. Both CD4 and CD8 molecules bind weakly to their respective MHC targets in the absence of TCR engagement. The cytoplasmic tails of both CD4 and CD8 molecules interact with a cytosolic tyrosine kinase (Lck) and, on TCR recognition of peptide/MHC complexes, delivers this kinase to the αβ TCR complex to initiate phosphorylation of the CD3 and ζ ITAMs (each CD3 chain tail has 1 ITAM, while each z chain tail has 3 ITAMs, adding up to a total of 10 ITAMs in the TCR complex). Phosphorylation of the two tyrosine residues in each ITAM leads to the recruitment of the ZAP70 tyrosine kinase, the subsequent phosphorylation of cytoplasmic and transmembrane adaptor molecules and the recruitment and activation of downstream enzymes leading to the induction of a range of activated transcription factors that contribute to the activation of genes relevant to T-cell proliferation and differentiation.

As mentioned above, activation of resting (primary) T cells requires both the activation of the αβ TCR complex (made up of the TCR, CD3 heterodimers, and the ζζ homodimer) as well as the separate engagement of the costimulatory receptor, CD28. The CD28 disulfide-linked homodimer (a member of the Ig supergene family) is constitutively expressed on resting T cells. CD28 interaction with its ligands, CD80/86, displayed on APC is required for the activation of resting $CD4^+$ T cell and $CD8^+$ T cells. Another member of the CD28 family, cytotoxic T lymphocyte antigen 4 (CTLA-4) (CD152), is expressed on activated T cells, but the interaction of CTLA-4 with the CD80/86 ligands delivers an inhibitory signal that limits the proliferation of activated T cells, thereby controlling T-cell expansion in response to antigen. Another CD28-related costimulatory molecule expressed on activated T cells is ICOS, which binds to its ligand displayed on APCs during T follicular helper cell generation.

Members of the TNF ligand superfamily, which are on activated T cells, can also participate in T-cell responses. The CD40 ligand (CD154) is expressed on activated $CD4^+$ T cells and on engagement of its receptor (CD40) on DCs and B cells, delivers a critical signal necessary for full activation and cytokine production by DCs, and for B-cell activation during responses to protein antigens. Other members of the TNF family expressed on activated T cells (eg, 4-1BB [CD137] and OX40 [CD134]) can also deliver costimulatory signals. In experimental influenza infection, blocking the interaction of OX40 with its ligand in the infected lungs results in efficient virus clearance but with a markedly diminished inflammatory response in the infected lungs.[198]

Integrins also play a critical role in T-cell activation and in the homing of naive and activated T cells to the SLO or sites of inflammation and/or

infection. The α_L β_2 integrin, LFA-1, is displayed on resting T cells, and through its interaction with its ligands, ICAM-1/ICAM-2, acts to enhance or stabilize the T-cell/APC interaction. LFA-1 expression is upregulated on activated T cells, and binding of LFA-1 to its ligands that are expressed at increased levels on inflamed vascular endothelium targets localizes activated T cells to inflammation sites. The α_4 β_1 integrin, VLA-1 (expressed very late in T-cell activation), also plays an important role in targeting effector T cells to infection sites through interaction with its receptor (VCAM-1) displayed on activated endothelium and is crucial for T-cell immune surveillance targeting viruses that can infect the central nervous system.

Antigen-Presenting Cells and the Induction of Adaptive Immune Responses

The hallmark of the adaptive immune system is specificity of foreign antigen recognition. For T cells, this means recognition of antigenic peptides bound to MHC class I or II molecules displayed on the cell surface. The T-cell response proceeds in two phases. First is the inductive phase: the activation of quiescent naive (or memory) T cells in response to recognition of specialized APC displaying the peptide/MHC complex, resulting in the generation of armed effector T cells. Second is the effector phase where cells displaying the appropriate peptide/MHC complexes are recognized by the activated T cells. The *classic* class I presentation pathway is ideally suited to generate the antigenic peptide/MHC class I complexes recognized by $CD8^+$ effectors in response to viral infection of any somatic cell type. Because antigenic peptide/MHC class I complexes are extremely stable, viral peptides displayed by MHC class I molecules displayed on the surface of infected cells are not transferred to surrounding uninfected cells. Consequently, the resulting destruction of bystander cells by $CD8^+$ T cells is negligible.

Due to the more stringent requirements for the activation of resting naive T cells, there has been considerable attention given over the past decade to the process of antigen processing/presentation by professional APCs (in particular dendritic cells or DCs) in the generation of peptide/MHC complexes during the inductive phase of the T-cell response. Currently, DCs fall into one of four main categories. The first category consists of conventional or classical DCs (both cDC1s and cDC2s); these are the most numerous DCs, and they arise from a bone marrow–derived, myeloid origin, common DC precursor. The second category, pDCs, are so-called because of their plasma cell–like morphology and surface expression of a CD45 isoform (ie, the B220 molecule, which, characteristically, is found only in B cells) and have been demonstrated to be the major source of IFN-α produced early (24-48 hours) after inflammatory stimuli, including virus infection. Thus, in addition to serving as a potential APC for T cells, pDCs serve as a major early innate immune defense against virus infection. They are derived from the bone marrow but from a distinct lymphoidlike precursor. The third category, monocyte-derived DCs, are a distinct subset of cells that assume a conventional DC-like phenotype but are induced during inflammation when monocytes differentiate into this DC lineage. Finally, Langerhans cells represent a distinct DC lineage that arises from the fetal liver and seeds the skin.

In support of their essential role in immune response induction, DCs (when mature) are 10-100 times more potent on a per cell basis as activators of naive T cells when compared with other immune cell APCs (eg, macrophages, B cells) and indeed are the primary APCs for naive T-cell activation in SLOs.

Given the critical role of DCs in the induction of the T-cell response (in particular, the antiviral $CD8^+$ T-cell response), viruses might be expected to have evolved strategies to inhibit the induction of $CD8^+$ T-cell responses in virus-infected DCs. As discussed elsewhere in this text, for individual virus genera, evidence indicates that infection of DCs by certain viruses may inhibit the APC capacity of DC.[167,170] Furthermore, productive virus infection of tissue DCs at body surfaces could also result in virus dissemination when the DC traffic to the SLO. These considerations, as well as the fact that certain viruses with narrow cellular tropism (eg., papillomavirus), therefore, are not capable of infecting DCs and providing polypeptides for processing via the classic class I pathway, led to the concept of cross-presentation of antigen (including, viral polypeptides) by DCs to $CD8^+$ T cells. Cross-presentation is largely limited to DCs, especially cDC1 cells, and is only relevant at the inductive phase of T-cell responses. This is the major mechanism for the induction of $CD8^+$ T-cell response to viruses such as papilloma and polio viruses, which presumably do not infect DCs (and for tumor cells, which cannot serve as professional APC). Most nonviral pathogens (eg, extracellular bacteria, fungi) trigger not only relevant $CD4^+$ T-cell responses but also some, presumably cross-presentation–induced, $CD8^+$ T-cell responses, even though the latter may not be relevant for the clearance of many of those pathogens.

Dendritic Cells Activate Naive T Lymphocytes in Secondary Lymphoid Organs

As with most microorganisms, viruses enter the body surfaces where the initial encounter with the immune system occurs. These body surfaces (eg, skin and mucosa of the GI, GU, and respiratory tracts) contain epithelial lining cells, which can serve as the initial cells supporting virus replication. The epithelial surfaces also contain DCs, which migrate to the SLO and deliver antigen to the adaptive immune cells that are trafficking from the blood to the SLO.

Dendritic cells localize to the epithelium within the epithelial cell layer (eg, Langerhans cells in the skin) at the junction of the epithelial basement membrane in GI and respiratory tracts, as well as in the mucosa and submucosa underlying the epithelial surface. The DCs at body surfaces are derived from circulating monocytic progenitors originating in the bone marrow, which are present in the blood and migrate to the body surfaces and differentiate into peripheral (tissue) DC. These tissue DCs exist as immature (inactive) cells at these sites, turn over at a low variable rate, and are replenished by the circulating blood monocyte progenitors entering the tissues.

Immature DCs are sessile cells that have a particular set of phenotypic markers or characteristics. They express low/intermediate levels of cell surface MHC class I and class II molecules; the latter (class II) molecules are found predominately not on the DC surface but within specialized endocytic vesicles. Immature DCs also express low levels of cell surface molecules such as CD80 and CD86, which serve as costimulatory ligands for naive lymphocytes, and also express other receptors of relevance such as CD40. These molecules play a critical accessory role in the triggering of naive antigen-specific (eg, virus-specific) T cells, ultimately leading to the generation of effector (ie, antiviral) T and B cells, and the formation of memory T and B cells directed to the pathogen. Immature DCs also have the ability to take up particulate and fluid-phase antigen into pinocytic/phagocytic vesicles with high efficiency. The enhanced capacity of these DC to take up material (including the remains of infected apoptotic cells) likely accounts for their unique capacity to serve as APC.

The initiation of an inflammatory response at the body surface (as produced by virus infection) triggers the DC activation (maturation) process. Activation of the tissue-resident DC results in the *de novo* expression/upregulation of chemokine receptors (notably, CCR7), which renders the activated DC capable of migrating out of the peripheral tissue, primarily through lymphatic vessels along a gradient of constitutively expressed CCR7 ligands, the CCL19/CCL21 chemokines produced by lymphatic endothelial cells. Activation of the tissue DCs is also accompanied by upregulated expression of MHC class I/II molecules and costimulatory ligands resulting in the maturation of the DC. Mature DCs

characteristically express high cell surface levels of MHC class I/II molecules and the costimulatory ligands, CD80/86 and CD40, which can be later triggered to induce or sustain DC maturation by activated $CD4^+$ T cells. Mature DCs migrate to the SLO where they act as the principal APCs for the induction of the adaptive immune response. Thus, DCs serve the dual role of delivery (concentration) of antigen to the SLO and acting as APCs to activate the rare antigen-specific T cells entering the SLO from the circulation.

Immature DCs can be activated by virus infection through at least three mechanisms:

1. Direct infection of immature DCs. The stimulus for DC activation/maturation is provided by the interaction of viral proteins or, more likely, viral nucleic acids with (and signaling through) microbial pattern-recognizing Toll-like receptors (TLR) expressed by DCs, and/or activation of intracellular antiviral signaling mechanisms mediated by the cytosolic RNA sensors including the retinoic acid–inducible protein I (RIG-I) and melanoma differentiation antigen-5 (MDA5) helicases, and RNA-activated protein kinase (PKR).

2. Uptake of virus and soluble antigen (or more likely apoptotic bodies enclosing portions of previously infected epithelial cells) by endocytosis or pinocytosis with activation of immature DCs through binding to one or more C-type lectin receptor(s) displayed on DCs with specificity for carbohydrates on viral glycoproteins/glycolipids or through the process of phagocytic uptake.

3. Activation/maturation of DCs (that have taken up viral antigens) by **inflammatory mediators** (ie, cytokines, such as TNF). These cytokines may be released by infected epithelial cells and tissue macrophages in response to TLR and/or intracellular viral signaling.

Direct infection of immature DCs and the subsequent migration of the activated/mature DC to the SLO would appear to be the most likely mechanism to ensure the induction of an effective antiviral adaptive immune response. Whereas this mechanism of viral antigen delivery to T and B lymphocytes in the SLO occurs, it begs the important question: *How do viruses with a very narrow cell tropism which are unable to either infect or express viral genes in hematopoietic cells like DC (eg, papillomaviruses) initiate an immune response?*

The capacity of immature DC to endocytose cellular debris/apoptotic remnants of infected epithelial cells provides an important mechanism for triggering adaptive immune responses. The endocytic uptake of virions or material from virus-infected cells may be the primary mechanism of viral antigen presentation to virus-specific naive $CD8^+$ T involving the *cross-presentation* of viral antigens. It is now recognized that of the two main categories of conventional DCs, called cDC1 and cDC2 cells, cDC1 cells are particularly competent in cross-presentation and activation of naive $CD8^+$ T cells, though like cDC2 cells they can also activate naive $CD4^+$ T cells. Antigen presentation and cross-presentation are described in more depth later in the chapter.

On entering the draining LN, activated (mature) DC migrates in response to a gradient of CCL19 and CCL21 to the paracortical T-cell regions in the vicinity of the HEV. Thus, antigen-bearing DC arrives at the precise location to interact with naive virus-specific T lymphocytes that have entered the draining LN from the circulation and, thereby, initiate the adaptive immune response.

Naive T lymphocytes have stringent requirements for activation that include both TCR antigen receptor engagement by the appropriate processed antigenic peptide/MHC complexes and engagement of costimulatory receptors (eg, CD28) displayed on naive T cells by their corresponding ligands (eg, CD80/86) along with peptide/MHC complexes by APC. Mature, antigen-bearing DCs are uniquely suited to carry out this process. The migration of these cells along with infectious virions (either cell-associated or free) from infected sites to the SLO initiate an immune response in the SLO and, more importantly, can spread infection to other sites in the body. One classic example of this is the dissemination of poxvirus from a peripheral infection site (body surface) to the SLO, where free (infectious) virions and infected cells carried from the inoculation site to the SLO can result in additional virus replication there, followed by virus entry into the bloodstream. Macrophages may serve as APCs in the induction of recall memory (secondary) immune responses at tissue sites where the requirement for memory T and B lymphocyte activation are less stringent. Indeed, mature migrant DCs that have entered the SLO in response to virus infection are often not the primary APCs for T-cell activation. LN-resident DCs can frequently capture viral antigen delivered by migrant DCs and present that antigen to naive T lymphocytes in the SLO—not by direct infection but by the transfer or "hand-off" of viral antigen from migrant antigen-bearing DCs to SLO-resident DCs. The relative contribution of direct antigen presentation by infected/antigen-bearing migrant tissue DCs, the cross-presentation of viral antigen by SLO DC, and the role of infectious virions delivered to the SLO to the induction of the T lymphocyte response have yet to be defined and will likely differ for different viruses. Intact virions and/or soluble (free, intact) viral antigen, however, undoubtedly contribute to the induction of effective antiviral antibody response by B lymphocytes.

Activation of T and B Lymphocytes in Secondary Lymphoid Organs

The precise localization of T cells, B cells, DC, and macrophages within the SLO is controlled by chemokines, which are largely produced by stromal cells of the SLO. In draining LN, naive (primary) T cells present in the circulation will enter the LN through the specialized HEV, where they encounter mature DCs displaying processed antigen bound to MHC molecules, which are localized to the HEV region (the T-cell zone). Most naive $CD8^+$ T cell and $CD4^+$ T cells entering the LN will not recognize the antigen (ie, they have TCR that fail to recognize the processed and presented antigen with sufficient avidity to activate the cells). These T cells will ignore the DCs and migrate from the LN cortex to the medulla, then enter the efferent lymphatics, and ultimately return to the bloodstream to continue their perpetual search for relevant antigen. A similar process of lymphocyte egress through the HEV occurs in the MALT. In the Peyer patches of the small intestine, antigen is taken uptake by mucosal DCs sometimes following direct viral antigen transfer through specialized intestinal epithelial cells, called microfold or M cells. Viruses that enter the bloodstream (causing viremia) as well as any antigen-bearing tissue DCs that, following maturation, gain access to the circulation will localize to the splenic white pulp. Here, circulating T and B lymphocytes enter the splenic white pulp by transiting through splenic arterioles where viral antigen-bearing DCs can encounter lymphocytes. The lymphocytes that do not recognize antigen will exit the splenic white pulp by entering trabecular veins and reenter the circulation.

The rare naive $CD8^+$ T cell and $CD4^+$ T cell that recognize processed antigenic peptides displayed on the APC surface in the SLO do so through TCR engagement. The activation of naive T cells leading to the induction of the adaptive immune response is a multistep process. For induction of antigen-specific (virus-specific) $CD8^+$ T-cell responses, the activation process requires interaction of the antigen-specific TCR chain complex with *processed* antigenic peptides presented by MHC class I molecules on the APC surface with sufficient avidity; TCR signaling is fully catalyzed by the interaction of the CD8 coreceptor on the T cell with a region of the MHC class I molecule distant from the site of peptide binding. The signals delivered by the TCR facilitated by the coreceptor are referred as signal 1. To fully activate naive $CD8^+$ (or $CD4^+$ T cells), activation of the CD28 costimulatory receptor on naive T lymphocytes by its ligands, CD80/86, which are displayed at high levels on mature (activated), antigen-bearing DC is required. Costimulatory signaling through CD28 constitutes signal 2, and the combination of signal 1 and signal 2 is required for

the activation and proliferation of naive T cells (Fig. 10.2).

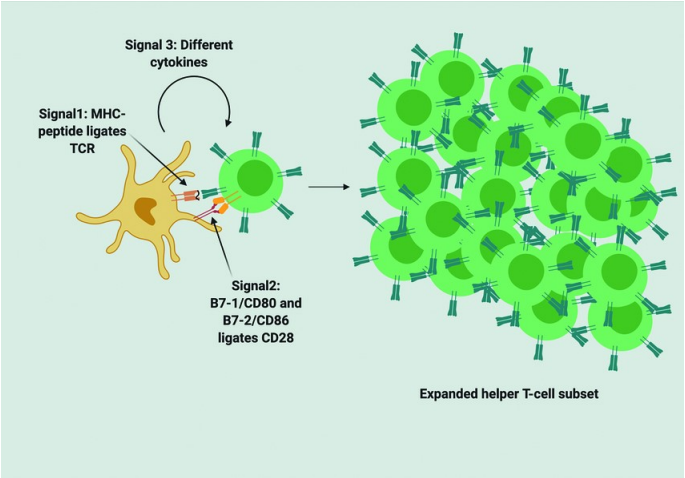

FIGURE 10.2 **T cells require two signals to be activated**. In the figure, the activation of naive $CD4^+$ T cells is depicted, but very similar processes activate naive $CD8^+$ T cells as well. Engagement of the T-cell receptor (TCR) on a naive $CD4^+$ T cell by MHC class II-peptide complexes on a dendritic cell induces TCR signaling (signal 1). Contemporaneous ligation of the CD28 costimulatory receptor on the naive T cell by the costimulatory ligands B7-1 or B7-2 (CD80/86) provides signal 2, resulting in the proliferation and activation of the original T cell to generate a clone of expanded effector T cells. Activation of T cells by cytokines is sometimes called signal 3.

The sequence of events resulting in the activation of antigen-specific naive $CD4^+$ T cell parallels the steps in $CD8^+$ T-cell activation, except that the antigen-recognizing TCR complex must bind (with sufficient avidity) the antigenic peptides bound to MHC class II molecules displayed by APC, and the CD4 coreceptor on $CD4^+$ T cells, in turn, interacts with a distinct site (outside of the region of peptide binding) on the MHC class II molecule. One important early consequence of $CD4^+$ T-cell activation by antigen is the upregulation of the expression of the CD154 molecule on activated $CD4^+$ T cells. CD154 (also called CD40 ligand or CD40L) is a member of the TNF gene family and, as its name implies, is a ligand for CD40 (a TNF receptor gene family member). CD40 is expressed on both activated/mature DC and B cells. Engagement of CD40 on DC and B cells by CD154 (CD40L) on activated $CD4^+$ T cells has important consequences for the function of these cells. Engagement of CD40 on DCs results in increased synthesis of certain cytokines (notably IL-12) by the antigen-bearing DC in the SLO, which promotes $CD4^+$ and $CD8^+$ T-cell differentiation into effectors. For B cells, the interaction between CD40-activated B cells and CD40L expressed on activated $CD4^+$ T cells is critical for the GC response and for B-cell differentiation into memory cells and antibody-secreting plasmablasts and plasma cells.

As a consequence of their interaction with antigen-displaying DCs, the naive T cells halt their transit through the SLO (ie, they are retained there). The APC/T-cell encounter leading to signal 1 transmission in the T cells appears to be of short duration (from 6 to 24 hours), after which the programming for T-cell activation/differentiation is independent of additional interaction with antigen. Delivery of signals 1 and 2, although necessary, is not sufficient in itself, however, to ensure full T-cell activation/differentiation and the generation of effector and memory T cells to the antigen. Additional signals, delivered by cytokines, can contribute to the T-cell activation/differentiation program in the SLO. These cytokines are primarily generated by cells of the innate immune system (eg, mature DC, NK cells, NK T cells), which enter the SLO in response to infection/antigen deposition in the SLO, and cytokine-derived signals that contribute to T-cell activation are sometimes called signal 3. IL-12 produced by mature (activated) DC in the SLO is a particularly critical cytokine for T-cell responses to viruses, because engagement of the IL-12 receptor on activated $CD8^+$ T cell and $CD4^+$ T cells promotes their differentiation into effector T cells with potent antiviral activity (eg, the generation of cytotoxic $CD8^+$ T cells).

Other cytokines produced during T-cell activation (eg, type 1 and type II interferons [INF-α or β and IFN-γ, respectively], IL-1, IL-4) by innate immune cells responding in the SLO to virus infection dramatically modulate the magnitude and type of both the effector and memory T-cell responses. These and other soluble mediators modify the course of T-cell activation/differentiation during the T cell's residence in the SLO.

Naive (primary) T cells are small resting cells, while activated proliferating T cells, called lymphoblasts, are larger. Proliferation of antigen-specific T-cell *clones* in the SLO leads to their differentiation into both effector T cells and memory $CD8^+$ T cell and $CD4^+$ T cells. T-cell proliferation is extremely rapid (cell cycle time of ≤6 hours) with estimates of individual naive T-cell precursors undergoing 8-20 divisions during this programmed proliferation. During their proliferative expansion and differentiation in the SLO, the responding T cells lose cell surface adhesion molecules (eg, CD62L) and receptors (eg, CCR7) necessary for naive T-cell circulation, and they upregulate the expression or express *de novo* adhesion molecules (eg, the β2 integrin, leukocyte function–associated antigen-1 [LFA-1] and β1 integrin, very late antigen-4 [VLA-4], respectively) and chemokine receptors (eg, CCR5, CXCR3) essential for effector T cells to localize to sites of inflammation. At the end of the proliferation/differentiation sequence, most activated antigen-specific effector T cells will exit the SLO (through the efferent lymphatics in the case of T cells responding in the draining LN), enter the circulation, and traffic to the site of infection/inflammation. The homing of activated T cells is controlled by chemokines released by innate immune cells (as well as by epithelial and endothelial cells and fibroblasts) at the site of inflammation/infection (eg, CXCL9 [Mig], CXCL10 [IP-10], CXCL11 [I-TAC] for CXCR3 and CCL3 [macrophage inflammatory protein-1α; MIP-1α], CCL4 [MIP-1β] for CCR5). This homing is also controlled by the inflammation-induced upregulation of integrin ligands (eg, intercellular adhesion molecule-1 [ICAM-1] for LFA-1 and vascular adhesion molecule [VCAM] for VLA-4) and adhesion receptors (P-selectin, E-selectin) on endothelial/epithelial cells at these sites.

The generation of effector T cells in the SLO responding to infection can occur in as few as 5-7 days in both experimental models and human viral infection. Given the rapid replication of most viruses, it is obviously essential to get specific T cells activated and mobilized as soon as possible through the concentration of antigen and the accumulation of the relevant rare antigen-specific T cells in the SLO, followed by rapid proliferative expansion/differentiation of these cells into effectors in the SLO. The rapid induction of an adaptive immune response to virus infection is not a foregone conclusion, however. The process of T- and B-cell activation can be delayed for weeks to months in the case of

infection with viruses such as HIV and HCV, which induce chronic infection.[77,131] In these instances, the virus has the capacity to suppress/delay the induction of the adaptive immune response.

The process of naive B-cell activation in the SLO is similar to naive T-cell activation. In the case of B-cell responses to viruses and other T-cell–dependent antigens, however, antigen-specific $CD4^+$ T cells play a critical role in driving B-cell activation/differentiation. The B cells that display a BCR antigen receptor (ie, the cell surface membrane-bound form of the Ig molecule that recognizes antigen) for an antigen present in the LN would encounter this antigen immediately after migrating out of the HEV in the paracortical (T-cell–rich area) of the LN. In the case of viral antigen, the relative contribution of free virus, soluble viral proteins, and viral proteins transported by migrant DC/macrophages from the infection site to the reservoir of antigen present in the SLO and available to specific B cells is not certain. Binding of antigen to the BCR (ie, cross-linking cell surface Ig) provides the initial stimulus (signal 1) for specific B-cell activation. Signal 1 delivery halts the constitutive migration of the B cell from the paracortical T-cell zone to the LN follicle and activates the chemokine-dependent migration of the B cells to the junction between the T-cell zone and the follicle. The strength of signal 1 can be greatly enhanced if the BCR coreceptor complex is ligated simultaneously with the BCR by interaction with complement components bound to antigen or antigen-antibody complexes. Cross-linking of the Ig receptor also induces internalization of the antigen-Ig complex into an endosomal compartment where the antigen is fragmented and associates with MHC class II molecules constitutively expressed by B cells. The antigen/MHC class II complexes are then cycled to the B-cell surface where they are available for recognition by antigen-specific $CD4^+$ T cells. Another consequence of signal 1 delivery (by antigen to B cells) is CD40 upregulation. The $CD4^+$ T cells, which interact with antigen-stimulated B cells, are themselves activated by prior encounter with antigen/MHC class II complexes on APC (ie, mature, antigen-bearing DC), and have upregulated CD154 (CD40L) expression. The activated antigen-specific $CD4^+$ T cells recognize the antigen/MHC complexes on the antigen-stimulated B cells and deliver signal 2 to the B cells in two forms: interaction of CD40L (on T cells) with CD40 (on B cells) and the release of T-cell–derived cytokines (notably, IL-4 and/or IFN-γ) whose synthesis is triggered in the $CD4^+$ T-cell TCR recognition of antigenic peptides displayed by the B cells. The fully activated (signals 1 + 2) B-cell lymphoblasts undergo programmed proliferation after migration to the follicles to produce GC, follicular structures consisting primarily of responding/proliferating B-cell lymphoblasts. The proliferation/differentiation of the GC B-cell lymphoblasts results in the formation of antibody-secreting plasma cells, which migrate from the LN to the sites of infection/inflammation, and more importantly to the bone marrow where the plasma cells serve as a depot of long-lived antibody-secreting cells. B cells that encounter antigen without $CD4^+$ T-cell *help* (ie, receive signal 1 but not signal 2) are capable of producing specific secreted antibodies; however, these antibodies will be of the IgM isotype and of low affinity. The isotype switch of antibody production from IgM to the IgG, IgA, and IgE isotypes, as well as the process of antibody affinity maturation, requires T-cell help (signal 2).

Viral Antigen Recognition by B Cells

Viral antigens are found on virions, on virally infected cells, as soluble molecules produced by virally infected cells, and as breakdown products from virions and infected cells. These antigens can be recognized by soluble circulating antibodies in plasma or tissues and by membrane-bound antibodies on the surface of B cells (ie, BCR).[2,51,74,134,147,152,157,179] If an individual has had previous exposure, particularly recently, to viral antigen(s) through infection or vaccination, then specific soluble high-affinity antibodies will likely be present in the plasma. A minority of these antibodies will be reactive with viral antigens presented on virions and virally infected cells and able to function antivirally. Most will be directed to a range of other viral antigens; they will be functionally inert but may be useful in the diagnosis of viral infection. In the case of prior infection or vaccination, memory B cells expressing specific antibody will be activated on contact with viral antigen, leading to a number of possible outcomes. One is the stimulation of these cells to enter GCs to undergo further rounds of affinity maturation as below. Another outcome is to differentiate to short-lived plasmablasts that will secrete soluble, specific high-affinity antibody and raise specific serum antibody levels, albeit on a limited time-scale. A third outcome is that the memory B cells, or subsequent GC B cells, will differentiate to form long-lived plasma cells in the bone marrow that will secrete specific antibody over long time periods, even decades. In the absence of a previous encounter with viral antigen, antibodies on the surface of naive B cells will bind antigen with relatively low affinity, setting in motion antibody affinity maturation and class-switching processes, which are discussed below.

Nature of B-Cell Epitopes

Most that is known about how antibodies recognize antigens at the molecular level has been determined from studies on the interaction of soluble antibodies or antibody fragments with antigen.[49,101,140,185,206] Given that B-cell surface antibody is essentially identical to soluble monomeric antibody, with an extra segment ensuring membrane localization, the conclusions should largely apply equally to cell surface antibody. Antibodies recognize molecular shapes, termed *epitopes*, on the surface of antigens. The antibody-combining site makes multiple contacts with the surface of the antigen to form complementary surfaces. The more complementary these surfaces are to one another—in terms of geometry and chemical character—the more favorable interactions will be formed between the antibody and antigen and the higher will be the affinity of the antibody for antigen. The affinity of the antibody for the antigen is one of the most important factors in determining the efficacy of the antibody *in vivo*.

The antibody-combining site is made up of residues contributed primarily from six highly variable segments or loops referred to as *hypervariable loops* or *complementary determining regions* (CDRs). The combining site can vary greatly in shape and character depending on the length and characteristics of the CDRs. Generally, most or all of the CDRs contribute to antigen binding, but their relative contributions vary. The heavy chain CDRs (particularly the third heavy chain CDR [CDRH3]) tend to contribute disproportionately to antigen binding. The CDRH3 in human antibodies can be very long, with a fingerlike appearance that could be used to bind into cavities on viral surfaces. The combining site of antibodies against smaller molecules such as carbohydrates and organic groups (haptens) are often more obviously grooves or pockets rather than the extended surfaces typically found in antiprotein antibodies.

On the antigen, epitopes come in as many different shapes and sizes as do antibody-combining sites. The area of antigen that contacts antibody, referred to as a *footprint*, is typically between about 400 and 1000 $Å^2$. All antibodies recognize a topographic surface of a protein antigen. Most usually, key residues in the epitope will arise from widely different positions in the linear amino acid sequence of the protein because of the manner in which proteins are folded. The linear sequence typically traverses from one side of the protein to the other a number of times. Such epitopes are described as discontinuous. Occasionally, key residues arise from a linear amino acid sequence. In such cases, the antibody may bind with relatively high affinity to a peptide incorporating the appropriate linear sequence from the antigen. Furthermore, the peptide may inhibit the antigen binding to the antibody. The epitope in such cases is described as *continuous*. An example of a continuous epitope would be a loop on the surface of the protein for which an antibody recognized successive residues in the loop. It should be noted, however, that an antibody

that recognizes a continuous epitope does not bind a random or disordered structure. Rather, it recognizes a defined structure that is found in the complete protein but can readily be adopted by the shorter peptide.

Antigenicity and Immunogenicity

A clear distinction is seen between the ability of an epitope to be recognized by antibody and its ability to stimulate an antibody response when presented to a host antibody system. A number of factors appear to be involved in how well a given epitope elicits an antibody response. One of the most important is the accessibility of the epitope on the protein surface.[118] Loops that protrude from the surface of the folded protein tend to elicit particularly good antibody responses. Sites that do elicit strong antibody responses on viral surface proteins will tend to be those in which mutations occur as the virus comes under selection pressure from the response in the phenomenon of neutralization escape. Figure 10.3 shows the sites on the hemagglutinin (HA) protein from the surface of the avian influenza virus that have mutated to avoid neutralizing antibody responses, with those at the "top" of the molecule distant from the viral membrane and most accessible to antibody. Natural infection and vaccination strategies typically induce antibodies to the top of HA and mostly to variable regions and therefore the antibodies tend to be strain specific. Changes within these immunodominant variable regions allow neutralization escape and dictate repeated annual influenza vaccinations to provide robust protection across large populations. More conserved regions, particularly within the stem of HA, induce weaker immune responses, but if these could be presented in a more immunodominant format, they might induce broadly neutralizing antibodies and thereby provide more universal vaccines to replace current annual vaccines.

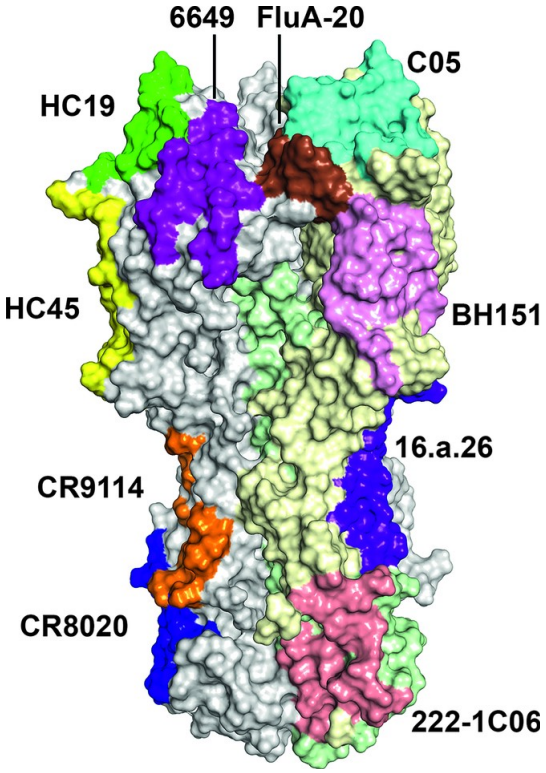

FIGURE 10.3 **Protective epitopes on influenza hemagglutinin (HA)**. The epitopes were determined from crystal and cryo-EM structures of Fab fragments derived from protective antibodies in complex with HA. The viral membrane is at the *bottom* of the figure. Many of the epitopes toward the top of the HA molecule are relatively variable between different influenza virus strains. FluA-20 targets a more conserved trimer interface epitope. The epitopes defined by broadly neutralizing antibodies CR9114, CR8020, and 16.a.26 in the stem of the HA molecule are also conserved especially in the different subtypes representing each of the two influenza A HA groups. These conserved epitopes are promising targets for more universal influenza vaccines. (Courtesy of Xueyong Zhu, Damian Ekiert, and Ian Wilson.)

Another factor that may influence immunogenicity is the precursor frequency of naive B cells bearing BCRs that can recognize features on the viral surface with reasonable affinity to trigger an antibody response.[3] Thus, it seems that the strong neutralizing antibody response elicited in many individuals by SARS-CoV-2 infection with the ancestral strain or vaccination with the S-protein from this strain is dependent, at least in part, on recognition of the ACE2-binding site on the receptor-binding domain (RBD) by naive human BCRs having a particular human heavy chain gene segment.[216] Such BCRs require little affinity maturation (see below) to bind the RBD with high-affinity and neutralize virus.

HIV is another virus in which highly exposed variable loops on the viral surface glycoprotein tend to be immunogenic.[210] Following primary infection, it takes some time (weeks) for neutralizing antibodies to reach a level where they interfere with virus replication.[160,201] These antibodies are often elicited to exposed variable loops on the virus. They are also elicited to regions of the HIV glycoprotein that, in certain isolates, lack glycans, so-called glycan holes in the glycan shield of the HIV envelope.[127] While antibodies are being elicited in early infection, the virus has diversified (ie, it has become a swarm of related viruses through the errors associated with reverse transcription of this RNA retrovirus). Among this swarm is a virus that has sequence changes in the epitopes targeted by the neutralizing antibody response that allows it to escape from the response. Extensive changes in loop length and sequence and "filling in" of glycan holes can occur with little or no reduction in the fitness of the virus so that the new virus becomes predominant. Eventually, a response is mounted to this virus and a second new virus emerges and so on. The antibody response chases the virus over many years but never appears to gain control.

An important consideration in relation to viral surface antigens and immunogenicity can be the spacing of the antigens on the virion surface.[11] It is well established that haptenated polymers, in which the haptens are spaced at 5-10 nm, can induce antibody responses in the absence of T-cell help. For vesicular stomatitis virus (VSV), in which the G protein is found in a highly organized quasicrystalline state on the virion surface, a strong immunodominant T-cell–independent neutralizing antibody response is induced by infection. A poorly organized recombinant form of VSV-G expressed in micelles induces a weaker B-cell response that is partially T-cell dependent. Soluble VSV-G alone, in the absence of adjuvant, fails to induce a B-cell response.

Generation of the Primary B-Cell Repertoire

The humoral immune system first senses the presence of novel viral antigens through the interaction of B-cell surface antibody (IgM and/or IgD) with antigen. Individual B cell express multiple BCRs of identical specificity. When these BCRs are occupied by antigen, the B cells are activated to divide and differentiate. The final results include the production of large amounts of specific, soluble high-affinity antibody and the generation of memory B cells that can be readily triggered to produce high-affinity antibody on repeated encounter with viral antigen.

The first encounter of viral antigen is with the primary B-cell repertoire of the individual. This repertoire is sufficiently large and diverse to recognize, with low or moderate affinity, in principle, essentially any molecular shape and, therefore, any viral variant. It is produced in B cells in the bone marrow by recombination of a limited set of germ-line segments. Hence, an individual's primary repertoire is unique to that individual and is in a constant state of flux. Briefly, the variable regions of antibody heavy and light chains are produced by V(D)J recombination in which numerous unique Ig genes can be made by joining different combinations of the V, D, and J segments at the heavy, and V and J segments at the light, chain loci. In humans, the potential heavy chain repertoire is ~45 V_H × 23 D_H × 6 J_H = 6.5 × 10^3 different combinations. Similarly, ~165 (33 V_λ × 5 J_λ) and 200 (40 Vκ × 5 Jκ) different combinations exist, for a total of 365 light chain (λ and κ) combinations. If we consider that each heavy chain could potentially pair with each light chain, then the diversity of the Ig repertoire is of the order of 10^6 possible combinations. Further diversity (junctional diversity) is generated because the joining of the V gene segments to (D)J is imprecise. In fact, the potential size of the human antibody repertoire is now estimated to be in the range of 10^{16}-10^{18}.[25]

Although mice and humans use combinatorial and junctional diversity as a mechanism to generate a diverse repertoire, in many species, including birds, cattle, swine, sheep, horses, and rabbits, part of the repertoire is generated by expression of a single functional gene with repertoire diversification being achieved by gene conversion, a process in which pseudo-V genes are used as templates to be copied into the assembled variable region exon. For example, in the chicken, during B-cell development in the bursa of Fabricius, rapidly proliferating B cells undergo gene conversion to diversify the antibody repertoire. Stretches of sequences from germ-line variable region pseudogenes, located upstream of the functional V genes, are introduced into the VL and VH regions. This process takes place in the ileal Peyer patches of cattle, swine, and horses, and in the appendix of rabbits.

B-Cell Activation by Viral Antigens

B cells can respond to both soluble and membrane-bound antigens, although it is likely that, *in vivo*, the most relevant interaction is with antigen on the surface of APCs.[13] The encounter of viral antigens with naive B cells expressing specific BCRs has two consequences that result in B-cell activation.[107]

First, a signal is transmitted into the B cell that is amplified via intracellular pathways and results in the activation of transcription factors that act to induce specific gene transcription promoting B-cell proliferation and differentiation. Cell signaling from the BCRs on naive B cells occurs when multivalent antigen clusters cell surface IgM (or IgD) molecules. The BCR is associated with a heterodimer of membrane-bound Igα and Igβ molecules, which bear immunoreceptor tyrosine activation motifs (ITAM) on their cytoplasmic domains. Following BCR clustering, tyrosines in the ITAM become phosphorylated to trigger a series of events that eventually lead to activation of transcription factors. Signaling by the BCR is modulated by coreceptors, most notably FcγRIIB and CD19. FcγRIIB is a potent inhibitor of B-cell signaling, and CD19 is an activating coreceptor. CD19 occurs linked to CD21, a receptor for the complement fragment, C3d. If, following complement activation, C3d has been covalently attached to viral antigen or to antibody-virus complex, the coreceptor complex can be linked to the BCR and BCR activation greatly enhanced.

Second, the BCR delivers viral antigens to intracellular sites where they are proteolytically cleaved, and some viral peptides are bound to MHC class II molecules. The peptide-MHC class II complexes are returned to the B-cell surface where they can be recognized by viral-specific TCR on $CD4^+$ T cells.[44] The specific subset of $CD4^+$ T cells specialized for helping B cells are T follicular helper (Tfh) cells, which can localize with B cells and provide help functions. The peptide-MHC class II complexes on the surface of the B cell stimulate the Tfh cell to produce cytokines and provide surface costimulatory molecules that promote B-cell proliferation and act on later generations of these B cells to promote differentiation to antibody-producing and memory B cells. The specific T helper cells have been primed earlier by DCs that present peptides to the T cells. Some viral antigens can activate B cells directly in the absence of T-cell help (so-called T-independent antigens).

It is important to note that the B-cell surface antibody and the TCR must recognize epitopes from the same molecular complex for the help signal to be delivered and B-cell activation to occur. Thus, a B cell that is expressing surface antibody to the surface protein of a virus could be activated by a T helper cell expressing a TCR to an internal viral protein if antigen challenge involved whole virions. A subunit vaccine consisting only of the envelope protein could not obtain help from such a T helper cell. Of interest, the process of shared T-cell help to B cells specific for a different viral protein may only occur for small viruses as the B cell and antibody responses to infection with vaccinia virus (a large pox virus used as the smallpox vaccine) are striking dependent on matched T-cell help.[171] This likely reflects a limit on the pathogen or particle size that a B cell can endocytose whole.

There are two pathways for B cells that have contacted specific T cells. In the first, after several rounds of proliferation, B cells can differentiate into plasmablasts in extrafollicular foci and secrete relatively large amounts of soluble antibody to the virion coat protein of our example. These antibodies are encoded by the unmutated germ-line repertoire and are likely to be of low to moderate affinity for viral antigen; they may be IgM isotype or class-switched to IgG or IgA.[47] The plasmablasts are short-lived with a lifespan of a few days. This early antibody is believed to be important as a first-line humoral response against viral infection. Some plasmablasts may migrate to the bone marrow and become long-lived plasma cells (see below).

In the second pathway established several days later and involving GCs in lymphoid tissues (see Section 2), the quality and versatility of the antibody to the virion coat protein can be greatly improved by affinity maturation.[3,44,47,59,87,93,105,109,194,196] In GCs[196] (see Section 2), B cells divide very rapidly, with cell cycles as short as 5-6 hours. Tfh cells are required for the formation and maintenance of GCs, they stimulate somatic hypermutation and selection of high-affinity clones, and they provide signals that regulate GC B-cell differentiation into plasma cells and memory B cells. Somatic hypermutation involves the introduction of nontemplated point mutations into V regions of the rapidly proliferating B cells at a rate on the order of 1 per 1000 base pairs per cell generation, which is ~10^6 times higher than the mutation rate of cellular housekeeping genes. The exact mechanisms by which mutations are introduced and preferentially targeted to appropriate V-regions, while constant regions of the Ig loci remain protected, are not clearly understood. Transcription through the target V region seems required, but is not necessarily sufficient, for somatic hypermutation. The enzyme activation-induced cytidine deaminase (AID) has been demonstrated to be essential for somatic hypermutation.[194] AID is a cytidine deaminase capable of carrying out targeted deamination of C to U and shows strong homology with the RNA-editing enzyme APOBEC-1. AID directly deaminates DNA to produce U:G mismatches. Selection from the vast array of B cells expressing slightly different mutated forms of cell surface antibody occurs ultimately on the basis of antigen affinity. B cells with the highest affinity for antigen acquire the most antigen, thereby leading to greater presentation of peptide/MHC class II complexes to T cells, which in turn provide the requisite cytokine signals for B-cell survival and selection. Although many B cells may seed a GC, only the descendants of a limited number of B cells will be present in the mature center.

Isotype switching, in which the constant region of IgM is replaced by that of another isotype leading to the expression of other isotypes, can frequently occur before the GC reaction as well as in GCs.[162] This will lead to the expression of, for example, IgG and IgA antibodies against the virion coat protein in the context of most viral infections. Isotype switching occurs through deletional DNA recombination events and involves repetitive DNA sequences or switch regions. The enzyme AID, described above, is critically involved in the process.

The B cells surviving the GC differentiate into plasma cells or memory B cells. Plasma cells accumulate in the spleen or draining LN during the early stages of acute infection, but as the immune responses subside, the majority of plasma cells are found in the bone marrow. These cells no longer express surface antibody but are committed to the secretion of soluble antibody—up to 10 000 antibody molecules per second. Because the half-life of IgG is of the order of 1-3 weeks, but specific antibody can be present for many years after antigen exposure, it appears that long-lived plasma cells maintain serum antibody levels and continue secreting antibody long after antigen has disappeared (see below). The half-lives of antibody responses in humans to measles and mumps viruses, for example, are estimated at more than 200 years.[8] Memory B cells can also last for many decades.[46,214] Memory B cells maintain surface antibody but secrete little if any antibody, unless activated. They divide slowly if at all. B-cell memory is considered in greater detail below.

Viral Antigen Recognition by T Cells

The T-cell response to viruses is largely mediated by T cells that utilize the TCR-αβ chain heterodimer to recognize a foreign antigen. One defining feature of the response of these cells is that TCRs recognize nonnative peptide fragments of foreign antigens (including viral polypeptides). Thus, in contrast to the immunoglobulin receptor (BCR), which is sensitive to antigen conformation, T-cell recognition of antigen is insensitive to three-dimensional antigen structure. Furthermore, T-cell recognition of antigens (eg, viruses) is primarily limited to the polypeptide constituents of the virus or, more precisely, to viral gene products expressed in infected cells, although some rare exceptions exist to this general rule, which are noted later in this chapter.

A second defining feature of the αβ TCR is that the antigen receptor recognizes these antigenic peptides bound to MHC molecules displayed on the surface of the antigen-containing (eg, virus-infected) cells. Thus, $CD4^+$ and $CD8^+$ T cells are restricted in their recognition of foreign antigen to cells displaying the foreign peptide complexed to the MHC molecule to which that T cell was selected during development in the thymus. This is the phenomenon of MHC restriction that defines antigen recognition by T cells. $CD8^+$ T cells will recognize cells displaying the foreign antigen peptide bound to one of several distinct MHC class I molecules expressed on the cell surface. $CD4^+$ T cells, likewise, are restricted in foreign peptide recognition by the cell surface MHC class II molecule to which the peptide fragment is bound.

The MHC locus is located on chromosome 6 in humans (chromosome 17 in the mouse) and extends over ~4 centimorgans of DNA (~4×10^6 base pairs). Two properties of the MHC locus product make it difficult for pathogens to evade the adaptive immune response. First, the MHC locus is polygenic. It encodes several different MHC class I and II gene products, and these differences in nucleotide/amino acid sequence control the range of peptide fragments that an individual MHC molecule can bind, so that every individual possesses a set of MHC molecules with a different range of peptide-binding specificity. Second, the MHC locus is highly polymorphic. Multiple versions (alleles) exist of each MHC gene product expressed in the population as a whole. In fact, the MHC genes are the most polymorphic genes in the human genome.

The MHC locus contains three major classes of genes: class I, II, and III. The MHC class I and II genes (and their products) were first identified because of their critical role as targets in graft rejection. Hence, the name for the human MHC locus (ie, HLA, for human leukocyte antigen locus), and H-2 or histocompatibility-2 locus for the corresponding genes in the mouse.

The MHC class I molecule is a heterodimer consisting of the MHC encoded 45-kd heavy (H) chain complexed noncovalently with a non-MHC locus–encoded small molecule, β-2 microglobulin (β-2M), which interacts with the H chain α_3 domain. Stable cell surface expression of the MHC class I molecule requires β-2M association as well as the presence of a peptide in the groove. Importantly, MHC class I molecules are expressed at varying levels on all nucleated cells of the body, with neurons being a notable exception. The expression levels of class I molecules on the cell surfaces can be upregulated by exposure of the cell to inflammatory mediators (eg, type I and II IFN). Therefore, the T cells that recognize peptide/MHC class I complexes (ie, the $CD8^+$ T cells) have the capacity to survey most body cells and interact with or destroy cells displaying the appropriate peptide/MHC class I complex. Three classical MHC class I loci (class Ia genes) exist in the human: HLA-A, HLA-B, and HLA-C (H-2K, H-2D, and H-2L in the mouse), and each gene is polymorphic (ie, displays multiple different alleles) within the human population.

Although both MHC class I and II molecules are similar in structure and function (ie, presenting foreign peptides), the difference in the cellular distribution of these molecules points to the role of the T-cell subsets ($CD8^+$ T cell and $CD4^+$ T cells) that recognize these molecules in the function of the adaptive immune system. For example, viruses have the potential to infect most nucleated body cells. Because these cells also express (to a varying degree) MHC class I molecules, they would be susceptible to recognition/destruction by activated effector T cells restricted by class I molecules in antigen recognition (ie, $CD8^+$ T cells). This simple association implies an important role of $CD8^+$ T cells in eliminating virus-infected cells and recovery from infection. By contrast, MHC class II molecules are primarily displayed on specific cells of the immune

system. Therefore, the main role of $CD4^+$ T cells, which recognize these molecules and the bound foreign peptides, is to activate and regulate the effector response of the other immune cells (eg, the recognition by activated $CD4^+$ T cells of peptide/MHC class II complexes on B cells to stimulate antibody production, the recognition of peptide/MHC class II complexes on macrophages harboring pathogens within intracellular vesicles to stimulate macrophage activation and pathogen destruction, and the recognition of peptide/MHC class II complexes on DC to stimulate cytokine production during the induction of adaptive immune responses).

Of course, the ability of $CD8^+$ T cell and $CD4^+$ T cells to interact with cells displaying foreign peptide/MHC complexes also depends on the ability of these foreign antigens to provide peptides to complex with the MHC class I and II molecules. As will be discussed below, the pathways by which foreign antigens gain access to and charge MHC class I and II molecules are distinct and dictate the contribution of $CD8^+$ T cell and $CD4^+$ T cells in the adaptive immune response to invading microorganisms.

Antigen Processing and Presentation to T Cells

The pathways of antigen processing and peptide presentation by MHC class I and II molecules to $CD8^+$ T cell and $CD4^+$ T cells were initially thought of as the *endogenous* and *exogenous* antigen presentation pathways, respectively, suggesting that endogenous proteins feed the class I pathway and peptides form exogenous proteins load MHC class II proteins; this initial notion is no longer helpful or even accurate. Indeed, from the viewpoint of viral immune responses, most naive $CD8^+$ T-cell activation likely involves exogenously derived viral proteins that are internalized by cDC1-type DCs and presented on MHC class I (often called cross-presentation). Similarly, endogenous cytosolic proteins are frequently captured in autophagosomes and reach the MHC class II pathway. The most useful way to segregate these two pathways is to recognize that for the MHC class I, pathway peptides are without exception generated in proteasomes, while for the MHC class II, pathway peptides are always generated in late endosomes/lysosomes. During viral infection, access to the cytosol and hence for proteasomal targeting is most efficiently achieved by infection of the cell by *de novo* synthesis of viral gene products. Infection of cells is the typical way that most virus-infected body cells are sensitized for recognition by activated $CD8^+$ T cells. Certain bacteria (eg, *Listeria monocytogenes*, *Salmonella*) and parasites (eg, malaria) can gain access to the infected cell cytosol, and these cytosolic pathogen-derived protein antigens can then access proteasomes, and the resultant peptides can enter the class I presentation pathway, as can strategies that introduce proteins directly into the cytosol of cells (eg, liposome-cell fusion). Certain cell types (most notably cDC1 type DCs) have the capacity to take up soluble or aggregated antigenic material (ie, apoptotic, infected cell debris) into phagosomes, allow these ingested proteins to leak into the cytosol, be processed in proteasomes, and thus have MHC class I molecules present antigenic peptides to naive $CD8^+$ T cells by a cross-presentation mechanism.

Protein antigens, both soluble and particulate (eg, bacteria, virions), which are internalized into the endocytic compartment of cells expressing MHC class II molecules, have the potential to enter the class II processing/presentation pathway and charge MHC class II molecules for recognition by $CD4^+$ T cells. Any foreign protein (including a viral membrane glycoprotein) expressed on an infected MHC class II–expressing cell can enter the class II pathway, if it can gain access to the endocytic compartment where processing occurs (Table 10.4).

TABLE 10.4 Features of viral antigen processing by the major histocompatibility complex (MHC) class I and class II presentation pathways

	Location	Proteolysis	MHC Loading Peptides
MHC class I pathway	Cytosol[a]	Proteasome[b] neutral pH	Endoplasmic reticulum
MHC class II pathway	Endosome[c]	Acid proteases low pH	Endosome[d]

[a]Viral proteins gain access to the cytosol by (1) *de novo* expression of viral proteins in infected cells; (2) direct virus-cell fusion at plasma membrane or in endosomes; (3) in specialized dendritic cells by phagocytic/endocytic uptake of virus or virus-infected cellular material into endosomes followed by endosome-ER fusion and retrograde transport of viral proteins in the cytosol.

[b]ERAP1 and ERAP2 aminopeptidases in the ER can modify the length of the viral peptide fragment produced by the proteasome after transport of the peptide into the ER by the transporter associated with antigen processing (TAP) transporter complex.

[c]Viral proteins in the form of virions and soluble and membrane-associated viral proteins must gain access to the endosome for fragmentation and binding to MHC class II molecules.

[d]Newly synthesized MHC class II molecules are blocked from loading peptides in the ER by the class II–associated invariant (Ii) complex, which is dissociated from class II molecules in the endosome by step-wise proteolytic cleavage of the Ii chain.

The steps in the processing (fragmentation) of polypeptides into peptides, as well as the transport and interaction of peptides with MHC molecules, not surprisingly, are different in the MHC class I and class II presentation pathways. Examination of these steps merits review because viruses have developed strategies to suppress the T-cell response by subverting the steps along these pathways.

Antigen Presentation by the Major Histocompatibility Complex Class I Pathway

Antigenic peptides bind newly synthesized MHC class I molecules in the ER of the antigen-bearing/infected cells. Therefore, the foreign polypeptide must be fragmented in the cytosol, peptides transported into the ER, and associate with a newly synthesized class I 45-kd heavy chain/β_2M chain complex before transport of the MHC/peptide complex from the ER through the secretory pathway to the cell surface (Fig. 10.4). Antigenic peptide production through fragmentation of cytosolic proteins is primarily carried out by the multisubunit, multicatalytic 20S/26S proteasome complex present in the cytosol. This enzyme complex accounts for most of the cytosolic protein degradation in all cells, and the proteasome is responsible for the generation of all self-peptides that are loaded on MHC class I during thymic selection. Two important

sources of proteasome substrates are newly synthesized self or foreign (eg, *de novo*) expressed gene products, such as viral proteins in an infected cell and preformed foreign microbes/microbial proteins that have gained access to the cell cytoplasm. The proteasome recognizes and degrades proteins ubiquitinated in a certain way, most commonly with at least four ubiquitin moieties attached to lysine 48 of the previous ubiquitin. This protein tagging involves the sequential action of the ubiquitin-activating enzyme (E1), several ubiquitin-conjugating enzymes (E2), and substrate-specific ubiquitin ligases (E3) to form polyubiquitinated proteins that can be captured by proteasomes. A significant fraction of newly synthesized proteins are misfolded and ubiquitinated. Defective ribosomal translation products may therefore be a major source of the protein substrates for MHC class I–binding peptides.

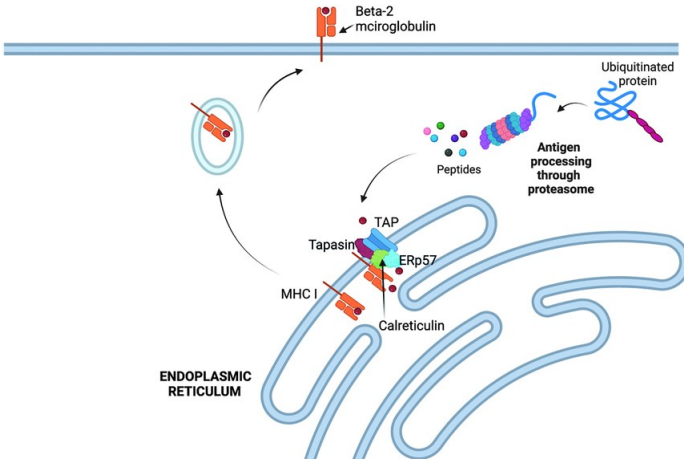

FIGURE 10.4 **The major histocompatibility (MHC) class I antigen presentation pathway**. Cytosolic proteins (or proteins that are delivered to the cytosol from outside the cell) are processively ubiquitinated. At least four tandemly attached ubiquitin units (in which the appropriate lysine residue of the ubiquitin, usually lysine 48, is modified by the next ubiquitin moiety) targets the protein to proteasomes. Peptide fragments are then transferred from the cytosol into the *ER* through the dimeric TAP (TAP-1/TAP-2) transporter complex. In the lumen of the ER, peptides with the appropriate anchor residues associate with the nascent 45-kd MHC class I/12-kd β2M molecules to form a stable complex, selection being assisted by the peptide loading complex that includes tapasin, ERp57, and calreticulin. Longer peptides are trimmed in the ER by the ERAP1 and 2 aminopeptidases, and vesicular transport results in transfer through the secretory pathway to the cell surface.

The proteasome is made up of a cap at either end and a core proteasome containing two identical outer α rings and two identical inner β rings, each ring containing seven proteins. The inner β rings contain three catalytic enzymes β1, β2, and β5 that preferentially cleave polypeptide substrates after hydrophobic and basic residues. This is noteworthy because MHC class I molecules preferentially bind peptides (in an MHC class I allele–dependent manner) with hydrophobic or basic *anchor* residues at their C-termini. Exposure of cells to certain cytokines (particularly, IFN-γ) induces the expression of three new proteasome subunits: iβ1, iβ2, and iβ5 (also called LMP2, MECL-7, and LMP7, respectively). These subunits replace existing subunits in the core proteasome, producing a second proteasome form, the immunoproteasome, that is present in IFN-treated cells. This replacement of the constitutive proteasome subunits with these inducible subunits changes the proteasome cleavage specificity, increasing the cleavage of polypeptides after hydrophobic residues and decreasing the cleavage after acidic residues (ie, peptides with acidic C-termini). Two of the IFN-γ–inducible proteasome subunits, iβ1 and iβ5, are encoded by genes within the MHC locus, suggesting a strong evolutionary selective pressure for the immunoproteasome in MHC function. IFN-γ also increases the production of antigenic peptides by inducing the expression of a multisubunit proteasome adaptor complex PA28 which, on binding to the ends of the core proteasome/immunoproteasome cylinder, increases the peptide efflux rate from the proteasome. Thus, a cytokine product, IFN-γ, produced by an innate immune cell type (NK cells) or adaptive immune effector cells (antigen-specific $CD4^+$ effector T cells) can enhance the display of antigen peptide fragments recognized by effector $CD8^+$ T cells. Another version of the proteasome, called the thymoproteasome, with a unique protease, iβt, is generated by cTECs, and this helps generate unique peptides for positive selection of $CD8^+$ single-positive T cells.

Proteasomes generate peptides 3-20 amino acids in length. Class I–bound peptides, in general, are 8-10 amino acids in length. Therefore, the proteasome peptide products that have the appropriate C-termini for MHC class I binding must also undergo cleavage at their N-termini. This is largely achieved in the lumen of the ER by the ER aminopeptidases ERAP1 and ERAP2. Overall, several studies have suggested that modifications of the proteasome core by inflammatory cytokines can facilitate the production of antigenic peptides (in cells infected with several different viruses), the recognition of which by $CD8^+$ T cells is dependent on these proteasome modifications and possibly the action of other cytosolic proteases.

Peptides generated in the cytosol are transported to the ER by the heterodimeric transporters associated with antigen presentation (TAP)-1/TAP-2 protein complex. This transporter complex is located within the ER membrane, forming a pore/channel there. Both proteins are members of the ABC family of adenosine triphosphate (ATP)-dependent small molecule transporters and are also encoded by genes mapping to the MHC locus. This transporter complex preferentially translocates peptide of 8-16 amino acids in length with hydrophobic or basic C-termini, and the TAP complex exhibits some restriction in transport efficiency of peptides with certain residues at the N-termini.

Newly synthesized MHC class I molecules must bind β-2M and have a stably bound peptide (of self or foreign origin) in their peptide-binding groove to gain the stable conformation necessary for it to exit the ER. This process is facilitated by a group of ER chaperones and enzymes that make up the peptide-loading complex. Within the ER, nascent class I α chain molecules are bound to the ER chaperone, calnexin until the 12-kd β-2M molecule binds, and calnexin is then replaced by the calreticulin scaffolding protein and the tapasin molecule (an MHC locus–encoded protein that forms a bridge between the class I α chain/β-2M complex and the TAP transporter). The binding of calreticulin and tapasin to the nascent MHC class I molecule stabilizes the complex, allowing the partially folded class I/β-2M complex to maintain a conformation (while it awaits a soluble peptide from the cytosol). The partially folded MHC class I molecule will selectively bind (select) only those peptides containing certain motifs; that is, common/conserved amino acid sequences distributed along the length of the peptide fragment. Each allelic form of the class I molecule has specificity for (binds to) a peptide containing an MHC class I allele, a specific peptide-binding motif. The ability of a specific MHC class I allelic variant to capture peptides displaying this conserved amino acid motif is dictated by the presence of polymorphic amino acid

residues in the binding cleft formed by the α_1 and α_2 domains. Another component of the peptide loading complex is the ERp57 thioreductase, which catalyzes disulfide interchange in the class I α chain during peptide loading. The ER luminal aminopeptidases ERAP1 and ERAP2 trims longer peptides. After proper peptide loading and folding, the stable class I/β-2M/peptide complex is freed from the chaperones and migrates from the ER to the cell surface. Note that, in uninfected cells, class I molecules still require a stably bound peptide to exit the ER and traffic to the cell surface. The sources of these *antigenic* peptides are degraded cellular (self) proteins.

The MHC class I presentation pathway is not restricted to proteins synthesized in the cytosol. Numerous examples are found of secreted and membrane proteins/glycoproteins that contain peptides that are recognized by $CD8^+$ T cells and, therefore, bound to MHC class I molecules. One way that these proteins can be degraded is if the polypeptide chains are generated in the cytosol as defective/mistranslated ribosomal products. Another way is retrograde transport of defective (misfolded) translation products that have been translocated out of the ER by the Sec61-dependent transport mechanism as part of constitutive ER-associated degradation or ERAD. Sec61 normally acts in the translocation of the translation products of membrane-bound ribosomes into the ER but can also shuttle intact (presumably defective) proteins in a retrograde fashion into the cytosol from the ER for degradation by the proteasome. The unique ability of professional APC (particularly cDC1 cells) to cross-present cellular constituents/fragments of virally infected cells may reflect the use of such a mechanism.

Antigen Presentation by the Major Histocompatibility Complex Class II Pathway

Antigen processing and presentation along the MHC class II pathway differs from class I presentation in several ways (Table 10.4). First, the class II pathway focuses primarily on antigens (both soluble and particulate) that typically enter cells by endocytosis or phagocytosis and are retained in endocytic compartments for subsequent processing (fragmentation) and loading of the peptide fragments into class II molecules. Cytosolic proteins that are captured by autophagy may also be delivered to endosomes and thus to the MHC class II pathway. The endocytic compartments of relevance to this pathway include early and late endosomes and lysosomes. Second, antigen fragmentation occurs in the low pH environment of the endosome (rather than in the neutral pH of the cytosol where proteasome-dependent MHC class I–binding peptides are generated). Third, both newly synthesized and recycled (from the cell surface) MHC class II molecules can capture and present peptide fragments to $CD4^+$ T cells. Fourth, unlike the strict length constraints (ie, 8-10 amino acids) for peptides bound to MHC class I molecules, peptides bound to class II molecules are at least 13 amino acids long and can be almost twice that length. As with the class I molecules, however, specific class II molecules (alleles) will selectively bind (select) peptides containing particular amino acids motifs (ie, peptides containing common/conserved amino acid distributed along the length of the peptide). As for class I molecules, these peptide-binding motifs are dictated by the presence of polymorphic amino acid residues in the class II-binding cleft (which differ for each class II locus gene product allele). In summary, class II molecules bind peptides produced from soluble/particulate antigen taken up by endocytosis in the same low pH compartment where protein fragmentation occurs. How then is class II processing achieved?

The MHC class II α and β chains, as with other membrane glycoproteins, are synthesized in the ER. After synthesis, the α:β chain heterodimer engages a type II membrane protein, the MHC class II–associated invariant (Ii) chain—invariant because the Ii gene is nonpolymorphic. The invariant chain forms a trimeric complex consisting of three class α:β heterodimers and three Ii subunits with each Ii subunit binding noncovalently to a class α:β heterodimer. This interaction of the class II α:β heterodimer with Ii serves two important functions. First, a region of Ii binds (with low affinity) to the peptide-binding groove/cleft of the nascent class II molecule in the ER and prevents the loading of peptides transported into the ER from binding to class II in this compartment. Thus, class II molecules do not bind the same spectrum of peptides as class I molecules, because they do not bind peptides in the ER. Second, Ii targets the class II molecules to the cell's low pH endosomal compartment (rather than the cell surface via the secretory pathway) where protein antigen fragmentation and peptide loading into the class II peptide–binding groove occurs.

Processing (fragmentation) of protein antigens in the MHC class II pathway is carried out by a variety of acid proteases, and at least one IFN-γ–induced lysosomal thiol reductase (GILT) located in the low pH endosomal compartment. Several related cathepsin cysteine proteases (eg, cathepsins S, L, B, F) and the unrelated cysteine protease, asparaginyl endopeptidase (AEP), have been implicated in antigen processing (fragmentation) in endosomes as inhibition of, or deficiency in, one or more of these proteases can affect the generation of certain antigenic epitopes recognized by $CD4^+$ T cells.

To bind peptides in the endosome, class II molecules must be liberated from Ii. This is achieved by the sequential cleavage of Ii by endosomal proteases (including, AEP, cathepsin S, and cathepsin L), freeing the class II α:β heterodimer from the membrane portion of the Ii, and leaving a short fragment of Ii (called *CLIP* for class II–associated invariant chain peptide), which remains bound to the peptide-binding groove of the class II molecule. CLIP must be removed from the class II molecule to make the class II–binding groove accessible to peptide fragmentation in the endosome, which is achieved through the action of a MHC-like molecule, DM (HLA-DM for human, H-2M for mouse), and which is encoded in the MHC locus and resides in the endosome. DM catalyzes the dissociation of CLIP from the class II α:β heterodimer. And, as with tapasin for class I molecules, DM stabilizes the class II molecule as the class II molecule interacts with, and sorts through, the myriad of antigenic peptides in the endosome, and it selects those peptides displaying the correct motif to allow these peptides to stably bind to the class II. It thus serves as part of the peptide loading complex that edits peptides for presentation by MHC class II molecules. This peptide selection process by class II molecules typically occurs in 2-4 hours (during the time that the class II molecules reside in the endosome). Once a stable peptide/class II complex forms, DM dissociates and the complex transits to the cell surface of MHC class II–expressing cells. *Empty* class II molecules (ie, lacking a peptide in the binding groove) are unstable. Consequently, in the absence of infection or specific exposure to foreign antigen (eg, vaccination), it is self-peptides derived from the endosomal proteolysis of cellular proteins (eg, soluble proteins taken up from the extracellular space by pinocytosis or the residues of phagocytosed apoptotic cells or cytosolic proteins captured by autophagy) that are bound to the MHC class II molecules on the surface of uninfected, class II–expressing cells.

Although *de novo* synthesized MHC class II molecules likely play a major role in capturing/presenting processed antigen to $CD4^+$ T cells, class II molecules can cycle back into the endosomes from the cell surface, and these *recycled* class II molecules may also capture/present antigenic peptide. Class II molecules containing self-peptides (or less frequently, class II molecules that escape the endosome and exit to the cell surface with CLIP peptide in their groove) appear able to reenter the endocytic compartment, exchange the bound peptide for a new peptide, and cycle back to the cell surface. By employing this recycling mechanism, MHC class II–expressing cells (in particular, professional APC, as with DC) would increase their chances of capturing and displaying foreign antigenic peptides to $CD4^+$ T cells.

Induction of T-Cell Responses to Antigen

The triggering of the T-cell proliferation program results in the rapid clonal expansion of antigen-specific T cells with about a 1000 times increase in specific T-cell numbers after 10-20 programmed divisions of individual specific precursors. This proliferative expansion of naive T cells is believed to occur primarily in the SLO. After antigen encounter, the proliferation/differentiation of T cells is rapid (ie, within 5-7 days) for most viral infections, leading to the generation of both effector T cells (and activated T cells that interact with [*help*] B-cell activation in the SLO) as well as memory T cells directed to the antigen (pathogen).

A major advance in the analysis of T-cell responses came with the development/application of MHC multimer technology, mainly involving MHC-peptide tetramers as probes for specific TCRs on flow cytometry. The development of this technology was based on two considerations. First, the realization that the formation of a stable MHC class I or II molecule required for the binding of peptide (with the appropriate MHC allele–specific binding motif) and, in the case of class I molecules, stable interaction with β-2M, allowed investigators to engineer soluble forms of the MHC class I molecules and express the molecules in a convenient expression system (eg, bacteria). The purified MHC molecule could then be refolded *in vitro* in the presence of a specific peptide corresponding to a known (or suspected) T-cell epitope to form a stable complex recognizable by the TCR on T cells directed to antigenic peptide/MHC complexes. Second, the antigen receptor on T cells (ie, the heterodimeric αβ TCR) does not undergo the affinity maturation exhibited by BCR and antibodies and, therefore, has a low intrinsic affinity for a single peptide/MHC complex (ie, estimated to average ~10^{-6} M), and the TCR presumably efficiently binds peptide/MHC complexes when the complexes are arrayed in a multivalent fashion on the cell surface. By forming multimers of refolded complexes of soluble MHC molecules and specific peptides, it was shown that stable interaction between peptide/MHC multimers and the TCR on the surface of the specific T cells could be achieved. By labeling the multimers with fluorescent tags, it was then possible to identify and quantitate antigen-specific T cells isolated from blood or tissue using flow cytometric methods. Another flow-based technique called *intracellular cytokine staining* (ICCS) relies on the ability of specific peptide—when complexed to the appropriate MHC allele to trigger the synthesis of cytokines *in vitro* by activated effector T cells whose TCR recognizes the peptide/MHC complex. By blocking cytokine release from the peptide-stimulated T cells (eg, with monensin/brefeldin A), the subset of T cells directed to the antigen can be enumerated by intracellular staining of accumulated cytokines with fluorochrome-tagged, anticytokine antibody. This technique has been extensively used to analyze the cytokine profile of T cells responding to acute or chronic viral infection (eg, HIV) in peripheral blood in humans and is routinely used to quantitate T-cell responses in both the SLO and peripheral sites in experimental virus infection models.

Effector Activities of B Cells

The antiviral activities of B cells are largely mediated by antibodies,[7,9,28,40,56,99,121,154,164] although B cells may have modulating effects on innate immunity. Antibodies are distinguished from T-cell effectors in that they have activity against free virus particles as well as against virally infected cells. They are the first line of defense against viral infection. In a very real sense, the adaptive antiviral activities of antibodies and T cells are complementary and should be considered together in attempting to understand immune responses to viruses. Nevertheless, it is revealing to consider the antiviral activities of antibodies at different layers of complexity[28]: *in vitro*, *in vivo* in the absence of other adaptive immune effectors as revealed by passive antibody transfer studies and *in vivo* in the presence of innate immunity and T-cell responses as in natural infection or following some vaccination strategies.

Antiviral Activities of Antibody *In Vitro*

As stated above, antibody can act against both free virus and infected cells. This is presented schematically in Figure 10.5 for an enveloped virus. Probably the most studied antiviral activity of antibody *in vitro* and one important for antibody protection *in vivo* is neutralization of free virus particles. One definition of neutralization is "the loss of infectivity which ensues when antibody molecule(s) bind to a virus particle, and usually occurs without the involvement of any other agency."[53] "Without the involvement of any other agency" (although rarely complement is included) indicates that neutralization is typically measured by simply incubating antibody, virus, and target cell together and demonstrating reduced infection. A second definition is "the reduction in viral infectivity by the binding of antibodies to the surface of viral particles (virions), thereby blocking a step in the viral replication cycle that precedes virally encoded transcription or synthesis."[97] Several mechanisms of neutralization of viruses likely operate. Perhaps one of the simplest mechanisms is based on steric obstruction of virus attachment or virus fusion and virus entry by the antibody molecule.[83,100,143,176,177] The relatively large bulk of the antibody molecule, very roughly similar to that of a typical viral spike for an enveloped virus, is suggested to be critical. Another mechanism of neutralization is inactivation of viral surface spikes for enveloped viruses. Many envelope spikes have relatively low stability—they are in conformations ("prefusion") such that interaction with host cell receptor proteins triggers extensive structural changes to permit the viral entry process.[133] Antibody binding can trigger conformational changes in such unstable spike proteins as shown in a number of instances, particularly for recombinant spike proteins,[133] and this is likely to be associated with neutralization. Aggregation of virions and prevention of viral egress (eg,[92,97,205,219]) from infected cells are other mechanisms described for neutralization, although the latter does not meet the strict definitions of neutralization above. Intracellular neutralization in which antibody intercepts virus in the cytoplasm of the target cell is a more recently described mechanism of viral inactivation that involves TRIM-21 degradation of nonenveloped viruses including adenoviruses, picornaviruses, and rotavirus.[19,62,200]

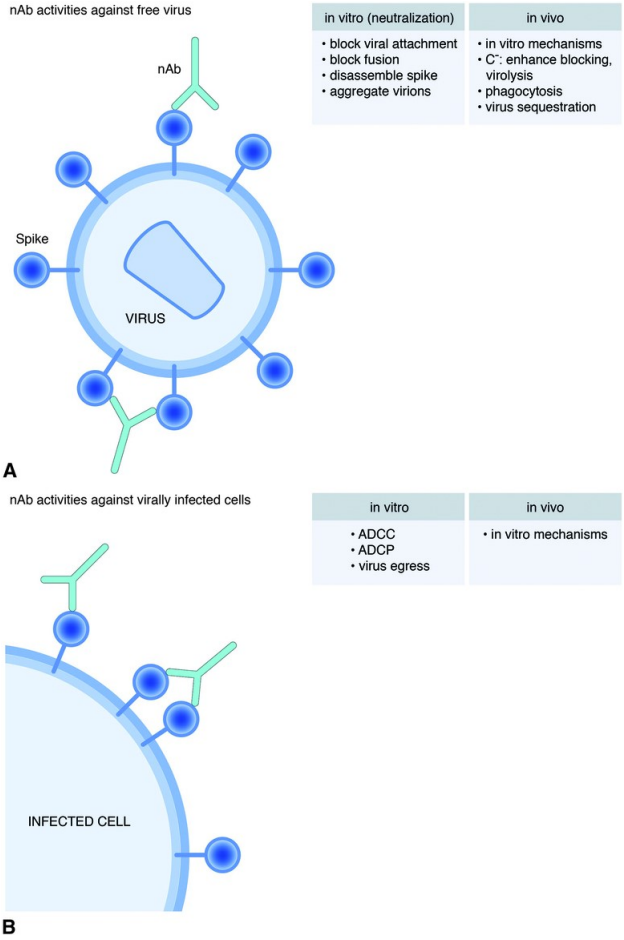

FIGURE 10.5 **Antibody activities against free virus particles and virally infected cells**. **A**. Activities against free virus particles. The primary activity is probably neutralization, whereby antibody molecules bind to virion surface proteins and block infection. Mechanisms of neutralization *in vitro* include blocking viral attachment to target cell receptors, blocking fusion of viral and target cell membranes, induction of conformational changes in virion surface protein that prevents entry, for example protein disassembly, and finally aggregation of virions. Virion-bound antibody molecules may also trigger lysis of virions via complement or phagocytosis of virions that can be assessed *in vitro* with complement or appropriate effector cells, respectively, and can be present *in vivo*. Sequestration by capture of virions on FcR-bearing cells and prevention of encounter with target cells is another possible *in vivo* mechanism of antiviral activity. An enveloped virus expressing only one surface protein is shown. **B**. Activities against virally infected cells. Neutralizing antibodies will bind to the proteins that are also expressed on virions (typically Env proteins). A range of activities can be assessed *in vitro* under appropriate conditions that may operate *in vivo*. Nonneutralizing antibodies will bind to proteins that are expressed on infected cells but not virions (eg, NS1 protein of dengue virus) or that are also expressed on virions but whose blockade may not lead to neutralization (eg, neuraminidase on influenza virions).

Mechanisms that invoke steric obstruction of viral entry by the relatively large size of the antibody molecule predict that the neutralizing efficacy of an antibody should to a first order be related to its affinity for antigen on the virion surface and the precise epitope recognized should be of lesser importance. Indeed, clear evidence exists that antibodies can neutralize viruses without binding directly to functional sites on the virion surface.[5,15,54,133,159,215] A particularly revealing instance of the importance of antibody size on a virion surface is the finding that antibodies to HA can interfere with the activity of neighboring neuraminidase molecules on the surface of influenza virus.[208] Models of neutralization based on steric interference by antibodies with viral entry can be very loosely termed *occupancy* or *coating* models, where the degree of coating of the virus surface by antibody to achieve neutralization differs between models. One model noted a striking linear relationship between the surface area of a set of viruses and the number of antibody molecules bound to virus at neutralization.[98,143] This implied that, for these viruses at least, a coating density corresponding to about half the available antibody sites occupied on the virus produced neutralization. This model is likely to be less applicable to complex viruses expressing multiple surface proteins (eg, the herpes or pox viruses).

One class of neutralizing antibodies that has received much attention in recent years is broadly neutralizing antibodies to highly antigenically variable viruses such as HIV, HCV, and influenza virus.[33,42] By definition, these antibodies recognize more conserved regions of the surfaces of highly variable viruses and have been much sought after as guides for the design of vaccines to the viruses.[28,29,75,104,156] Most recently, the emergence of variants of SARS-CoV-2 and the desire to have antibodies and vaccines to prevent future coronavirus pandemics has prompted searches for broadly neutralizing antibodies to coronaviruses, particularly to sarbecoviruses and more generally to beta-coronaviruses.[31,32,55]

Antibody activity against free virus particles can be augmented by Fc-mediated effector systems in several ways.[22,28,117] First, complement activation by virion-bound antibody and deposition of complement components on the virion surface can enhance neutralization.[180] Occupancy/coating models might argue that this reflects an increased coating of molecules on the virion that hinders productive interaction of virion and target cell. Second, complement activation can lead directly to virolysis by deposition of the terminal components of complement in the viral membrane. Third, Fc and complement receptors can bind antibody or complement-coated virions, leading to phagocytosis followed by inactivation in an intracellular compartment within the phagocyte. This process has been described *in vitro* for the picornavirus foot-and-mouth

disease virus (FMDV) and is believed to be important *in vivo* in protection against FMDV.[128] It is likely that neutralizing antibodies, which coat the viral surface, will be most effective in triggering virolysis or phagocytosis. An antigen present at relatively low density on the surface of a virion could, however in principle, bind antibody without mediating neutralization. Such nonneutralizing antibody could nevertheless trigger virolysis or phagocytosis.

Antibodies can act, not only against free virions but also against infected cells by binding to viral proteins expressed on the surface of virally infected cells (Fig. 10.5). Fc-mediated effector systems can lead to cell lysis or clearance via complement-dependent cytotoxicity (CDC) or antibody-dependent cellular cytotoxicity (ADCC). In the case of CDC, activation of the classic pathway by antibody complexing arrayed viral proteins on the infected cell surface can lead to C3b deposition and uptake by effector cells or the deposition of the terminal complement components in the infected cell membrane resulting in lysis. For ADCC, the antibody array on the infected cell surface is recognized by Fc receptors on effector cells triggering killing of the infected cells. Antibody can also inhibit (1) virus release or egress from infected cells (eg,[65,205]) by simply binding to viral proteins at the infected cell surface and (2) cell-to-cell transmission of virus[26,142,166] by mechanisms that are thought to be very similar to those that lead to virus neutralization. Higher concentrations of neutralizing antibody are generally required to inhibit cell-to-cell transmission than are required to inhibit infection by free virions,[4,84,114,142,158,166,186] although this not always the case.[186] Binding of antibody to the infected cell surface, particularly of neurons, has also been suggested to inhibit viral replication inside cells, presumably via signaling mechanisms.[63,113] It is expected that neutralizing antibodies will be effective against infected cells if they bind to surface molecule presentations on infected cells that are also expressed on virions. Antibodies that bind to molecules expressed on infected cells but not virions, for example, the NS1 proteins of dengue virus[78] or Zika virus,[204] can be effective against infected cells, although they are nonneutralizing.

Polymeric IgA and IgM have been shown capable of endosomal neutralization of virus. These antibodies are actively transported over the mucosal epithelium after binding to the polymeric Ig receptor and may, during transport, contact and neutralize transcytosing viruses.[18,36,64,70,94,124,125]

Finally, antibody can enhance viral infection *in vitro* under certain circumstances, generally in the presence of subneutralizing concentrations of neutralizing antibodies.[23] Enhancement is mediated by Fc receptors in some cases (eg, dengue virus)[71,73] but not in other cases where enhancement is observed with antibody Fab fragments.[183,184] The occupancy model of neutralization described above explains enhancement of infection as an effect that occurs at low occupancy of virion sites in the presence of permissive cells (eg, those bearing Fc receptors). As antibody concentrations increase, coating of the virus increases, eventually resulting in neutralization.

Antiviral Activities of Antibody *In Vivo*

The classic approach to determine the protective activities of antibody *in vivo* is to passively transfer immune sera or monoclonal antibodies to a naive animal, challenge with virus, and observe the outcome. This approach has consistently shown—for many different viruses, animal models, and challenge routes—a good correlation between the protection achieved and antibody serum neutralizing activity measured *in vitro*.[97,143] However, it should be noted that the correlation is not perfect, and there are many cases in the literature where there are varying degrees of breakdown of a linear correlation. For example, several broadly neutralizing antibodies, including some directed to the base of the HIV envelope spike (Membrane Proximal External region or MPER antibodies), appear to "punch above their weight" in that they are more effective *in vivo* than would be anticipated from their *in vitro* neutralization titers.[80,82,148] A similar deviation from a linear relationship between neutralization has been described for influenza antibodies[187] and a combination of SARS-CoV-2 neutralizing antibodies.[165] Antibody effector function triggered unequally by different neutralizing antibodies but yet important for protection may be contributory in these latter observations. It should also be noted that even a perfect correlation between neutralization and protection does not necessarily mean that neutralization is the decisive mechanism of protective activity. Neutralizing antibodies are probably those that bind most effectively to free virions and to virus-infected cells (at least for many enveloped viruses) so that, in principle at least, any of the mechanisms of antiviral activity presented in Figure 10.5 could be operative in protection.

Generally speaking, protection is achieved when neutralizing antibody titers in the serum of the animal at the time of virus challenge are relatively high, usually of the order of 1:100 or higher. In other words, the serum of the animal can be diluted 100-fold and 50%-90% (depending on the study) neutralization achieved *in vitro*.[28,148] This suggests that considerable apparent over-capacity with regard to neutralization is required to achieve protection. In some instances, protection can be described as sterilizing in that no evidence is seen of viral replication following challenge. Serum neutralizing titers (IC80) of 1:380 or greater provide sterilizing immunity in the lungs of cotton rats challenged with respiratory syncytial virus (RSV)[151] and titers of 1:700 (IC50) provide sterilizing immunity against challenge of macaques with chimeric simian-human immunodeficiency virus (SHIV) in an aggregate comparison of studies with different viruses, neutralizing antibodies and challenge routes.[148] In other instances, such as challenge with lymphocytic choriomeningitis virus (LCMV) in a mouse model[209] and with Ebola virus in a guinea pig model,[144] high titers of neutralizing antibody do not provide sterilizing immunity but do prevent disease. In most instances, however, it has not been established whether sterilizing immunity has been achieved.

A number of possible explanations exist for the apparent over-capacity in neutralization activity required for protection in many animal studies. If the assumption is that neutralization is the dominant protective mechanism, then for some viruses/animal models/challenge routes, it may be necessary for protection for antibody to "mop up" essentially every last virus particle requiring an excess of antibody. With the same assumption, the protective activity may be achieved at a tissue site with a lower antibody concentration than that of serum, again leading to an apparent over-capacity. Alternatively, protection may require an additional activity of neutralizing antibody distinct from neutralization. For instance, it may be that activity against infected cells, as well as (or in some cases even instead of) activity against free virions, is needed to provide protection. This would be consistent with observations that antibody concentrations required for, for example, blocking cell-to-cell transmission are typically higher than required for neutralization of free virus particles.

Animal model studies provided early evidence that mechanisms other than neutralization can be important in protection by neutralizing antibodies. In some cases, protection was found to be as effective with $F(ab')_2$ fragments, which lack the Fc domain and, therefore, are unable to trigger effector functions, as the corresponding whole IgG molecule. In other cases, however, $F(ab')_2$ fragments that are equally active as whole IgG molecules at neutralization *in vitro* were ineffective at protection. For yellow fever virus,[168] it was shown that neutralizing mouse IgG1 antibodies (poor activators of effector functions) are ineffective at protection, whereas IgG2a molecules (good activators) of the same specificity was effective. In many of the early examples in mouse models in which the Fc part of IgG is important, protection was independent of

complement.[143] This implied that protection by neutralizing antibodies in these cases most likely required activity against infected cells and involves ADCC or phagocytosis. More recently, antibodies engineered to reduce or eliminate or enhance complement activation and/or Fc receptor (FcR) binding have been used to study the contributions of effector functions to antibody protection and therapy. The overall picture that has emerged has been that the contribution of effector function, particularly FcR-mediated, to protection varies with the antibody-virus combination considered even for antibodies directed to the same viral target protein and that effector function tends to be more significant for therapy than for protection.[22,95,117] For example, FcR binding has been shown to contribute to protection against SHIV in monkeys for one bnAb but not for another more potent bnAb directed to a different site on the HIV Env protein.[72a,79,81,145] Effector function does contribute to clearance of virus in monkeys by nAbs, but the effects are modest and enhanced FcR binding does not enhance clearance and even decreases it.[10,199] In mouse models of HIV infection, FcR binding enhances virus control but only over certain nAb titer ranges.[24] For influenza, nAbs to the stem region are critically dependent on effector function for protective activity, whereas those to the head region are not.[52] For Ebola virus, protective antibodies show varying dependency on FcR interactions.[21] For SARS-CoV-2, nAbs have been described whose protective activity is influenced by effector function activity and those whose activity is independent of such activity.[165,207] Therapy of SARS-CoV-2 infection is more dependent on effector function than prophylaxis.[207]

Many examples of protective activity are exhibited by nonneutralizing antibodies in passive transfer studies in animal models. This activity appears to be directed at infected cells (Fig. 10.5) and generally appears to be somewhat less potent than that of neutralizing antibodies. For instance, a number of cases have been reported where neutralizing antibodies are protective against higher challenge doses or more pathogenic viruses than nonneutralizing antibodies. In many cases, protection by nonneutralizing antibodies is shown to depend critically on the Fc part of the antibody molecule and to occur in complement-deficient mice, suggesting that ADCC or phagocytosis may be crucial in clearing antibody-complexed infected cells. Protection with nonneutralizing antibodies is mostly restricted to those antibodies directed against enveloped viruses.

Passive transfer of polyclonal IgG preparations from immunized animals or convalescent humans has been shown to be effective in prophylaxis for several viruses, including hepatitis A virus, HBV, HCV, HSV, measles virus, rabies virus, RSV, smallpox virus, and varicella-zoster virus (VZV). Currently, three purified hyperimmune globulin preparations from human donors are in clinical use to prevent against serious disease due to HBV, human cytomegalovirus (HCMV), and VZV. A polyclonal antibody preparation against rabies virus, in combination with vaccination, is used as a postexposure prophylactic after virus exposure. The first monoclonal antibody, a humanized, neutralizing anti-RSV monoclonal antibody has now been in clinical use for more than two decades to protect at-risk infants.[68] However, increasingly a new generation of highly potent broadly strain cross-reactive nAbs ("super-antibodies") are being considered for clinical use.[197] These nAbs are typically generated by deeply mining the responses of convalescent individuals with potent neutralizing sera using single B cell isolation approaches. During the COVID-19 pandemic, many potent nAbs were isolated from convalescent donors and shown to have prophylactic effect in animal models and then in humans.[69] A large-scale clinical trial of an anti-HIV nAb showed complete protection against exposure to sensitive viruses with serum neutralizing titers of the order of 100s × *in vitro* neutralizing titer, concordant with the discussion above.[41] In the case of HIV, given the known properties of the virus, it is likely that the nAb, where protective, provided sterilizing immunity, that is, there was no significant replication of virus. In many cases involving passive nAbs, it is unlikely that the titers of transferred antibody achieve the levels necessary to offer sterilizing immunity, although this has not been widely studied. Rather, it would seem that neutralizing antibody sufficiently blunts the infection to allow the development of other protective mechanisms, presumably a $CD8^+$ T-cell response, active antibody responses, and innate immunity (see below). The protection of young infants by maternal neutralizing antibodies likely falls into this category. Maternal antibodies may "attenuate infection during the initial months of life, thereby creating optimal conditions for the natural immunization of the child as a result of infection."[220]

In the case of nAbs and established viral infection, the dogma has tended to be that they are relatively ineffective, particularly the later in the infection the antibodies are administered. For example, the RSV nAbs palivizumab and motavizumab are clinically effective prophylactically but not therapeutically.[86,155] SARS-CoV-2 nAbs have been shown to be effective prophylactically and when administered shortly after the onset of infection but not later in infection.[69] However, the dogma of lack of nAb efficacy in ongoing more mature infection is being increasingly challenged by the availability of highly potent cross-neutralizing Abs.[197] Thus, bnAbs are being investigated for a role in HIV therapy and cure,[12,38,136] and anti-Ebola nAbs are highly effective in monkeys in preventing death after symptom onset and appear also effective in symptomatic human infection.[43,90,146,153]

Many important human viral pathogens gain entry to the host via mucosal surfaces. Passive transfer studies show that antibodies present in the mucosal compartments at the time of exposure can protect against viral challenge.[50,94,137] Both mucosal secretory IgA (sIgA) and systemic IgG have been shown to be effective. Dramatically, nonneutralizing IgA can protect against rotavirus challenge in mice by an intracellular neutralization mechanism.[27]

Effector Activities of T Cells

The categorization of αβ TCR T cells into $CD8^+$ and $CD4^+$ subsets not only demarcates the MHC molecules that restrict recognition (ie, class I or class II) but also has functional significance at the effector level (Table 10.5). $CD8^+$ T-cell effector cells ($CD8^+$ T_E) are capable of destroying antigen-displaying cells (eg, virus-infected cells expressing the appropriate peptide/MHC class I complex) by direct cell-to-cell contact. $CD8^+$ T_E also produce/secrete several cytokines with antiviral activity (eg, IFN-γ, TNF-α) on TCR engagement. $CD4^+$ T-cell effectors ($CD4^+$ T_E) primarily function by release of cytokines (notably, IFN-γ, IL-17 and IL-22, and IL-4, IL-5, and IL-13) in response to antigenic stimulation. $CD4^+$ T_E, however in some instances, can also acquire killing capacity, that involves the same genes used by $CD8^+$ T cells, and they can kill by direct contact with cells displaying the appropriate peptide/MHC class II ligand recognized by the TCR complex. The differentiation of the naive T cells into T_E, in particular naive $CD4^+$ T-cell differentiation into T_H1, T_H2, T_H17, or T_{FH} cells, is regulated by a variety of factors (as discussed below).

TABLE 10.5 Effector activation of activated $CD8^+$ and $CD4^+$ T cells

Effector Type	Target Cell	Effector Mechanism
$CD8^+$ T cell	MHC class I^+	• Direct cytolysis (cell-cell contact) • Granule exocytosis (perforin/granzyme) • FasL (T cell)—Fas (infected target cell) interaction Cytokine synthesis • IFN-γ, TNF
$CD4^+$ T cell—T_H1	MHC class II^+	Cytokine synthesis • IFN-γ, TNF
$CD4^+$ T cell—T_H2	MHC class II^+	Cytokine synthesis • IL-4, IL-5, IL-13
$CD4^+$ T cell—T_H17	MHC class II	Cytokine synthesis • IL-17A, IL-17F, IL-22

MHC, major histocompatibility complex; IFN, interferon; TNF, tumor necrosis factor.

$CD8^+$ Effector Mechanisms

The $CD8^+$ effector T cells or CTLs destroy *target* cells (eg, virus-infected cells) by direct cell-to-cell contact, by two distinct mechanisms. One mechanism is by granule exocytosis.[79] Mature (fully differentiated) $CD8^+$ CTLs contain lytic granules within their cytoplasm, and TCR engagement on the CTL by peptide/MHC class I complexes on the target cell results in the formation of the immunologic synapse. In response to TCR engagement/synapse formation, these cytoplasmic granules are directed by the cellular microtubule-organizing center along actin filaments to the synapse formation site where the granule contents are released into the synaptic cleft. The adhesive interaction between the CTL and the target cell is stabilized/strengthened through the interaction of LFA-1 (on CTLs) with its ligand, ICAM-1 (on the target cell). The lytic granules contain a protein, perforin, which has a sequence homology to the complement component C9. The granules also contain a set of serine proteases, known as *granzymes* (for granule enzymes), which are present in a proenzyme form within the CTL granule and which are activated (by granule-associated cathepsin C) on granule exocytosis. Because of its homology to C9, some of the perforin monomer released onto the target cell can intercalate and polymerize (in the presence of extracellular Ca^{++}) forming a pore within the target cell plasma membrane allowing the granzymes access to the target cell cytosol. However, most of the perforin and granzymes initially stay bound together with serglycin and granulysin (the latter exists in humans but not in rodents) and are endocytosed by target cells at the immunological synapse formed between the $CD8^+$ CTLs and their targets. It is in acidified endosomes that most perforin activation occurs, endosomes are disrupted, and released granzymes are transferred into the cytosol. The granzyme family of serine proteases consists of at least 10 members in humans (including granzyme A, B, C, and K). They function by activating cell death pathways in target cells, including both direct activation of caspases and indirect activation of the mitochondrial pathway of caspase activation and apoptosis. The best studied granzyme, granzyme B, is present in both $CD8^+$ CTLs and NK cell lytic granules and acts by proteolytic cleavage and activation of procaspases (procaspase 3 → caspase 3) and proapoptotic Bcl2 family members (eg, BID → tBID) resulting in the DNA fragmentation and mitochondrial damage characteristic of apoptosis. An additional granule-associated lytic molecule, granulysin, can form pores, primarily in bacterial membranes, and may play a role in the destruction of certain bacteria by direct lysis.

CTLs can also destroy target cells by the upregulation (in response to TCR engagement) of the TNF family protein, CD154 (FasL, CD95L) on the CTL, and engagement of its receptor, the TNF receptor family member, CD95 (Fas), on the infected target cell. CD95 engagement results in the recruitment/activation of caspases and apoptotic death of target cells. Studies in experimental models of virus infection suggest that both the Fas/FasL and the granule exocytosis mechanisms can contribute to the elimination of virus-infected cells, and virus clearance by $CD8^+$ T_E.[192] The relative contribution of each lytic mechanism to virus clearance differs for different viruses.

The $CD8^+$ T_E also produce a number of cytokines in response to TCR engagement by antigen, most notably IFN-γ and TNF-α. The production/secretion of these effector cytokines appears to be tightly regulated and requires TCR-dependent signaling in the $CD8^+$ T_E. IFN-γ exhibits its antiviral effects through upregulation of MHC molecule expression and stimulation of the MHC class I processing/presentation pathway in infected cells. Because IFN-γ is a potent activator of tissue macrophages, activated macrophages would also have the capacity to take up and destroy virus/virus-infected cells. TNF-α, as can the other member of the TNF ligand family, CD154 (FasL), induce apoptosis of infected cells expressing the receptor for TFN-α and also can signal the production of proinflammatory/antiviral cytokines through receptor-dependent NF-κB activation.

$CD4^+$ T_E Effector Mechanisms

An essential role of $CD4^+$ T_E in antiviral immunity is to provide *help* for responding B cells in the SLO in the production of antiviral antibody. $CD4^+$ T cells also play a role, not yet completely defined, in the development and maintenance of the memory $CD8^+$ T-cells response during virus infection.[173,203] $CD4^+$ T_E express effector activity through the release of cytokines on TCR engagement (ie, recognition of specific peptide/MHC class II complexes on target cells).

Specific cytokines produced mainly by DCs at the time of T-cell activation can induce the differentiation of $CD4^+$ T cells into specialized subsets,

each of which produces a different constellation of effector cytokines. Interleukin-12 (IL-12) is primarily a product of activated DC and macrophages and exists as a heterodimer consisting of the p40 and p35 subunits. IL-12 interacts with its receptor on naive and activated $CD4^+$ T cells as well as $CD8^+$ T cells, signaling through signal transducer and activators of transcription 4 (STAT-4) to activate a number of genes. The outcome of this signaling process is to promote the differentiation of $CD8^+$ T cells into activated cytolytic effector cells and to drive the differentiation of $CD4^+$ T cells along a pathway leading to effector $CD4^+$ T cells capable of secreting IFN-γ on TCR engagement (ie, the generation of T_H1, T *helper* 1 effector T cells). The overall effect of IL-12 on T cells is to generate activated effector T cells that are efficient at viral clearance.

Interleukin-2 is a cytokine produced by both $CD4^+$ T cells and, to a lesser extent, $CD8^+$ T cells, during the initial phase of T-cell activation/differentiation. Engagement of the high-affinity IL-2 receptor (expressed only after T-cell activation) by IL-2 drives T-cell proliferative expansion. Although IL-2 was initially believed to be the primary T-cell growth factor (acting in an autocrine fashion to stimulate T-cell proliferation), T-cell activation/proliferative expansion occurs normally in the absence of IL-2 (eg, in IL-2–deficient patients or experimental animals with a targeted disruption of the IL-2 gene). Therefore, it appears that, in the absence of IL-2, other cytokines (eg, IL-15) can support the normal T-cell expansion in response to antigenic stimulation. As with many cytokines, IL-15 can be produced by a variety of cell types, both constitutively and in response to inflammation. IL-2 is of central relevance in the maintenance and function of regulatory T cells. A genetic deficiency in IL-2 results not in a defective T-cell response to antigen but in exaggerated T-cell proliferation (lymphoproliferative disease) and the development of autoimmune responses caused by a major functional defect in regulatory T cells.

A number of effector cytokines, including IFN-γ, IL-17A, and IL-22, are important in the context of containing viral infections. IFN-γ is produced primarily by activated $CD4^+$ T cell and $CD8^+$ T cells in response to TCR engagement and by NK cells after engagement of stimulatory NK cell receptors. The role of IFN-γ in augmenting antigen presentation (ie, upregulation of MHC class I and II expression, immunoproteasome subunit induction) has been discussed above. IFN-γ also plays a critical role in activating mononuclear phagocytes (macrophages) to destroy infected intracellular bacteria, and it presumably plays a similar role in the destruction of virus and, possibly, virus-infected cells when armed effector T cells respond to viral antigen at peripheral sites of virus infection. The early production of IFN-γ during the initiation of T-cell responses to antigen can drive T-cell differentiation to a type 1 (T_H1) pathway (characteristic of antiviral T-cell responses). The IFN-γ gene is rendered transcriptionally active by exposure of responding primary T cells to IL-12 resulting in IFN-γ production by activated effector T cells on subsequent TCR engagement by antigens and the induction of the T-bet transcription factor. IFN-γ ligates its receptor and induces the activation of STAT-1.

A combination of TGF-β, IL-6, and IL-23 contributes to the differentiation and maintenance of T_H17 cells, and these cells, which secrete large amounts of IL-17A and IL-22, are frequently induced during viral infections in parallel with the induction of T_H1 cells. IL-17A enhances the recruitment of neutrophils at sites of infection and IL-22 enhances barrier function at epithelial surfaces. T_H17 cells are therefore most functionally relevant in the context of clearing extracellular bacterial and fungal pathogens. Immune responses seen in viral infections are typically known as type I immune responses because they involve the activation of T_H1 and, activated $CD8^+$ T cells, NK cells and other type I innate lymphoid cells (ILC1s; which secrete IFN-γ). Type 3 innate lymphoid cells (ILC3s, that secrete IL-17A and IL-22) and T_H17 $CD4^+$ T cells may also frequently be activated.

While type I immune responses are important in the control of viral infections, type II responses are generally not of relevance in this context. The key $CD4^+$ T-cell subset that contributes to type II immunity is the T_H2 subset that secretes IL-4, IL-5, and IL-13. The induction of T_H2 $CD4^+$ T cells appears to play a pivotal role in the adaptive immune response to helminth (worm) and certain other parasitic infestations. T_H2 $CD4^+$ T_E are also now recognized to orchestrate allergic responses to non-pathogen–derived environmental antigens (eg, pollen, dander, dust mites) with development of IgE antibodies and eosinophil infiltration in response to these innocuous antigens. Exposure of responding $CD4^+$ T cells to IL-4 early in the activation/differentiation sequence is essential for the generation of T_H2 effector T cells in the SLO. The early low-level production of IL-4 by activated T cells before their commitment to T_H1, T_H2, or T_H17 differentiation may be sufficient to render the IL-4/5/13 gene locus capable of high-level IL-4, IL-5, and IL-13 production by $CD4^+$ T_H2 effectors following TCR engagement. The source of the IL-4 driving T_H2 cell differentiation is, however, still unclear. However, IL-4 produced by activated T cells, especially cells destined to become T follicular helper cells, serves both as a B-cell growth–promoting factor and also contributes to Ig class–switching during B-cell activation/differentiation (for certain isotypes). Engagement of the IL-4 receptor activates STAT-6 to mediate the effect of IL-4 on responding B and T cells. As will be discussed, IL-4 and IFN-γ act antagonistically to regulate T-cell differentiation and T-cell effector generation into T_H1 or T_H2 effectors.

Whereas virus infection, in general, drives $CD4^+$ T-cell differentiation toward the development of T_H1 and T_H17 $CD4^+$ T_E responses, apart from inducing T_{FH} cells, evidence indicates that, in certain chronic human infections, T_H2 $CD4^+$ T_E responses may predominate.[35,178] Because the induction of the T_H2 $CD4^+$ T_E response with IL-4 (and IL-10) production can suppress the development of a T_H1 $CD4^+$ T_E response characteristic of the adaptive immune response to virus infection, this form of virus-induced immune deviation could potentially result in the inhibition of virus clearance, leading to the development of persistent infection. However, states of induced dysfunction of $CD8^+$ T cells including $CD8^+$ T-cell exhaustion, discussed below, are likely far more relevant in the context of severe and chronic infections.

The Phenomenon of $CD8^+$ T-Cell Exhaustion/Dysfunction

Most viral infections of epithelial organs are cleared by virus-specific $CD8^+$ CTLs that induce the apoptotic death of infected cells. Clearly both severe acute as well as chronic viral infections have the potential to induce organ loss. It is in these contexts (as well as in the context of some antitumor $CD8^+$ T-cell responses) that $CD8^+$ T cells instead of becoming potent effectors are epigenetically altered and assume a terminally differentiated and dysfunctional state, anthropomorphically described as “exhaustion.” “Exhausted” $CD8^+$ T cells retain some function; they still kill infected target cells but less efficiently. So, dysfunctional “exhausted” T cells appear to have evolved to subserve two functions (1) to maintain an attenuated level of target cell killing that helps keep a viral infection partly in check but in so doing (2) to prevent organ loss. However, this phenomenon, with attendant immune dysfunction, does result in chronic infection, viral persistence, immunopathology, and the failure to eliminate certain antigenic tumors.

Exhausted $CD8^+$ T cells are induced by chronic antigen stimulation and likely the milieu of severe inflammation as well, though that is less well defined. While PD-1–mediated inhibitory signaling is required in exhausted T cells, PD-1 itself is expressed on most activated $CD4^+$ and $CD8^+$ T cells and cannot on its own define the exhausted state. The process of exhaustion is a continuum. Exhausted/dysfunctional $CD8^+$ T cells exist broadly in two forms within the continuum. These include initially generated self-renewing "stemlike" progenitor PD-1^{Hi} TCF-1^+ cells that have some features of central memory cells and express high levels of the PD-1 inhibitory receptor. These cells are still plastic and "rescuable," but they give rise to terminally differentiated exhausted/dysfunctional $CD8^+$ T cells that have been molded by epigenetic remodeling into an irreversibly dysfunctional state and can no longer be rescued. These terminally exhausted T cells express both the PD-1 and TIM-3 inhibitory receptors, are no longer dependent on the TCF-1 transcription factor, and instead express TOX-1.

The PD-1 inhibitory receptor contains cytosolic tyrosine-based ITSM (immunoreceptor tyrosine–based switch) and ITIM (immunoreceptor tyrosine–based inhibitory) motifs. Ligation of PD-1 by its ligands, PD-L1 or PD-L2 (typically expressed on DCs but also induced on some tumors) induces the tyrosine phosphorylation of the ITSM and the recruitment of SHP-2, which can dampen T-cell activation. PD-1 is clinically considered as an "immune checkpoint" molecule. PD-1 blockade by therapeutic antibodies has become a major, often "curative," therapy in some antigenic cancers. Though checkpoint blockade can reverse chronic infection in animal models, the risk of adverse effects, even possible organ loss, has so far tempered its clinical use in chronic viral infections.

Regulatory T-Cell Function in Antiviral Adaptive Immune Responses

Homeostasis in the immune system depends on a balance between the responses to control viral infection and the reciprocal responses to prevent excessive immune responses. Regulatory T cells (T_{reg}) have been reported to play a crucial role in suppressing immune responses to self-antigen and in preventing autoimmune diseases. T_{reg} also control immune responses to pathogens, including viruses. T_{regs} are categorized as naturally occurring, thymus-derived T_{reg}, or induced, peripheral T_{reg}, which are particularly abundant in the gut and the placenta.

There is some knowledge regarding the suppressive function of T_{reg} cells. Suppressive activity by T regs and other inhibitory $CD4^+$ T cells is broadly mediated by secretion of immunosuppressive cytokines (ie, IL-10, transforming growth factor β [TGF-β]) or by CTLA-4–mediated capture and degradation of B7 on DCs following cell-cell contact. IL-10 inhibits immune responses in many ways including the suppression of TNF and IL-12 production by DC and macrophages; TGF-β also inhibits immune responses in numerous ways including attenuation of the induction of the transcription factor, T-bet that is relevant in T_H1 $CD4^+$ T cells, activated $CD8^+$ T cells, and NK cells for IFN-γ production especially in the context of viral and other intracellular infections. In addition, TGF-β produced by T_{reg} cells induces IL-10 production by T_H1 cells through SMAD-induced activation of the IL-10 promoter. Given the effect of IL-10 and T_{reg} cells on the inhibition of the expression of MHC class II and costimulatory molecules by DC, it is likely that cytokine-mediated suppression might occur at the level of APC. CTLA-4 present at high levels on $CD4^+$ $CD25^+$ T_{reg} cells also functions at the APC level; it has been shown to impair the provision of signal 2 for T-cell activation in SLOs, since CTLA4 can capture and remove B7 from DCs by a process called transendocytosis.

T_{regs} and other inhibitory cytokine producing T cells have been implicated in the suppression of cellular immune responses directed against pathogens, including chronic viral infections. IL-10–producing T_{reg} cells have been shown in several chronic infections (eg, HSV, EBV, HCV). EBV infection is associated with the induction of T_{reg} cells specific for latent membrane protein 1 (LMP1) during the lytic cycle. In case of HCV infection, HCV-specific CTL traffic to the liver produces IL-10 and reduces liver inflammation. In addition, the frequency of $CD4^+$ $CD25^+$ T_{reg} cells is greater in chronically infected patients than in recovered or healthy patients,[17,34,139,182] suggesting that T_{reg} cells play a role in HCV persistence. Apparently, suppression mediated by $CD4^+$ $CD25^+$ T cells isolated from patients chronically infected with HCV is not cytokine-mediated, because neutralizing antibodies to either IL-10 or TGF-β do not reverse suppression.[17] The presence of $CD4^+$ $CD25^+$ T_{reg} and their suppression of effector T cells from patients with HCV indicate that these T_{reg} cells play a role in HCV persistence. It was also found that the frequency of $CD4^+$ $CD25^{hi}$ T cells in patients with hepatocellular carcinoma is greater than in individuals chronically infected with HCV.[139] Importantly, the reduced number of $CD4^+$ $CD25^+$ T_{reg} in patients infected with HCV is associated with the development of autoimmune disease such as cryoglobulinemia characterized by B-cell proliferation and autoantibody production. This provides compelling evidence that T_{reg} cells play a dual role in viral infection: (1) prevention of viral clearance and (2) the regulation of autoimmunity.

Even though T_{reg} cells might be involved in suppression of host immune responses to viral infection, immune responses to viral infection can nevertheless result in host tissue damage in many virus-mediated diseases. Thus, immunoregulatory mechanisms (including the induction of T_{reg} cells) are paradoxically essential to control virus-induced immunopathology. Direct evidence of a role for T_{reg} cells in preventing immunopathology has come from studies using mouse models of viral infection. Theiler's murine encephalomyelitis virus (TMEV) infection induces $CD4^+$ T-cell–mediated demyelinating disease.[76] TMEV-specific $CD4^+$ T-cell blasts transferred into susceptible, irradiated C/cByJ mice accelerate clinical disease and enhance TMEV-specific, delayed-type hypersensitivity (DTH) and proliferation in these animals. Significantly, $CD8^+$ T cells from infected C/cByJ mice suppress the *in vivo* disease progression as well as virus-specific, T-cell responsiveness in recipients of TMEV-specific $CD4^+$ T-cell blasts. The transfer of virus-specific $CD8^+$ T_{reg} cells at the time of Theiler's virus infection has been shown to reduce inflammation by preventing the pathogenic role of $CD4^+$ T cells. In case of HSV infection, depletion of $CD4^+$ $CD25^+$ T cells before viral infection increases the generation of virus-specific $CD8^+$ T-cell responses and viral clearance.[188,189] In contrast, the severity of T-cell–mediated lesions in the cornea of HSV-infected mice were increased on removal of $CD4^+$ $CD25^+$ T cells. Thus, $CD4^+$ $CD25^+$ T_{reg} cells are likely involved in reducing the severity of immune-mediated inflammatory lesions by preventing the pathogenic effects of $CD4^+$ T_H1 cells, as well as limiting the migration of these cells to inflammatory sites. During chronic viral infections, T_{reg} cells might be beneficial to the host by maintaining a balance between efficient effectors and memory responses, but with a low level of inflammation to limit host tissue damage. Understanding how T_{reg} induction occurs during infection could be helpful for designing therapeutic intervention against chronic infection.

Adaptive Immune Memory

Two features define the adaptive immune system and distinguish it from the innate immune system are (1) exquisite specificity for antigen and (2) the establishment of immunologic memory. Immunologic memory is perhaps the most important consequence of the induction of an

adaptive immune response. As a result of clonal expansion of antigen-specific B or T lymphocytes, and a lower activation threshold for memory cells, the cellular immune system can respond more rapidly/efficiently to previously encountered pathogens. The capacity of B and T cells to adapt to a previously encountered antigen, together with circulating antibodies, is the basis for vaccination. Memory B and T cells generated after infection or vaccination are generally long-lived. In humans, memory T-cell responses (or circulating antibody titer) can be detected decades after pathogen exposure, under conditions where subsequent reexposure to (subclinical infection with) the organism or persistent infection is unlikely. Memory B and T cells directed to an antigen are usually present at a frequency 100-1000 times higher than the corresponding naive immune cell precursors of memory T and B cells. The factors controlling the formation/duration of the memory immune responses are not yet well understood, but several cytokines may play an important role in maintaining the viability and basal (homeostatic) proliferation of memory cells.

B-Cell Memory

The phrase "B-cell memory" is often equated with long-term humoral immunity.[6,9,37,102,107,202] Two principal mechanisms exist: (1) specific memory B cells expressing BCR to viral antigens, so that viral infection leads to rapid activation of specific B cells and ultimately the production of high-affinity, class-switched antibody to virus and (2) preexisting serum and tissue high-affinity, class-switched antibody to virus from long-lived plasma cells in the bone marrow.

Memory B Cells

Memory B cells[6,37,60,102,103,169] express class-switched, somatically mutated surface antibody and can be detected as antigen-specific cells using labeled antigen and a technique such as flow cytometry. They are in a resting state and do not secrete antibodies unless stimulated by antigen. When this stimulation is carried out *in vitro*, the memory B cells can be readily detected by enzyme-linked immunospot (ELISPOT) assays. In mice, multiple subtypes of memory B cells have been defined by a number of cell surface markers and gene activation markers. After clearance of virus on first exposure, memory B cells accumulate in the spleen and other lymphoid tissues and circulate in the blood. Reexposure to virus leads to rapid secondary antibody responses to viral antigens. This response arises because of rapid proliferation and differentiation of memory B cells in a $CD4^+$ T-cell–dependent manner. The specific B-cell population expands massively and differentiation to plasmablasts generates a burst in specific antibody production and in antibody levels. Thus, repeated exposure to antigen is one way in which memory B-cell levels can be maintained.

Although controversies have existed over the years, it appears that memory B cells can be long-lived even in the absence of antigen. An elegant experiment by Maruyama et al.[123] is persuasive. Mice were engineered so the memory B cells expressing a BCR against antigen-1 could be switched *in vivo* to express a BCR specific for antigen-2. B cells expressing BCR to antigen-2 were identified as persisting in the mice as well as B cells expressing BCR to antigen-1, although the mice had never encountered antigen-2. It should also be noted that BCR expression is required for B-cell survival[106] so the possibility exists that nonspecific BCR stimulation, perhaps via a low-affinity antigen interaction, is needed for persistence of B-cell memory. Alternatively, the BCR may receive a signal from another molecule such as a cytokine or a molecule such as a B-cell–activating factor (BAFF).

One interesting phenomenon related to memory B cells is that of *original antigenic sin* (OAS),[135,195,212] or, closely related, "imprinting".[126,163] OAS was first proposed to describe a phenomenon whereby an individual, originally infected with a virus and then later with variant of this virus, makes an antibody response during the second viral infection that reacts more strongly to the original virus than the newer variant.[48] Boosting of memory B cells against the first virus dominates activation of naive B cells to the second virus, resulting in a condition whereby specific antibody responses to the second virus will not be as great compared with a naive host that has never encountered the first virus. OAS has been reported in both humans and animals and against a range of viruses including dengue virus, influenza virus, Japanese encephalitis virus, West Nile virus, Zika virus, and enterovirus. OAS presents a challenge to the design of vaccines for viruses that exist as diverse variants in the population, most notably for influenza.[58,126]

Long-Lived Plasma Cells

Plasma cells are terminally differentiated, nondividing cells able to secrete relatively large amounts of antibody.[1,39,47,88,89,115,161,190,191] At one time, the dogma was that plasma cells were short-lived, although some reports had described longer-lived plasma cells. It now appears clear, however, that two populations of plasma cells exist. Short-lived plasma cells (plasmablasts) survive for only a few days, produce antibody in extrafollicular foci, and are probably crucial in the very early response to pathogen. In mice, it has been shown clearly that the second population of plasma cells, secreting high-affinity antibody, is long-lived. Irradiation experiments have shown that the half-life of plasma cells secreting antibody to LCMV was 94 days in the bone marrow and 172 days in the spleen.[175] Pulse chase experiments showed that plasma cells secreting specific antibody to ovalbumin survived without cell division for a minimum of 3 months.[120] These half-lives constitute a sizable proportion of the total lifespan of the mouse. Plasma cells likely live for many years in humans and thereby contribute to the maintenance of antibody levels over decades.[66] The bone marrow niche appears to provide survival signals to plasma cells, because *in vitro* such cells survive for only a few days. It has been questioned whether plasma cells could survive for decades in humans and one possibility is that plasma cells are being periodically replenished from specific memory B cells by bystander activation and differentiation.

Long-term Humoral Immunity

Humoral responses can be measured in the sera of humans many years after the last known contact with the pathogen (Table 10.6). Similarly, many vaccines induce serum antibody responses that are present decades later.[150] A key question has been: are these responses maintained by intrinsic mechanisms or is there a periodic boosting of immunity through contact with antigen? This question can be very difficult to answer given the unknowns associated with typical human contacts with pathogens. Studies,[45] however, suggest, for at least two vaccines, that serum antibody levels are maintained in the absence of antigen boosting.

TABLE 10.6 Humoral response to acute viral infection in humans

Example	Virus Family	Persistence of Antibody
Systemic infections		
Chikungunya	*Alphaviridae*	30 y
Rift Valley fever virus	*Bunyaviridae*	12 y
Dengue	*Flaviviridae*	32 y
Yellow fever	*Flaviviridae*	75 y
Measles	*Paramyxoviridae*	65 y
Mumps	*Paramyxoviridae*	12 y
Polio	*Picornaviridae*	40 y
Hepatitis A	*Picornaviridae*	25 y
Smallpox	*Poxviridae*	40 y
Vaccinia	*Poxviridae*	75 y
Rubella	*Togaviridae*	14 y
Mucosal infections		
Coronavirus	*Coronaviridae*	12 mo
Influenza virus	*Orthomyxoviridae*	30 mo
RSV	*Paramyxoviridae*	3 mo
Rotavirus	*Reoviridae*	12 mo

Modified from Slifka MK, Ahmed R. Long-term humoral immunity against viruses: revisiting the issue of plasma cell longevity. *Trends Microbiol*. 1996;4(10):394-400. Copyright © 1996 Elsevier, with permission. Ref.[174]

A large cross-sectional study of poliovirus immunity in Sweden, a country from which the virus has been eradicated and which only used inactivated poliovirus as a vaccine, showed substantial antipoliovirus antibody titers in all age groups.[20] Virtually no differences in titers were found in the different age groups, indicating the maintenance of antibody titers over decades in the absence of further vaccination or exposure to live virus. Notably, in the same study, declining antibody titers against tetanus and diphtheria were observed.

Two studies have looked at smallpox vaccination using vaccinia virus.[46,72] Vaccinia is an excellent model for investigating immune memory because the virus is typically cleared from the site of infection within a month, does not persist, and does not spread systemically in healthy individuals. Furthermore, smallpox was declared eradicated in 1980, and vaccinia immunization was discontinued in the United States in 1972. Nevertheless, specific memory B cells could be detected in U.S. individuals more than 50 years after their last vaccination.[45,46] Further, memory B cells seemed to show a bimodal kinetics. A drop from peak responses occurred at vaccination to an ~10-year time point, but stable levels were seen between 10 and 60 years. Serum antibody responses could be identified at 60-75 years after vaccination.[46,57,72] Because overall antivaccinia antibody levels correlated well with neutralizing antivaccinia antibody levels, it was postulated that different specificities may be equally well preserved. Further, the results suggest, as originally posited by Jenner more than 200 years ago, that protective immunity against lethal smallpox infection may be lifelong.[173]

Finally, it is apparent from Table 10.6, that mucosal antibody responses are much shorter-lived than serum responses. This may indicate that plasma cells initially produced at mucosal sites migrate to the bone marrow and contribute less to mucosal antibody production.

T-Cell Memory

Unlike the Ig receptors on B cells, the genes encoding the TCR on $CD4^+$ T cell and $CD8^+$ T cells do not undergo any additional somatic mutations and memory T cells do not, therefore, exhibit affinity maturation after antigen encounter. Memory T cells distinguished functionally from their naive precursors by being present at increased frequency (a result of clonal expansion of naive antigen-specific T cells) and by their lower activation threshold (ie, decreased requirement for CD28 costimulation) to trigger cell proliferation/differentiation. Certain memory T cells can also rapidly express effector activity (eg, proinflammatory/antiviral cytokines, such as IFN-γ and TNF-α) within hours after TCR engagement on these T cells and without DNA synthesis (additional cell proliferation).

Naive T-cell activation/proliferation and memory T-cell population formation/maintenance are controlled by three cytokines: IL-2, IL-7, and IL-15. The receptors on T cells for these three cytokines (and for a few others including IL-4, IL-9, and IL-21) have a common feature—these heterodimeric and trimeric receptors have a common signaling subunit, the so-called *common γ chain* (γ_c), which participates in both ligand (cytokine) binding and Janus kinase (JAK)/STAT-dependent signal transduction. IL-2 and IL-15 can drive proliferation of activated naive T cells after TCR engagement and IL-4, which engages another member of the γ_c family of cytokine receptors, will also support proliferation of differentiating T_H2 $CD4^+$ T cells. Current evidence suggests that, once memory T cells are formed, they can undergo basal/homeostatic low-level proliferation, which is IL-15–dependent, and long-term memory T-cell viability (ie, suppression of apoptosis) is supported by IL-7, which

upregulates/sustains the expression of antiapoptotic Bcl-2 gene family members in developing memory T cells.

Although activated naive T cells give rise to both effector (T_E) and memory (T_M) T cells, the relationship of the two T-cell subtypes is unclear and it is still debated whether T_E give rise to T_M in a linear progression or if T_E and T_M are separate cellular subsets. T_M can be distinguished from naive T cells and, to a lesser extent, from T_E by the expression of certain cell surface molecules (eg, isoforms of CD45) differentially expressed on T_M and naive T cells. Several lines of recent evidence indicate that a further subdivision may exist of $CD4^+$ T-cell and $CD8^+$ T-cell T_M into central memory (T_{CM}), peripheral/effector memory (T_{EM}), and tissue-resident (T_{RM}) memory populations. T_{CM} express cell surface molecules such as CD62L and the chemokine receptor CCR7, which facilitate the trafficking of T_{CM} from the blood into the SLO (particularly the LN). So, T_{CM} mimic the recirculation pattern of naive T cells (blood 2799 → SLO → blood) and respond to antigen delivered to the SLO; and, as occurs with naive T cells, T_{CM} may therefore require both activation and proliferation to express effector activity. By contrast, T_{EM} do not display the homing receptors for the SLO and have been suggested to reside primarily in the blood and peripheral tissues where they can rapidly respond to a pathogen at the initial site of pathogen entry in the periphery. Unlike T_{CM}, T_{EM} appear to undergo limited proliferation in response to antigen but rapidly express antimicrobial effector activity in response to infection. T_{CM} and T_{EM} are maintained by a stemlike memory population that expresses the TCF-1 transcription factor. Some memory cells enter peripheral tissues and reside there, undergoing self-renewal at these sites. These cells constitutively express CD103 and CD69 and are important for clearing viruses in some peripheral organs. Although these classifications of memory T cells based on cell surface markers are useful, evidence from the analysis of the immune response to virus infection in humans suggests that considerable heterogeneity exists in cell surface marker expression on circulating T cells in the peripheral blood. Thus, under conditions of natural infection (and possible vaccination), the memory T-cell response may consist of a continuum of activation/differentiation states—at least, based on activation/differentiation marker expression.

Viral Strategies to Evade the Adaptive Immune Response

Immune responses to viruses involve complex molecular and cellular interaction between the virus and its host. Thus, any stage in this interaction could be targeted by a pathogen and used for its own benefit. The systematic study of viral genomes reveals that most viruses have evolved some means of escaping or subverting immune defenses and that some viruses have many genes devoted to this purpose. Whereas the large, more complex DNA viruses encode viral proteins to avoid immune recognition, RNA viruses usually encode smaller numbers of proteins compared with DNA viruses with large genome materials. Regardless of virus type (DNA or RNA), it seems that many, and possibly all, pathogens that cause chronic infections have evolved strategies to subvert the immune responses of the host (Table 10.7). These strategies include evasion of humoral and cellular immunity by antigenic variation, interference with antigen processing and presentation, and modulating the production of cytokines. Understanding the complex interactions between the immune system of the host and the invading viral pathogen will eventually enable researchers to devise better strategies for preventing viral diseases.

TABLE 10.7 Viral strategies to avoid host adaptive immunity

Escape by mutations
Escape by latency
Escape by destruction of immune cells
Escape by subverting antigen processing and presentation
Inhibition of T-cell–mediated target cell lysis
Interference of cytokine function

Viral Evasion of Humoral (B-Cell) Immunity

Viruses use a number of mechanisms to evade humoral immune responses and viral neutralizing antibodies in particular (reviewed in Refs.[30,110,133,172]). Viral strategies to evade neutralizing antibody responses to the viral surface proteins include (1) mutation of surface proteins by antigenic drift and shift, and recombination, most notably for highly antigenically variable viruses such as influenza virus, HIV, and HCV; (2) masking of conserved epitopes; (3) glycan shielding as seen for HIV and Ebola viruses, for example; (4) surface protein decoys that may “mop up” neutralizing antibodies under certain conditions, for example, as with HBV; (5) original antigenic sin or imprinting; (6) irregular surface protein spacing that tends to reduce immunogenicity; and (7) multiple surface proteins and virus forms, for example, poxviruses encode multiple proteins for entry. Viruses can also evade humoral responses by spreading directly between cells, upregulating and hijacking host complement regulatory proteins, encoding antagonistic Fc and complement receptors, and inducing immunosuppression.

Viral Evasion of Cellular (T-Cell) Immunity

Viruses have multiple strategies to subvert T-cell responses. Two well-characterized subversion mechanisms (ie, inhibition of antigen processing/presentation and interference with cytokine function) are highlighted below.

Escape by Subverting Antigen Processing and Presentation

A number of viruses have devised strategies to impair presentation of their antigens by the MHC class I pathway, thus reducing activation of antigen-specific $CD8^+$ T cells as well as recognition of virus-infected cells by $CD8^+$ T cells. This stresses the importance of this cell subset for antiviral defense. Nearly every step of the MHC class I presentation pathway can be interfered with, and some viruses encode multiple proteins that act at different levels of the MHC class I–processing pathway (Table 10.8): (1) inhibition of MHC class I synthesis, (2) antigenic peptide generation, (3) transporter associated with antigen processing, and (4) the cell surface expression of MHC class I molecule expression. Although interference of the MHC class II antigen–processing pathway by virus is less common, however, some evidence indicates that viruses are able to inhibit this pathway.

TABLE 10.8 Inhibition of antigen presentation via the major histocompatibility complex (MHC) class I pathway

Steps to Interfere With MHC Class I Pathway	Virus-Encoded Proteins
Inhibit MHC class I synthesis	Lentivirus (Vpu), SARS-CoV-2 ORF-6
Inhibit transporter associated with antigen processing (TAP)	
• Expression	EBV (vIL-10), HCMV (UL111A)
• Function	HCMV (US6), HSV (ICP47)
Inhibit MHC class I transport	
• Retain MHC class I in the endoplasmic reticulum (ER)	HCMV (US3), adenovirus (E3-19K)
• Retain MHC class I in the pre-Golgi compartment	MCMV (m152)
• Dislocate MHC class I to the cytoplasm	HCMV (US11, US2)
• Dislocate MHC class I to lysosomes	MCMV (m6/gp48), SARS-CoV-2 ORF-8
• Bind to cell surface MHC class I molecules	MCMV (gp34)
• Increase endocytosis of MHC class I molecules	HIV (nef), HHV-8 (K3, K4)

EBV, Epstein-Barr virus; HCMV, human cytomegalovirus; HSV, herpes simplex virus; MCMV, murine cytomegalovirus; HIV, human immunodeficiency virus; HHV, human herpesvirus.

Inhibition of Class I or II Major Histocompatibility Complex Synthesis

Viral proteins, including HIV Tat protein, have been reported to suppress/inhibit MHC gene promoter activity.[85] It has been shown for HIV Tat protein suppression that the activity of the MHC class I gene promoter was decreased up to 12 times. The SARS-CoV-2 ORF6 protein interferes with type II interferon–meditated STAT1 activity, thus limiting the induction of NLRC5 an MHC class I gene transactivator.[213] ORF6 also separately interferes with the nuclear import of NLRC5.[213] In respect to the inhibition of MHC class II expression, HCMV can impair MHC class II expression through two distinct pathways. MHC class II molecules are expressed only on a subset of cells, and this expression is regulated at the transcriptional level through control elements that include those that allow both constitutive and cytokine-induced transcription of the MHC class II genes. The MHC class II transactivator (CIITA) is essential for constitutive and induced transcription and is the rate-limiting factor of MHC class II production. One of the four promoters controlling CIITA production is activated by IFN-γ, which, on binding to its receptors, triggers through a Janus kinases signaling cascade, leading to transcription of IFN-inducible genes. The inhibition of IFN-γ–stimulated MHC class II expression occurs by two different mechanisms: (1) inhibition of JAK/STAT signaling[132] and (2) repression at the CIITA promoter.[111]

Inhibition of Antigenic Peptide Generation

The metalloproteases, CD10 (endopeptidase) and CD13 (aminopeptidase N), are downregulated during HCMV infection.[149] CD10 expression is apparently blocked at the transcriptional or translational level, whereas CD13 seems to be retained within the ER compartment. These endopeptidases play a role in peptide processing in both MHC class I and II antigen presentation pathways. Both CD10 and CD13 peptidases are expressed on the cell surface and trim antigenic peptides to a size that allows their binding to the groove of class I or II molecules.

Inhibition of Peptide Transport

Many of the strategies used by viruses to inhibit the transport of antigenic peptides are reviewed elsewhere.[116] The peptide transporter TAP is needed to shuttle peptides from the cytoplasm to the ER, in which they associate with MHC class I determinants. TAP peptide transport is inhibited by a protein of HCMV, US6, which acts from the luminal site of the ER. HCMV US6 protein specifically binds at the ER-luminal loops of TAP signals across the membrane to the nucleotide-binding domains. This binding prevents ATP hydrolysis of TAP, which is necessary for peptide transport.

The ICP47 polypeptide from HSV inhibits TAP by binding to TAP's peptide-binding site, thus preventing its association with other peptides. This results in an insufficient number of peptides in the ER for binding to MHC class I molecules. In contrast, TAP-independent peptide loading of MHC class I molecules is not affected by US6 or ICP47. As described below, EBV encodes a protein that weakly binds the IL-10 receptor. As with cellular IL-10, the EBV protein reduces expression of TAP and of MHC class II.

Nontranscriptional Inhibition of Major Histocompatibility Complex Class I Cell Surface Expression

Modulation of MHC class I expression has been reported in a number of viral systems including adenoviruses, HCMV, HSV, HIV, and SARS-CoV-2. HCMV US3 protein, a type I membrane protein, prevents maturation of MHC class I molecules by retaining them in the ER compartment. US3 protein binds to MHC class I molecules in a transient fashion but retains them efficiently in the ER. The US3 luminal domain is responsible for ER retention of US3 itself, whereas both the US3 luminal and transmembrane domains are necessary for retaining MHC class I in the ER. In contrast to HCMV US3 protein, HCMV US2 and US11 catalyze the dislocation of MHC class I products, resulting in their rapid degradation. US11 protein uses its transmembrane domain to recruit MHC class I products to human homologue of yeast Der1p, a protein essential for the degradation of MHC class I molecules catalyzed by US11, but not by US2. HCMV US2 has been shown to differentially affect surface expression of MHC class I but only targets membrane-bound (not soluble) HLA-G1 antigen for degradation.

Adenovirus expresses a protein E3/19K, which is an ER-retained protein; it has a cytosolic ER retention signal in the C-terminus of its cytoplasmic tail (–DEKKMP). The 19K binds certain murine MHC class I molecules (eg, A2, K^d, L^d, but not K^k, or D^d) and holds them in the ER. This results in decreased MHC class I expression and decreased CTL recognition. An immediate early gene product of HSV, the ICP47 gene product, interferes with transport of peptides from the cytoplasm to the ER, thereby depriving MHC class I molecules in the ER of peptides. This results in both the ER peptides and destabilization and retention of MHC class I molecules in the ER. The SARS-CoV-2 ORF8 protein reduces host MHC class I expression protein expression by targeting MHC class I protein for autophagy and lysosomal degradation.[218]

Interference of Cytokine Functions

Cytokines (eg, IFN and TNF) induce intracellular pathways that activate an antiviral stage or apoptosis and thereby limit viral replication. A large number of cytokines induce mechanisms that enhance immune recognition and/or immune responses to protect against viral infection. In addition, antiviral cytokines play a pivotal role in removal of infected cells by NK cells or CTL. Thus, it is not surprising that viruses use immune evasion strategies to control the function of cytokines.

Recently, viral modulation of cytokines by several viruses has been reported. Not included here are descriptions of the ability of viruses like SARS-CoV-2 and Ebola among many others to compromise the production of type I interferons—those issues are considered in Chapter 8. Three different mechanisms have been shown to affect the activity of cytokines more relevant to adaptive immunity (Table 10.9). Viruses produce cytokine homologues, which bind to the same cytokine receptors. Alternatively, viruses generate antigens that mimic cytokine receptors and, thus, neutralize the corresponding factors. Finally, they can directly interfere with the action of cytokines by generating soluble cytokine-binding proteins. The function of viral homologues of cytokine and their receptors are diverse. The virus-encoded cytokine homologs might be involved in inactivating inflammatory cytokines or redirecting the immune responses.

TABLE 10.9 Viral modulation of the cytokine system

Interrupt cytokine production
• Interfere with cytokine and chemokine synthesis
• Inhibit the generation of functional cytokines
Interfere with cytokine action
• Encode homologs of cytokines and cytokine receptors
– Type I interferon (IFN) homolog: VV (B18R)
– IFN-γ homolog: VV (B8R)
– Interleukin (IL)-6: KSHV (K2)
– IL-8 homolog: HCMV (UL146, 147)
– IL-10 homolog: EBV (BCRF1), HCMV (UL111A)
• Generate soluble cytokine receptors to neutralize cytokines
– IFN-γ receptor: myxoma virus (MT-7)
– IL-1βR: VV WR (B15R)
– TNFR homolog: orthopoxvirus (crmB, crmD)
Interfere with cytokine effector function
• Alter cytokine signaling pathway

HCMV, human cytomegalovirus; EBV, Epstein-Barr virus; TNFR, tumor necrosis factor receptor.

Inhibition of cytokine production has been shown by poxvirus; cowpox virus (CPV) cytokine response modifier (CrmA) protein inhibits the production of caspase-1, which prevents the proteolytic cleavage of prointerleukin—1β (pro–IL-1β) to mature IL-1β. In addition, the attachment of measles virus to its cellular receptor, CD46, a complement-regulatory protein, inhibits the production of IL-12. Many virus-encoded mechanisms are involved in blocking the effector functions of cytokines, such as the antiviral state induced by IFN or apoptosis triggered by TNF, and intracellular antagonists of TNF or IL-1/Toll-like receptor signaling. Interestingly, LMP1 of EBV recruits components of tumor necrosis factor receptor (TNFR) and CD40 signal transduction machinery, which induces biological responses to help viral replication.

Receptor Binding and Modulation of Immune Cell Function

Measles virus binds to, and enters, monocyte/macrophages using CD46 molecule (a C3b receptor) as its receptor for entering cells; cross-linking CD46 inhibits the production of IL-12 by macrophages. Therefore, measles-induced immune suppression may be related to the failure of infected APC to make the proinflammatory cytokine IL-12. Another IL-12 homolog, UL111A, is encoded by HCMV.

Cytokine and Cytokine Receptor Homologs

Alterations in cytokine function represent a newly appreciated mechanism of evasion. One of the most striking examples of this mechanism has been reported in the EBV. EBV has apparently cannibalized the gene for the human IL-10 cytokine. The viral genome, gene BCRF1, encodes a protein with 70% amino acid homology to human IL-10. IL-10 inhibits cytokine production by T_H1 type T cells and monocytes (macrophages) through its action on macrophage function. IL-10 also activates B lymphocytes and upregulates BCL-2. The viral IL-10 has all of the same activities as human IL-10.

The understanding the role of viral immunomodulatory proteins in the context of infection is limited, mainly because of the lack of appropriate experimental models of infection. In many cases, we can only predict the *in vivo* function of a viral protein in view of a known function of cytokines. As expected, inactivation of poxvirus-soluble cytokine receptors (eg, the myxoma virus vTNFR and vIFN-γR, or the vaccinia virus vIFN-α/βBP) leads to virus attenuation. The attenuated phenotype of the myxoma virus vIFN-γR (M-T7) mutant might also be attributed to the ability of M-T7 virus to bind chemokines, which is consistent with increased leukocyte recruitment to sites of infection. The consequences of the inactivation of a viral immunomodulatory protein on the outcome of infection, however, might be unpredictable. Deletion of vaccinia vIL-1βR exacerbates vaccinia virus infection in a mouse intranasal model because of enhanced systemic activity of the proinflammatory cytokine IL-1β, which might cause increased fever and weight loss, leading to enhanced mortality of the infected host. This indicates that some viral immunomodulatory proteins might downregulate immune-mediated pathology to favor equilibrium with the host, rather than to increase viral replication.

Virus-Induced Immune Dysregulation and Autoimmune Disease

Many chronic diseases can occur when the immune system is active, often causing the affected tissues to be inflamed and abnormally infiltrated by lymphocytes and other leukocytes. No active infection is associated with these diseases, however. Thus, these diseases are caused by the immune system itself, which attacks cells and tissues of the body. Chronic diseases of this kind are known as *autoimmune disease* because they are caused by immune responses directed toward self-components of the body. Several genetic risk factors and protective elements have been shown to influence the susceptibility of autoimmune disease. A considerable discordance in incidence of autoimmune disease comparing identical twins indicates, however, that in many cases, additional factors such as environment modulators could influence the incidence of autoimmune diseases.

Indeed, viral infections, particularly chronic viruses, are shown to enhance autoimmune disease in susceptible individuals, because infections frequently induce strong inflammatory responses in various organs.[138,141] Several major pathways exist through which viruses can initiate or more likely modulate autoimmunity. First, direct infection of target cells/organs can cause the release of sequestered autoantigens and enhance antigen presentation. Second, local inflammation might alter the repertoire of self-epitopes presented by APC by altering the antigen degradation properties of the proteasome. Third, presentation of pathogen epitopes with structural or sequential similarity to self-epitopes might specifically activate autoreactive lymphocytes. Some viral infections, however, can also act to ameliorate autoimmunity. Several reports support the association of autoimmune diseases with viral infection.[16,61,108,129,181,217] Indeed, associations with infectious agents have been suggested for a multitude of autoimmune diseases, including type 1 diabetes (TID), multiple sclerosis (MS), and ankylosing spondylitis. Attempt to establish a direct epidemiologic, statistically relevant association between microbial infections and various autoimmune disorders, has been unsuccessful so far.

Hepatitis C virus has been reported to be involved in the cause of autoimmune disorders, including myasthenia gravis, autoimmune hepatitis, cryoglobulinemic vasculitis, and rheumatoid diseases. It has been also speculated that serious liver injury occurs in chronic HCV infection, and autoimmune mechanisms may contribute to hepatic destruction.[112] Anti-liver–kidney microsome type 1 (LKM-1) autoantibodies directed against the cytochrome P450 2D6 (CYP2D6) are considered specific markers of type 2 autoimmune hepatitis.[119,211] Interestingly, LKM-1 autoantibodies are also found in 5% of sera from patients chronically infected by HCV. Molecular mimicry between HCV proteins and CYP2D6 has been proposed to explain the emergence of these antibodies. Indeed, recent studies revealed cross-reactivity caused by molecular mimicry at the B-cell level between CYP2D6 and HCV NS3, NS5a proteins.[122] This might explain the presence of anti-LKM in patients with chronic HCV.

Epstein-Barr virus has been linked with chronic autoimmune disease (eg, MS or systemic lupus erythematosus [SLE])[67,91] because self-reactive B lymphocytes are easily susceptible to EBV infection. Recent studies have strengthened the epidemiological link between EBV infection and MS.[16] Additionally, in mechanistic studies, antibodies that are generated against EBNA-1 cross-react with GlialCAM in the brain and spinal cord in MS patients, resulting in an autoimmune response derived from molecular mimicry.[108] Studies analyzing changes in viral persistence in SLE provide compelling evidence that EBV infection is perturbed in the development of SLE. The increased viral load is caused by an increase in the numbers of latently infected cells, particularly in patients with active disease. In addition, patients with SLE have aberrant expression of viral latent and lytic genes in the blood. This suggests that immune dysfunction in SLE alters the regulatory mechanisms of EBV persistence such that B-cell dysregulation might be involved in viral persistence. More thorough and complete studies on changes in viral persistence in SLE would help in the understanding of the nature of EBV-mediated immune perturbation and further provide new insight into the mechanisms involved in regulating the virus.

Future perspectives

Acknowledgments

Studies of tumor viruses have provided fundamental insights into carcinogenesis, identified the causes of some human cancers, and led to novel strategies to prevent and treat these cancers. Some viruses cause cancer by affecting the activity of crucial regulatory nodes that normally control cell proliferation and survival, whereas others indirectly enhance tumor formation by influencing cellular mutagenesis, inflammation, and

immunity. Because of their intimate association with central cellular machinery, tumor viruses are important tools for understanding all human cancers, not just those induced by viruses. For example, studies of tumor viruses led to the discovery of cellular oncogenes and tumor suppressor proteins and to the elucidation of many important aspects of mitogenic signal transduction, cell cycle control, and carcinogenesis. Indeed, the concept that cancer is a genetic disease emerged largely from tumor virology. In addition, viruses can induce specific types of cancer in humans, and cancer risk is reduced by vaccines and antiviral agents that prevent or treat infection by some of these viruses.[247] This chapter reviews some of these remarkable successes and discusses some gaps in our knowledge.

Brief Introduction to Cancer and Cell Transformation

Cancer as a Disease

Cancer, a collection of diseases characterized by inappropriate cell survival and proliferation, is responsible for ~9.5 million deaths annually worldwide. Agents that cause cancer include ionizing radiation and ultraviolet light, chemical carcinogens, genetic predisposition, and specific infectious agents, including some viruses. Cancer can be prevented by exposure reduction (eg, smoking cessation for lung cancer, avoidance of excessive ultraviolet light for skin cancer), screening and early treatment programs (eg, colonoscopies for colon cancer and Pap smear screening for cervical cancer), and vaccination against some virus-induced cancers.

Each cancer is characterized by a unique landscape of mutations, chromosomal rearrangements, copy number variants, and epigenetic and gene expression profiles. Tumorigenesis is largely the consequence of mutations in genes that regulate key cellular processes such as proliferation, cell death, metabolism, and response to stress. Mutations that directly contribute to tumor growth and survival are known as driver mutations. Because many cancers are genetically unstable, tumor cells also carry passenger mutations with no known role in tumorigenesis. Distinguishing driver and passenger mutations and determining their consequences is a major focus of cancer research.

Two major classes of driver genes are oncogenes and tumor suppressor genes. These genes often encode proteins or noncoding RNAs (ncRNAs) that function as key regulators of cell proliferation, death, or genomic integrity. Oncogenes stimulate tumorigenesis and are typically activated or overexpressed in cancer, whereas tumor suppressors inhibit tumorigenesis and are inactivated or deleted in cancer. Although in rare cases these mutations are inherited, the most frequent cause of oncogene activation or tumor suppressor inactivation are mutations occurring after fertilization (known as somatic mutations). Thus, many chemical and physical carcinogens are mutagens. Some tumor viruses encode proteins that directly activate cellular oncogenes, inactivate tumor suppressors, or regulate the pathways controlled by oncogenes and tumor suppressor genes, whereas others act more indirectly, for example by affecting genome integrity and mutagenesis, resulting in progressive loss of cell growth control. The elucidation of the roles of oncogenes, tumor suppressor genes, and mutations in cancer is a major accomplishment of biomedical research, with direct impact on cancer prevention and therapy. Studies of tumor viruses have played an outsized role in these discoveries.

Cell Transformation as a Model of Cancer

Most studies of tumor viruses are performed in cultured cells. Many noncancer cells growing in culture have strict requirements for survival and proliferation. For example, adherent cells often cease proliferation when they reach confluence on a surface (ie, display contact inhibition), require attachment to a solid surface for growth, depend on serum in the culture medium, and display a finite lifespan. In contrast, cells isolated from tumors often display altered properties such as escape from contact inhibition, ability to form multicellular foci on a surface or colonies in semisolid medium, reduced serum requirements, and unlimited growth potential. Most strikingly, these cells often form tumors upon inoculation into animals. Cells displaying these properties are called transformed cells, although some transformed cells display only a subset of these phenotypes. Infection with some viruses that induce tumors in animals can transform cells in culture. In most cases, viral DNA persists in transformed cells, but the cells usually do not express all viral genes and do not produce infectious virus. In fact, in many cases productive infection is incompatible with transformation, because virus production can result in cell death. Therefore, in transformed (and tumor) cells, viral replication functions are often inactivated by mutation, integration of the viral genome into the cell genome, or other events. In general, maintenance of the transformed phenotype requires continuous expression of viral oncogenes.

Studies of transgenic mice expressing viral oncogenes in specific cell types in their natural tissue setting have also been valuable and mitigate some of the potential artifacts of studying cultured cells. Importantly, mouse models allow a combination of viral and host genetics, in which wild-type or mutant viral oncoproteins are expressed in different mouse strains or in gene knockout backgrounds. Among other contributions, studies of transgenic mice demonstrated that viral oncogenes can induce tumors in the correct tissue context and that the host cell genetic background can greatly influence cancer risk.

History of Tumor Virology

Discovery of Tumor Viruses and Viral Oncogenes

Early studies of tumor viruses focused on isolation of viruses from naturally occurring tumors in animals and description of the effects of these viruses in experimental animals. The first tumors shown to be transmitted by viruses were avian myeloblastosis in 1908 and avian sarcomas in 1911, caused by avian myeloblastosis virus (AMV) and Rous sarcoma virus (RSV), respectively.[99,238] Study of these and related retroviruses and their mechanisms of oncogenesis provided numerous important insights into pathways of growth regulation and carcinogenesis. Indeed, some of the most important proteins in signal transduction and human cancer including Ras and Myc were first identified as retroviral oncoproteins. Diverse taxonomic groups of viruses with DNA genomes can also cause tumors: polyomaviruses, papillomaviruses, adenoviruses, herpesviruses, hepadnaviruses, and poxviruses. Thus, the ability to induce tumors is not associated with a particular virus family, genome structure, or mode of virus replication. The types of tumors induced by viruses are also diverse and include sarcomas (tumors of mesenchymal cells), leukemias and lymphomas (tumors of hematopoietic cells), and carcinomas (tumors of epithelial cells).

The first identified viral oncogene was the *src* oncogene of RSV. Retroviruses have an RNA genome, which is reverse transcribed into double-stranded DNA that integrates into the host cell's genome. This integrated viral DNA (known as a provirus) consists of three genes—*gag*, *pol*, and *env*—that encode proteins required for virus replication (Fig. 11.1A). Infection of chick embryo fibroblasts with RSV causes cell transformation, but RSV mutants exist that lost tumorigenic and transforming activity without affecting viral replication.[89] Thus, oncogenesis and transformation are not required for RSV replication. The transformation-defective mutant genome was smaller than wild-type RSV, suggesting

that viral sequences responsible for transforming activity—an oncogene eventually named *src*—were missing from the mutant (Fig. 11.1A).[66] A key discovery was the origin of *src*. Hybridization experiments with *src*-specific DNA probes revealed the presence of homologous sequences in DNA from uninfected chickens and other species.[271] Thus, the *src* gene of RSV, designated *v-src*, was derived from a normal cell gene named *c-src*, which is present in the germline of all vertebrates. This progenitor cellular gene is referred to as a proto-oncogene and was incorporated in the recent past into the retroviral genome. DNA tumor viruses also contain viral oncogenes, but usually they are intrinsic viral genes that were not recently acquired from the cell. For many virus-induced cancers, viral oncogenes play a predominant role, but for others, viral oncogenes play little if any role.

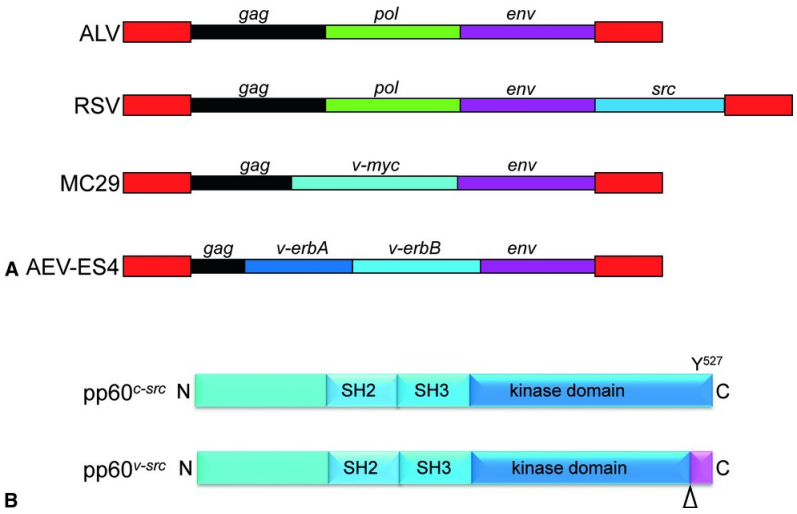

FIGURE 11.1 **Retroviral genomes and oncogenes**. **A**. Genome maps of the indicated avian retroviruses. The red segments represent the viral long terminal repeats (LTRs). The *black*, *green*, and *purple* segments represent the viral replication proteins, *gag*, *pol*, and *env*, respectively. Viral oncogenes are shown in blue. ALV (avian leukosis virus) does not contain a viral oncogene and is not an acute transforming virus. **B**. Schematic diagrams of *src* oncoproteins. $pp60^{c\text{-}src}$ is shown at the top and $pp60^{v\text{-}src}$ is shown at the *bottom*. Structural domains of both proteins are labeled, as is the C-terminal regulatory tyrosine at position 527 (Y527) in $pp60^{c\text{-}src}$. In $pp60^{v\text{-}src}$, the site of the frameshift mutation is indicated by the *triangle*, with out-of-frame sequences downstream of the mutation shown in *lavender*.

Development of New Tools that Revolutionized Biology

Intense studies of tumor viruses in the 1970s and 1980s led to the development of many important research tools and reagents, including restriction mapping, site-directed mutagenesis, gene transfer, whole genome sequencing, and recombinant DNA technology. Widespread application of these tools revolutionized genetics and molecular biology.[84,225]

These techniques were largely developed with small DNA tumor viruses because the virus particle and its genome could be isolated in pure, clonal form from infected, permissive cells for detailed analysis. The key advance for DNA analysis was the use of restriction endonucleases to study DNA isolated from tumor viruses, primarily the monkey polyomavirus, SV40. Crucially, these enzymes cleave DNA at specific, short nucleotide sequences and generate specific fragments of DNA, which can be placed in their proper order in a "restriction" map of the viral genome (Fig. 11.2).[77,79] Genetic elements such as the origin of viral DNA replication and viral transcription units could then be positioned on the map. Restriction endonucleases were also used to localize mutations[78] on the viral genome, compare viral strains, and construct specific mutations at predetermined sites in the genome for functional studies.[206] In addition, transfection techniques were developed to introduce viral DNA segments into cultured cells to determine their biological activities. Reverse transcriptase, a retroviral enzyme that catalyzes synthesis of DNA from an RNA template, was used to convert cellular RNA into DNA. Importantly, restriction endonucleases and reverse transcriptase allowed molecular cloning of cellular DNA in recombinant form, providing an unlimited supply of pure cellular genes for analysis. These techniques allowed the analysis of ever larger genomes, beginning with SV40 itself and bacteriophage ΦX174, and culminated in the complete sequencing of the genomes of many higher organisms including humans. These advances revolutionized our understanding of biology, gave birth to the biotechnology industry, and continue to transform clinical medicine.

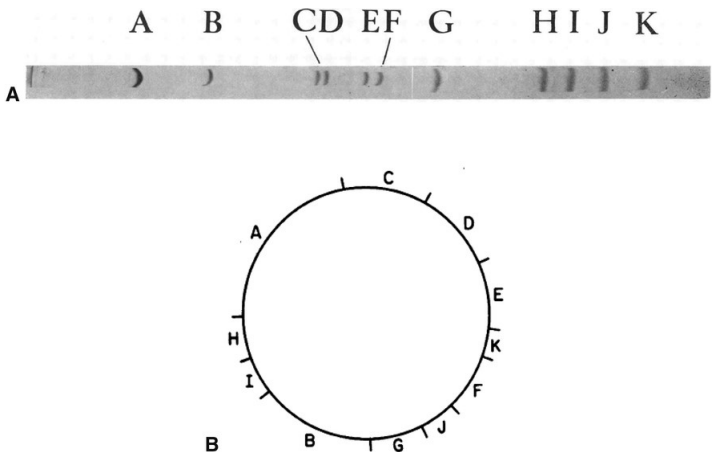

FIGURE 11.2 **Restriction endonuclease digestion generates discrete DNA fragments that can be assembled into a physical map of the viral genome**. **A**. Studies of tumor viruses themselves shed light on many areas of biology including fundamental aspects of eukaryotic gene expression, DNA replication, cell signaling, protein trafficking, and cell cycle control. Transcription factors, nuclear localization and polyadenylation signals, transcriptional enhancers, and mRNA splicing, for example, were discovered by studies of small DNA tumor viruses.[84,225] The impact of these studies is highlighted by the numerous Nobel Prizes awarded to tumor virologists (Table 11.1).

Cellular Targets of Tumor Viruses

In untransformed cells, cell division is regulated by intrinsic oscillators that ensure the orderly progression of the cell division cycle and by external stimuli that dictate entry or exit from the cell cycle or modulate the activity of the cell cycle machinery. Like soluble growth factors, many viral oncoproteins stimulate DNA synthesis. Thus, the signal transduction pathways activated by growth factors are a useful framework to understand the function of viral oncogenes (Fig. 11.3).

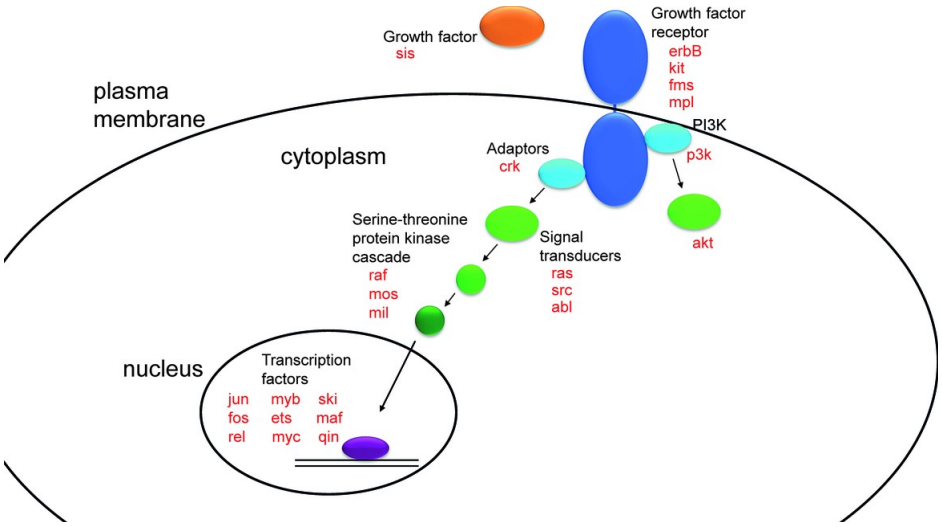

FIGURE 11.3 **Mitogenic signal transduction pathways and retroviral oncogenes**. Schematic representation of mitogenic signal transduction from the cell surface. Binding of a growth factor to a receptor tyrosine kinase initiates signal transduction pathways involving adaptor proteins, signal transducing proteins, and serine/threonine kinases, indicated by the colored ovals. This results in the phosphorylation of transcription factors to alter gene expression and execute pro-proliferative or antiapoptotic signals. Components of this pathway transduced by acute transforming retroviruses are listed in red.

Most cells grown in culture require a basal nutrient medium supplemented with serum, which contains numerous factors required for cell attachment to a surface, cell survival, and proliferation. Polypeptide growth factors such as platelet-derived growth factor (PDGF) and epidermal growth factor (EGF) bind to specific cell surface receptors to initiate mitogenic signaling. Growth factor receptors are often transmembrane proteins with an extracellular ligand binding domain, a membrane-spanning domain, and an intracellular catalytic domain. For receptor tyrosine kinases (RTKs), ligand binding induces dimerization and/or reorientation of the receptors, resulting in activation of the tyrosine kinase activity of the receptors and in tyrosine phosphorylation of the receptor itself (Fig. 11.4). Receptor tyrosine phosphorylation in turn generates specific binding sites for a variety of signaling proteins and initiates a cytoplasmic signaling cascade involving a series of serine/threonine kinases and associated proteins that ultimately causes the activation of transcription factors, such as activator protein-1 (AP-1) and Myc, resulting in altered expression of various cellular genes (Fig. 11.3).[27,29,61,240]

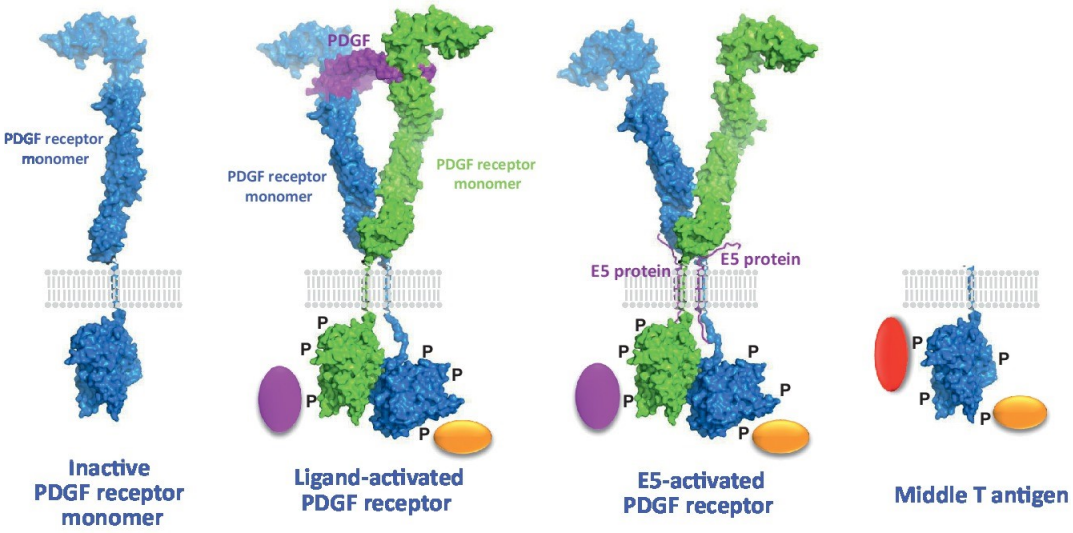

FIGURE 11.4 **DNA virus oncoproteins that mimic or activate receptor tyrosine kinases**. The left diagram shows a monomeric, inactive receptor tyrosine kinase with the cytoplasmic kinase domain at the bottom. The second diagram from left shows a dimer of two PDGF receptor molecules activated by PDGF binding. The Ps in the cytoplasmic domain represent phosphorylated tyrosines that serve as docking sites for signaling proteins, which are represented by ovals. Third diagram from left shows a dimer of two PDGF receptor molecules activated by the BPV E5 protein binding to the transmembrane domain of the receptor. The current model of the E5 protein/PDGF receptor interaction proposes two E5 dimers in the complex,[159] but only two E5 molecules are shown here for clarity. The diagram on the right shows phosphorylated murine polyomavirus middle T antigen bound to cellular signaling proteins. (Modified from DiMaio D. Viral miniproteins. *Annu Rev Microbiol*. 2014;68:21-43. Copyright © 2014 by Annual Reviews.)

The signaling cascade mobilized by growth factor treatment leads to cell cycle entry.[166] Progression to the G1 phase of the cell cycle results in the increased expression of several hundred genes that encode proteins that function in nucleotide metabolism, DNA replication, and cell cycle progression. The expression of these genes is controlled by the E2F-family of transcription factors in association with a member of the retinoblastoma family of tumor suppressors, which consists of three proteins, $p105^{Rb}$, p130, and p107 (collectively called RB). During growth arrest, E2F4/5 recruits p130 to the promoters of E2F-regulated genes and anchors a multiprotein complex that represses transcription (Fig. 11.5). Mitogenic signaling increases the expression of cyclin D, which binds and activates the cyclin-dependent kinases (cdks), cdk4 and cdk6.

Activated cdk4 and cdk6 phosphorylate p130, as well as the other RB proteins, thereby inhibiting their interaction with E2F4/5. This leads to the degradation of the repressive complex and to derepression of E2F1, E2F2, and E2F3, which then bind the promoters of E2F-regulated genes and stimulate transcription (Fig. 11.5).

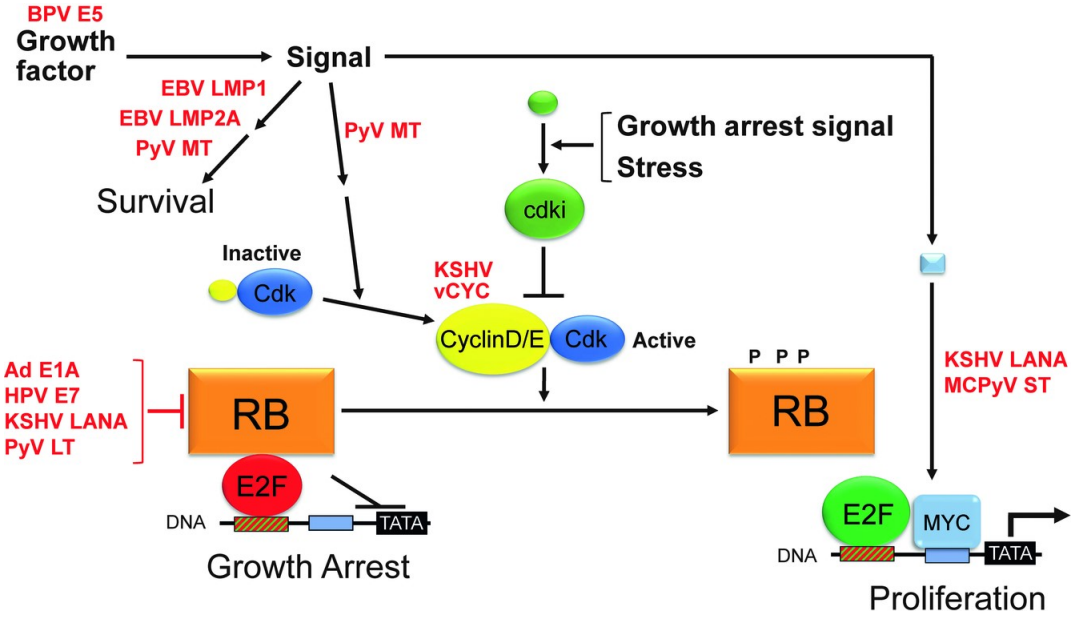

FIGURE 11.5 **Multiple DNA tumor viruses antagonize RB function**. During growth arrest, E2F-binding sites in promoters of growth-regulated genes are occupied by a repressive complex containing an E2F family member bound to an RB family member. Growth factors initiate a signaling cascade that ultimately leads to increased levels of Myc and cyclin family members. Cyclin binding to cyclin-dependent kinase (cdk) stimulates phosphorylation of RB and loss of the repressive complex. The promoters are then occupied by activating members of the E2F family and Myc, resulting in increased transcription of genes required for cell cycle progression and cell proliferation. Growth arrest or stress signals activate cdki's that inhibit cdk activity. As described in the text, multiple DNA tumor virus oncoproteins shown in red promote cell survival, stimulate RB phosphorylation, directly inhibit RB action, or induce expression of Myc family members. PyV MT, murine polyomavirus middle T antigen.

Cells often respond to stress by halting cell cycle entry even in the presence of a mitogenic signal, due to increased expression and activation of proteins that inhibit cdks (cdk inhibitors, cdki's) (Fig. 11.5). The *INK4A* family of cdki's, exemplified by p16 (*CDKN2A*), specifically inhibit cdk4/6. When p16 is active, RB proteins remain hypo-phosphorylated, and E2F-regulated genes are repressed. The WAF1 family of cdki's, exemplified by p21 (*CDKN1A*), inhibits multiple cdks and halts cell cycle progression at any stage. The expression of p21 is controlled by the tumor suppressor p53, which was discovered as cellular binding partner of SV40 large T antigen, a protein required for viral DNA replication.[177,188] p53 is a transcription factor that integrates responses to multiple stresses such as hypoxia, nutrient depletion, and DNA damage (Fig. 11.6). Under normal conditions, p53 levels are low due to a feedback loop with the ubiquitin ligase mdm2: p53 stimulates transcription of the mdm2 gene and the resulting increased mdm2 levels cause p53 ubiquitination and degradation. Stress activates kinases that phosphorylate p53 and render it unable to interact with mdm2. This results in increased p53 levels that then activate transcription of p21, leading to cell cycle arrest. Prolonged p53 activation leads to increased levels of cell death proteins such as Bax, resulting in apoptosis. Activation of mitogenic signaling or inhibition of tumor suppressor proteins such as RB and p53 can stimulate cell proliferation or enhance cell survival. Not surprisingly, most viral oncogenes activate signal transduction cascades or inhibit tumor suppressor pathways or the cell cycle machinery (Figs. 11.3, 11.5, and 11.6).[26]

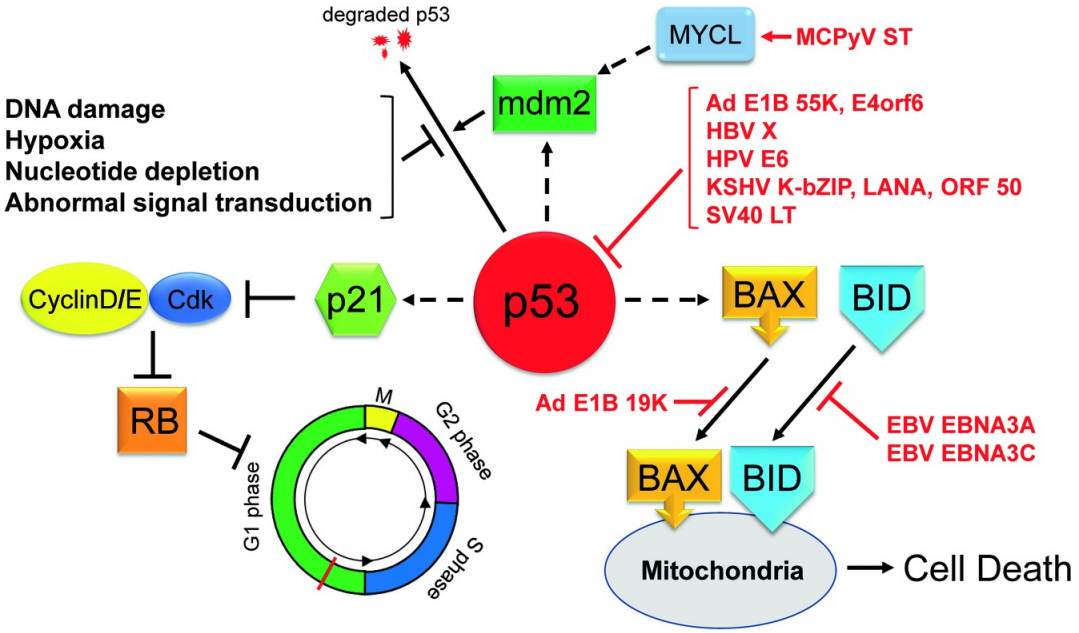

FIGURE 11.6 **Multiple DNA tumor viruses antagonize p53-mediated growth arrest and apoptosis**. Under normal conditions, p53 is maintained at a low level by a feedback loop in which p53 stimulates transcription of the mdm2 gene, and the resulting increased levels of mdm2 lead to p53 degradation. Stress signals activate kinases that phosphorylate p53, thereby disrupting its interaction with mdm2 and preventing degradation. The resulting increased p53 levels stimulate transcription of cdki's such as p21, which inhibit the ability of cyclin-dependent kinases to phosphorylate RB, resulting in cell cycle arrest. p53 also stimulates the transcription of multiple cell death genes such as Bax, which cooperates with Bid to penetrate the mitochondrial membrane and induce cell death. The circle at the bottom left represents the cell cycle. As described in the text, the DNA tumor virus oncoproteins shown in red interfere with p53 expression or action.

All viruses with DNA genomes must deal with the cellular DNA damage response (DDR). In response to DNA damage, the MRN DNA repair complex binds to DNA ends, recruits DNA repair proteins to sites of damage, and activates the ATM serine-threonine kinase. Activated ATM phosphorylates p53, leading to p53 activation, p21 induction, and ultimately loss of RB phosphorylation and repression of E2F-dependent transcription. Replicating viral DNA itself can trigger the DDR.[299] Furthermore, aberrant activation of mitogenic signaling pathways by viral oncoproteins can induce unscheduled cellular DNA synthesis leading to a DDR, apoptosis, or cellular senescence.[95] The p53 and RB pathways play critical roles in these processes, which could ultimately limit the production of viral progeny particles. Therefore, neutralization of these tumor suppressor pathways by viral oncoproteins also interferes with checkpoints that arrest the cell cycle in response to DNA damage, thereby removing these barriers to tumorigenesis. Furthermore, when these checkpoints fail, the resulting inaccurate DNA repair coupled with unscheduled DNA synthesis fosters the accumulation of mutations, some of which further contribute to the erosion of growth control.

In the next two sections, we describe the action of some important viral oncoproteins. In the sections on specific carcinogenic human viruses, we mention putative viral oncogenes whose mechanism of action is less well defined.

Mechanism of RNA Virus Oncogene Action

Numerous retroviruses can cause tumors in animals. Oncogenic retroviruses can be divided into two broad classes, based on the speed of tumor induction. *Acute transforming* retroviruses like RSV induce tumors rapidly (often within weeks in experimental animals) and usually transform cells in culture. As noted above, these viruses carry oncogenes responsible for rapid and efficient tumorigenesis and cell transformation. *Nonacute* oncogenic retroviruses induce tumors in animals more slowly (over months) and do not carry oncogenes or transform cells in culture. Rather, they induce tumors by affecting expression of cellular proto-oncogenes or tumor suppressor genes.

Overview of Retroviral Oncogenes

In general, acute transforming retroviruses contain viral oncogenes that are derived from cellular protooncogenes (Table 11.2). These oncogenes are inserted in various places in the retroviral genome and usually cause a viral replication defect by disrupting genes involved in viral replication (Fig. 11.1A). Cellular proteins encoded by protooncogenes, which generally play positive roles in stimulation of cell growth or division, are tightly regulated. The viral oncoproteins often differ from their parent cellular proteins by mutations and/or fusion to a retroviral replication protein, which release the tight regulatory control imposed on the normal cellular homologs, thereby activating the viral proteins compared to their cellular counterparts.

[a]Oncogenes (or closely related oncogenes) mutated or overexpressed in some human cancers are shown in bold.

[b]In cases where different viruses encode closely related oncogenes, only a single virus is listed as an example.

[c]The nomenclature of viral oncoproteins refers to basic structural data: p, protein; gp, glycoprotein; pp, phosphoprotein; the numbers designate the molecular weight in kilodaltons; the superscript indicates the genes from which the coding information is derived in a 5′-3′ direction. These oncoproteins are frequently fused to a viral replication protein: *gag*, *pol*, or *env*.

[d]Name of the human gene according to the HUGO gene nomenclature committee.

Abbreviations: AEV, avian erythroblastosis virus; AMV, avian myeloblastosis virus; AP-1, activator protein-1; ASV, avian sarcoma virus; FeSV, feline sarcoma virus; NF-κB, nuclear factor-κB; MSV, murine sarcoma virus; MuLV, murine leukemia virus; PI3K, phosphotidylinositol 3-kinase.

The product of the *src* oncogene was the first oncoprotein characterized biochemically. *src* encodes a 60-kD phosphoprotein designated $pp60^{v\text{-}src}$ that phosphorylates tyrosine residues in proteins.[35,70,149] $pp60^{v\text{-}src}$ was the first tyrosine kinase discovered, and it phosphorylates many cellular protein substrates linked to oncogenesis. The kinase domain of $pp60^{v\text{-}src}$ is located downstream of two short protein domains known as "*src* *h*omology" (SH) domains (Fig. 11.1B): SH2 domains bind phosphotyrosine residues in specific sequence contexts in their target proteins, while SH3 domains bind proline-rich protein segments.[170,199] SH2 and SH3 domains are important protein-protein interaction motifs that are also present in many cellular proteins.

In viral oncoproteins, mutations may disrupt inhibitory elements present in the cellular protein. For example, pp60$^{c\text{-}src}$ has a C-terminal regulatory domain that contains a tyrosine residue at position 527 (Y^{527}). When Y^{527} is phosphorylated, it binds the SH2 domain in the same molecule of pp60$^{c\text{-}src}$, resulting in a closed conformation in which the kinase is inactive.[305] Dephosphorylation of Y^{527} displaces the SH2 domain and activates *src* kinase.[73] Of note, the viral protein pp60$^{v\text{-}src}$ contains a frameshift mutation that removes Y^{527} and as a consequence is constitutively in the open, kinase-active configuration (Fig. 11.1B).[278,281] Other viral oncoproteins contain amino acid substitutions that disrupt regulatory mechanisms (eg, the *v-ras* proteins) or are fused to viral proteins so that oncogenic activity is enhanced (eg, the *v-abl* protein). In some cases, the viral oncogene product is identical to the protooncogene product but is overexpressed from the retroviral genome (eg, the *v-myc* protein).

Retroviral Oncoproteins as Components of Signal Transduction Pathways

As described in an earlier section, untransformed cells in culture require growth factors that bind to cell surface receptors and trigger signaling cascades. Genes encoding many components of these signal transduction pathways have been captured by acutely transforming retroviruses (Fig. 11.3 and Table 11.2). Indeed, many of these components were first identified as retroviral oncogene products.

The *v-sis* oncogene encodes a version the PDGF B chain and can transform only cells that express the PDGF receptor, providing a molecular explanation for the cell-type specific action of some oncogenes.[60,210] Other retroviral oncogenes encode activated versions of RTKs. The *v-erbB* oncogene encodes a mutant EGF receptor that lacks the extracellular EGF binding domain and an autoinhibitory domain at the C-terminus.[88,141] As a result, the *v-erbB* protein signals in a constitutive, EGF-independent manner. Other constitutively activated RTKs encoded by acute transforming retroviruses include the stem cell factor receptor (*v-kit*) and the colony-stimulating factor 1 receptor (*v-fms*),[148,254,316] and the *v-cbl* oncogene encodes a ubiquitin ligase that regulates RTK abundance.[157] The *v-mpl* oncogene encodes a constitutively active version of the thrombopoietin receptor.[82,160] The ability of oncogenes to activate or serve as activated growth factor receptors provides a simple explanation for the reduced serum requirements of transformed cells.

Other oncogenes encode proteins that bind to RTKs or transmit signals from them. The *src* family are nonreceptor tyrosine kinases that mediate signaling from activated RTKs. In addition to *v-src* itself, the *src* family members *v-fps*, *v-fes*, and *v-yes* were captured by other acute transforming retroviruses.[129] An important lipid kinase is phosphoinositol 3′ kinase (PI3K), which delivers survival and proliferative signals to cells upon RTK activation. The gene encoding PI3K was captured as the *v-p3k* oncogene.[51] The *v-crk* oncogene encodes a receptor-associated adaptor protein that lacks enzymatic activity but contains SH2 and SH3 domains that assemble proteins into signal transduction complexes with RTKs.[197] The *v-abl* oncogene encodes a cytoplasmic tyrosine kinase that is activated by fusion to the retroviral gag protein.[302]

Other retroviral oncoproteins are cytoplasmic kinases that phosphorylate proteins on serines or threonines as part of the signal transduction cascade initiated by growth factor binding. These include proteins encoded by *v-raf*,[156,231] *v-mos*,[250] and *v-akt*[21] that ultimately lead to phosphorylation and nuclear translocation of mitogen-activated protein kinases.[171,313] v-*akt* encodes a homologue of Akt, a key kinase in downstream signaling from PI3K.[21,51] For the viral oncogenes that encode kinases, unregulated enzyme activity or overexpression causes overactive signaling through the corresponding signal transduction pathways.

v-Hras and *v-Kras* encode cytoplasmic guanosine triphosphatases (GTPases) that bind guanosine diphosphate [GDP] or guanosine triphosphate [GTP]. The GTP-bound form of Ras, which is generated by RTK activation, triggers signals that result in cell proliferation (eg, by binding and activating Raf kinase), but tras proteins are inactive when bound to GDP.[30,100,190] Active GTP-bound Ras cycles back to the inactive form through the action of its intrinsic GTPase activity, which is stimulated by GTPase activating proteins (GAPs).[285] The v-H*ras* and v-K*ras* proteins contain missense mutations at key residues that reduce the ability of GAP to stimulate GTP hydrolysis.[285] As a consequence, the v-*ras* proteins accumulate in the active, GTP-bound form and signal constitutively.

Many genes first identified as retroviral oncogenes are also mutated in sporadic human cancer (Table 11.2). In some cases, the specific genetic alterations in human cancer closely parallel the activating mutations in the retroviruses themselves. Drugs targeting the protein products of cellular protooncogenes can successfully treat human cancers containing mutations that activate Abl, EGF receptor, ErbB2 (an EGF receptor family member), PDGF α receptor, stem cell factor receptor, PI3K, and B-Raf.

Nuclear Retroviral Oncoproteins

Some retroviral oncogenes encode versions of cellular transcription factors. The *v-myc* oncogene is derived from *c-myc*, which encodes a protein (Myc) involved in early responses to mitogenic stimuli and binds directly to promoters/enhancers of target genes.[289] Early after a mitogenic stimulus, levels of Myc transiently rise, leading to activation of some genes, such as those encoding E2F and cyclin D, and repression of other genes including those encoding cdki's.[96] *v-myc* transforms cells because it is constitutively overexpressed from the retroviral long terminal repeat (LTR), which contains transcriptional regulatory elements. The *v-myb* oncogene is derived from *c-myb*, which encodes a transcription factor important in hematopoietic cell development.[24,128] Two additional interesting retroviral oncogenes are *v-fos* and *v-jun*, which encode mutant subunits of AP-1.[29,232] In normal cells, early after mitogenic stimulation, Fos-Jun heterodimers form and activate promoters/enhancers containing AP1-sites, leading to expression of target genes important for cell division and growth.[205] The *v-jun* and *v-fos* proteins contain structural alterations, such as a deletion that removes an auto-inhibitory segment from *c-jun*, resulting in oncogenic activation.[32]

The *v-erbA* protein is a dominant negative form of the thyroid hormone receptor-α, a sequence-specific DNA binding protein.[243,298] *v-ErbA* inhibits transcription of THR-α–responsive genes and blocks erythroid cell differentiation, resulting in enhanced proliferation of undifferentiated erythroid progenitors.[76] The *v-rel* oncogene encodes a mutant subunit of the nuclear factor-κB (NFκB) transcription factor family important for B-cell development.[117] Point mutations and fused sequences from retroviral *env* activate *v-rel*.[280]

Although most retroviral oncogenes were acquired from the host cell genome, some retroviral oncogenes are derived from viral envelope proteins. For example, the oncoprotein of Friend spleen focus forming virus, designated gp55, is a deleted form of a retroviral *env* protein.[65] gp55 binds the erythropoietin receptor (EpoR),[184] leading to constitutive downstream signaling and oncogenic transformation.[65]

Insertional Activation of Cellular Proto-oncogenes by Nonacute Transforming Retroviruses

Prototype nonacute oncogenic retroviruses include avian leukosis virus (ALV) and various murine leukemia viruses (MuLVs). These viruses lack viral oncogenes and do not transform cultured cells, and tumors arise in animals many months after infection. Most nonacute retroviruses induce tumors by transcriptional activation of cellular proto-oncogenes by the integrated proviral genome. Pioneering experiments investigating tumorigenesis by these viruses were conducted on chicken B-cell lymphomas induced by ALV. DNA from many of these tumors contained the ALV provirus inserted into the same chromosomal region in independent tumors, adjacent to the *c-myc* proto-oncogene (which was first identified as the oncogene in an acute transforming retrovirus).[142,253] This insertion placed *c-myc* under control of the strong promoter/enhancer in the proviral LTR, resulting in increased transcription of *c-myc* (Fig. 11.7). The viral LTR can act as either a promoter or an enhancer to cause transcriptional activation of protooncogenes. Murine leukemias induced by M-MuLV also commonly result from activation of *c-myc*.[251] Thus, *c-myc* can be activated either by transduction by acute transforming retroviruses or by proviral insertion by nonacute transforming retroviruses.

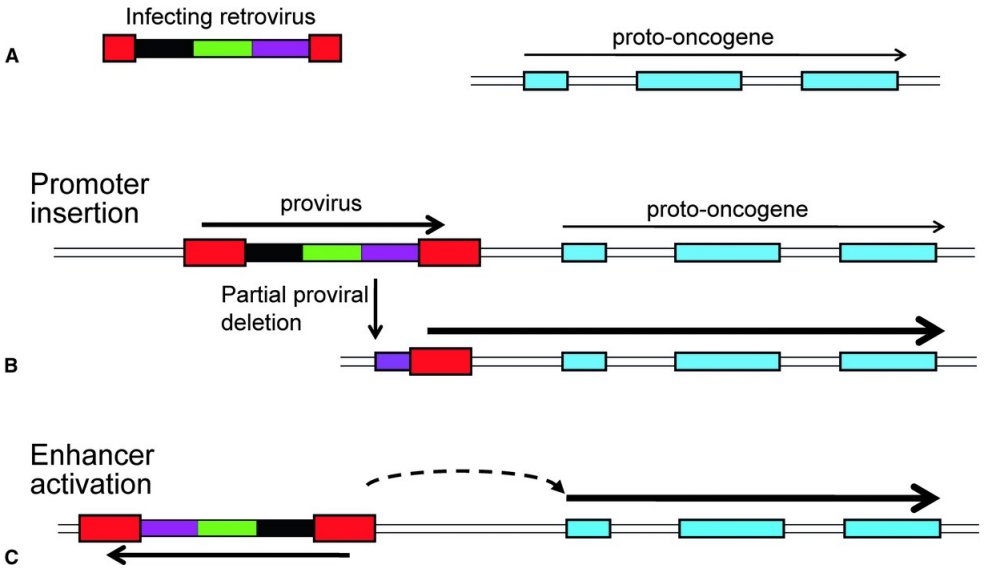

FIGURE 11.7 **Insertional activation of cellular proto-oncogenes**. Color scheme as in Figure 11.1A. **A**. Infecting retrovirus is shown at left and target protooncogene with three exons (*blue*) is shown at right. The *arrow* indicates the direction of transcription, and the thickness of the arrow represents the level of expression. **B**. Promoter insertion mechanism. After insertion of the provirus upstream of the proto-oncogene in the same transcriptional orientation, a portion of the provirus is often deleted, activating the right viral LTR to drive increased transcription of the proto-oncogene. **C**. Enhancer activation mechanism. After insertion of the provirus in the opposite orientation as the protooncogene (or downstream of the oncogene, not shown), the transcriptional enhancer in the viral LTR drives increased transcription of the proto-oncogene.

Proviral insertion can also activate other proto-oncogenes. For example, the mouse mammary tumor virus (MMTV) activates *int-1* (later renamed *wnt-1* after its *Drosophila* homolog[234]). *Wnt-1* protein is an important molecule in the *Wnt-β-catenin* signal transduction pathway, which is mutated in a wide variety of human cancers, most notably colorectal adenocarcinoma.[37] MuLV insertion can activate genes encoding other important cell cycle regulators including cyclin D2, DNA binding proteins of the *ets* family, and the macrophage colony stimulating factor. The LTRs of the M and F strains of MuLV activate different protooncogenes in T-cell lymphomas and erythroid leukemias, respectively, reflecting the different signaling pathways important for transformation of different cell types.

The genomes of many animals contain complete or partial integrated retroviral genomes, known as endogenous retroviruses. Certain strains of mice develop leukemia at a high frequency due to spontaneous activation of these endogenous viruses, which in turn infect new cells and insertionally activate cellular proto-oncogenes.[71] Recombination can also occur between exogenous infecting MuLVs and endogenous proviruses to generate recombinant viruses with altered tropism or heightened oncogenicity.[273]

In addition to LTR-mediated activation of proto-oncogene transcription, related mechanisms of oncogene activation also involve integration of proviral DNA into the cell genome. For example, proviral insertion can introduce new splice sites or transcriptional elements resulting in the synthesis of aberrant proteins or disrupt microRNA-mediated downregulation of cellular proto-oncogenes. Finally, proviruses can inactivate p53 or NF-1 by inserting into the coding region of these tumor suppressor genes.[22,178]

Mechanism of DNA Virus Oncogene Action

Unlike most retroviral oncogenes, DNA tumor virus oncogenes were not captured in the recent past from the host cell genome but rather are intrinsic viral genes that usually have been part of the viral genome for millions of years of viral evolution and play essential roles in virus replication or persistence (Table 11.3). In many cases, these genes encode proteins that mobilize the cellular DNA replication machinery to support the production of many progeny viral DNA genomes, so it is not surprising that increased cell proliferation can result from sustained expression of these proteins. Most DNA virus oncoproteins function by binding to cellular proteins and modulating their activities (Table 11.3). DNA tumor viruses often encode more than one oncoprotein that cooperate to transform cells. Some DNA virus oncoproteins stimulate cellular mitogenic signal transduction pathways, whereas others inactivate cellular tumor suppressor pathways (Figs. 11.4, 11.5, and 11.6). Still others impair immune surveillance against tumor virus replication and cancer (eg,[233]). It is striking that diverse DNA tumor viruses modulate a limited number of common cellular targets, implying that there are relatively few crucial nodes that regulate cell proliferation and survival (Table 11.4).

TABLE 11.3 Selected DNA virus oncoproteins and their major targets

Viral Oncoprotein	Cellular Target
Adenovirus E1A	RB family members, p300/CBP, CtBP
Adenovirus E1B 19K	Bak, Bax
Adenovirus E1B 55K	p53
Adenovirus E4orf6	p53
Bovine papillomavirus E5	PDGF β receptor
Epstein-Barr virus EBNA2	RBP-Jκ/CBF1, glycogen synthetase kinase
Epstein-Barr virus LMP1	Tumor necrosis factor signaling components, PI3K
Epstein-Barr virus LMP2A	*src* family members
Hepatitis B virus X protein	p53
Human papillomavirus E5	EGF receptor
High-risk human papillomavirus E6	p53, PDZ proteins, E6-AP, DNA repair and apoptosis machinery
High-risk human papillomavirus E7	RB family members, p21, p27, E2F1, cyclin-dependent kinases
KSHV K-bZIP	p53
KSHV LANA	p53, RB family members, chromatin proteins
KSHV ORF 50	p53
KSHV vCYC	Cyclin-dependent kinase 6
Polyomavirus large T antigen	p53 (not murine polyomavirus or MCPyV), RB family members
Polyomavirus middle T antigen	*src* family members, PI3K, PP2A, shc
Polyomavirus small T antigen	PP2A, MYCL (MCPyV)

EBNA, Epstein-Barr virus nuclear antigen; EGF, epidermal growth factor; KSHV, Kaposi sarcoma–associated herpesvirus; LMP, latent membrane protein; MCPyV, Merkel cell polyomavirus; PDGF, platelet-derived growth factor; PI3K, phosphotidylinositol 3-kinase; PP2A, protein phosphatase 2A; RB, retinoblastoma; vCYC, vCyclin.

TABLE 11.4 Common targets of DNA virus oncoproteins

p53	Large T antigen (some polyomaviruses, eg, SV40) High-risk HPV E6 Adenovirus E1B 55K and E4orf6 KSHV K-bZIP, LANA, and ORF 50 Hepatitis B virus X protein
RB family members	Large T antigen (all polyomaviruses) High-risk HPV E7 Adenovirus E1A KSHV LANA
Src family members	Polyomavirus middle T antigen EBV LMP2A
PI3K	Polyomavirus middle T antigen, EBV LMP1
PP2A	Polyomavirus small T antigen and middle T antigen

EBV, Epstein-Barr virus; HPV, human papillomavirus; KSHV, Kaposi sarcoma–associated herpesvirus; LANA, latency-associated nuclear antigen; LMP1, latent membrane protein 1; LMP2A, latent membrane protein 2A; PI3K, phosphotidylinositol 3-kinase; PP2A, protein phosphatase 2A; SV40, simian virus 40.

DNA Virus Oncoproteins that Activate Mitogenic Signaling Pathways

One of the first DNA virus oncoproteins characterized was the membrane-anchored middle T (MT) antigen of murine polyomavirus.[286] MT constitutively associates with a cellular tyrosine kinase that was later identified as none other than pp60$^{c\text{-}src}$, the product of the *c-src* protooncogene captured by RSV![74,93] MT binding activates the kinase activity of pp60$^{c\text{-}src}$, which then phosphorylates tyrosines in the large cytoplasmic domain of MT, thereby generating binding sites for cellular signaling proteins that contain SH2 domains such as PI3K and protein phosphatase 2A (PP2A) (reviewed in Ref.[245]) (Fig. 11.4). Because many of the proteins that bind MT also bind to the cytoplasmic domain of ligand-activated RTKs, MT mimics an activated RTK that delivers a constitutive mitogenic signal.

The bizarre bovine papillomavirus (BPV) E5 protein uses a related mechanism to transform cells. The shortest known oncoprotein, the E5 protein is only 44 residues long and extremely hydrophobic, essentially a free-standing transmembrane domain.[248] The E5 protein binds specifically to the transmembrane domain of an RTK, the PDG β receptor, causing receptor dimerization and sustained ligand-independent activation, which results in cell transformation (Fig. 11.4).[83,121,222,223] Thus, like the retroviral oncogene *v-sis*, the which encodes PDGF itself, the E5 protein causes constitutive activation of the PDGF receptor, but E5 uses entirely different biochemical interactions to drive receptor activation.

The E5 proteins from certain HPV types display weak transforming activity in cultured cells and contribute to cancer development in transgenic mice. The HPV16 E5 protein increases the sensitivity of the EGF receptor to EGF, and the EGF receptor is required for the growth-promoting effects of the HPV16 E5 protein in transgenic mice.[114,274] HPV16 E5 has also been reported to modulate the activity of vacuolar H^+-ATPase, act as a viroporin, and downregulate major histocompatibility antigens.

DNA Virus Oncoproteins that Inactivate Tumor Suppressor Pathways

All members of the *Polyomaviridae* encode a nuclear protein, large T antigen (LT), a multifunctional protein that consists of four folded domains separated by flexible unstructured regions: a J domain near the amino-terminus, a DNA-binding domain (OBD) that binds the origin of viral DNA replication, a zinc-binding domain, and an ATP-dependent helicase domain that, in some polyomaviruses, also binds p53.[224] The region between the J domain and OBD contains docking sites for several cellular proteins including an LXCXE motif that binds members of the RB family.

SV40 LT is a potent oncoprotein that transforms cells in culture and induces neoplasia in transgenic mice, primarily by inhibiting the activity of p53 and RB (Figs. 11.5 and 11.6).[1] LT activities that function directly in viral DNA replication are not required for transformation. In contrast, transformation is impaired by mutations that disrupt LT binding to RB proteins or p53. LT binds to RB-E2F repressive complexes and dislodges E2F from RB, resulting in de-repression of E2F-regulated genes and cell cycle entry. Energy for E2F displacement is derived from hsc70-mediated ATP hydrolysis stimulated by the LT J domain. Nearly all LT proteins contain a J domain and LXCXE motif, so this mechanism appears conserved.

LT action on RB is sufficient to stimulate cell proliferation, but this is accompanied by p53-dependent apoptosis. LT also binds and inactivates p53 so it is unable to bind the promoters of growth arrest genes like p21 or apoptosis inducers like PUMA, BID2, and BAX. The combined effects of stimulating proliferation by binding RB and blocking cell cycle arrest and apoptosis by binding p53 are major contributors to the transforming activity of LT. Unlike SV40 LT, Merkel cell polyomavirus (MCPyV) LT does not bind p53.[59,183] Rather, the p53 pathway is blocked by a small T antigen (ST), which consists of the same amino-terminal J domain as LT and a carboxy-terminal series of metal binding motifs. MCPyV ST associates with MYCL (the product of *L-MYC*, a member of the c-*myc* gene family) and prevents repression of MYC-regulated genes including the gene encoding mdm2 (Fig. 11.6).[58,214] The resulting increased levels of mdm2 stimulate the degradation of p53. SV40 ST is required for the transformation of some cell types. ST binds to the catalytic subunit of PP2A and alters its substrate specificity.[241]

Adenoviridae and *Papillomaviridae* oncoproteins also antagonize RB to stimulate proliferation and p53 to block apoptosis (Figs. 11.5 and 11.6). The major adenovirus oncogenes are E1A and E1B, and the major HPV oncogenes are E6 and E7. The protein products of these genes are

not enzymes; rather they act by binding to and modulating the activity of cell proteins. Human adenovirus type 5 encodes two E1A isoforms, 289R and 243R, both of which bind RB proteins via an LXCXE motif and stimulate E2F-dependent transcription and cell proliferation. RB binding displaces E2F so it can stimulate transcription. The high-risk HPVs E7 proteins also bind RB through an LXCXE motif and stimulate their degradation by the proteasome, thereby inhibiting their ability to block E2F-dependent transcription.

The proliferation induced by E1A or E7 is accompanied by p53-dependent apoptosis. Therefore, like polyomaviruses, HPV and adenovirus proteins antagonize p53. The adenovirus 5 E1B 55K protein binds p53 and disrupts its association with transcription factors. E1B 55K also acts in concert with the viral E4 ORF6 protein to stimulate p53 degradation. In addition, the E1B 19K protein mimics the cellular antiapoptotic Bcl-2 protein and sequesters BAX, thereby blocking apoptosis downstream of p53 signaling. The HPV E6 protein also binds to p53 and targets it for ubiquitination by the E3 ubiquitin ligase E6AP, resulting in p53 proteasomal degradation. Thus, cells expressing E1B or E6 are functionally devoid of p53.

Viral oncoproteins from three different DNA virus families, with different genome structures and infectious cycles, have converged on RB-E2F and p53 to manipulate cell proliferation and death (Table 11.4). However, these are not the only targets of these viral oncoproteins relevant to tumorigenesis. LT, E1A, E1B 55K, E7, and E6 all associate with multiple cellular proteins that control the DDR, innate immunity, or gene expression (Table 11.3). High-risk HPV E6, for example, has a short, carboxy-terminal motif that binds cell proteins containing PDZ domains, and HPV E7 binds cdk's and E2F1.[17] Mutational studies have linked some of these interactions to transformation in cell culture.

Herpesvirus Oncoproteins

Epstein-Barr virus (EBV) and Kaposi sarcoma–associated herpesvirus (KSHV) encode numerous oncoproteins. EBV expresses several nuclear antigens (EBNAs). EBNA2 is essential for immortalization of B lymphocytes[69,136] and in some settings cooperates with EBNA-LP to increase transcription of genes involved in cell proliferation or signaling.[193,266,294] EBNA2 is recruited to promoters by binding the cellular transcription factor RBP-Jκ, which also mediates signaling through the receptor for Notch, thus mimicking an active Notch receptor.[130,187] Consistent with this view, activated Notch can partially restore B-cell transforming activity to EBV EBNA2 mutants.[125,216] Expression of EBNA3A and EBNA3C is also necessary for B-cell immortalization. These proteins cooperate to silence expression of the cdk inhibitor $p16^{INK4A}$ and the proapoptotic protein Bim.[3,261,306] EBNA3C also cooperates with activated Ras to transform rodent cells in culture and inhibits apoptosis by binding to p53.[306]

Cell transformation and tumor formation by EBV are indirectly supported by EBNA1, which initiates viral DNA replication and ensures maintenance of the viral genome during cell division.[308] EBNA1 is also required to activate latency genes and been reported to alter signaling pathways including p53, TGF-b, and NFkB and to block cell death by upregulating the pro-survival gene, survivin.[191,288,303]

EBV LMP1 and LMP2A are both multipass membrane oncoproteins. LMP1 is essential for EBV-mediated transformation of human B cells and can transform cultured epithelial cells and fibroblasts.[154,161,162,201,220,293] In transgenic mice, LMP1 can induce epithelial and B-lymphocytic hyperplasia, which can progress to lymphoma.[175,194] LMP1 activates c-jun N-terminal kinase (JNK) and p38/MAPK pathways leading to activation of NF-κB, which is necessary for transformed cell growth.[40,97,98] In addition, LMP1 binds to several tumor necrosis factor (TNF) receptor–associated factors (TRAFs), receptor interacting protein (RIP), and a TNF receptor–associated death domain (TRADD) protein.[152-154,201] These proteins also bind to the pro-survival CD40 form of the TNF receptor. Thus, LMP1 mimics a constitutively active CD40 TNF receptor to deliver a pro-survival signal.[287] LMP1 also binds PI3K, which may contribute to its pro-survival effects by activating akt.[80] LMP2A is required to maintain viral latency and transforms epithelial cells in culture. It activates Src and Lyn leading to activation of the PI3K pathway.[111,239,249]

KSHV expresses latency-associated nuclear antigen (LANA), a large multifunctional protein required for the establishment and maintenance of the extrachromosomal viral genome.[10,72,147] LANA can transform cultured fibroblasts in cooperation with activated Ras and causes lymphocyte hyperplasia and lymphomas in transgenic mice.[104] LANA binds and inhibits p53 and RB and interacts with a number of transcription factors and chromatin-associated proteins such as histone H2A/B, Brd4, STAT3, and ATF4/CREB2.[14,186,212,297] In addition, LANA stabilizes β-catenin, which leads to increased expression of cyclin D and Myc.[110] LANA also upregulates telomerase expression and activates important signal transduction pathways including Wnt, Notch, PI3K, MAPK, and JAK/STAT, leading to the release of angiogenic factors.[176,202,291]

KSHV also encodes oncoproteins that are homologous to cellular proteins, including v-Cyclin or vCYC, which binds and activates CDK6 leading to RB phosphorylation and cell cycle entry. Unlike cellular cyclin D, vCYC is resistant to inhibition by cdki's.[54,279] KSHV also expresses vIRF3, a homolog of the cellular transcription factor IRF3 that promotes cell growth, interacts with p53, and downregulates p53-mediated transcription.[15,55,113] In addition, vIRF3 displaces the Myc inhibitory protein MM-1α, leading to Myc-mediated transcriptional activation.[192] The KSHV-encoded FLICE-inhibitory protein (vFLIP) stimulates B-cell proliferation and survival and induces lymphomas in transgenic mice.[11,64] vFLIP binds to and antagonizes IKKγ, resulting in NFkB activation.[56,119,276] In addition, KSHV encodes active homologues of several cellular chemokines and cytokines, such as v-IL6. Finally, KSHV expresses several microRNAs that have been implicated in cell transformation.

KSHV expresses a lytic program in some cancers, and several lytic viral genes have been reported to have oncogenic properties. These include ORF50 and K-BZIP, which interfere with p53 activity[133,215]; K1, which transforms cells and encodes a transmembrane glycoprotein that mimics signaling by the B-cell antigen receptor and activates the PI3K pathway[180,228,229]; and vGPCR, which encodes a constitutively active protein homologous to G protein–coupled receptors.[50] vGPCR activates various mitogenic and pro-survival signaling pathways, displays transforming activity in cultured cells, and can induce tumors in mice that resemble Kaposi sarcoma (KS).[8,45,198] Finally, KSHV encodes vBcl-2 and vIAP, lytic proteins that are homologous to Bcl-2 and survivin, respectively, that inhibit apoptosis and contribute to lymphoma formation in transgenic mice.[56,57,64,295]

Human Tumor Virology

Eight viruses are currently recognized as human carcinogens: human immunodeficiency virus (HIV) and seven tumor viruses: human papillomavirus (HPV), hepatitis B virus (HBV), hepatitis C virus (HCV), Epstein-Barr Virus (EBV), Kaposi sarcoma–associated herpesvirus

(KSHV), human T-cell leukemia virus type 1 (HTLV-1), and Merkel cell polyomavirus (MCPyV). These viruses cause almost 1.5 million cancers in humans each year, more than 10% of the worldwide cancer burden (Table 11.5).[81] The fraction of cases of specific cancers attributed to viruses ranges from about 10% (for gastric cancer and EBV) to essentially 100% (for cervical cancer and HPV) (Fig. 11.8). Virus-induced cancers preferentially occur in immunosuppressed individuals.

TABLE 11.5 Cancers associated with viral carcinogens[a]

Virus	Major Associated Cancers	Annual Cases[b]
Human papillomavirus (HPV)	Cervical carcinoma, other anogenital cancers, oropharyngeal and other head-and-neck carcinomas[c]	694 000
Hepatitis B virus (HBV)	Hepatocellular carcinoma	360 000
Hepatitis C virus (HCV)	Hepatocellular carcinoma, non-Hodgkin lymphoma	156 000
Epstein Barr virus (EBV)	Burkitt lymphoma, nasopharyngeal carcinoma, non-Hodgkin lymphoma, gastric carcinoma	157 000[d]
Kaposi sarcoma–associated herpesvirus (KSHV)	Kaposi sarcoma, primary effusion lymphoma, multicentric Castleman disease	42 000
Human T-cell leukemia virus type-1 (HTLV-1)	Adult T-cell leukemia/ lymphoma	4000
Merkel cell polyomavirus (MCPyV)	Merkel cell carcinoma	—[e]
Human immunodeficiency virus (HIV)	Various cancers	—[f]

[a]Viruses classified as carcinogens by the International Agency for Cancer Research of the World Health Organization or the National Toxicology Program of the United States Department of Health and Human Services.

[b]Infection-associated cases worldwide in 2018 as estimated by de Martel et al. (2020).[81]

[c]Only high-risk HPV (eg, HPV16 and HPV18) are associated with the cancers listed here. Other HPV types are associated with skin cancer, which is not included in this tabulation.

[d]This total does not include EBV-associated gastric cancers, which number in excess of 50 000 cases annually.

[e]MCPyV is thought to be responsible for several thousand deaths annually worldwide.

[f]HIV is classified as a human carcinogen but is not generally regarded as a tumor virus. Many cancers associated with HIV infection are caused by the tumor viruses listed in this table.

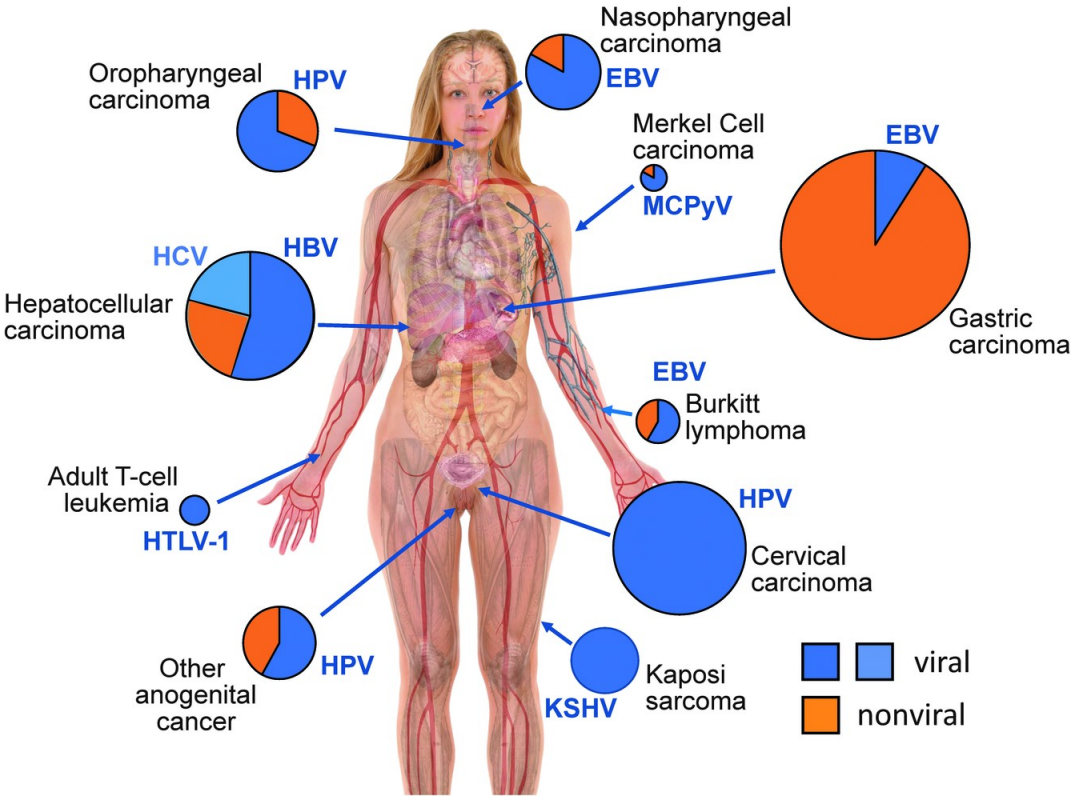

FIGURE 11.8 **Fraction of cancers caused by tumor viruses**. The sizes of the circles represent the incidence of the indicated cancers (data for males and females are aggregated), and the *blue pie* slices show the fraction that is attributable to the indicated virus. KSHV is also associated with 100% of primary effusion lymphoma and 50% of multicentric Castleman disease, two rare lymphoid malignancies.

Discovery of Human Tumor Viruses and Establishing Causality

The search for human tumor viruses was stimulated by the discovery of viruses that cause tumors in mammals.[301] This search took on special urgency in the 1960s with the startling discovery that some stocks of the poliovirus vaccine administered to tens of millions of people were contaminated with SV40, which induces tumors in hamsters.[94,118] Fortunately SV40 does not appear pathogenic in humans.

It took decades to identify and validate human tumor viruses, in part because there is no universal agreement on criteria needed to establish causality. This search was further complicated by several factors. Tumor viruses typically cause cancer in only a small fraction of infected people. In fact, some tumor viruses including EBV and MCPyV are ubiquitous, while their associated cancers are relatively rare. Virally induced cancers usually arise decades after the initial infection, which can obscure epidemiological links. Virus action is not sufficient for cancer. Rather, tumor viruses cooperate with cellular mutations, copy number variants, and epigenetic changes to induce tumors. Finally, for some viruses (eg, EBV and MCPyV), the cancer does not produce virus, while for others (eg, HBV and HCV), productive infection appears to be necessary for tumorigenesis. For HPV, benign tumors (warts) are a normal feature of productive infection, but the cancer cells do not produce virus. The presence of a virus (or a viral genome) in tumor tissue may merely signify that the tumor provides favorable cellular conditions for productive virus infection or latency. Thus, presence of viral DNA in cancer cells does not establish viral cause.

EBV, HPV, and MCPyV are very different viruses that cause distinct cancers, but they share common features that indicate a driver role in tumorigenesis. First, all or part of viral genome is present in all tumor cells and persists as cells proliferate. Second, the tumor cells express one or more viral oncoproteins that transform cells in culture, and continuous oncoprotein expression is required to maintain the transformed phenotype. Notably, tumors associated with EBV, HPV, and MCPyV have a mutational landscape and gene expression profile consistent with the known actions of the viral oncoproteins, and in MCPyV-associated skin cancer, EBV-associated gastric cancer, and HPV-associated head-and-neck cancer, the mutation signature of virus-associated tumors differs from the signature of the same type of tumor lacking viral genomes.

Tumors induced by KSHV, HCV, and HBV often contain cells undergoing productive virus infection. KSHV expresses genes during latency or productive infection that transform cells in culture and/or induce tumors in transgenic mice, consistent with a driver role for KSHV in these tumors. HCV does not encode proteins that are clearly oncogenic and viral genes are not expressed in all tumor cells, suggesting that productive infection plays an indirect role in hepatocellular carcinoma (HCC) by inducing liver damage leading to an accumulation of cellular mutations that drive tumorigenesis. The relative contribution of HBV-induced liver damage and viral gene action to cancer development is not clear.

If a virus is causative, treatments that reduce or eliminate infection should decrease cancer risk. This has been observed with HBV and HPV vaccines and with HCV antiviral therapy, but even this finding does not necessarily indicate a direct carcinogenic role for the virus. For example, HIV antiviral therapy has greatly reduced the incidence of KS, but the proximate causative agent is KSHV, not HIV. Thus, although HIV is classified as a carcinogen, it is not considered a tumor virus. Given the diversity of viruses and carcinogenic mechanisms, we propose that it is not appropriate to demand a rigid set of criteria akin to Koch's postulates to infer causality. Rather, the accumulation of multiple, independent, and diverse pieces of evidence are required to establish causality (Table 11.6), and any one type of evidence may take on greater or lesser importance depending on the particular virus and the particular cancer.

TABLE 11.6 Lines of evidence implicating a virus in cancer causation[a]

	HPV	MCPyV	EBV	KSHV	HBV	HCV	HTLV-1	HIV
Prior infection with a specific virus is epidemiologically linked to increased risk of a specific cancer	+	+	+	+	+	+	+	+
At least part of the viral genome is present and expressed in all or a subset of cases of a specific type of cancer	+	+	+	+	+		+	
The virus or viral genes alone or in combination transform cells in culture	+	+	+	+	+	+	+	
Continuous viral gene expression in transformed cells is required for the transformed phenotype	+	+	+					
One or more viral genes with transforming activity is expressed in human cancer cells	+	+	+	+	+		+	
The virus or viral genes induce cancers in laboratory animals, preferably the same type of cancer the virus is associated with in humans	+	+	+	+	+	+	+	
Mutational landscape and gene expression profile in cancer is consistent with known functions of the viral oncoprotein(s)	+	+						
Mutation signature of virus-associated cancers differs from that of non-virus-associated cancers of the same type	+[b]	+	+[c]					
Antiviral therapy or prophylactic vaccination reduce risk of specific virus-associated cancer	+			+	+	+		+

[a]+ indicates that the listed virus meets the criterion. Many of these criteria will not be met by a hit-and-run viral carcinogen.

[b]For oropharyngeal cancer.

[c]For gastric cancer.

Each of the known human tumor viruses was associated with cancer by different approaches,[301] but the detection of viral nucleic acids in tumor cells has become the standard route of discovery of new tumor viruses, resulting in the discovery of KSHV and MCPyV by Chang and Moore and their colleagues. However, it is also possible that a virus could trigger carcinogenesis and then depart without leaving residual viral genes or gene products in the cancer cells. This hypothetical mechanism is termed “hit-and-run” carcinogenesis.[209] For example, animal studies suggest that skin carcinogenesis triggered by cutaneous HPV types may involve a hit-and-run mechanism in which the virus potentiates ultraviolet light–mediated mutagenesis but is not needed to maintain the cancerous state.[292] DNA sequencing to identify viral genomes in cancer cells will not identify instances of hit-and-run carcinogenesis.

Principles of Viral Carcinogens

Several unique features of tumor viruses and HIV have important implications for human cancer (Fig. 11.9).[85] The direct action of classic carcinogens such as chemical mutagens or radiation is restricted to the individual exposed to the carcinogen, but infectious carcinogens can be transmitted from one host to another, often to many other hosts and at a great distance from the initial exposure. Unlike chemical and physical carcinogens, viral carcinogens can amplify, mutate, evolve, and spread. Mutations might affect virus transmissibility or carcinogenicity or the susceptibility of the infection or the resulting cancer to prevention or treatment. Viruses can also specifically modulate the immune system, which can in turn can affect virus replication, spread, or pathogenicity. Notably, exposure to viral antigens can generate an immune response that inhibits subsequent infection. Viruses can also influence oncogenesis and cancer therapy in many ways in addition to by acting as direct carcinogens. For example, infection may induce or suppress a DNA damage or immune response or alter the metabolism of xenobiotics, which could affect cancer development or response to treatment. Most importantly, prevention or treatment of the underlying infection can reduce cancer risk. Indeed, the most important laboratory-based advances in cancer prevention in recent decades are interventions against virus-associated cancers: vaccines that prevent HBV or HPV infection and drugs that cure HCV infection and suppress HIV, HBV, and herpesvirus replication. In addition, HBV, HCV, HTLV-1, and HIV have been removed from the blood supply in much of the world, and public health measures such as needle exchange programs and encouragement of safe sex practices have reduced transmission of some tumor viruses and HIV. Widespread use of these and future preventive and therapeutic approaches will significantly reduce the worldwide cancer burden.

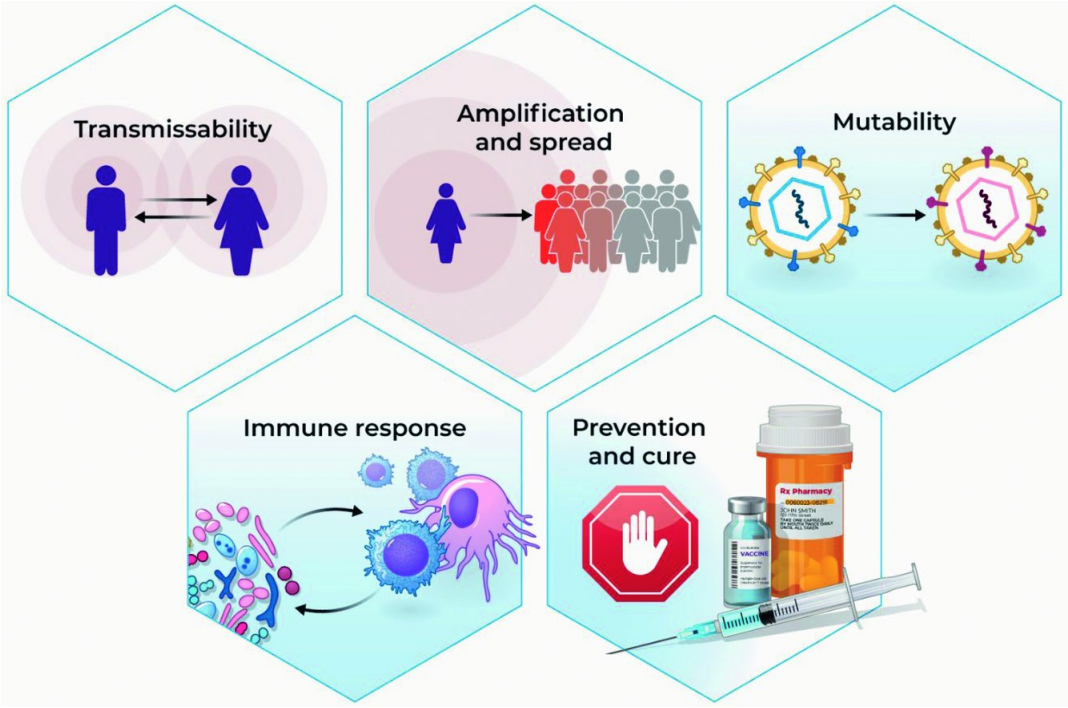

FIGURE 11.9 **Characteristic features of viral carcinogens**. The figure shows schematic diagrams of the key ways viral carcinogens differ from classic chemical and physical carcinogens. See text for details. (From DiMaio D, Emu B, Goodman AL, et al. Cancer microbiology. *J Natl Cancer Inst*. 2022;114(5):651-663. Reproduced by permission of Oxford University Press.)

Human Tumor Virus Action

Carcinogenic viruses employ diverse mechanisms to induce cancer, ranging from HPV and MCPyV, whose carcinogenic activity is dependent on viral oncogenes, to HIV with no oncogenes at all (Fig. 11.10).[112] HPV, MCPyV, EBV, and KSHV express strong, well-characterized oncoproteins that stimulate cell proliferation, inhibit cell death, and/or cause genetic instability, and they deploy immune evasion strategies that may promote tumor development. In contrast, HBV, HCV, and HTLV-1, lack clearly defined oncogenes (although each encodes proteins that can induce transformation or tumorigenesis when overexpressed). It is thought that the main contribution of HIV to carcinogenesis is through immunosuppression.[131]

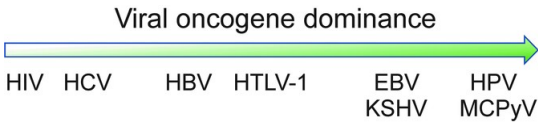

FIGURE 11.10 **Viral oncogenes and human cancer**. Schematic diagram illustrating the different degrees to which carcinogenic viruses depend on viral oncogenes. Some viruses such as HPV and MCPyV encode strong oncogenes that play the dominant role carcinogenesis, whereas HIV contains no oncogenes and appears to induce tumors indirectly by inhibiting immune function. Other carcinogenic human viruses display intermediate degrees of oncogene dependence.

For all human tumor viruses, only a few percent of infected people develop cancer. Some germline sequence variants in humans are associated with higher risk of developing cancer in response to certain virus infections, but even in people carrying these variants, cancer risk is low. However, individuals with primary immunodeficiency display a higher incidence of many cancers, including virus-induced cancers. Furthermore, the development of human viral cancers typically follows persistent or latent infection (often of decades-long duration) and preferentially occurs in the setting of immune suppression or chronic inflammation. These features of viral carcinogenesis suggest that additional, rare stochastic events such as the accumulation of specific mutations are required for cancer formation in humans. Consistent with the view that mutations are key, cancers induced by viruses contain many mutations, although usually not as many mutations as in nonviral tumors.[42,311] The specific cellular genes mutated in virus-induced tumors and the specific types of mutations are often distinct from mutations in sporadic cancers. Notably, the host responses to infection, including chronic inflammation or DNA damage, can induce mutations that can cooperate with the direct carcinogenic effects of the viral oncoproteins.

An important aspect of carcinogenesis initially discovered by studies with tumor viruses is “oncogene addiction,” namely the concept that ongoing expression of the transformed or tumorigenic state requires continuous oncogene expression. This was first shown with temperature-sensitive mutants of RSV, where the transformed phenotype was extinguished at the nonpermissive temperature.[195] Oncogene addiction suggests that inhibition of viral oncogene action may provide novel cancer treatment opportunities.

Finally, 85% of virus-induced cancers occur in low- and middle-income countries (LMICs), where they cause significant mortality. Many factors contribute to this disparity including the high prevalence of HIV and HBV in sub-Saharan Africa and Asia, respectively. Cancer outcomes in LMICs are driven in large part by environmental and behavioral risk factors, inadequate preventative and early detection programs (such as Pap smear screening for cervical cancer), and limited access to vaccines and treatment (*eg*, see Ref.[2]). In addition, poor nutrition is likely to impair host defense against infections and cancer development.

Human Papillomaviruses

In terms of the number of cancer cases, the most important human tumor viruses are the HPVs, a large group of nonenveloped viruses that contain an ~8000 base-pair double-stranded DNA genome encoding ~10 proteins.[317] HPVs are transmitted via direct contact with infected skin or mucosal tissue and infect billions of people worldwide. Infection causes papillomas or warts, benign epithelial cell tumors of the skin and mucous membranes. Although warts are usually self-limited, genital warts (condyloma acuminata) and laryngeal papillomas can be serious medical conditions.

In aggregate, 5% of human cancer is thought to be triggered by HPV infection.[246] High-risk mucosal strains of HPV such as HPV16 and HPV18, which were first discovered in cervical cancer DNA samples by zur Hausen and colleagues,[33,91] are responsible for virtually all cancers of the uterine cervix (the most common HPV-associated cancer) and a substantial fraction of vulvar, vaginal, anal, penile, and oropharyngeal cancer (Fig. 11.8). Cervical cancer is caused by numerous types of high-risk HPV, but a single high-risk type, HPV16, is responsible for the great majority of other HPV-associated anogenital and oropharyngeal cancers.[116] In addition to HPV, smoking, exogenous estrogen, and other infections also contribute to cervical cancer risk. In high-income areas of the world, robust Pap smear cervical cancer screening and treatment programs have greatly reduced the prevalence of cervical cancer, but it is still a major cause of death in LMIC.[2] Genetically distinct HPV types are also implicated in nonmelanoma skin cancer, particularly in immunosuppressed individuals.[139]

Most people infected with HPV do not develop HPV-associated cancer, and the cancers that do arise occur in the setting of persistent HPV infection years or decades after initial infection, presumably because HPV-infected cells must accumulate additional mutations to form cancers.[90,150] Indeed, cervical cancer has a high tumor mutational burden with tumors frequently containing many chromosomal translocations and somatic mutations.

Most cervical cancers continuously express the high-risk HPV E6 and E7 oncogenes, usually from viral DNA integrated into the host cell genome. Viral DNA integration may enhance expression of the viral oncogenes and affect expression of nearby cellular genes including *c-myc*.[221,296] As described in an earlier section, the E6 and E7 oncoproteins, among other activities, inactivate the p53 and RB tumor suppressor pathways, respectively, resulting in growth stimulation and genomic instability, which presumably contributes to the mutational burden of these cancers. The oncoproteins from the high-risk HPV types are more active at inactivating tumor suppressor pathways than are the proteins from the low-risk types, such as HPV6 and HPV11, which cause genital warts, not cancer. The HPV E5 oncogene is expressed in some but not all cervical cancers, and its role in human carcinogenesis is unclear. In addition, HPV deploys a number of immune evasion strategies that allow persistent HPV infection, which is an important risk factor for cancer development.[126] For example, high-risk HPV E7 binds directly to STING, a mediator of foreign DNA sensing, and inhibits interferon induction.[179]

HPV-associated squamous cell carcinoma of the oropharynx and tonsils occurs predominantly in males and is less aggressive than classic head-and-neck cancer, which is caused by tobacco and alcohol use.[4] It is not clear if the same pathogenic mechanisms are responsible for HPV-associated oropharyngeal and cervical cancer. Because only a fraction of oropharyngeal cancers contains HPV DNA, it is instructive to compare the mutations in HPV-negative vs HPV-positive head-and-neck cancer. These studies showed that p53 is mutated in over 80% of HPV-negative tumors, while nearly all HPV-positive tumors express wild-type p53. This is consistent with removal of p53 by the HPV E6 oncoprotein, thereby relieving the selective pressure for mutational inactivation of p53.

Repression of E6/E7 expression in cervical cancer cell lines or in HPV-induced cervical tumors in genetically engineered mice reactivates dormant tumor suppressor pathways and causes cellular senescence, apoptosis, or tumor regression.[123,124,155] Thus, continuous expression of the HPV oncogenes is required to maintain ongoing proliferation of the cancer cells, suggesting that strategies that interfere with E6/E7 expression or action may have an antitumor effect in patients with cervical cancer.[213]

Although no specific antiviral drugs target HPV, there are several highly effective prophylactic vaccines. The major HPV capsid protein, L1, can self-assemble to form noninfectious viruslike particles (VLPs) that elicit neutralizing antibodies.[63,168,315] L1 VLP vaccines protect against infection by the HPV types in the vaccine and reduce the risk of cervical cancer, generating high confidence that cervical carcinoma incidence will steeply decline in vaccinated populations in coming years.[172,181,263] All deployed HPV vaccines contain HPV16 (as well as other HPV types), so they should eventually prevent the great majority of HPV-associated anogenital and oropharyngeal cancer.[116] Unfortunately, however, vaccine coverage is suboptimal in much of the world, particularly in LMIC. Small clinical studies suggest that therapeutic vaccination with the E6 and E7 proteins can generate cytotoxic T cells that specifically kill cancer cells expressing these proteins.[167] The combination of vigilant screening and treatment of precursor lesions, prophylactic and therapeutic vaccination, and yet-to-be developed drugs that inhibit HPV replication or the progression or maintenance of HPV-associated cancers may lead to the eradication of cervical cancer.

Merkel Cell Polyomavirus

Merkel cell carcinoma (MCC) is a rare but aggressive neuroendocrine skin cancer that is frequently associated with immunosuppression and sunlight exposure.[19,101] MCPyV was discovered because its DNA is clonally integrated into the host cell of about 80% of MCC specimens.[107] Clonal viral DNA integration implies that virus infection occurred early during tumorigenesis, consistent with a causal role. MCPyV infection is widespread in humans, with over 80% seropositivity in individuals over 50 years of age. This virus has a typical polyomavirus ~5000 base pair genome encoding capsid proteins and LT and ST, both of which can induce tumors in transgenic mice.[257,267,290] Ongoing expression of the viral oncogenes is required for growth of MCC cells in culture.[146]

As is the case for other polyomaviruses, MCPyV LT binds and inactivates RB, leading to the transcription of E2F-regulated genes.[143] As a consequence of viral DNA integration, MCC tumors generally express a truncated form of LT preserving the amino-terminal J domain and RB binding site, but inactivating the replication functions of LT.[107,256] ST is also a major MCPyV oncogene that, as described above, indirectly neutralizes the p53 pathway by inducing mdm2. The ST-MYCL complex also drives transcription of LSD1, a demethylase that inhibits ATOH1-dependent transcription. Because ATOH1 is required for neuroendocrine cell differentiation, ATOH-1 inhibition contributes to maintaining cells

in a stemlike state.[138]

Twenty percent of MCCs lack MCPyV DNA and display a mutational signature consistent with UV exposure, while this signature is not present in virus-associated MCC.[120,137] Furthermore, nonviral MCCs carry many mutations and chromosomal rearrangements, whereas virus-associated tumors contain few mutations and typically have a normal karyotype.[269,270] Nevertheless, many of the same cellular processes and pathways are altered in both virus-associated and nonviral MCC. For example, in virus-associated MCC, RB and p53 are inactivated by LT and ST, respectively, whereas UV-associated MCCs frequently carry mutations that inactivate RB and p53.[122,137,143] Similarly, in tumors driven by MCPyV, ST binds and activates MYCL, while MYCL is often overexpressed in nonviral MCC.[219,270]

Epstein-Barr Virus

Epstein-Barr virus, a γ-herpesvirus with a large (~170 000 base pair) double-stranded DNA genome, can replicate in both B lymphocytes and epithelial cells, a cell tropism that is reflected in the cancers associated with EBV. More than 90% of the adult human population is seropositive for EBV. Although many EBV infections are subclinical, EBV causes infectious mononucleosis, a usually mild disease caused by polyclonal expansion of B lymphocytes.

EBV is associated with several human cancers including Burkitt lymphoma (BL), classic Hodgkin lymphoma and other B cell tumors, nasopharyngeal carcinoma, and gastric carcinoma. EBV is latent in cancer cells with the viral genome tethered to the host chromosomes and only a small subset of viral genes is expressed. There are four types of EBV latency defined by unique viral gene expression profiles.[300] In latency 0, the only viral genes expressed are the ncRNAs EBER-1 and EBER-2 and other transcripts named BARTs that include viral miRNAs and other ncRNAs. In latency I, EBNA1 is expressed in addition to these ncRNAs. Latency II is characterized by the additional expression of LMP1, LMP2A, and LMP2B. Finally, in latency III, viral gene expression is expanded to include EBNA2, EBNA3A, EBNA3B, EBNA3C, and EBNA-LP. Each type of EBV-associated cancer displays a characteristic latency pattern.

Burkitt Lymphoma. BL is an aggressive B cell lymphoma that occurs in endemic, sporadic, and immunodeficiency-associated forms.[28,38] EBV DNA is found in about 95% of the endemic BL and in about 30% of sporadic and immunodeficiency-associated BL.[300] Endemic BL is a common pediatric tumor in sub-Saharan Africa, and its development usually requires cooperation between EBV and malaria. All BLs carry a fusion of c-*myc* and an immunoglobulin (Ig) gene resulting in overexpression of Myc, which drives cell proliferation and induces apoptosis. EBV blocks Myc-induced apoptosis, thus allowing the survival of cells carrying the Ig-*myc* translocation.[165] In nonviral BL, apoptosis is abrogated by loss-of-function mutations in the p53 pathway or in downstream apoptosis effectors (reviewed by Ref.[282]).

EBV-positive BL displays latency I with EBNA1 being the only viral protein expressed. Inhibition of EBNA1 function in BL cell lines induces apoptosis, showing that ongoing action of EBNA1 is required for the survival of these cells.[165] BL cells also express EBER1 and EBER2 and viral miRNAs. During the establishment of latency, other early viral proteins including EBNA2, EBNA3A, and EBNA3C are transiently expressed. However, the combination of Myc overexpression and EBNA2 induces apoptosis.[163,217] Apoptosis is blocked by ENBA3A and EBNA3C, which silence the proapoptotic BIM gene. EBNA2 is usually then epigenetically silenced and latency I established. However, in a subset of BL, EBNA2 is deleted, causing repression of additional EBV genes including *BHRF1*, the viral homolog of Bcl-2, thereby blocking Myc-induced cell death.[164]

Classic Hodgkin lymphoma. EBV is associated with 10%-75% of classic Hodgkin lymphoma (CHL) cases, depending on the disease subtype.[169,300] EBV is in latency II, and the cells express EBNA1, LMP1, LMP2, and EBER. CHL cells have aberrantly rearranged Ig genes that trigger cell death, but LMP1 and LMP2A appear to block death by activating the NFkB pathway.[39,41]

Nasopharyngeal carcinoma (NPC) and *gastric carcinoma* are other EBV-associated cancers that exhibit latency II. Over 95% of NPC cases harbor EBV DNA, as do 10% of gastric cancers.[6,20,43,218] Gastric cancers can be grouped into distinct subtypes based the number and types of mutations.[43] EBV-associated gastric cancers form a distinct molecular subtype characterized by DNA hypermethylation, mutations in the PI3K pathway, and amplification of *JAK2* and *CD274*. These tumors rarely carry p53 mutations, while p53 is frequently mutated in non-EBV associated cancers. This unique genetic signature suggests a driver role for EBV in a subset of gastric cancers. *NPC* predominantly occurs in certain areas in Southeast Asia.[252] The basis for this striking geographical distribution is not known, but environmental factors such as a diet rich in fermented and preserved foods may play a role.[309] In addition, host HLA genotype affects the risk of EBV-induced NPC.[185]

EBV also causes lymphoproliferative disease in individuals with immunodeficiency, including central nervous system lymphomas in patients with acquired immunodeficiency syndrome (AIDS) and following bone marrow transplantation. Adoptive immunotherapy with EBV-specific donor T cells can control EBV-related lymphomas in bone marrow transplant recipients, demonstrating the utility of targetting viral tumor antigens in immunotherapy.[144]

Kaposi Sarcoma–Associated Herpesvirus

Kaposi sarcoma–associated herpesvirus (KSHV) is another oncogenic γ-herpesvirus, with a ~165 000 base pair double-stranded DNA genome first detected in KS lesions.[53] The KSHV genome contains numerous genes homologous to cellular genes, which were presumably acquired by the viral genome in relatively recent evolutionary times. As described in an earlier section, many of these genes play key roles in cell growth control. KSHV infects multiple cell types and is usually latent in endothelial cells and B lymphocytes, where it expresses a limited number of viral genes including LANA, v-cyclin, v-FLIP, kaposins, v-IRF3, and viral miRNAs.[132,174] In addition to a causal role in KS, the virus has also been linked to primary effusion lymphoma (PEL), multicentric Castleman disease, and some diffuse large B-cell lymphomas.[49,211,265] The pathogenesis of KSHV-associated cancer is complex and poorly understood.[203]

Kaposi sarcoma. KS is a systemic disease affecting multiple cell types and organs including the skin, with a prominent vascular endothelial component.[5] Unlike many other tumors, KS lesions are not monoclonal and display features consistent with paracrine signaling, and cells derived from these lesions often do not display properties of transformed cells. KS is caused by KSHV infection, often in the setting of immunosuppression.[53] While all tumor cells harbor KSHV, the viral gene expression pattern varies in different cases, with some expressing only

latent genes while others display a lytic gene expression pattern.[86,87] Once a relatively rare tumor, the incidence of an aggressive form of KS increased greatly during the AIDS epidemic, but the incidence of AIDS-associated KS has dramatically decreased since the introduction of effective treatments for HIV infection.[25,102] In addition, the appearance of new KS lesions in AIDS patients is suppressed by treatment with the antiherpesviral drug, ganciclovir, which targets herpesvirus DNA polymerase.[48]

Primary effusion lymphoma. PEL occurs in AIDS patients, and all cases of PEL contain the KSHV genome.[7,204] These cancers overexpress *c-myc* due to the action of KSHV LANA. In addition, the PI3K, mTOR, and MAPK pathways appear critical for PEL survival.[23,36,189,259] PELs rarely contain activating PI3K mutations or loss-of-function mutations in PTEN, a negative regulator of PI3K, suggesting that viral proteins mediate the activation of these pathways. In fact, two KSHV proteins, K1 and vGPCR, have been reported to activate the PI3K pathway.[9,264,283]

KSHV is also associated with *multicentric Castleman disease (MCD)*, a polyclonal lymphoid malignancy and *KSHV-positive diffuse large B-cell lymphoma*, rare lymphoid malignancies associated with HIV infection and other forms of immunosuppression.[211,265] The mechanisms of carcinogenesis in these diseases is poorly understood, but recently progress in understanding MCD has been reviewed.[47]

Hepatitis B Virus

Chronic infection by HBV and HCV leads to the development of ~80% of HCC (Fig. 11.8).[226] HBV is a bloodborne pathogen that infects approximately one-third of people worldwide and causes acute and chronic hepatitis, as well as the majority of HCC.[18] HBV contains a small, partially double-stranded DNA genome and undergoes a complicated replication cycle involving RNA replicative intermediates.[275] In some HBV-infected individuals (particularly those infected as infants), infection becomes persistent. Persistent infection can lead to chronic liver damage (chronic active hepatitis [CAH]), which has a significant likelihood of progressing to HCC. Individuals coinfected with HBV and hepatitis delta virus, a satellite virus with an RNA genome, are at increased risk of developing HCC.[235] More than one billion people are vaccinated against HBV, representing a major public health triumph.

There are three major HCC subtypes.[44] HBV is most often associated with cluster 1 tumors, which are characterized by the overexpression of *MKI67*, *MYBL2*, and other cell cycle markers; a low frequency of *CDKN2A* silencing; and p53 mutations but not *hTERT* promoter mutations or overexpression. In addition, HBV-positive HCCs tend to have a mutational signature associated with exposure to the carcinogenic fungal natural product, aflatoxin. HBV-associated HCC frequently has integrated HBV genomes. In some cases, integration occurs near genes that are upregulated including *CCND1*, *CCNE*, *GLI2*, and *hTERT*, which are linked to cell cycle progression.[44,277,314]

Unlike the other DNA tumor viruses, HBV does not contain strong oncogenes, and its precise role in the development of HCC is unclear. However, HBV vaccination reduces the incidence of HCC, providing definitive evidence that HBV plays a causal role in this cancer (Fig. 11.11).[52,230,310] In addition, antiviral therapy can reduce HCC risk in patients with chronic HBV infection, especially if treatment is initiated early in the disease.[304] Three broad, nonexclusive hypotheses have been proposed to explain the role of HBV in HCC. First, HBV acts as an indirect mutagen in which HBV replication causes inflammation, cell death, and repeated cycles of hepatocyte proliferation and mutagenesis during regeneration resulting in the accumulation of cellular mutations that lead to cancer formation.[235] Second, mutagenesis or gene activation mediated by HBV DNA integration into the cell genome drives HCC.[105,284,311] Finally, it is possible that a viral oncogene contributes to tumorigenesis. For example, the HBV *X* gene has been implicated in cell transformation and tumorigenesis in transgenic mice.[16,260] *X* affects cellular gene expression and may interfere with p53 function.[106]

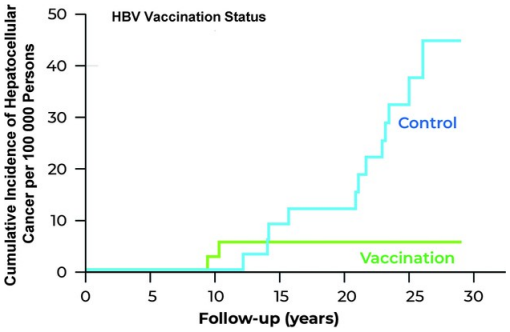

FIGURE 11.11 **HBV vaccination can prevent cancer**. Graph shows the cumulative incidence of hepatocellular carcinoma in HBV vaccinated and unvaccinated subjects as a function of years of follow-up. (Based on data published by Qu C, Chen T, Fan C, et al. Efficacy of neonatal HBV vaccination on liver cancer and other liver diseases over 30-year follow-up of the Qidong hepatitis B intervention study: a cluster randomized controlled trial. *PLoS Med*. 2014;11(12):e1001774. Hepatitis C Virus

HCV belongs to the *Flaviviridae* family and has an ~9600-base single-stranded, positive-sense RNA genome.[62] HCV causes viral hepatitis and HCC and is also associated with non-Hodgkin B-cell lymphoma.[207,242] HCV is transmitted by blood, sexual activity, and intravenous drug use. Many HCV infections are inapparent and not diagnosed until late in the disease. In most populations, a few percent of people are seropositive for HCV, but rates of HCV positivity in Egypt approach 40% in some demographic groups because the virus was inadvertently transmitted during other medical interventions.[108] Unlike the situation with HBV, where a relatively small proportion of infections become chronic, HCV usually results in chronic infections and cirrhosis. In fact, HCV is the most common reason for liver transplantation in the Western world. HBV/HCV coinfections confer elevated risk of HCC development.

HCV lacks strong oncogenes, but viral structural genes have transforming or tumorigenic activity in various assays, in part by inducing genomic

instability.[182,200,262] The carcinogenic potential of HCV is thought to derive primarily from its cytolytic activity in hepatocytes and the resulting inflammation, cell regeneration, and mutagenesis. HCV-positive tumors are associated with *CDKN2A* promoter silencing and *hTERT* promoter mutation.[44] Direct acting antiviral drugs that target HCV replication proteins such as proteases and polymerase can cure HCV infections in nearly all patients infected with common virus strains, and successful treatment reduces the risk of HCC.[151,158]

Human T-Cell Leukemia Virus Type 1

Human T-cell leukemia virus type 1 (HTLV-1), the first discovered human retrovirus, infects ~20 million people worldwide, with high endemic areas in Latin America, the Caribbean, Africa, and Japan.[227,307] HTLV-1 is transmitted by infected blood and other body fluids. Breast-feeding is a primary mode of HTLV-1 transmission, and refraining from this practice appears to reduce the incidence of vertical HTLV-1 transmission.[31] HTLV-1 infection is associated with adult T-cell leukemia/lymphoma (ATL) and some inflammatory diseases.[115] ATL typically arises several decades after HTLV-1 infection and is rapidly progressive, and it occurs in only a small fraction of infected individuals, suggesting the importance of additional, possibly nonviral events such as the accumulation of cellular mutations. Host genetics can also influence the risk of developing ATL.

HTLV-1 contains several accessory genes in addition to *gag*, *pol*, and *env*. During normal infection, the multifunctional accessory protein Tax regulates HTLV-1 gene expression from the viral LTR by interacting with cellular transcription factors.[75] Tax can induce lymphoid and mesenchymal tumors in transgenic mice and appears to play a role in transforming T lymphocytes by affecting transcription of cellular genes, inducing genomic instability, and influencing a variety of other cellular processes.[12,115,127,140] HTLV-1 also expresses a DNA binding protein, HBZ (a B-zip factor) that can induce lymphomas in animals.[244] HBZ but not Tax is invariably expressed in ATL cells. HBZ and Tax may cooperate in tumorigenesis, with Tax playing an initiating role and HBZ playing a role in tumor maintenance.[196]

Retroviral Oncogenesis in Gene Therapy Trials

Because retroviruses can stably deliver genes into cell DNA, they have been used as gene transfer vectors to correct inherited genetic disorders such as immunodeficiency syndromes.[208] One early trial studied treated boys with X-linked severe combined immunodeficiency (X-SCID), which is caused by mutations in the IL2 receptor γ gene (*IL2RG*). In this trial, hematopoietic progenitor cells were isolated from X-SCID patients, infected *ex vivo* with an MuLV-based vector lacking viral genes but expressing *IL2RG*, and then reinfused.[135] This treatment corrected the SCID defect, but a majority of the subjects subsequently developed T-cell acute lymphoblastic leukemia. Molecular analysis of the tumors revealed that the retroviral vector had integrated near the *LMO2* or the *CCND2* protooncogene, resulting in increased oncogene transcription.[134] Thus, the gene therapy vector appears to cause insertional activation of cellular protooncogenes. Similar outcomes involving other protooncogenes also occurred in trials treating other immune disorders.[34,173,272] Improved viral vectors have been developed that appear to reduce the incidence of these adverse outcomes (eg, see Ref.[145]).

Human Immunodeficiency Virus

HIV is a lentivirus that, like other retroviruses, undergoes reverse transcription and stable integration into the host cell genome. HIV infects $CD4^+$ T lymphocytes and can persist in a latent state for many years. In the absence of treatment, HIV infection eventually leads to profound T-cell depletion and severe immunosuppression, resulting in AIDS and fatal opportunistic infections. Worldwide, more that 40 million people have succumbed to AIDS, and HIV currently infects more than 30 million people. HIV is a bloodborne pathogen, transmitted by blood transfusions, needle sharing, and unprotected sexual contact. Public health measures such as blood donor screening has reduced certain modes of transmission.

HIV infection confers substantial excess risk for many cancers, and cancer prognosis in HIV-infected individuals is often worse than for people without HIV.[67,68] In North America, cancer accounts for up to 20% of deaths in HIV-positive individuals. Cervical cancer, KS, and non-Hodgkin lymphoma in the context of an active HIV infection establish the diagnosis of AIDS and are known as AIDS-defining cancers (ADCs). Interestingly, ADC are caused by tumor viruses—HPV, KSHV, and EBV. It is thought that HIV-induced immunosuppression allows unrestrained tumor virus replication and the resulting carcinogenic stimulus.[109]

Combination antiretroviral therapy that inhibits HIV enzymes required for virus replication—reverse transcriptase, integrase, and protease—suppresses HIV replication, and now millions of people are successfully treated (but not cured) for their HIV infection. Antiretroviral therapy substantially reduces the incidence of ADCs, demonstrating that antiviral therapy can prevent cancer.[236,255] Despite this decrease, people living with treated HIV remain at increased risk for ADCs compared to uninfected people. They are also at increased risk of other malignancies known as non-AIDS-defining cancers, which now account for two-thirds of cancers in HIV patients, with lung cancer being the most common.[103,258] It is not known if this elevated risk is due to residual immune dysfunction despite good HIV control or to some other factor.[237]

Human Endogenous Retroviruses

About 8% of the human genome is the remnant of ancient retrovirus infections of the germline. There is limited understanding of the role, if any, of human endogenous retroviruses (HERVs) in cancer. Most HERVs are epigenetically silenced, but they are often derepressed in cancer and might stimulate tumorigenesis by expressing carcinogenic gene products or by influencing the expression of cellular genes.[13] Conversely, agents that reverse repression of HERVs in cancer cells may stimulate a protective immune response.[312] These divergent possibilities suggest that HERVs may play a complex role in cancer formation that deserves further attention.

Future Perspectives

Tumor virology has provided important insight into mechanisms of carcinogenesis and led to powerful new approaches to prevent cancer, but many key questions remain, some with immediate public health consequences. How do we consolidate and extend the successes already

achieved in preventing and treating cancers caused by viruses, are there additional viruses that cause human cancers, and how do we prepare ourselves against emerging tumor viruses?

Efforts must be redoubled to provide better coverage with existing and future HPV and HBV vaccines, particularly in LMIC. Prophylactic vaccines are also needed for HCV, EBV, KSHV, and HIV. Recent advances in structural biology and vaccine design (including viral vaccine vectors and mRNA vaccines) and better understanding of conformation-specific antigens generate hope that effective vaccines against these viruses are attainable. Because of the relatively small number of people affected by MCC and ATL and the cost of vaccine development, testing, and distribution, vaccines against MCPyV and HTLV-1 are less likely to be developed. HIV, HBV, and HCV antivirals reduce cancer incidence, so the development and distribution of drugs against these viruses should continue apace. However, because of the expense of some of curative regimens, prophylactic vaccines seem the best long-term solution.

Have we discovered all of the human tumor viruses and do known tumor viruses cause additional cancers? Reports have linked cancers to viruses other than the known carcinogenic human viruses. Several studies have reported human cytomegalovirus (hCMV) DNA sequences in glioblastomas.[92] However, neither hCMV DNA or mRNA has been detected in tumor sequencing projects. Similarly, JC polyomavirus (JCPyV) DNA sequences have been reported in colorectal preneoplastic lesions and cancers but are not present in tumor sequence databases. It is unclear if hCMV and JCPyV are just passengers or are contributing to these neoplasias.

There appears to be a link between HPV and BK polyomavirus (BKPyV) and a small fraction of urinary tract tumors. BKPyV DNA sequences have been detected in urinary tract tumors associated with post renal transplant immunosuppressive therapy, and HPV and BKPyV genomes were found integrated in 19/268 sequenced bladder cancers. These tumors expressed the HPV E7 and E6 or the BKPyV LT oncogenes.[46] While half of the virus-negative tumors harbored p53 mutations, all of the virus-positive tumors expressed wild-type p53. Similarly, mutations in the RB-E2F pathway were found in virus-negative, but not virus-positive tumors. This pattern suggests that HPV and BKPyV drive a small subset of urinary track carcinomas.[268]

Although available cancer sequencing data suggest that unrecognized tumor viruses are unlikely to cause a substantial number of human cancers, it is possible that viruses cause human cancer via a hit-and-run mechanism. If this occurs, the number of cancers triggered by viruses may be higher (possibly even substantially higher) than is currently appreciated. Epidemiological data may provide initial clues of such associations, but novel laboratory- and computation-based methods will be required to explore this issue definitively. Cancers whose incidence is decreased by antiviral strategies are prime candidates for detailed investigation into possible viral causes.

A final concern is emerging tumor virus infections. It is possible that some viruses with cancer-causing potential or immunosuppressive properties exist but have not yet entered the human population from their natural animal hosts. If such an event occurs, it probably will not be immediately recognizable as a cause of cancer, because the time-course of virus-induced tumorigenesis in humans typically lasts decades. Therefore, the emergence of a new carcinogenic virus might not be recognized until long after the initial introduction of the virus into humans, providing years for the virus to become established and widely disseminated in humans. We must fortify ourselves against this possibility by continuing to conduct studies of basic virology, biochemistry and structural biology, viral immunology, and related areas so that we have the knowledge to rapidly counter newly emerging viral disease. We must also build and maintain strong surveillance programs to rapidly identify new viruses in the human population so that we can combat them before they spread widely.

Since tumor viruses were discovered in 1908, tumor virology has progressed through several phases. Descriptive studies evolved into mechanistic ones, tools developed to study tumor viruses were deployed to revolutionize all of biology, and hints of associations between viruses and cancer led to clear understanding of the carcinogenic activities of specific viruses in humans and ultimately to powerful new interventions to prevent certain cancers. Additional studies of viruses and cancer will continue to have important impact on biomedical science and public health.
